Cortical gamma oscillations are associated with cognitive processes and are altered in several neuropsychiatric conditions such as schizophrenia and Alzheimer's disease. Since dopamine D₃ receptors are possible targets in treatment of these conditions, it is of great importance to understand their role in modulation of gamma oscillations. The effect of D₃ receptors on gamma oscillations and the underlying cellular mechanisms were investigated by extracellular local field potential and simultaneous intracellular sharp micro-electrode recordings in the CA3 region of the hippocampus *in vitro*. D₃ receptors decreased the power and broadened the bandwidth of gamma oscillations induced by acetylcholine or kainate. Blockade of the D₃ receptors resulted in faster synchronization of the oscillations, suggesting that endogenous dopamine in the hippocampus slows down the dynamics of gamma oscillations by activation of D₃ receptors. Investigating the underlying cellular mechanisms for these effects showed that D₃ receptor activation decreased the rate of action potentials (APs) during gamma oscillations and reduced the precision of the AP phase coupling to the gamma cycle in CA3 pyramidal cells. The results may offer an explanation how selective activation of D₃ receptors may impair cognition and how, in converse, D₃ antagonists may exert pro-cognitive and antipsychotic effects.

Keywords: gamma rhythm, dopamine D₃ receptors, hippocampus CA3 region, cognition, schizophrenia, antipsychotics

INTRODUCTION

Cognitive impairment is common in individuals with neuropsychiatric disorders such as schizophrenia, mood disorders, Alzheimer's disease, autism spectrum disorder, and Parkinson's disease (Millan et al., 2012). Many efforts have been made to develop drugs to maintain or enhance cognitive processes but the available treatments still have limited pro-cognitive effects. Despite some progress in treating cognitive deficits in schizophrenia with second-generation

Abbreviations: 5-HT₃ receptor, 5-hydroxytryptamine 3 receptor; ACSF, artificial cerebrospinal fluid; AP, action potential; D₁ receptor, dopamine D₁ receptor; D₂ receptor, dopamine D₂ receptor; D₃ receptor, dopamine D₃ receptor; D₄ receptor, dopamine D₄ receptor; DA, dopamine; KA, kainate; K_i, dissociation constant; LFP, local field potential; Physo, physostigmine.

antipsychotics, management of negative and cognitive symptoms remains one of the most pressing and unresolved problems of neuropsychopharmacology (Miyamoto et al., 2012).

In recent years, there has been increasing recognition of the role of D₃ receptors in cognition (Nakajima et al., 2013). Behavioral studies in a variety of animals have shown that activation of D₃ receptors impairs attention, working memory, object recognition, associative learning, episodic memory, and spatial learning (Ukai et al., 1997; Smith et al., 1999; Watson et al., 2012), whereas blockade or knockout of this receptor seems to exert pro-cognitive effects (Glickstein et al., 2005; Laszy et al., 2005; Loiseau and Millan, 2009; Xing et al., 2010). Accordingly, in humans, activation of these receptors has been shown to impair cognitive performance, whereas their blockade seems to have pro-cognitive effects (Cools et al., 2006; Hamidovic et al., 2008; Gross et al., 2013). Despite the increasing evidence for D₃ receptor involvement on cognitive processes, the underlying mechanism is still not understood (Nakajima et al., 2013).

Gamma band (30–90 Hz) oscillations have been implicated in a range of aforementioned cognitive processes (Axmacher et al., 2010; Powell et al., 2014) and are known to be generated by the synchronous firing of perisomatic parvalbumin containing fast-spiking basket cells (Gulyás et al., 2010). An increasing number of studies have demonstrated that gamma oscillations are altered and instable in schizophrenic patients and have led to the hypothesis that disturbances in gamma band network activity may be involved in the pathophysiology of the disease (Uhlhaas and Singer, 2010). Associations between gamma disturbances and positive, negative and cognitive symptoms have been observed (Light et al., 2006; Lee et al., 2010; Mulert et al., 2011) making gamma rhythm abnormalities an emerging biomarker in schizophrenia with a potential for use in drug development. In our previous study on the effects of first and second generation antipsychotics on hippocampal gamma oscillations (Schulz et al., 2012a) we found that among 19 investigated receptors, the 5-HT₃ and D₃ receptors seemed to be most strongly implicated in the effect of antipsychotics on hippocampal gamma oscillations. Indeed, elevated D₃ receptor expression have been found in the central nervous system of schizophrenic patients (Gurevich et al., 1997). Moreover, D₃ receptor polymorphisms have been reported to be associated with schizophrenia (Jönsson et al., 2003; Talkowski et al., 2006) and poorer working memory and executive functioning tasks (Szekeres et al., 2004).

In present study, we investigated the effect of D₃ receptors on hippocampal gamma oscillations and its underlying cellular mechanisms. Our findings show that D₃ receptor activation decreases the power, coherence and dynamics of gamma oscillations and that this effect is accompanied by a reduction of the firing rate in CA3 pyramidal cells and the synchrony of their spiking within the gamma cycle. In light of the relationship between hippocampal gamma rhythms and higher cognitive functions, our data offer an explanation how D₃ receptor activation may exert anti-cognitive action and

how its blockade may have pro-cognitive and antipsychotic effects.

MATERIALS AND METHODS

Slice Preparation

Hippocampal slices were prepared from Wistar rats of both sexes at an age of 6–9 weeks (180–230 g). Animal procedures were conducted in accordance with the guidelines of the European Communities Council and the institutional guidelines approved by the Berlin Animal Ethics Committee (Landesamt für Gesundheit und Soziales Berlin, T0330/12). All efforts were made to minimize animal suffering and to reduce the number of animals used. Animals were anesthetized with isoflurane and then decapitated. Their brains were removed and immersed in ice-cold artificial cerebrospinal fluid (ACSF; in mM: NaCl, 129; KCl, 3; NaHCO₃, 21; NaH₂PO₄, 1.25; MgSO₄, 1.8; CaCl₂, 1.6; glucose, 10) aerated with carbogen gas (95% O₂/5% CO₂). The brain was cut into 400 μm thick horizontal slices containing the hippocampal formation with a vibratome (DSK microslicer DTK-1000, Dosaka, Japan). Slices were immediately transferred to an interface-type recording chamber perfused with warm and carbogenated ACSF (36°C, flow rate 1.7 ml/min). Slices were left for recovery for at least 1 h before starting the experiments.

Extracellular Recordings

Local field potentials were recorded from stratum pyramidale of area CA3b with glass pipettes filled with ACSF (resistance < 3 MΩ) as earlier described (Klaft et al., 2012; Çalişkan et al., 2015). Recordings were amplified by a custom-made amplifier, low-pass filtered at 1 kHz and sampled at 5 kHz by a CED 1401 interface (Cambridge Electronic Design, Cambridge, UK). Gamma oscillations were induced by bath application of either 10 mM acetylcholine (ACh) and 2 mM physostigmine (Physo) or 100 nM kainic acid (KA) and stabilized after 90 and 50 min, respectively. Drugs were applied 100 and 60 min after the application of ACh/Physo and KA, respectively, for a period of 60 min. Antagonists, if appropriate, were applied 40 min prior to the agonist or the wash out of ACh/Physo. Note that for the better oxygen supply in the tissue, gamma oscillations were evoked in an interface-type chamber showing slower equilibration of slices with drugs than in submerged chambers (Hájos et al., 2009).

Intracellular Recordings

Intracellular recordings were made after the induction of ACh-induced gamma oscillations from CA3b pyramidal cells in the slice with sharp microelectrodes filled with 2 M K⁺-acetate (resistance 70.3 ± 5.4 MΩ) as described earlier (Schulz et al., 2012b). Intracellular signals were amplified by a SEC-05 LX amplifier (npi electronics, Tamm, Germany), low-pass filtered at 2 kHz and sampled at 10 kHz using the CED 1401 interface. Recordings were done in bridge mode. Cells were impaled during the induction of gamma oscillations. The measurements were started after the stabilization of gamma oscillations but at

least 20 min after penetration. Only cells were accepted which showed stable overshooting APs over the full period of the experiment.

Materials

KA, Physo, PD-128907, PG-01037, and L-741,626 were purchased from Tocris Bioscience (Bristol, UK). ACh was purchased from Sigma–Aldrich (Taufkirchen, Germany).

Data Analysis and Statistics

For the analysis of oscillations, power spectra were calculated every 2 min with a 2-min window throughout the recording and peak power, peak frequency and half bandwidth (at 50% of peak power) were determined off-line by using a custom-made script for the Spike2 software (Cambridge Electronic Design, Cambridge, UK). Since absolute power values vary substantially among slices, they were normalized in every slice to a 10-min period before the drug application, the ACh/Physo washout or the corresponding time in control experiments. Data are presented as mean \pm SEM. Statistical comparisons between the drug-induced effects and the time-matched control experiments were made using Student's *t*-test. Significance level was set at $p < 0.05$.

Phase histograms of APs from intracellular recordings in relationship to the extracellular gamma cycle and the corresponding LFP waveform averages were calculated by the Spike2 software over time windows covering 1000 APs each. 0° represents the trough of the LFP gamma cycles. Occurrence of fast components at the negative peak of gamma oscillations (most probably spikes in pyramidal cells adjacent to the electrode tip) made a low-pass filtering (100 Hz) of the data necessary (Fisahn et al., 1998). Although the FIR filter preserves the shape and phase of the signal better than the infinite impulse response (IIR) filter, we observed a minimal $\sim 10^\circ$ shift in phase which, however, did not bias the calculated changes in phase accuracy or preferred phase induced by drugs. Analysis of the phasic AP timing resulted in a mean vector for each cell. Its mean phase Φ and vector lengths r were used to calculate the mean vectors and the circular standard deviations for the cell populations of different drug conditions (Schulz et al., 2012b). Time-frequency-analysis of LFPs was carried out offline using the Spike2 software.

RESULTS

Dopamine Inhibits Cholinergically Induced Gamma Oscillations in the Hippocampus

Perfusion of the hippocampal slices with acetylcholine (ACh, 10 μ M) and Physo (2 μ M) induced gamma oscillations in the CA3 pyramidal layer with a peak power of $429.22 \pm 253.26 \mu V^2$, a peak frequency of 37.6 ± 0.71 Hz and a half bandwidth of 3.92 ± 0.82 Hz. A narrow half bandwidth in the power spectrum of the oscillation indicates a high temporal coherence and regular oscillations, whereas a wide gamma band means low coherence and less regular oscillations.

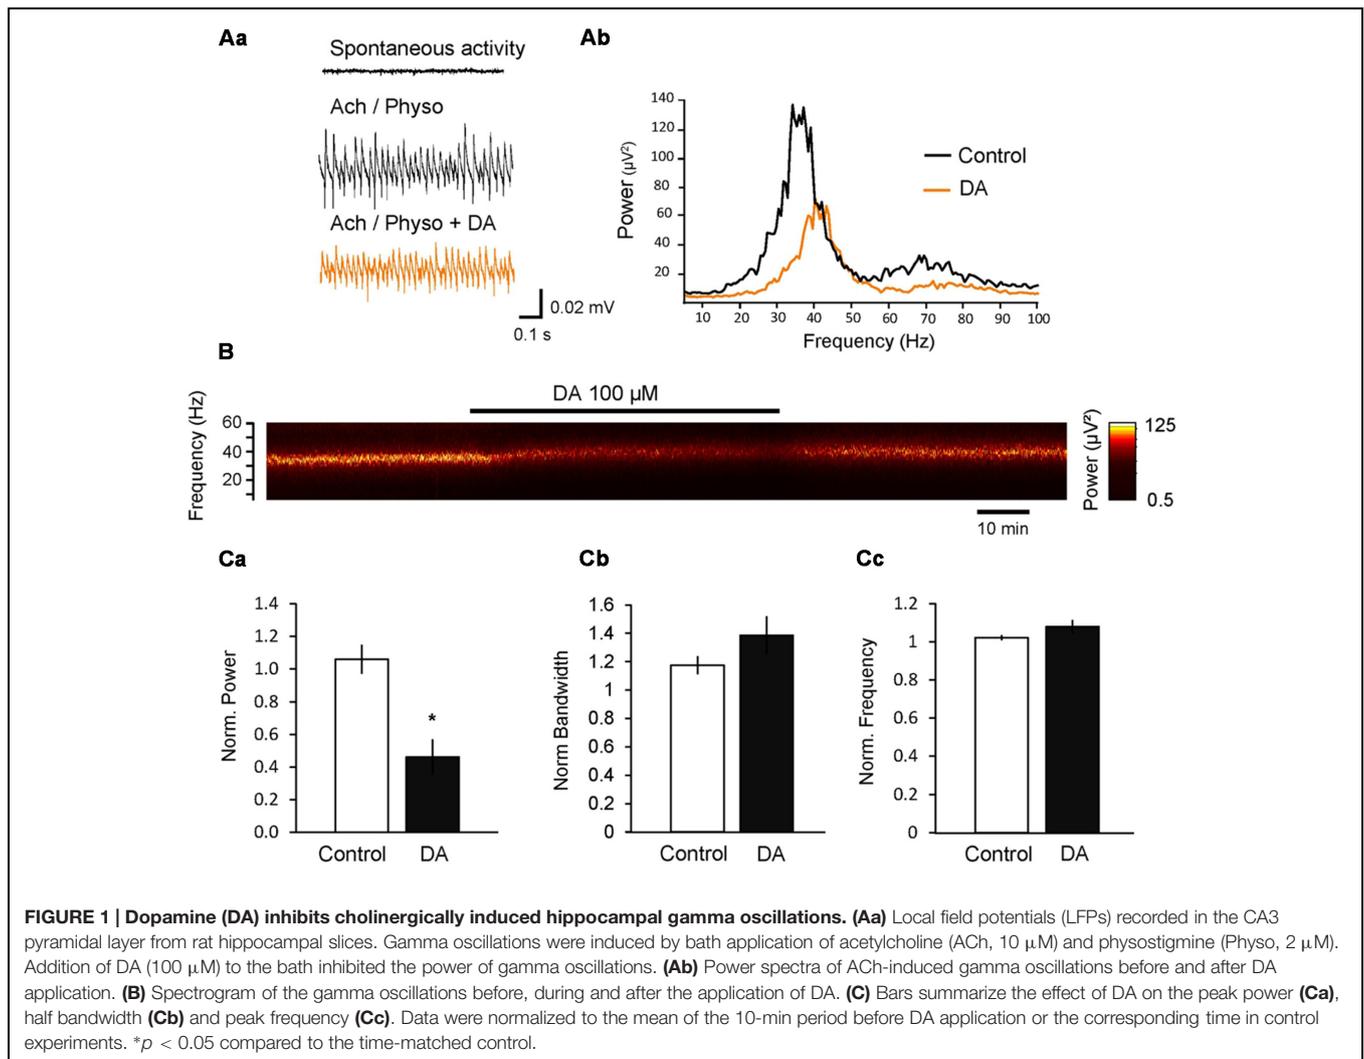

Application of dopamine (DA; 100 μ M) decreased the power to $46.2 \pm 10.8\%$ ($n = 6$; $p < 0.001$, compared to control power change to $106.1 \pm 8.9\%$, $n = 12$; **Figure 1**), whereas the peak frequency did not change significantly ($108.0 \pm 3.5\%$, $p = 0.057$ compared to control frequency change to $102.2 \pm 1.0\%$; **Figure 1**). We also investigated the effect of DA on the width of the gamma band (half bandwidth) and found that DA did not affect significantly the bandwidth of the oscillation ($138.7 \pm 14.1\%$, $p = 0.123$ compared to control half bandwidth change to $117.4 \pm 6.1\%$; **Figure 1**).

Dopamine D₃ Receptors Inhibit Cholinergically Induced Gamma Oscillations in the Hippocampus

Our previous study on the effects of antipsychotics on gamma oscillations suggested that among DA receptors, only the activation of D₃ receptor altered gamma oscillations significantly (Schulz et al., 2012a). To further investigate the effect of these receptors on gamma oscillations, we next applied PD-128907 (10 μ M), a selective DA D₃ agonist and found that it decreased the power to $43.4 \pm 8.1\%$ ($n = 8$, $p < 0.001$ compared to control; **Figure 2**) and broadened the half bandwidth of the gamma oscillations to $216.6 \pm 37.0\%$ ($p = 0.003$, compared to control; **Figure 2**). The peak frequency of the oscillation did not change ($100.2 \pm 4.9\%$, $p = 0.642$ compared to control; **Figure 2**). To confirm whether indeed the D₃ receptors are responsible for the effect of PD-128907, we repeated the experiments in the presence of PG-01037 (10 μ M), a selective antagonist at D₃ receptors. PG-01037 itself did not significantly alter gamma oscillations (power: $133.0 \pm 22.9\%$, $p = 0.212$; bandwidth: $113.9 \pm 12.8\%$, $p = 0.780$; frequency: $101.1 \pm 1.0\%$; $n = 7$; $p = 0.475$ compared to control; **Figure 2D**) but antagonized the effect of PD-128907 on power ($96.0 \pm 20.1\%$, $n = 7$, $p = 0.024$ compared to PD-128907 alone, **Figure 2**) and half bandwidth ($123.0 \pm 14.3\%$, $p = 0.047$ compared to PD-128907 alone, **Figure 2**), whereas the frequency of the oscillation was not changed ($103.1 \pm 14.7\%$, $p = 0.607$ compared to PD-128907 alone, **Figure 2**). On the contrary, L-741,626 (10 μ M), a selective D₂ receptor antagonist, did not reverse the effect of PD-128907 (power: $33.0 \pm 9.8\%$, $n = 7$, $p = 0.422$; half bandwidth: $162.0 \pm 31.3\%$, $p = 0.199$; frequency: $96.8 \pm 6.5\%$, $p = 0.543$ compared to PD-128907 alone). These data indicate that PD-128907 reduced the magnitude and precision of gamma oscillations via selective activation of D₃ receptors.

D₃ Receptors Inhibit Kainate-Induced Hippocampal Gamma Oscillations

Gamma oscillations can also be induced by activation of KA receptors on pyramidal and basket cells (Fisahn et al., 2004), showing a different pharmacological profile compared to ACh-induced gamma oscillations (Schulz et al., 2012b). To test whether D₃ receptors can also modulate KA-induced gamma oscillations, we applied KA (100 nM) on hippocampal slices and reliably induced gamma oscillations in the CA3 pyramidal layer with a peak power of $943.31 \pm 388.64 \mu V^2$, a peak frequency of 42.72 ± 0.96 Hz and a half bandwidth

of 3.72 ± 0.85 Hz. Application of PD-128907 decreased the power to $67.7 \pm 11.9\%$ ($n = 5$; compared to KA control: $142.9 \pm 12.2\%$, $n = 5$; $p = 0.002$) and broadened the bandwidth to $119.4 \pm 5.7\%$ (compared to KA control: 79.2 ± 8.2 ; $p = 0.004$; **Figure 3**). The frequency increased to $105.0 \pm 1.8\%$ (compared to KA control: $95.2 \pm 0.6\%$; $p = 0.001$). We compared the effects of PD-128907 on ACh- and KA-induced gamma oscillations in **Table 1**. As seen, we did not find any statistical different effects on any parameters between the two induction protocols.

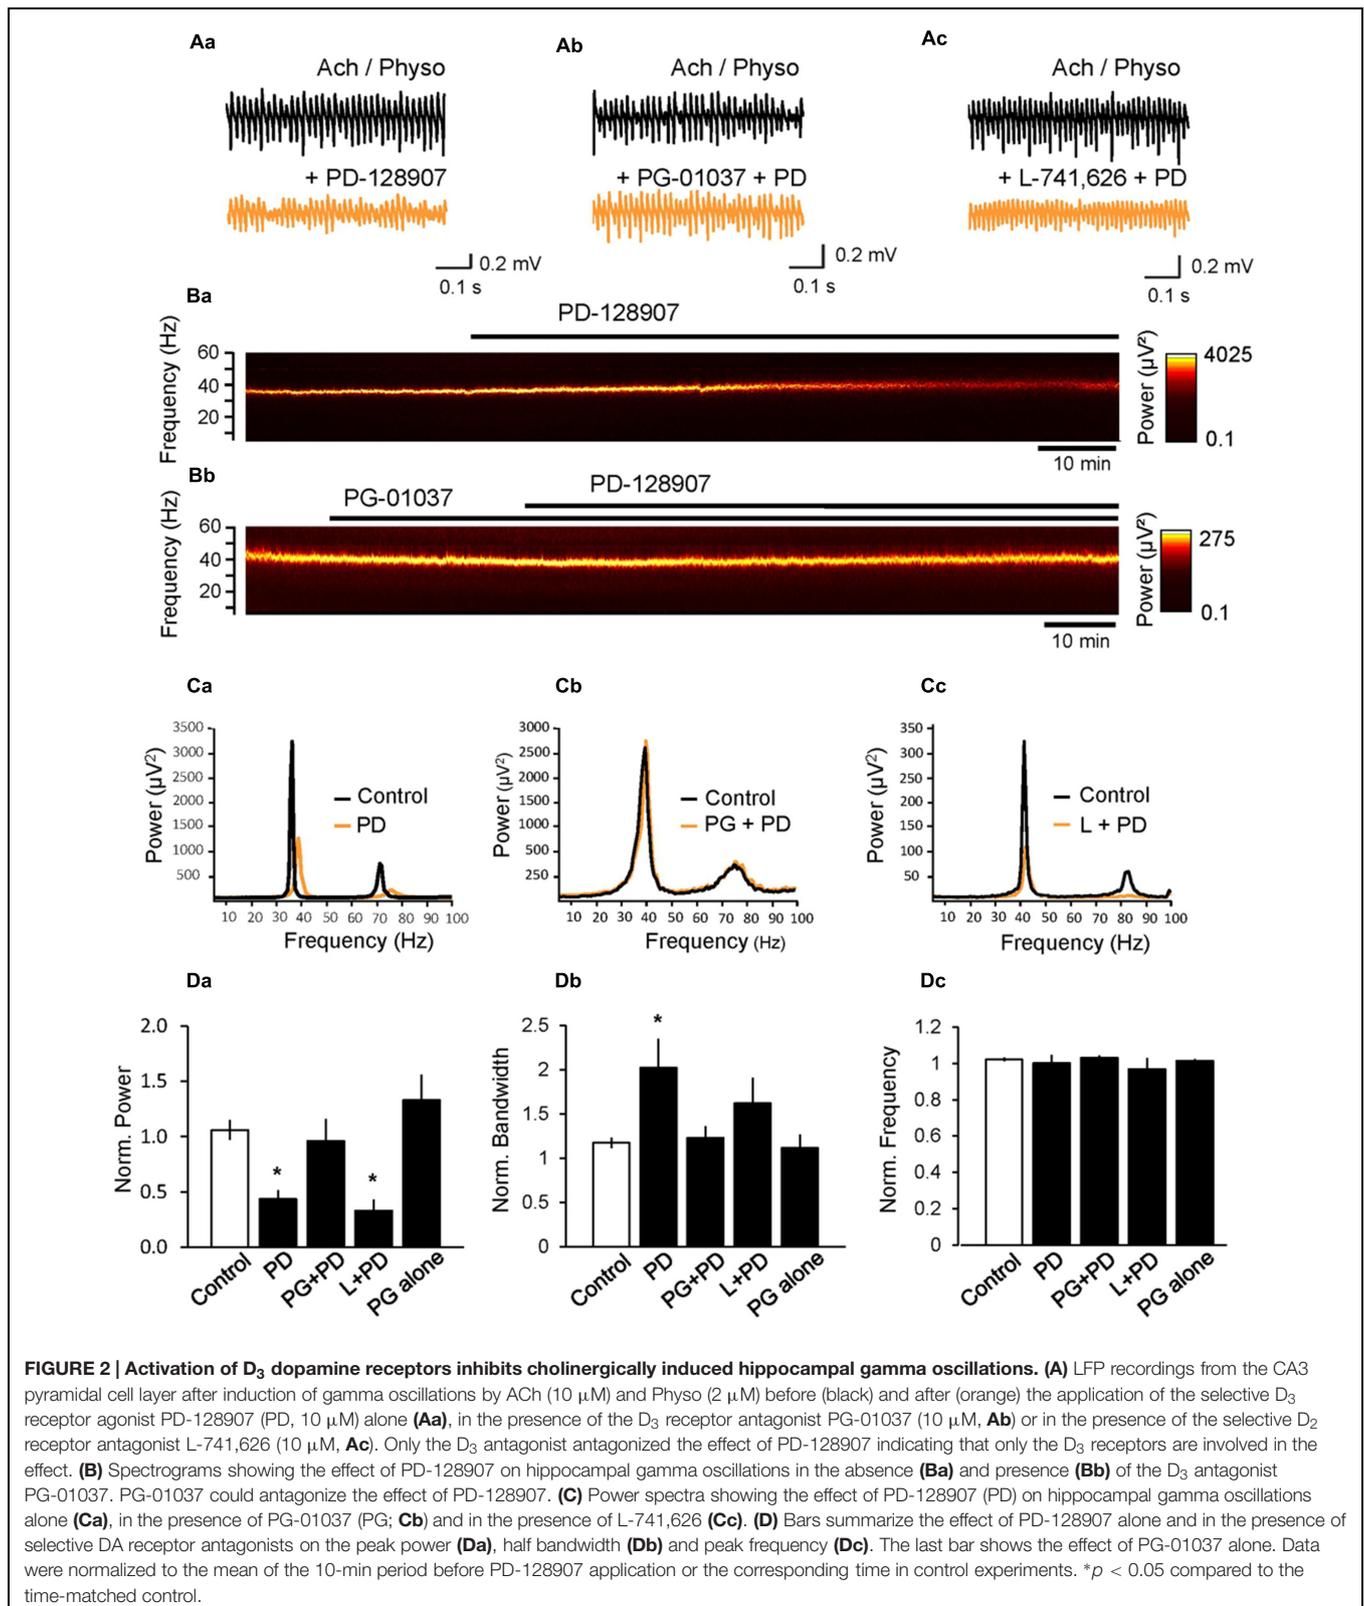

TABLE 1 | Effects of PD-128907 on ACh- and KA-induced gamma oscillations.

Oscillation parameter	ACh (10 μ M) + Physo (2 μ M)	KA (100 nM)
Peak power (mV ²)	43.4 \pm 8.1%*	67.7 \pm 11.9%*
Peak frequency (Hz)	100.2 \pm 4.9%	105.0 \pm 1.8%*
Half bandwidth (Hz)	216.6 \pm 37.0%*	119.4 \pm 5.7%*

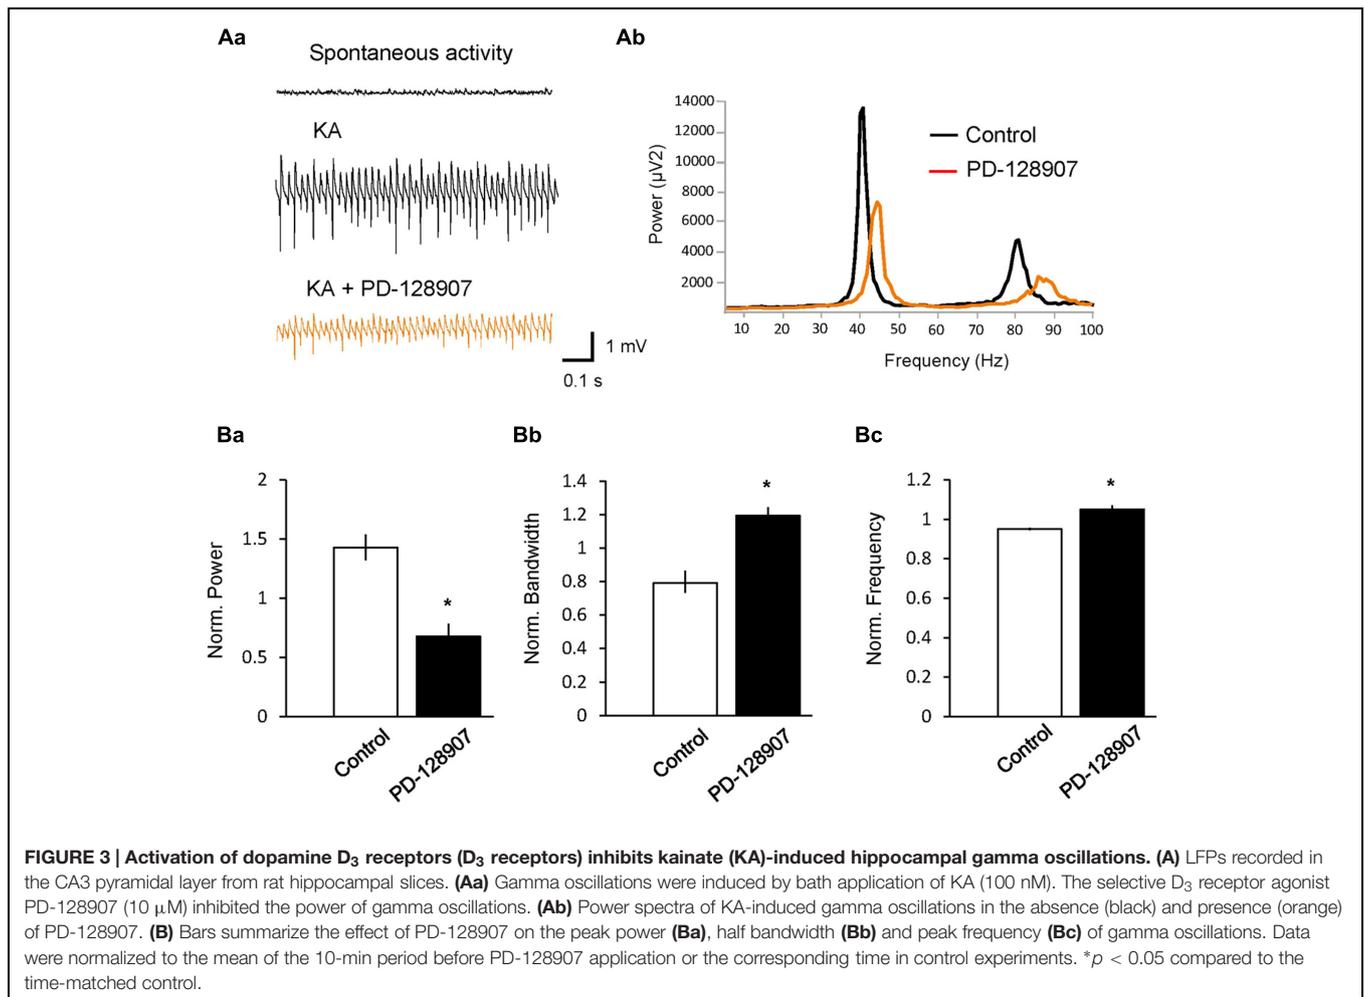

Data were normalized to the baseline period before PD-128907 application. * $p < 0.05$ compared to control experiment.

D₃ Receptors Slow Down the Development of Gamma Oscillations

Since *in vivo* cortical network activity is dynamic and characterized by appearing and disappearing synchronization, we next investigated whether D₃ receptors could have an effect on these dynamics. To do so, gamma oscillations were first induced by ACh and Physo (baseline state) and then washed out after stabilization of the oscillations either in the presence or the absence (control) of the D₃ antagonist PG-01037. As a consequence of the removal of the ACh and Physo, the gamma oscillations became progressively less powerful, faster and less synchronized (**Figure 4A**). After 40 min of washout of ACh and Physo (wash-out state), the gamma power showed massive reduction ($5.8 \pm 1.6\%$ of the baseline state, $n = 9$; $p < 0.001$ compared to baseline state), and both the frequency (43.4 ± 1.4 Hz; $p = 0.013$ compared to baseline state 38.9 ± 1.1 Hz) and the half bandwidth (13.2 ± 1.4 Hz; $p = 0.010$ compared to baseline state 4.1 ± 0.8 Hz; **Figure 4A**) increased. Blockade of the D₃ receptors by PG-01037 (10 μ M) did not affect the desynchronization of the gamma oscillations

(power: $4.3 \pm 1.4\%$ of the baseline state, $n = 7$, $p = 0.497$ compared to the control washout state; frequency: 41.5 ± 1.4 Hz, $p = 0.368$; bandwidth: 11.3 ± 1.1 Hz, $p = 0.340$; **Figure 4**). Next, ACh and Physo were re-perfused to the ACSF to investigate

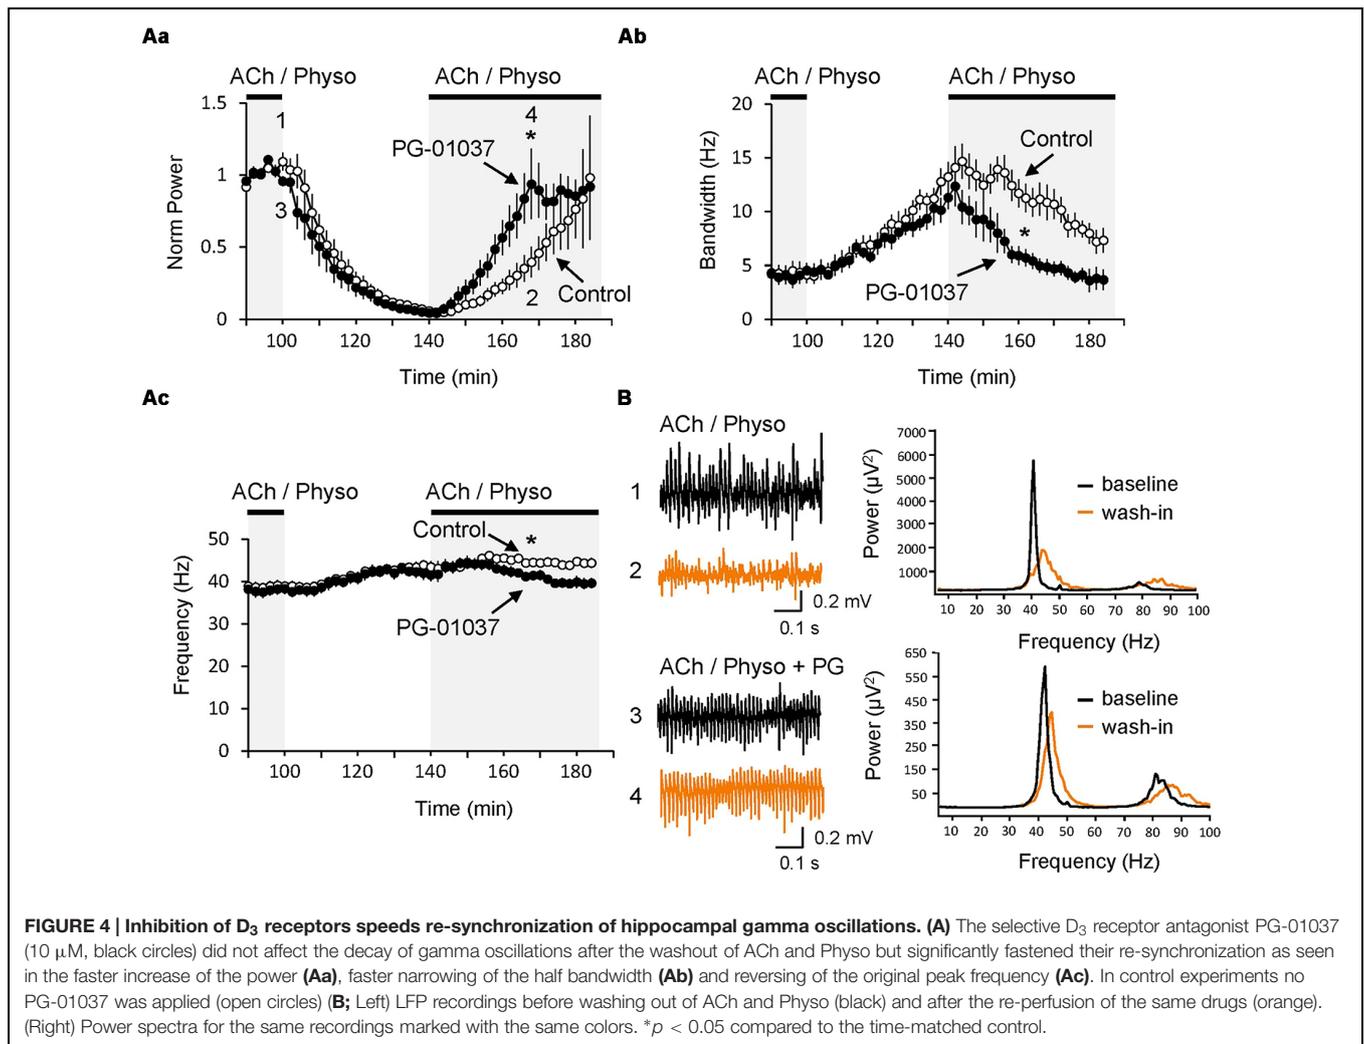

the dynamics of neuronal network resynchronization. In the control experiment, 30 min after the renewed presence of ACh and Physo (re-wash-in state), the power increased significantly to $39.6 \pm 10.56\%$ of baseline ($p = 0.009$ compared to wash-out state) and the half bandwidth started to decrease to 10.9 ± 1.6 Hz ($p = 0.232$ compared to wash-out state; **Figures 4Aa,b**). In contrast, the frequency in the re-wash-in state was unchanged when compared to wash-out state (44.5 ± 1.1 Hz; $p = 0.497$ compared to wash-out state; **Figure 4Ac**).

Interestingly, PG-01037 strongly facilitated the re-synchronization of the oscillations (**Figure 4**). 30 min after wash-in of ACh and Physo (re-wash-in state), the gamma power and the half bandwidth returned back to values comparable to those initially present during the baseline state (power: $93.7 \pm 24.4\%$ of baseline, $p = 0.044$ compared to control experiments; half bandwidth: 4.9 ± 0.7 Hz compared to the baseline state 4.0 ± 0.8 Hz, $p = 0.012$ compared to the control experiments; **Figures 4Aa,b**). Also the frequency decreased, but failed to recover to values of the baseline state. However, compared to the control group at the same time, it is significantly reduced (41.1 ± 1.0 Hz compared to control group 44.3 ± 0.9 Hz, $p = 0.031$; **Figure 4Ac**).

D₃ Receptors Alter Firing Properties of CA3 Pyramidal Cells

To investigate the mechanisms underlying the gamma oscillation inhibition by activation of D₃ receptors, we recorded membrane potential from CA3 pyramidal cells by means of intracellular sharp electrodes after stabilization of cholinergic gamma oscillations. During gamma oscillations, a robust membrane potential oscillation was observed with a mean frequency of 30.2 ± 2.5 Hz and a peak-to-peak amplitude of 1.78 ± 0.57 mV. The frequency of these membrane potential oscillations was comparable to the frequency of the LFP oscillations measured in parallel by the extracellular electrode (LFP: 33.5 ± 1.57 Hz; $p = 0.292$). Application of the D₃ receptor agonist PD-128907 reduced the peak-to-peak amplitude of the membrane potential oscillations to 0.86 ± 0.26 mV ($p = 0.047$), whereas their frequency was not changed (29.1 ± 2.8 Hz, $p = 0.424$).

The cells fired APs at a rate of 9.8 ± 2.4 Hz ($n = 7$) phase-locked to the gamma oscillations (Rayleigh test, $p < 0.001$ for each cell; Moore's test, $p < 0.05$ for the cell population, $n = 7$). Circular analysis of APs related to the gamma cycle revealed a mean phase Φ of $15.3 \pm 15.3^\circ$ (mean \pm circular

standard error; 0° = trough of the gamma cycle) and a mean vector length r of 0.71 ± 0.07 after low-pass filtering, indicating a rather high accuracy of neuronal firing within the gamma cycle ($r = 1$ would mean that all cells fired all APs at the very same phase with maximal synchrony, $r = 0$ that all APs were equally distributed over the gamma cycle).

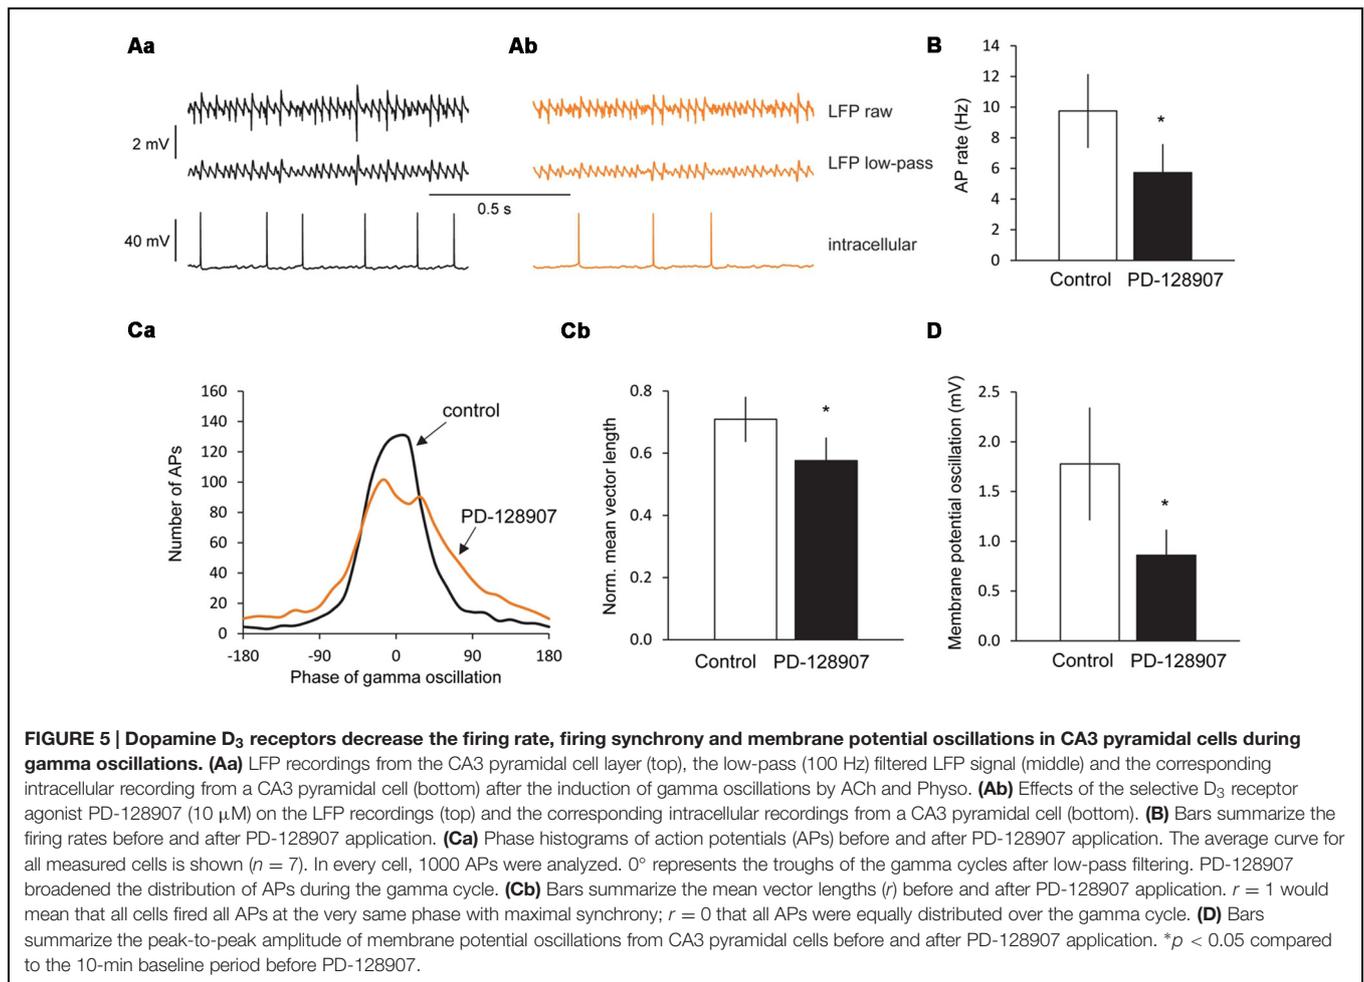

PD-128907 reduced the firing rate of pyramidal cells to 5.7 ± 1.9 Hz ($p = 0.045$, $n = 7$). Whereas Φ did not change ($17.3 \pm 18.4^\circ$, $p > 0.05$) indicating that the cells still fired at the same phase within the gamma cycle on average, r decreased to 0.58 ± 0.07 ($p = 0.027$, Hotelling test for paired samples; Figure 5) suggesting that the synchrony of spike timing was reduced after D₃ receptor activation.

Analyzing spontaneous APs during gamma oscillations before and after PD-128907 application revealed that neither the AP half-width (control: 1.02 ± 0.04 ms; PD-128907: 1.04 ± 0.05 ; $p = 0.680$, not shown) nor the AP amplitude (control: 54.0 ± 3.2 mV; PD-128907: 54.1 ± 4.4 mV; $p = 0.978$, not shown) were affected.

DISCUSSION

D₃ Receptors and Cognition

While preclinical and clinical data suggest that activation of D₃ receptors impairs cognitive processes and blockade or knock out of the receptors have pro-cognitive effects (Nakajima et al., 2013), much less is known about the underlying mechanisms. Our data on hippocampal gamma oscillations may offer an explanation. The hippocampus, expressing D₃ receptors (Bouthenet et al., 1991; Richtand et al., 1995; Khan et al., 1998), is involved in a line of cognitive cues also affected by D₃ receptors (Rubin et al., 2014). Moreover, gamma oscillations in the hippocampus play a key role in signal processing necessary for working memory, attention, learning and retrieval of memory by transiently enabling the communication between neurons and neuronal groups in different brain areas (Lisman and Jensen, 2013). In particular, the CA3 area of the hippocampus with its strong recurrent collateral associative connectivity is thought to keep information in the working memory by means of synchronous oscillation of pyramidal cells belonging to the assembly coding

the pattern until it is stored in the synapses between CA3 pyramidal cells (Rolls, 2013). ACh release in the cortex closely follows the time-course of attention-demanding events (Parikh et al., 2007). Stronger gamma band modulations in V4 correlated with faster reaction times (Womelsdorf et al., 2006; Buehlmann and Deco, 2008) suggesting that the dynamic changes of gamma oscillations have behavioral consequences. Our results suggest that D₃ receptor antagonists might exhibit their pro-cognitive effects by modulation of the dynamics of hippocampal gamma oscillations.

Dopaminergic neurons release DA within the forebrain in two different modes: the low tonic and the high phasic transmission mode. The tonic release underlies the background, steady state level of extracellular DA and is mediated by dopaminergic neuron population activity whereas the phasic release is produced by the activation of dopaminergic neuron firing by behaviorally relevant stimuli (Grace, 1991). High affinity D₃ receptors may be activated during the tonic mode by the lower level of DA within the target sites, whereas low affinity receptors may only be activated by higher DA levels reached only during the phasic release. Our results suggest that the two release modes might trigger opposing effects and DA, by activating different receptors, may increase the signal-to-noise ratio: during the background

release, gamma oscillations are inhibited by the high affinity D₃ receptors. Salient stimuli may transiently increase DA levels in the forebrain activating low affinity DA receptors, such as the D₄ receptor, which may increase gamma oscillations and thus cognitive processes such as attention, perceptual grouping, spatial navigation, and memory (Andersson et al., 2012).

D₃ Receptors and Schizophrenia

Besides genetic studies (Jönsson et al., 2003; Talkowski et al., 2006) there are also pharmacological evidences for the involvement of D₃ receptors in schizophrenia. The atypical antipsychotic amisulpride is a pure D₂ and D₃ receptor antagonist with *K_i* values of 1.7 and 2.5 nM, respectively (Tadori et al., 2011). Aripiprazole, another atypical antipsychotic, has a partial agonistic profile at both D₂ and D₃ receptors with *K_i* values of 2.5 and 4.2 nM, respectively (Tadori et al., 2011). Because of the 7–40-fold higher affinity of endogenous DA for the D₃ versus D₂ receptors (Tadori et al., 2011), the D₃ occupancy by these drugs might be lower (Girgis et al., 2011). Indeed, aripiprazole was only effective against cognitive impairment and negative symptoms at doses similar to or higher than its antipsychotic-like effective dose, suggesting that a higher D₃ occupancy is needed for these effects (Adham et al., 2014).

Cariprazine is a newly developed antipsychotic with profound pro-cognitive effects and very high affinity for the D₃ receptor of 0.08 nM compared to the D₂ receptors: 0.6 nM (Kiss et al., 2010). At a dose equivalent to the ED₅₀ for antipsychotic like efficacy, cariprazine showed high levels (above 80%) of both D₂ and D₃ occupancy which may contribute to its better therapeutic outcome against cognitive and negative symptoms (Adham et al., 2014).

In individuals with schizophrenia, altered and instable gamma oscillations have been observed (Kwon et al., 1999). Our data suggest that antipsychotics with high affinity for the D₃ receptor exert their antipsychotic effects by normalizing altered gamma oscillations. Since schizophrenia is characterized by disturbed (i.e., alternately enhanced *and* reduced) gamma oscillations, we suggest that partial agonism/antagonism at the D₃ receptor may be a better therapeutic approach to treat schizophrenia than a pure antagonism. Partial agonists may stabilize gamma network activity at different circumstances such as different DA levels (Kiss et al., 2010; MacDonald and Bartolomé, 2010).

Cellular Mechanisms Underlying the Inhibition of Gamma Oscillations in the CA3

We did not find significant differences between the effects of D₃ receptors on ACh and KA-induced gamma oscillations (Table 1) as seen, e.g., for purinergic receptors (Schulz et al., 2012b). This may indicate that D₃ receptors exert their non-specific inhibition of the gamma circuitries in the hippocampus by acting at a downstream target involved in both types of gamma oscillations. D₃ receptors are G_i protein-coupled and decrease the intracellular level of cAMP (Missale et al., 1998). In the hippocampus they have been described on pyramidal cells (Khan et al., 1998; Swant et al., 2008). Hippocampal gamma oscillations are generated by synchronous rhythmic inhibition of pyramidal cell firing by fast spiking perisomatic parvalbumin⁺ interneurons (Gulyás et al., 2010). Their activation is due to excitatory drive supplied through feed forward or feedback excitatory inputs from granule and pyramidal cells, respectively. CA3 pyramidal cells fired APs at a rate of ~10 Hz during gamma oscillations which was reduced by activation of D₃ receptors to ~6 Hz. Thus, within one gamma cycle in the presence of D₃ agonists, less pyramidal cells fired. Moreover, the synchrony of the firing at a given phase of gamma oscillations was also reduced, suggesting that the coupling of APs to the gamma cycle became less accurate.

D₃ receptors have been found to selectively downregulate T-type Ca²⁺ channels in the axon initial segment of auditory brainstem interneurons, which in turn reduced the AP output

of these cells (Bender et al., 2010). Given the fact that axon initial segment Ca²⁺ transients have been observed also in pyramidal cells (Schiller et al., 1995), D₃ receptors might also effectively inhibit the firing frequency and synchrony in the hippocampus by this mechanism. We also observed that D₃ receptors inhibited membrane potential oscillations during gamma activity. These oscillations might reflect rhythmic synaptic inputs onto pyramidal cells, and their inhibition suggests that D₃ receptors affect these inputs. Indeed, D₃ receptor activation decreased the amplitude of inhibitory postsynaptic currents in CA1 pyramidal cells evoked in stratum radiatum possibly by causing endocytosis of GABA_A receptors in the apical dendrites (Swant et al., 2008).

CONCLUSION

Fast network oscillations are the groundwork for cognitive processes such as attention, perceptual grouping, spatial navigation and memory. Moreover, disturbed gamma oscillations have been observed in diverse diseases such as schizophrenia, Alzheimer's disease and autism. Our results show that activation of D₃ receptors decreases power, coherence and dynamics of hippocampal gamma oscillations and provide a possible explanation how agonists may impair cognition and how antagonists exhibit pro-cognitive and antipsychotic effects. The complex network dynamics engendered by D₃ receptor activation help shed further light on the generation and maintenance of gamma oscillations in the brain, and may one day be useful in developing targeted treatment options for a variety of neuropsychiatric conditions.

AUTHOR CONTRIBUTIONS

CL conducted and analyzed field potential recordings, SS and KH performed and analyzed intracellular recordings, RK had important role in interpreting the data, ZG designed and analyzed the experiments and drafted the manuscript, all authors revised the manuscript.
