Editorial on the Research Topic

Impacts of Tropical Landscape Change on Human Diet and Local Food Systems

The impacts of changing diets on land use and land cover has been an important area of research in recent years (Foley et al., 2011; Tilman and Clark, 2014; Fanzo and Davis, 2019; Willett et al., 2019). This special issue looks at the reverse side of this relationship – how land use change affects the diets of local communities living in landscapes where change is taking place. Clear links between forest cover and diet and nutritional outcomes have been shown (Johnson et al., 2013; Ickowitz et al., 2014; Rasolofson et al., 2018; Fisher et al., 2019), while more recent work has started to disentangle the differential impacts of land use type, composition and configuration on diets and the consumption of specific food groups (Rasmussen et al., 2019; Gergel et al., 2020). This special issue brings together a collection of papers that examine the effects of land use and land use change on diet and nutritional outcomes in the tropics. It assembles papers from a wide range of disciplines, covering the links between forest conservation, deforestation, hydropower development, and changing patterns of agricultural production on diets and nutrition across a range of settings.

Rasolofson et al. use data from the Demographic and Health Surveys (DHS) to examine the effects of forests on nutritional status, particularly stunting, across 25 low and middle-income countries. The authors compare the prevalence of stunting for children with and without access to forest, with access being defined as living in communities within 3 km of the nearest forest edge and with at least 30% forest within a 5 km radius around the community center. They find that the percentage of stunted children among those with access to forest is 30.25%, while the stunting prevalence for children without access is 37.36%. The authors argue that access to forest significantly reduces child stunting (at least 7.11% points average reduction) – and that forest conservation therefore is a potentially effective nutrition-sensitive intervention.

Like Rasolofson et al. and Borgerson et al. also argue that forest conservation can address malnutrition, but they reach this conclusion through concerns about the sustainability of bush-meat hunting. In their study of 13 communities in Masoala National Park in Madagascar, they find high rates of food insecurity and malnutrition as well as high reliance on forests for food, particularly wild meat. They also find that although forests make important contributions to

nutrient consumption, the extraction rates for wild meat are unsustainable. They thus advocate for conservation to reduce unsustainable hunting by helping communities to gain access to domestic sources of nutrient-rich foods.

Using data from 1,783 households across seven sites (in Bangladesh, Burkina Faso, Cameroon, Ethiopia, Indonesia, Nicaragua, and Zambia), Baudron et al. examine the pathways through which forests contribute to household dietary diversity and consumption of fruits, vegetables, and meat. Using piecewise structural equation modeling, they compare the relative importance of a direct pathway (e.g., consumption of forest food), an income pathway (income from forest products used to purchase food from markets), and an agroecological pathway (forests and trees sustaining farm production). The results show major variation in the relationships between forest cover, pathways, and dietary outcomes across sites. Forest cover and dietary quality were positively related in some sites but negatively in others, and the importance of different pathways was also highly variable. The study highlights the significant variation in both the relationship between land use change and diets across settings, and the mechanisms that underly those relationships.

Rasmussen et al. examine how household wealth, on-farm production, and landscape context (forest cover and market access) are related to the dietary profiles of rural households in Ethiopia. Through cluster analysis of data from the World Bank's Living Standard Measurement Survey (LSMS), they identify three main household diet types: low diversity; high diversity rich in fruits and vegetables; and high diversity with increased consumption levels of oils, fats and sugars. The low diversity diet was mostly found among low- to middle-wealth households who farmed cereal grains. Households with diverse fruit-vegetable diets were most often engaged in coffee-agroforestry farming and tended to live in landscapes with higher forest cover. Finally, households with highly diverse oil-sugar diets tended to be wealthier and situated closer to roads. The study highlights the complex interactions among factors correlated with diverse diets and shows how even small increases in forest cover can increase dietary diversity and consumption of healthy foods.

While the previous papers look at how and under what conditions forests contribute to diets, Friant et al. and Acharya et al. investigate what happens to diets and nutrition when these forests are lost.

Friant et al. bring to light the ways in which dietary patterns differ across intermediate stages of deforestation and market integration in Cross River State in Nigeria. Using data on dietary diversity and food access collected from 528 households across six communities, they find that although forest-edge communities consumed less green leafy vegetables and less bushmeat than forest-interior communities, they consumed more dairy, eggs, beans, and other fruits and vegetables. Also, households from forest-edge communities exhibited significantly lower household food insecurity access scores. They conclude that in the intermediate stages of deforestation, communities may be able to get the "best of two worlds" with increased access to markets and continued access to forests.

Acharya et al. use Demographic and Health Survey data from 15 countries in Sub-Saharan Africa to explore the relationships between deforestation and the double burden of malnutrition. They find that forest cover loss is marginally associated with a higher probability of having an overweight woman and a stunted pre-school child in the same household, but not with having an overweight and anemic woman or an overweight and stunted child in the same household.

Golden et al. expands the focus of this collection of papers by examining dams as a unique form of land use change with the potential to have major impacts on human diets. Their paper examines the impact of dams on aquatic food resources in the Lower Mekong Basin (LMB), where over 100 dams are planned or in construction. Expanding on past modelling, they estimate that the loss of subsistence fish resources associated with dam building could greatly increase the number of people in the LMB who are at risk of protein, zinc, thiamine, niacin, calcium and iron deficiency.

Like Friant et al. and Sibhatu also finds some positive effects of land use change on diets. Sibhatu analyzes the impacts of oil palm adoption on about 700 households in Jambi, Indonesia over a 2-year period. He finds that oil palm adopters consumed more diverse foods at a household level than non-adopters and that they were less likely to be undernourished or to be micronutrient inadequate. This shows the potential positive effects of some land use changes; however, as Sibhatu himself (Sibhatu, 2020) and others have noted (Nurhasan et al., 2020), these findings may be very specific to the sample here in which both adopters and non-adopters of oil palm primarily cultivated plantation cash crops as opposed to food crops (Purwestri et al., 2019).

Finally, Sunderland and Vasquez address conservation of forests, warning against an overly protectionist stance that may have negative impacts on the food and nutrition security of local communities in forest-protected adjacent areas. After reviewing the many ways that forests contribute to the food and nutrition security of forest adjacent communities, they lay out some of the tensions between the conservation community and local people when protection of forests reduces access to forests for local communities that rely on them for their food and nutrition security. They call for greater integration and respect for the rights of local communities to access forests for food and a rights-based and participatory approach to conservation that emphasizes synergies between biodiversity conservation and food security.

As a collection, these papers have several implications for research and policy. Although previous papers examining large secondary data sets have shown fairly consistent relationships between forest cover, land use, and diet quality (Johnson et al., 2013; Ickowitz et al., 2014; Galway et al., 2018; Rasolofoson et al., 2018), this collection of new papers suggests that the impact of land use change on diet quality and food systems is heterogenous. The context-specific trajectories that explain these different results across sites remain very poorly

understood and are fueling a dynamic area of research as several of these studies show. Understanding these complex relationships is imperative for designing policies that ensure peoples' access to sustainable sources of sufficient quantities of nutritious foods.
