Background: Oxytocin is a stress-attenuating and pro-social neuropeptide. To date, no study has looked at the effects of oxytocin in modulating brain activity in depressed individuals nor attempted to correlate this activity with attribution of mental activity in others. **Method:** We enrolled 10 unmedicated depressed adults and 10 matched healthy controls in a crossover, double blind placebo controlled fMRI 40 i.u. intra-nasal oxytocin study (20 i.u. per nostril). Each subject performed *reading the mind in the eyes task* (RMET) before and after inhalation of oxytocin or placebo control for a total of 80 scans. **Results:** Before oxytocin administration, RMET engaged the medial and lateral prefrontal cortex, amygdala, insula and associative areas. Depressed subjects showed increased anterior ventral activation for the RMET minus gender identification contrast whereas matched controls showed increased dorsal and frontal activity. Compared to placebo, oxytocin in depressed subjects showed increased activity in the superior middle frontal gyrus and insula, while controls exhibited more activity in ventral regions. Oxytocin also led to inverse effects in reaction times on attribution task between groups, with controls getting faster and depressed individuals slower to respond. **Conclusion:** Depression is associated with increased paralimbic activity during emotional mental attribution of others, appearing to be distinctly modulated by oxytocin when compared to healthy controls. Further studies are needed to explore long-term exposure to pro-social neuropeptides on mood in depressed populations and assess their clinical relevance.

Keywords: oxytocin, fMRI, mentalization, theory of mind, depression

INTRODUCTION

Mentalization, a developmentally derived ability to affectively and cognitively infer the mental state of others is crucial to sociality and is enhanced by propitious genetics and secure attachments (Choi-Kain and Gunderson, 2008; Hartmann, 2009). Mentalization allows individuals to estimate others' states of mind, and one's reactions and reflections upon that approximation represent an advantageous ability given that humans need good social bonds for maximum health, adaptation, and richer relationships. It begins in infancy and is facilitated by positive social interactions (Fonagy and Target, 2007) and early attachment experiences (Meins et al., 2002).

Although little is known about the neurophysiology of such experiences, there is evidence that oxytocin, a neuropeptide, promotes positive social interactions and preferences (Hurlemann et al., 2010, Winslow and Insel, 2004; Zak et al., 2005), enhances socially reinforced learning and faces recognition (Marsh et al., 2010, Guastella et al., 2008), exerts anxiolytic effects and is a key modulator of early mother-infant bonding and maternal caretaking (Panksepp, 2005).

It is increasingly released in affectively rich dyadic settings such a when social attunement occurs between mother and infant, in breastfeeding, early skin to skin contact, and later in sexual intercourse and climax (Nelson and Panksepp, 1998; Uvnas-Moberg, 1998). Conversely, low levels of oxytocin have been linked to depression (Bell, 2006), with patients experiencing and observed to possess "dis-affiliation" with others. Also, critical social events marked with insecure attachment or losses of significant others often precipitate depressive symptoms (Anisman, 1984). Functional neuroimaging studies consistently find abnormal ventral limbic and paralimbic activity in depression (Price and Drevets, 2009) – the very same regions implicated in the mediation of social relatedness and mentalization (Choi-Kain and Gunderson, 2008; Hartmann, 2009).

Theory of mind (ToM) is a research and conceptual rubric of an "imagined involvement" that was derived from studies of autism. Mentalization is a higher order capacity, either deficient in clinical populations or progressively enhanced with better caretaking and affective attunement. The failure to evolve mentalization partially

explains pervasive developmental disorders (Ozonoff et al., 1991; Happe, 1994; Happe et al., 1996), schizophrenia (Pilowsky et al., 2000) and reduced social interactions in depression (Uekermann et al., 2008). Lower social function is associated with higher risks for symptom recurrence 1 year after recovering from a major depressive episode (Uekermann et al., 2008). The interest in mirror neurons (Rizzolatti and Fabbri-Destro, 2008) provides a potential neural basis for intent prediction of others. Imaging studies using single photon emission computed tomography (SPECT) (Vogeley et al., 2001b), positron emission tomography (PET) (Happe et al., 1996) or fMRI (Gallagher et al., 2000) have utilized different ToM paradigms (Stuss et al., 2001; Vogeley et al., 2001a) with mixed results. These studies do, however, shed light upon functional networks correlated with mentalization and the social nature of the self and point to the amygdala, the superior temporal gyrus, and medial and orbito-frontal cortex as keys to this high-order mental process.

A "Reading the Mind in the Eyes test" (RMET) (Baron-Cohen et al., 2001) was developed to study emotional mental attribution. This task requires the subject to infer the mental state of an individual from the expression in their eyes and immediately surrounding areas, a measure of imagined involvement as opposed to an appraisal task. Brain regions previously shown to be significantly activated by the task include fronto-temporal neocortical regions, such as left dorsolateral prefrontal cortex, medial frontal cortex and superior temporal gyrus as well as non-cortical regions such as left amygdala, left hippocampus, bilateral insula and left striatum, with some of the brain changes being culture specific (Johnston et al., 2005; Baron-Cohen et al., 2006; Williams et al., 2008).

To date, no studies have investigated the functional neuroanatomy of mentalization in depression nor the effects of oxytocin in modulating brain activity in depressed individuals. Accordingly, we used the RMET task and an intra-nasal oxytocin challenge to investigate mentalization in unmedicated depressed patients and healthy controls. We hypothesized that depressed patients may show greater limbic activity during the mentalization task compared to matched controls, and that oxytocin will lead to a significant decrease in ventro-limbic activity when compared to placebo.

MATERIALS AND METHODS
DESIGN
This is a randomized double-blind crossover design to investigate the acute effects of intra-nasal oxytocin on mentalization in unmedicated depressed patients and matched controls. Primary outcome measures consisted of functional blood oxygen level dependent MRI (BOLD fMRI) scans. Secondary outcome measures were behavioral measures (speed of reaction time). This study was approved by the Medical University of South Carolina (MUSC) Institutional Review Board funded by a grant from the Hope for Depression Research Foundation, and collaboratively conducted with the MindBrain Consortium at Summa Hospitals, Akron, Ohio.

SUBJECTS
Subjects were recruited from the MUSC outpatient psychiatric services, the Mood Disorders Program (MDP) and through local advertisement. We screened 15 Healthy and 20 Depressed subjects and enrolled 22 adult subjects. All subjects signed written informed consent. Depressed patients met criteria for major

depressive episode by Structured Clinical Interview for DSM-IV Axis I Disorders (SCID-I) criteria of less than 24 months in duration with an antidepressant treatment history form (ATHF) severity one or less failed trials. Healthy controls were screened for any active DSM-IV-TR Axis I diagnosis (with the exception of caffeine or nicotine abuse). Subjects were off all psychotropic medications for at least 2 weeks prior to first scanning session. Subjects were excluded if they were medically unstable or had an active neurodegenerative or epilepsy disorder. All presented data are from subjects who completed a baseline clinical assessment visit along with two scanning sessions over a maximum of 3 weeks period.

SCANNING AND DRUG INHALATION PROCEDURES
At each scanning session, subjects underwent two identical blood oxygentation dependant (BOLD) fMRI scans before and approximately 10 min after inhalation of study drug (20 IU oxytocin or placebo per nostril; Lee-Silsby Pharmacy, Cleveland, OH, USA). The oxytocin dose is comparable to that used previously in human studies of behavior (Epperson et al., 1996a,b; Ditzen et al., 2007). Randomization and subject's assignment were performed by MUSC Investigational Drug Services and the McClellan Banks Pharmacy. Data was unmasked after study completion and all data were locked. Subjects abstained from alcohol and nicotine for 12 h before the experiment.

READING THE MIND IN THE EYES PARADIGM
We adapted the reading the mind in the eyes paradigm (RMET) for presentation in the scanner and an event-fMRI design. We used the Integrated Functional Imaging System (IFIS-SA) (Invivo, Orlando, FL, USA) to visually present the paradigm and record responses of the participants. The RMET task consisted of three conditions: affect attribution of faces cropped around the eyes in rectangular shape (referred in the text as RMET), gender identification of the same photographs, and a basic motor cued response. Possible attribute adjectives, gender attributes ("male," "female") and motor cues ("yes," "no") were positioned at the four corners with optimal or normed responses equally randomized for all presentations. Participants pressed a hand-pad button to indicate their attribute of choice. On the hand-pad, the left and right index fingers corresponded to the top left and top right corners of images, and the left and right thumbs corresponded to the bottom left and bottom right corners of images. This entire paradigm consisted of 32 events for each condition (96 events total presented in a fixed-randomized order) and lasted approximately 769 s. The duration of each event lasted 7 s, separated by a jittered inter-stimulus black screen [inter-stimulus interval (ISI) range 6–4753 ms, ISI average = 1008 ms].

IMAGE ACQUISITION
Images were acquired using a 3T MRI scanner (Intera, Philips Medical System, Netherlands) with a SENSE parallel imaging head-coil. A sagittal reference image was first acquired, to guide positioning of the functional scans along the anterior commissure-posterior commissure line. For scanning during the RMET paradigm, echoplanar (EPI) transverse images were acquired with the following parameters: 414 volumes, repetition time = 1867 ms, echo time = 30 ms, flip angle = 90°, field of view = 208 mm, matrix = 64×64, SENSE factor = 2, 32 slices, 3.25 mm with no gap, yielding a voxel size of $3.3 \times 3.3 \times 3.25$ mm^3.

DATA ANALYSIS

Demographics and psychological measures

Descriptive statistics were performed using SPSS 16.0 for Macintosh (SPSS Inc., Chicago, IL, USA) and included mean, standard deviation, Student's *t*-test, Pearson Chi-square test. All tests were two-tailed at 0.05 significant level and assumed equal variance.

fMRI data processing methods

fMRI image data was first transferred to a workstation where it was converted into Analyze format using MRICro[1] and then subjected to the following pre-statistics processing steps using FMRI FEAT (FMRI Expert Analysis Tool) Version 5.92, part of FSL (FMRIB's Software Library[2]). Each dataset was spatially normalized into an high resolution structural scan MNI template with FLIRT (Jenkinson and Smith, 2001; Jenkinson et al., 2002) We applied MCFLIRT for motion correction (Jenkinson et al., 2002) and reviewed all datasets for remaining motion, which was less than 0.5 mm along all three major axes (x, y, z) for all subjects. In addition, we applied non-brain removal using BET (Smith, 2002); spatial smoothing using a Gaussian kernel of FWHM 8.0 mm; grand-mean intensity normalization of the entire 4D dataset by a single multiplicative factor and highpass temporal filtering (Gaussian-weighted least-squares straight line fitting, with sigma = 50.0 s).

Behavioral data

Individual responses collected by IFIS during RMET were collated, checked for missing responses and collated in an Excel spreadsheet. Reaction Time (RT) and Accuracy of Response (AC) were noted. Final analysis included mean, standard deviation, Student's *t*-test, and Pearson Chi-square test. All tests were two-tailed and assumed equal variance.

For mixed models examining the effects of drug by time, pre-drug administration conditions were coded in the dataset as "0," post-drug were coded as "1," placebo conditions were coded as "0" and oxytocin conditions were coded as "1." Hierarchical Linear Modeling (HLM) was implemented using PROC MIXED in SAS (SAS Institute Inc., Cary, NC) to assess the linear effect of the interaction of "time" (pre to post-drug administration) and "treatment type" (oxytocin versus placebo) on reaction time and accuracy of response between groups (thereby by testing a series of $2 \times 2 \times 2$ mixed models). HLM has been shown to handle nested models with serially dependent data points and randomly distributed missing values appropriately (Raudenbush and Chan, 1993; de Leeuw and Kreft, 1995; Hoffman and Gavin, 1998; Nezlek and Zyzniewski, 1998). Additionally, this approach is growing in popularity among clinical and educational researchers due to its flexibility and appropriateness for data typically encountered in clinical and social science research (Sliwinski and Hall, 1998; Kuo et al., 2000; McGuigan et al., 2003). The covariance structure was "unstructured" and the estimation method was REML.

fMRI statistical analysis

Time-series statistical analysis was carried out using FILM with local autocorrelation correction (Woolrich et al., 2001). Potentially confounding motion over time was regressed out. Z (Gaussianized T/F)

statistic images were thresholded using clusters determined by $Z > 2.3$ and a (corrected) cluster significance threshold of $p = 0.05$ (Worsley, 2001) for identification of voxels with statistically significant activation during three conditions in individual subjects (fixed effect). We then performed a group mean (baseline depressed + matched controls) and unpaired *t*-tests between oxytocin and placebo conditions (random effect; FLAME 1 + 2 option).

RESULTS

Eight unmedicated depressed subjects (eight females, four African-Americans, four Caucasians) and nine matched controls (eight females, five African-Americans, four Caucasians) completed all assessments required for this study. The mean age for depressed subjects was 35.5 years (SD = 10.62), ranging from 26 to 60, and for controls, 36.4 years (SD = 11.40), ranging from 25 to 59. Mean years of education post high school were 2.56 (SD = 1.95) for depressed subjects and 4.22 (SD = 1.79) for controls. Co-morbidities of depressed subjects included a past history of alcohol dependence ($n = 2$), social phobia ($n = 1$), obsessive compulsive disorder ($n = 1$), panic disorder without agoraphobia ($n = 2$), anxiety ($n = 1$), and anorexia nervosa ($n = 1$). All subjects were right handed. Sixteen subjects were employed either part or full time, and one was a homemaker. The patient cohort had significant depressive and anxiety symptoms compared to healthy controls and tended to show reduced capacity for empathy but not? overall emotional intelligence as measured by the Mayer–Salovey–Caruso Emotional Intelligence Test (MSCEIT) (Mayer et al., 2003) (See **Table 1**). There was a significant inverse correlation between subjective depressive symptoms (IDS-SR) and empathy quotient (df = 21, $r^2 = 0.35$, $p = 0.004$).

BEHAVIORAL RESULTS

Reaction time

Figure 1 shows reaction time slope changes with intra-nasal oxytocin in healthy controls and depressed subjects across RMET, gender attribution, and motor cued response. A significant effect was found for the slope of the drug × time × group reaction time (RT) interaction during RMET [$F(1,2551) = 5.99$, $p = 0.015$]. A decreased RT slope was found in healthy matched controls [$t(2551) = 2.20$, $p = 0.028$] relative to an increased slope in depressed subjects [$t(2551) = 2.45$, $p = 0.015$], suggesting that oxytocin administration was associated with faster reaction times in the healthy cohort and slower reaction times in the depressed cohort after controlling for placebo and pre-drug performance. A significant effect was also found for the slope of the drug × time × group RT interaction during gender attribution [$F(1,2510) = 14.82$, $p < 0.0001$]. Again, a decreased RT slope was found in healthy matched controls [$t(2510) = 4.27$, $p < 0.0001$] relative to an increased slope in depressed subjects [$t(2510) = 3.85$, $p < 0.0001$]. Again, this suggests that oxytocin administration was associated with faster reaction times in the healthy cohort and slower reaction times in the depressed cohort after controlling for placebo and pre-drug performance. *Lastly,* a significant effect was found for the slope of the drug × time × group RT interaction during motor cued response [$F(1,2507) = 6.87$, $p = 0.009$]. Oxytocin administration was associated with decreased RT slope in healthy matched controls [$t(2507) = 2.92$, $p = 0.004$] relative to an increased slope in depressed subjects [$t(2507) = 2.62$, $p = 0.009$] after controlling for placebo and pre-treatment performance. The mean effect size

Table 1 | Demographics and clinical characteristics of unmedicated depressed subjects and their matched healthy controls. Significant differences were found in depressive symptoms (HDRS, IDS-SR, ANPS-Sadness), anxiety symptoms (STAY-I and ANPS-Fear), and capacity to care (ANPS-Care). Note that a trend for differences on Empathy Quotient and ANPS-Spirituality.

	Depressed	Controls	Significance
Age	M = 35.5, SD = 10.62	M = 36.4, SD = 11.40	0.86

Table 2 | Reaction times (RT) in milliseconds and accuracy of response (AC) in unmedicated depressed subjects and their matched healthy controls during fMRI sessions. Data represent mean and standard deviation across three variables (RMET, gender attribution, and cued-motor response) and four conditions (pre-oxytocin, post-oxytocin, pre-placebo, and post-placebo).

	Pre-placebo	Pre-oxytocin	Post-placebo	Post-oxytocin
RT RMET				
Matched controls	4396.3 ± 1499.8	4198.5 ± 1728.6	4092.5 ± 1560.8	4222.8 ± 1293
Depressed	3945.1 ± 1260.7	4201.6 ± 1169.3	3878.5 ± 1328.3	4119.8 ± 1297.2
RT gender attribution				
Matched controls	2168.7 ± 958.3	2126.1 ± 853.3	2023.2 ± 950.7	1936.4 ± 710.3
Depressed	1673.7 ± 651.6	1787.4 ± 717.6	1648.3 ± 774.5	1771.3 ± 880.8
RT motor cued response				
Matched controls	1416.8 ± 592	1464.4 ± 730.2	1363.1 ± 791.9	1351.7 ± 465.6
Depressed	1214.7 ± 472.9	1257.6 ± 505	1134.6 ± 461.8	1240.5 ± 395.9
AC RMET				
Matched controls	60.6%	59.4%	64.2%	67.9%
Depressed	65.8%	67%	67%	70.6%
AC gender attribution				
Matched controls	89.4%	82.8%	87.8%	90%
Depressed	87.2%	88.1%	83.8%	86.9%
AC motor cued response				
Matched controls	98.1%	94.1%	93.1%	97.8%
Depressed	96.9%	97.5%	95.6%	97.2%

(Cohen's d) across all RT for oxytocin is small at 0.18. **Table 2** shows the mean values (and standard error) for each variable pre to post-oxytocin or placebo.

Accuracy of response
There were no significant changes with accuracy of response (AR) across variables or conditions. **Table 2** summarizes the findings described above and **Table 2** shows the mean values (and standard error) for each variable pre to post-oxytocin or placebo. No significant antidepressant effects of oxytocin were observed in this provocation-paradigm study.

FUNCTIONAL IMAGING
The corresponding brain atlas coordinates and the fMRI activations for healthy controls and depressed subjects are presented in Table 3.

Baseline mean groups

During the RMET task, at baseline and prior to inhaling study drug, depressed and normal control subjects showed statistically significant activations of the visual cortex, associated visual areas, the fusiform gyrus, and various limbic areas, along with the anterior cingulate. The depressed group showed significant activation in the right anterior cingulate gyrus (BA32), insula and middle frontal gyrus (BA6), left superior parietal lobe (BA7) and head of the caudate. The two groups were not significantly different in intensities or areas of activation on the mentalization task. They did however differ when contrasting RMET minus gender identification (see **Figure 2**). The depressed group showed predominantly ventral activations with left inferior frontal gyrus, superior temporal gyrus, subgenual cingulum and head of the caudate. The healthy controls showed activations in the superior and middle frontal gyri, the orbito-frontal cortex and middle temporal gyrus (BA21, 22).

Oxytocin versus placebo

Depressed group. During RMET, there was significant activation with oxytocin compared to placebo in bilateral superior temporal gyrus (BA38, 41, and 22), right insula, right precentral gyrus (BA44), bilateral cingulate gyri (BA32), left anterior cingulum (BA24), left supramarginal gyrus (BA40), right inferior frontal gyrus (BA47), right superior and middle frontal gyri (BA8, 9, and 10) (see **Figure 3**). On motor cues, oxytocin led to significant increases in bilateral superior and medial frontal gyri (BA6, 8 and 9). Gender identifications and RMET minus gender identifications did not differ between oxytocin and placebo conditions.

*Matched healthy controls.* During RMET, there was significant activation with oxytocin compared to placebo in right parahippocampal gyrus extending to the amygdala, inferior frontal gyrus (BA47), left head and tail of the caudate and superior temporal gyrus (BA22

FIGURE 1 | Reaction time slope changes with intra-nasal oxytocin in healthy matched controls (blue) and depressed subjects (red) across RMET, gender attribution and motor cued response.

FIGURE 2 | Baseline RMET minus Gender Attribution: Predominant ventral activations in unmedicated depressed subjects at baseline (red) compared to superior frontal and temporal activations in healthy matched controls (blue).

and 38) (see **Figure 4**). On Motor Cues, oxytocin led to significant increases in right superior temporal gyrus (BA41 and 42) and right cerebellum. Gender identifications and RMET minus gender identifications did not differ between oxytocin and placebo conditions.

DISCUSSION

To our knowledge, this is the first study investigating intra-nasal oxytocin in unmedicated depressed and matched controls using fMRI. We employed RMET, a visual perceptual task that involves more affectively valenced decision making and mental attributions of other people. The task emphasizes affective "involvement" rather than cognitive "appraisal." At baseline, the two groups were significantly different in their distress symptoms and capacity to empa-

thize. Along with activating attentional and visual networks, RMET also involved anterior ventromedial regions. Oxytocin differentially affected normal and depressed cohorts. In controls, oxytocin enhanced activation of ventromedial, amygdala, parahippocampal and semantic associative areas. Depressed subjects showed increases in higher order cognitive areas and insula. Oxytocin also showed opposite effects in reaction times with increased speed of response in healthy controls and a slowing among the depressed.

MENTALIZING IN DEPRESSION

The mentalization task is a novel paradigm in this population. It is relatively complex and recruits several complementary limbic, attention and high-level executive networks. Pathological states
FIGURE 3 | Baseline (green) and added activations with oxytocin compared to placebo (red) in unmedicated depressed subjects during RMET.
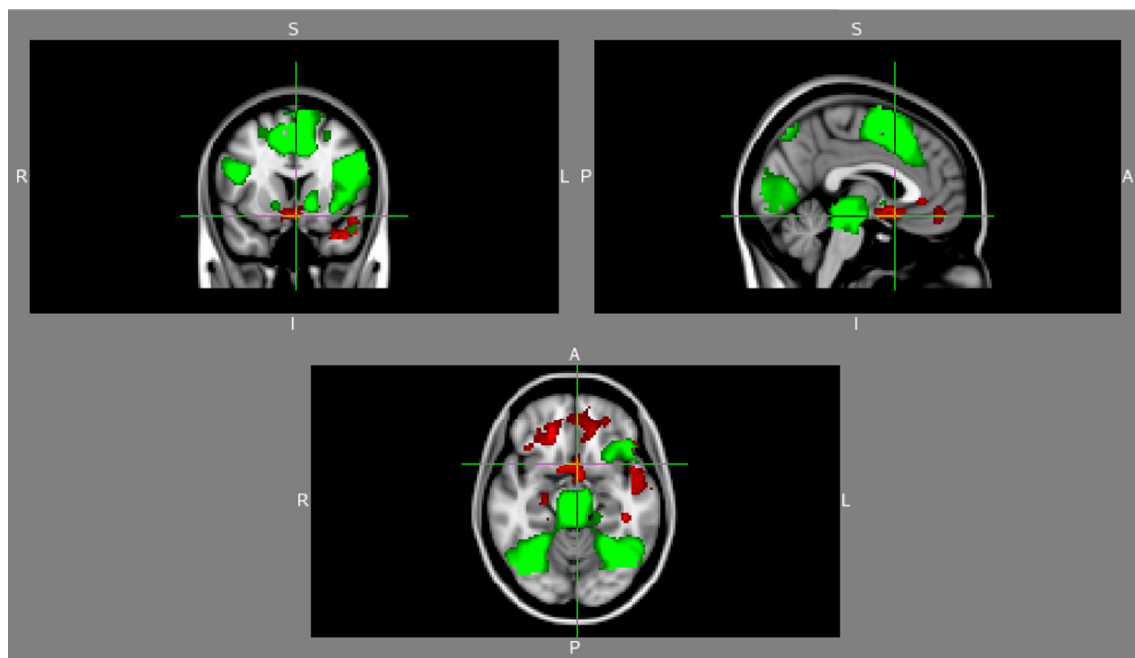

FIGURE 4 | Baseline (green) and added activations with oxytocin compared to placebo (red) in healthy matched controls during RMET.

such as depression degrade mentalization (Uekermann et al., 2008), perhaps by limiting emotional involvement with all things and people in their experiential world and reflection upon their internal world, functioning more in a purely cognitively appraised, distant or disconnected fashion. The results reported here suggest that depression may represent a homeostatic alteration in contributions of these systems to executing this task compared to healthy controls.

Many of the findings we report are in line with abundant existing evidence of limbic and executive dysfunction in depression (Green et al., 2007; Northoff, 2007). The distinct increase in ventro-limbic activity is also reminiscent of mood induction studies (George et al., 1995; Mayberg et al., 1999). But the direct consequences of such dysregulation in not clear since behavioral performance on RMET in depressed patients was not significantly different from controls

and did not appear biased towards negative affect. The task itself may not be difficult enough to tease out such biases (Domes et al., 2007). Whether these differences in functional activity are associated with state or trait markers also remains unclear.

Although we did not see any significant difference between groups with RMET contrast, we did find higher anterior subgenual cingulate activation and anterior temporal pole during RMET minus gender attribution in depressed, suggesting that mentalization preferentially linked processing of perceptual inputs to internal visceral emotional experiences (**Figure 2**). This contrasts with activations of anterior frontal pole, supramotor and working memory areas in healthy controls. Note that both groups exhibited activations of semantic and word processing regions but there too, activity was more restricted to the inferior frontal gyrus in depressed patients. These finding, along with a relatively faster reaction times in depressed patients, suggests that this cohort mentalized in a more primary, impulsive way, whereas in healthy controls the task engaged a more distributed network that involved higher order abstract cognitive and emotional integrative regions (Petrides and Pandya, 2007).

THE EFFECTS OF OXYTOCIN ON MENTALIZATION
Our fMRI data reveals that intra-nasal oxytocin has a differential effect upon the brain of depressed and normal people, as if in the state of depression, oxytocin "recruits" a more emotionally reflexive appraisal state that is less affectively reflective. Oxytocin increased primarily emotional circuits as in the cingulate (BA24) and insula in depressed patients during RMET. These increases appear to be in the same general directions as baseline activation patterns (**Figure 3**). Conversely, oxytocin increased ventral activity in healthy controls adding a different and substantial "primary affective appraisal" regional component (amygdala, parahippocampus) along with social appraisal (BA25 and 32) to baseline activation pattern (**Figure 4**). This is in contrast with reports of reduced activation of the amygdala in response to fear-inducing visual stimuli coupled with oxytocin inhalation (Kirsch et al., 2005). Oxytocin also moderately decreased the reaction time in healthy controls. This is in line with reports of oxytocin improving RMET in healthy individuals when analyses focused on the more complex and difficult items (Domes et al., 2007), In contrasts, depressed patients remained faster at their responses than controls but tended to show a more deliberative response to the situations. Oxytocin did not alter the accuracy of responses in either group.

LIMITATIONS
Number of subjects is relatively small although the total scans analyzed is 80. Individual variability and total sample size cannot identify main responders. The exclusion of one male subject in healthy controls did not significantly change the results. The effect size on behavioral response (RT) is small and perhaps due to relatively small single dose of oxytocin and the intra-nasal route. Added to this are the small size of the olfactory nasal mucosa, the small instillation volume and the relatively fast turnover of cerebrospinal fluid which will render the total amount of active oxytocin that reached the brain small (Pontiroli, 1998; Petrides and Pandya, 2007). Oxytocin is also known to gradually degrade into several metabolites that may reduce the potency of the preparation (Claybaugh and Uyehara, 1993; Burbach et al., 1998). The effect size on RT may have been influenced by the relative simple to moderate difficulty in the RMET images themselves which may limited the range of improvement after oxytocin inhalation (Domes et al., 2007).

In summary, we have shown that depressed subjects perform a mental attribution task differently than healthy matched controls. In addition, a single dose of intra-nasal oxytocin has distinct effects on functional activity of networks involved in a mental attribution task and enhances cognitive and emotional appraisal. These effects appear to be dependent on the distress levels of individuals, their likely capacity to empathize and the underlying homeostasis of the affective primary brain processes. It is not clear from our study what role, if any, oxytocin may have in modulating and perhaps treating depressive symptoms. Other studies of this important component of depressive pathology are needed with likely longer exposure and repeated oxytocin administration.
