The Global Ocean Ship-Based Hydrographic Investigations Program (GO-SHIP) provides a globally coordinated network and oversight of 55 sustained decadal repeat hydrographic reference lines. GO-SHIP is part of the global ocean/climate observing systems (GOOS/GCOS) for study of physical oceanography, the ocean carbon, oxygen and nutrient cycles, and marine biogeochemistry. GO-SHIP enables assessment of the ocean sequestration of heat and carbon, changing ocean circulation and ventilation patterns, and their effects on ocean health and Earth's climate. Rapid quality control and open data release along with incorporation of the GO-SHIP effort in the Joint Technical Commission for Oceanography and Marine Meteorology (JCOMM) *in situ* Observing Programs Support Center (JCOMMOPS) have increased the profile of, and participation in, the program and led to increased data use for a range of efforts. In addition to scientific discovery, GO-SHIP provides climate quality observations for ongoing calibration of measurements from existing and new autonomous platforms. This includes biogeochemical observations for the nascent array of biogeochemical (BGC)-Argo floats; temperature and salinity for Deep Argo; and salinity for the core

Argo array. GO-SHIP provides the relevant suite of global, full depth, high quality observations and co-located deployment opportunities that, for the foreseeable future, remain crucial to maintenance and evolution of Argo's unique contribution to climate science. The evolution of GO-SHIP from a program primarily focused on physical climate to increased emphasis on ocean health and sustainability has put an emphasis on the addition of essential ocean variables for biology and ecosystems in the program measurement suite. In conjunction with novel automated measurement systems, ocean color, particulate matter, and phytoplankton enumeration are being explored as GO-SHIP variables. The addition of biological and ecosystem measurements will enable GO-SHIP to determine trends and variability in these key indicators of ocean health. The active and adaptive community has sustained the network, quality and relevance of the global repeat hydrography effort through societally important scientific results, increased exposure, and interoperability with new efforts and opportunities within the community. Here we provide key recommendations for the continuation and growth of GO-SHIP in the next decade.

Keywords: GO-SHIP, ship-based observations, multidisciplinary ocean research, contemporaneous ocean observations, global ocean change and variability, health, essential ocean variables, essential climate variables

INTRODUCTION

The Global Ocean Ship-based Hydrographic Investigations Program (GO-SHIP²), building on the successes of hydrographic surveys such as the international geophysical year, IGY (1957/58); the Indian Ocean expedition IIOE (\approx 1959–1965); the Geochemical Sections Study, GEOSECS (1968–1978); the transient tracers in the ocean program, TTO (1979–1983); the World Ocean Circulation Experiment, World Hydrographic Survey /Joint Global Ocean Flux Study, WOCE/WHP/JGOFS (1986–1996); and the Climate Variability program (1995–current, CLIVAR, 2018), maintains the global survey of select hydrographic sections. Hereafter, “GO-SHIP” refers to the global hydrographic observations with modern standards that began with WOCE in the 1990s.

Global Ocean Ship-Based Hydrographic Investigations Program, in combination with earlier programs, has led to improved understanding of the role of the ocean in climate variability and change, carbon cycling, and biogeochemical responses to climate change. GO-SHIP data have been, either exclusively or in combination with other data, used to document: (1) heat and freshwater storage and flux, (2) ocean circulation and circulation variability, (3) sequestration of anthropogenic carbon, (4) ventilation of deep and shallow water masses, and (5) changes in biogeochemical properties such as inorganic carbon, pH, oxygen and nutrients. The data have also been extensively used for model initialisation, calibration and validation. Talley et al. (2016) provide a comprehensive review of the science achievements of GO-SHIP; here we summarize those achievements and their societal impacts.

¹Significant ocean science programs and research activities are listed in **Table 1**. GO-SHIP data centers are identified in **Table 2**.

²<http://www.go-ship.org>

Assessment of Ocean Change Heat and Fresh Water Changes

Argo floats now routinely sample the upper ocean (0–2000 m) and provide monthly estimates of upper ocean heat and freshwater change, whereas the global ocean below 2000 m depth is currently primarily sampled through GO-SHIP (Talley et al., 2016). GO-SHIP data have revealed that the deep ($z > 2000$ m) oceans have warmed from the 1990s to 2000s, storing some of the excess heat entering Earth's climate system and contributing to global sea level rise (SLR) through thermal expansion (Purkey and Johnson, 2010, 2013; Kouketsu et al., 2011; Desbruyères et al., 2016). The GO-SHIP global sampling has shown that the deep warming is significantly larger in regions of the global ocean ventilated largely by Antarctic Bottom Water (AABW) with the strongest warming in the Southern Ocean near AABW formation sites and decreasing to the north (Sloyan et al., 2013). The deep warming equates globally to a 0.07 W m^{-2} average flux applied over Earth's surface area (Purkey and Johnson, 2010; Rhein et al., 2013).

During the 2010s, GO-SHIP completed a reoccupation of the global hydrographic survey (**Figure 1**). The extended time-series has shown rapid AABW changes, including accelerated freshening in the Australian-Antarctic Basin and accelerated warming in the Southwest Pacific Basin in the last decade (Menezes et al., 2017; Purkey et al., 2019). In contrast, Johnson et al. (2014) find, in the Southwest Atlantic, that near-bottom warming in the Argentine Basin was reduced or absent from 2005 to 2014 compared to between 1989 and 2005, although warming continued in the bottom Brazil Basin. The difference in deep heat uptake between regions suggests different dynamical controls and/or regional variability in forcing the deep ocean. Further investigations are required to thoroughly understand these mechanisms. GO-SHIP observations have clearly shown that the ocean below 2000 m is varying and

plays a significant role in the Earth energy and freshwater balance (Palmer et al., 2019). The detection of deep ocean variability has highlighted the need for more deep ocean observations, and in-part has led to the development and beginning of implementation of deep Argo float deployments that cover the full water column (Johnson et al., 2015; Jayne et al., 2017).

Circulation and Mixing

Global Ocean Ship-Based Hydrographic Investigations Program coast-to-coast sections provide a unique data set to monitor and documents changes in the large-scale basin circulation of the global ocean (e.g., Ganachaud and Wunsch, 2000; Sloyan and Rintoul, 2001; Lumpkin and Speer, 2007; McDonagh et al., 2008; Katsumata et al., 2013; Talley, 2013; Mercier et al., 2015; Hernandez-Guerra and Talley, 2016). GO-SHIP data have been combined with other components of the observing system, including satellite altimetry sea surface height and Argo float velocity (e.g., Roemmich et al., 2007) or OceanSITES boundary current transport and midocean arrays (e.g., Carton and Hakkinen, 2011; Carton et al., 2014) to investigate key questions regarding basin circulation. In addition full-depth temperature, salinity and velocity profiles have been used to investigate the spatial and vertical distribution of ocean mixing (Kunze et al., 2006; Huussen et al., 2012; Talley et al., 2016).

Transient Tracers

Anthropogenic transient-tracers such as chlorofluorocarbons (CFCs) and sulfur hexafluoride (SF₆), collected as part of GO-SHIP, enable the science community to investigate the pathways, rates, and temporal variations in the processes ventilating the ocean on decadal timescales (Johnson et al., 2008; Wanninkhof et al., 2013b; Purkey et al., 2018). In addition, CFC and other tracer data are used to reconstruct the spatial and temporal evolution of anthropogenic carbon in the global ocean (Sabine and Tanhua, 2010; Khatiwala et al., 2013; Wanninkhof et al., 2013a); to estimate apparent oxygen utilization rates (Jenkins, 1977; Stanley et al., 2012); and to separate observed changes in oxygen and nutrients into physical (e.g., solubility, circulation, and mixing) and biological processes (Jenkins, 1998; Emerson et al., 2001; Mecking et al., 2006; Sonnerup et al., 2013, 2015; de la Paz et al., 2017). Transient tracers observations have revealed decadal scale variability of ventilation (e.g., Waugh et al., 2013; Tanhua et al., 2017).

Anthropogenic Carbon and Ocean Acidification

The tracking of global ocean uptake of anthropogenic carbon since the 1990s has only been possible due to the sustained GO-SHIP decadal survey. Changes in DIC concentration between repeat sections reflect both anthropogenic carbon uptake as well as natural variations in circulation and organic matter remineralization (Sabine and Tanhua, 2010).

Using GO-SHIP data a number of methods have been developed to estimate the ocean's anthropogenic carbon uptake and inventory (Gruber et al., 1996; Friis et al., 2005). Based on these methods, Kouketsu and Murata (2014) estimated an anthropogenic storage rate of 2.9 (± 0.4) Pg C year⁻¹ for the most recent decade (Figure 2). Gruber et al. (2019) provide a comprehensive analyses of GO-SHIP, and other ocean interior data and determine an uptake of 2.6 (± 0.3) Pg C year⁻¹ between 1994 and 2006. Data-constrained ocean models for the period 1994–2010 suggest an ocean mean annual uptake rate of approximately 2.3 Pg C year⁻¹. This equates to approximately 27% of the total anthropogenic carbon emissions absorbed by the ocean over this time period (Khatiwala et al., 2013).

Takatani et al. (2014) used the GO-SHIP reference and high-frequency sections to show that the rate of anthropogenic carbon increase in the western North Pacific subtropical gyre over the past two decades is consistent with atmospheric CO₂ increases. The mean rate of anthropogenic carbon inventory change over the past few decades varies from 0.22 (± 0.05) mol m⁻² year⁻¹ to 0.94 (± 0.10) mol m⁻² year⁻¹, depending on the depth to which the ocean is ventilated (Talley et al., 2016). There is still

considerable debate on whether this uptake is stored locally or exported (Sabine et al., 2004; van Heuven et al., 2011) and what water masses are involved (e.g., Gruber et al., 1996; Sabine et al., 2004; van Heuven et al., 2011; Pardo et al., 2014; Groeskamp et al., 2016). Once the anthropogenic carbon enters the ocean it is redistributed by the ocean circulation. It has been found that the deep western boundary currents serve as important ventilation pathways and carry an appreciable amount of anthropogenic

United Kingdom data is stored at BODC. ⁷NOAA/NCEI (Patrick Caldwell) accepts suitable S-ADCP data from international as well as domestic suppliers.

⁸Via GCCs to ICOADS for non-SAMOS ships. ⁹At least two of the three parameters DIC, Talk and pH are required (Dickson, 2010). ¹⁰United States GO-SHIP tracks and links to all of its component datasets: <http://usgoship.ucsd.edu>. ¹¹Knap et al. (1996). ¹²Hooker et al. (2005). ¹³N/A: Currently not available but highly desired.

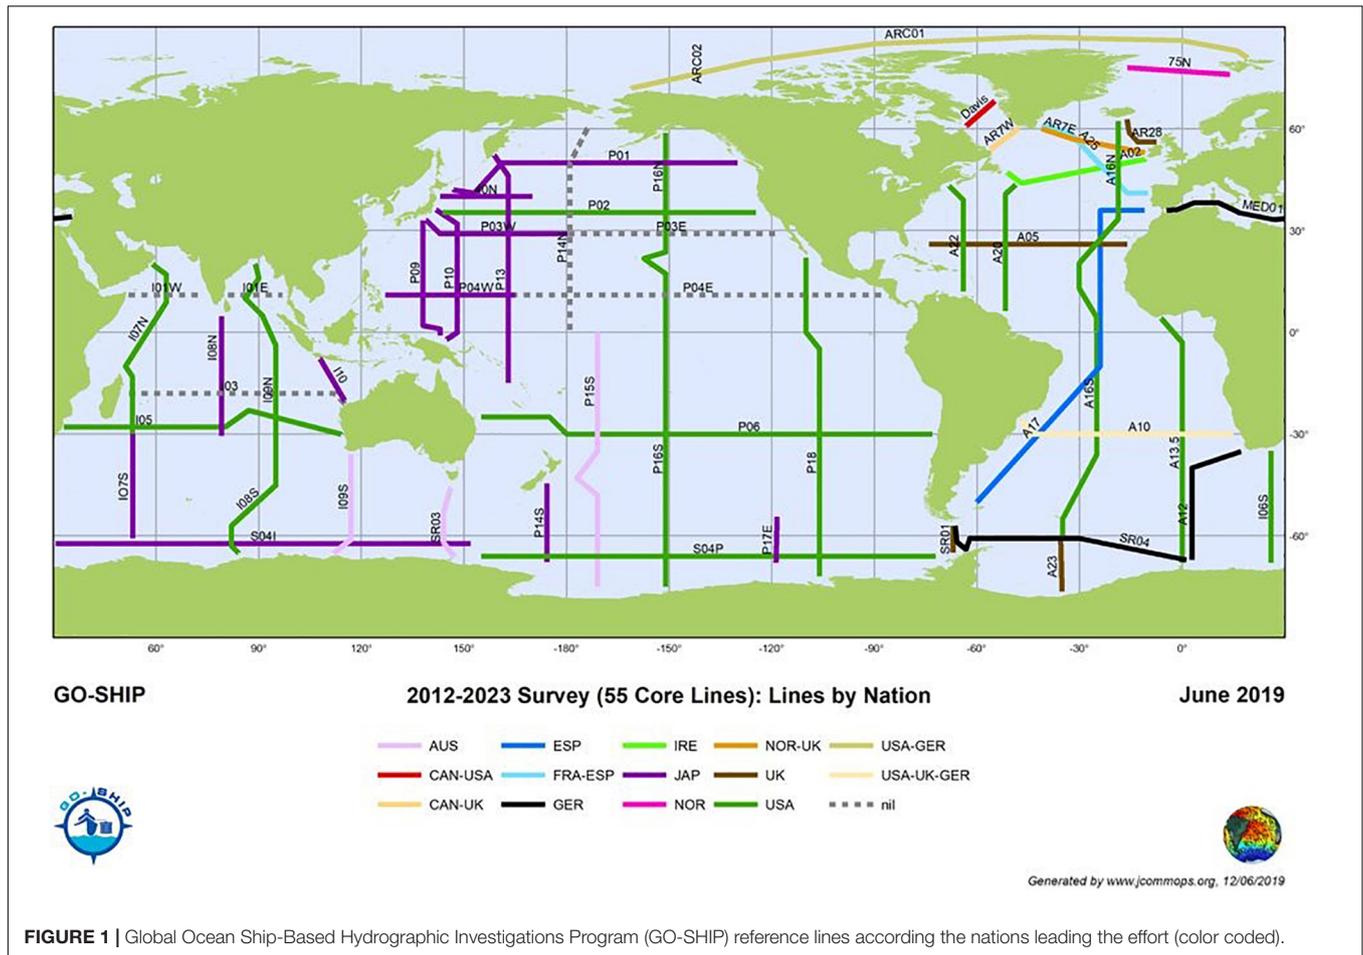

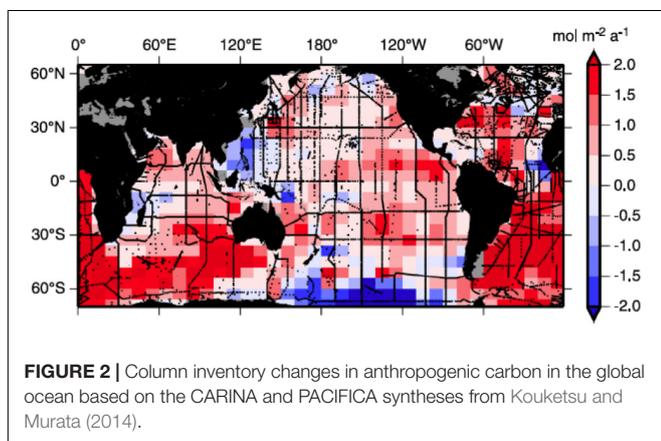

FIGURE 1 | Global Ocean Ship-Based Hydrographic Investigations Program (GO-SHIP) reference lines according to the nations leading the effort (color coded).

carbon into the interior (Körtzinger et al., 1999; Murata et al., 2010; Brown et al., 2010; Waters et al., 2011; Ríos et al., 2012; Sloyan et al., 2013; Guallart et al., 2015; Carter et al., 2019).

The increase in ocean carbon concentration due to anthropogenic carbon uptake and rising ocean temperature has also led to ocean acidification (Feely et al., 2009; Doney et al., 2009; Jiang et al., 2015). Results from GO-SHIP and the

earlier programs (Feely et al., 2004, 2009; Key et al., 2004; Sabine et al., 2004; García-Ibáñez et al., 2016), have shown a pH change in the surface water of approximately -0.002 year^{-1} from 1991 to 2006 along sections in the North Pacific (for a summary, see Rhein et al., 2013). Based on frequently repeated GO-SHIP section in the North Atlantic it was shown how Meridional overturning circulation transports acidification signal to the deep waters (Perez et al., 2018).

Oxygen and Deoxygenation

Large and systematic changes in oxygen, mostly reductions, have been documented over the last two decades through GO-SHIP and additional local time-series data (e.g., Keeling et al., 2010; Hahn et al., 2017). Based on modeling studies (Deutsch et al., 2005) and correlations with physical forcing (Johnson and Gruber, 2007), it is suggested that the oxygen changes are mainly driven by physical forcing changes. The deoxygenation in the open-ocean thermocline over the past two decades is consistent with the expectation that warmer waters will hold less dissolved oxygen (the solubility effect) and that warming-induced stratification leads to a decrease in the transport of dissolved oxygen from surface to subsurface waters (the stratification effect) (Matear and Hirst, 2003; Deutsch et al., 2005; Frölicher et al., 2009).

Nutrients

Global Ocean Ship-Based Hydrographic Investigations Program provides high quality ocean nutrient data. The observed nutrient changes are due to a combination of both physical and land-use changes; physical stratification and wind changes and use of fertilizer in agriculture production leading to riverine discharge of nitrate to the ocean (Doney, 2010). A study by Kim et al. (2014), using derived excess nitrate, N^* measurements and ventilation rates from CFCs, determined that the atmospheric deposition of anthropogenic nitrate in the western North Pacific is leading to excess nitrate in the upper water column. Note, $N^* = NO_3 - R_{N:P} * PO_4$, where NO_3 and PO_4 are the measured nitrate and phosphate concentrations and $R_{N:P}$ is the Redfield ratio of 16:1. The excess nitrate was highest close to Asia with rates decreasing eastward across the North Pacific and suggests implications for the ecosystem from nitrate to phosphate limitation (Kim et al., 2014).

Multi-Variable Analyses

The value of a suite of contemporaneous ocean variables in GO-SHIP has been demonstrated in a number of studies. Oxygen data combined with transient-tracer data provides evidence regarding the timescales at which the ocean ventilation changes occur. The combination of oxygen data with carbon data (e.g., Sabine et al., 2008) and pH data (e.g., Byrne et al., 2010) has allowed separation of DIC/pH changes along the GO-SHIP sections into anthropogenic and ventilation/remineralization components, including their respective effects on carbon storage and ocean acidification. Ko et al. (2018) estimated net community production (NCP) in the N-depleted oligotrophic oceans on the basis of the seasonal changes in surface water partial pressure of CO_2 , pCO_2 , and DIC in absence of nutrients, largely based on GO-SHIP cruises. The combinations of ocean tracers and carbon have been used to investigate air-sea gas exchange and reconstruct the spatial and temporal evolution of anthropogenic carbon in the global ocean. All of these biogeochemical variables rely on high quality temperature and/or salinity data for many of their analytical analysis techniques.

GO-SHIP Measurement Attributes

Global Ocean Ship-Based Hydrographic Investigations Program's unique capability of high-quality, contemporaneous ocean observations has and will continue to support physical, biogeochemical and importantly multidisciplinary ocean research. The provision of physics, biogeochemistry and increasingly biological/ecosystem ocean observations, combined with other observing systems (satellites and *in situ* platforms including increasing use of autonomous platforms) will support many of the user requirements of the observing system, such as climate monitoring and reporting and ocean health, in particular those identified by the UN Sustainable Development Goals³. GO-SHIP data are required to monitor the Earth's energy imbalance, and provide a significant contribution, and decadal

anchor point, to enabling tracking of the global carbon budget (Le Quéré et al., 2018). While the high quality data are generally provided in delayed-mode, the data are used in the calibration of near-real-time data that are heavily used by climate and ocean operational service providers.

GO-SHIP: STRUCTURE AND OVERSIGHT ROLE

As a component of the Global Climate Observing System (GCOS) and the Global Ocean Observing System (GOOS), it provides necessary international coordination and scientific oversight for repeat hydrography. The initial GO-SHIP Panel was established in 2007 to develop a strategy for a sustained global repeat hydrography program as a contribution to the OceanObs09 Conference (Hood et al., 2010).

As GO-SHIP established itself as an integral component of the Global Ocean Observing System (GOOS) network, the initial panel has evolved to a science committee with Executive Group and Steering Group Members committee representing all nations that execute GO-SHIP reference lines. The GO-SHIP co-chairs serve on the Joint Technical Commission for Oceanography and Marine Meteorology Observation Coordination group (JCOMM OCG).

The main tasks of the national representatives and international GO-SHIP committees are to:

- Develop international agreements for a sustained international repeat ship-based hydrography program, including a strategy and program plan,
- Advocate for national contributions to this strategy and participation in the global program,
- Provide a central forum for communication, coordination, and best practices, and
- Partner in syntheses of hydrographic data, in collaboration with regional, national, international, and global research programs.

Ship-based hydrography remains the only method for obtaining coincident reference standard, high-quality, high lateral and vertical resolution measurements of a suite of physical, chemical, and biological parameters over the full water column. The GO-SHIP principal scientific objectives are: (1) understanding and documenting the large-scale ocean water property distributions, their decadal changes, and drivers of those changes; and (2) addressing questions of the large physical, biogeochemical, and biological changes anticipated for the future ocean. This includes increasing dissolved inorganic carbon (DIC), warming, acidification, deoxygenation, and increased stratification of the ocean due to atmospheric CO_2 increases and associated warming caused by changes in the Earth's radiation balance. The observations will aid understanding of interaction of anthropogenic perturbations with natural cycles of water, including sea-ice, and with changes in circulation and ventilation processes. The addition of biological and ecosystem measurements will enable GO-SHIP to determine trends and variability in key indicators of ocean health.

³<https://www.undp.org/content/undp/en/home/sustainable-development-goals.html>

Currently 10 nations contribute to the GO-SHIP reference and high frequency lines (**Figure 1**) and GO-SHIP lines increasingly benefit from multi-national participation and support (see section “Multi-Nation Voyages”). Approximately a third are performed by the United States with support from the National Science Foundation (NSF) and the National Oceanic and Atmospheric Administration (NOAA); some Level 3 optical measurements (**Table 2**) are being supported by the National Aeronautics and Space Administration (NASA). Australia is a core contributor to observations in the Southern Ocean, relying on other nations for measurement of transient tracers (United States, Japan). Japan has been active in observing the Pacific; their large contributions extend to the Southern Ocean and the Indian Ocean. The United Kingdom has increased its participation in long line cruises with focus on Atlantic zonal sections and Atlantic sector Southern Ocean sections. Germany has had a long-standing effort in the Mediterranean Sea and in the Southern Ocean sector of the Atlantic, and recently completed a joint multi-nation effort with Brazil, Argentina, and South Africa that has aided the GO-SHIP capacity building activities. Spain continues its long-term commitment to Atlantic meridional and zonal sections, one of them with biennial occupancy. France and Spain contribute through a biennial line in the northern North Atlantic. Ireland led its first GO-SHIP cruise in the North Atlantic with participation from Germany, United States, United Kingdom, and Canada. Canada and Norway occupy annual lines at high northern latitudes in the Atlantic.

The GO-SHIP cruises are completed by highly qualified and experienced observing teams. The observations meet the highest standards necessary (“climate quality⁴”), increasingly facilitated by use of certified reference materials (CRMs). The strict GO-SHIP data release policy is grounded on the premise that the data are a shared community resource and should be publicly available as soon as possible. The use of high quality GO-SHIP *in situ* data continues to grow with the expanding use of autonomous ocean observing platforms, now including those that measure biogeochemical parameters and small physical changes in the deep ocean. GO-SHIP’s high quality global data are essential and irreplaceable for global climatologies that are used for calibration and reference standards for these autonomous sensors, particularly given decadal changes in ocean properties.

Global Ocean Ship-Based Hydrographic Investigations Program comprises sections in three different categories, and measurements in three priority levels. The sections are categorized as follows:

Decadal Full GO-SHIP (Reference or Core Lines)

These are a series of zonal and meridional lines that go coast to coast (or ice edge) and full depth of the ocean (**Figure 1**) at a target spacing of 30 nautical miles, sometimes less in regions of strong property gradients. Currently the reference network is 55 cruises sampling all major ocean basins. Level 1 data (see below) are collected at least once per decade on these sections.

⁴Climate quality is defined as measurements of quality sufficient to assess long term trends with a defined level of confidence.

High Frequency GO-SHIP

A subset of core GO-SHIP lines are occupied at higher frequencies (annual, biennial) typically with limited parameters, but with at least one decadal full GO-SHIP cruise with all Level 1 and many Level 2 and 3 measurements. High frequency cruises must (i) occupy the regular line end-to-end, (ii) cover full depth, and (iii) comply with the data policy.

Associated GO-SHIP

Repeat hydrographic sections that do not necessarily meet the sampling density and are not coast-to-coast/ice, which (i) deliver high quality data, (ii) establish full depth stations below 2000 m at least every 240 nm, (iii) are repeated at least once per decade with sufficient Level 1 parameters to quantify decadal change in inorganic carbon and heat inventories, (iv) at a minimum resolution of 60 nm, and (v) comply with the data policy.

Measurement Levels

Measurements in GO-SHIP are prioritized based on the overall goals of the program. GO-SHIP ranks the measurements as Level 1, 2, or 3. Level 1 “core” measurements are the highest priority for the scientific objectives; Level 2 are desirable and often include measurements of high interest for the particular region; and Level 3 are ancillary measurements. Level 3 measurements may include new instrumentation and experimental techniques that benefit from validation using the core measurements. The parameters for Level 1 and some Level 2 can be found in **Table 2** with a full list at <http://www.go-ship.org/DatReq.html>.

The enduring legacy of GO-SHIP is dependent on ready access of the quality data. These yield the scientific and synthesis products, and discoveries. The value of easy access to a unified dataset for the global ocean, and recognition of the GO-SHIP contribution to these products, is important to sustain the GO-SHIP effort.

DATA PROCEDURES AND ACCESS

Data Acquisition: Best Practices, Standards, and Data Consistency

The acquisition of GO-SHIP data involves several steps. GO-SHIP data acquisition and laboratory analyses follow best practices, including providing standardized metadata and quality control. The quality-controlled (QC’d) data are submitted to central depositories in a timely fashion where they are checked and made available to the community at large. Coordination and assistance in these steps by the GO-SHIP science committee and JCOMMOPS coordinator are an important part of the program. Once collected and archived, GO-SHIP data form the basis for essential synthesis products and calibration of autonomous observations. The World Ocean Atlas (WOA) is a synthesized product based on the physical, oxygen, and nutrient data. For carbon and other biogeochemical analysis, the Global Ocean Data Analysis Project (GLODAP) is a major bottle data synthesis product involving extensive additional quality control in the form of cross-over adjustments. A tool to facilitate

primary QC and coherent submission of bottle data was recently published⁵. The most recent complete version is GLODAPv2 (Olsen et al., 2016) with an update in 2019, GLODAPv2.2019 (Olsen et al., 2019). Calibrated GO-SHIP CTD data are an important input for autonomous observations such as Argo floats. Climatologies of physical and biogeochemical parameters are produced by several national data centers, incorporating GO-SHIP data.

The process of acquiring quality oceanographic data commences with cruise planning and follows a multi-step process to final product. Full documentation of these steps and easy access to the procedures at sites such as the online International Oceanographic Data and Information Exchange (IODE) best practices depository⁶ facilitate the process. This documentation is very useful to new participants in the program and when considering the inclusion of new measurements. The “how to” information is regularly reviewed to provide information and incorporate new procedures relevant to the planning and running of GO-SHIP sections.

Measurement techniques for all Level 1 and some Level 2 parameters are described in the GO-SHIP Repeat Hydrography Manual: A Collection of Expert Reports and Guidelines, often referred to as the GO-SHIP hydro manual (Hood et al., 2010). Chapters of the manual and other pertinent best practices related to GO-SHIP can be found at <https://www.oceanbestpractices.net/handle/11329/371>. As requirements change, parameters are included or deleted as Level 1 measurements. For example, currently the required transient tracer variables are under discussion. The CFCs, which are currently Level 1, are analyzed by only a limited number of laboratories; moreover the atmospheric inputs have changed over time, with CFC-11, and CFC-12 concentrations leveling off in the atmosphere, reducing their usefulness as transient tracers. However, SF₆, which is included in CFCs and measured from the same samples, continues to increase in the atmosphere and this variable is becoming more useful in meeting the GO-SHIP science objectives.

At present, GO-SHIP requires the following data-release timelines (Talley et al., 2016)⁷:

- Preliminary datasets for all Level 1 and Level 2 ship-based measurements released within 5 weeks of the cruise
- Final datasets for all Level 1 and Level 2 ship-based measurements released within 6 months of the cruise
- Final datasets within 24 months for all Level 3 data

The relatively rapid release of data is motivated by their usefulness for climate studies and the observed rapid change in the ocean, which are of increasing societal importance. The GO-SHIP data policy is stringent and geared toward rapid, open dissemination, with a clear structure for all data to undergo quality control, and to be sent to and available from recognized

data centers. All data collected as part of the program need to be submitted to a designated data management structure for quality control and dissemination for syntheses. As indicated in the recommendations, this is an ongoing effort.

The GO-SHIP suite of observations includes a significant number of Essential Ocean Variables (EOVs) and some are Essential Climate Variables (ECVs), reflecting their importance, spanning the physical, biogeochemical, and biological/ecosystem ocean (Table 2). These variables are collected by various national laboratories and universities, and rely on the international ocean research community to collaborate to collect and analyze samples following a suggested procedure and accuracy (Hood et al., 2010). Standardized collection and analysis procedures to ensure consistency of observations amongst the nations involved in the program are of utmost importance.

Global Ocean Ship-Based Hydrographic Investigations Program actively supports efforts to improve the standard and consistency amongst the research community involved in collection. In recent years, GO-SHIP has endorsed two Scientific Committee on Oceanic Research (SCOR) working groups: Toward comparability of global oceanic nutrient data (COMPONUT), and Integration of Plankton-Observing Sensor System to existing global sampling programs (P-OBS). These working groups bring together an international group of experts to develop agreed standards and procedures required to review and develop commonly agreed methodologies. GO-SHIP relies on these groups of experts to revise its hydrographic manual and update Best Practices. A significant outcome of the COMPONUT group has been the adoption of certified reference material and inter-laboratory calibration for nutrients that included 69 laboratories from 30 countries (Aoyama et al., 2012; Aoyama, 2018) and an updated chapter of Best Practices for nutrient analyses (Becker et al., 2019)⁸.

The production and increased use of reference materials and standards are critical for accurate measurements and their use is advocated in Best Practice procedures. Standard seawater has long been used for bottle salinity analyses, but other new reference materials have increased the quality of data. For example, use of reference material for inorganic carbon has led to a two to threefold increase in accuracy of the measurements of DIC and TALK (Dickson et al., 2003). Reference materials come in different forms including primary standards (such a pure CO₂ and compressed gas standards for pCO₂ and CFC analyses), standard solutions for titrants (such as KIO₃ for Winkler O₂ and HCl for Alkalinity), and increasingly well-characterized seawater for the parameter of interest (for dissolved organic matter (DOM), DIC, Total Alkalinity (TALK), and inorganic nutrients).

Reference materials are produced by manufacturers or by individual investigator's academic institutions. There can be a significant cost that, in some instances, leads to insufficient use, although costs may be subsidized by national funding agencies. Salinity, DIC, TALK, DOM and nutrients references are prepared from natural seawater; oxygen standardization is based a calibrated iodate standard. Many of the references are “certified,” that is tied to a primary standard, but nutrient

⁵<https://github.com/ocean-data-qc/ocean-data-qc> Final datasets for all Level 1 and Level 2 measurements performed at a shore-based laboratory within 6 months of the shore based analysis (except for helium/tritium where the goal is 15-months after sample collection). Shore-side analyses in practice often do not meet these targets.

⁶<https://www.oceanbestpractices.net/handle/11329/3>

⁷<http://www.go-ship.org/DatReq.html>

⁸<http://www.ioccp.org/index.php/nutrients>

standards are consensus values (Aoyama et al., 2012; Aoyama, 2018). The reference materials are often used as calibrants and values measured are adjusted to the certified reference material values. For example CTD salinity (conductivity) and oxygen sensor values are adjusted to bottle salinity and oxygen measurements on GO-SHIP cruises. Bottle measurements have been declining significantly on high frequency and associate GO-SHIP cruises, and on non-GO-SHIP cruises, which typically have much less chemistry, but which all include CTD profiles. Column 5 of **Table 2** indicates the priority variables in need of reference materials.

The research vessels used in GO-SHIP cruises are equipped with a number of (often semi-automatic) instruments. Seawater is pumped into the vessel through an intake, usually 1–8 m below the draft line. Temperature, salinity, and other parameters including dissolved oxygen and $p\text{CO}_2$ in this intake water are continuously measured and reported. The intake temperature data have been used in the calibration of satellite SST (e.g., Reynolds, 1988). Sea surface salinities are obtained from thermosalinograph and stored in the GOSUD database. The underway $p\text{CO}_2$ data are integral to the global surface ocean carbon data set (SOCAT) (Bakker et al., 2016), particularly in regions with little shipping traffic, that provides information necessary for air-sea carbon exchange and surface water ocean acidification monitoring.

Data Repositories and Accessibility

Global Ocean Ship-Based Hydrographic Investigations Program collects a large suite of measurements across multiple ocean disciplines. Thus there are multiple types of GO-SHIP datasets, including hydrographic, velocity, underway, and meteorological data, and the data therefore flow into different data centers and archives (**Table 2**). Development of a central data portal tracking and linking all component data sets is essential, including formal agreements on depositories, interoperability, and exchange, that extend beyond the vertical CTD and rosette-sample chemistry profile data for which there is a long-standing GO-SHIP archive. Several nations contributing to GO-SHIP provide concise links to all data types collected during each cruise (e.g., United States GO-SHIP's cruise data tracker), but there is no parallel international structure.

In addition to providing a centralized link to the component datasets from each GO-SHIP cruise, providing stable locations for submission and retrieval of some of the GO-SHIP data types is essential. Examples are the Level 1 shipboard acoustic Doppler profiler (S-ADCP) and lowered acoustic Doppler profiler (L-ADCP) velocity data, and underway data sets including Level 1 continuous sampling of temperature, salinity and $p\text{CO}_2$ as well as Level 2 discrete surface chemistry collected in conjunction with the continuous underway sampling. There is increased recognition of the importance of data storage, and the need of exposure of the data and ease of retrieval in order to sustain and increase use of GO-SHIP data. However, funding for such activities has been lagging. Not having a clear unified strategy and resources to address data issues in global oceanography has hampered oceanographic data dissemination, in general.

That is, there is no dedicated data center or depository for all of the different types of international GO-SHIP data nor is there an international GO-SHIP requirement to submit data to a specific data center or link to a specific portal. However, GO-SHIP has identified and endorsed data centers for each type of GO-SHIP data (e.g., **Table 2**) and strongly recommends that data be sent to these data centers within the agreed data submission timelines (see section “Data Acquisition: Best Practices, Standards, and Data Consistency”). For several national efforts, the data submission requirements and timelines are mandated.

Full water column hydrographic profiles (CTD and discrete chemistry sampling) comprise the core data set for GO-SHIP. The most commonly used center for these data is the CLIVAR and Carbon Hydrographic Data Office (CCHDO). The mission of CCHDO is to deliver the highest possible quality global CTD and hydrographic data to users. These physical and biogeochemical data include observations carried out during numerous other past and ongoing oceanographic research programs. For GO-SHIP, the CCHDO captures the Level 1 processed CTD data, all Level 1 bottle data, and as much Level 2 and 3 bottle data as possible. The GO-SHIP JCOMMOPS-based project officer and CCHDO have close interactions and exchange information regarding voyage status and data submission. These links need to be strengthened further to ensure that each GO-SHIP cruise data set is available to the community. A challenge is that there is currently no international requirement or structure to ensure that all of the completed data sets are available from a central source. The permanent repository for hydrographic data is at NOAA National Center of Environmental Information (NCEI) and routine connection between NCEI and CCHDO assure that the permanent archive is regularly updated.

CLIVAR and Carbon Hydrographic Data Office data managers work with GO-SHIP principal investigators and GO-SHIP committee members to ensure the open and timely availability of all the high quality repeat hydrography data to the international science community. GO-SHIP and CCHDO have established a strong working relationship. This is highlighted by the recent addition of an interactive map of GO-SHIP sections on the CCHDO website and direct links to data from the GO-SHIP web site. This has greatly enhanced data searching and access. GO-SHIP, JCOMMOPS and CCHDO have undertaken an audit of GO-SHIP Data Availability at CCHDO. This essential cooperative effort will be further enhanced through the JCOMMOPS Ship Coordinator, partly (but currently ad-hocly) funded by (multi) national GO-SHIP funding sources such as AtlantOS, CSIRO, and NOAA. GO-SHIP envisages that communication between the ship coordinator and CCHDO will allow for increased tracking of the international collection of CTD and bottle data and pursuit and submission of data to CCHDO.

While bottle and CTD data are well managed through CCHDO, data management efforts for several other GO-SHIP measurements as less advanced. Level 1 velocity data for GO-SHIP are collected using S-ADCP and L-ADCP instrumentation. The S-ADCP and L-ADCP data acquired during GO-SHIP cruises can now be submitted to the Hawaii Currents group (**Table 2**). Establishing and maintaining a long-term data archive

for all GO-SHIP velocity data, extending back through the CLIVAR and WOCE surveys that preceded it, is highly desirable, and a recommendation is to establish a routine data management system subscribed to by all GO-SHIP operators.

Underway data, predominantly T, S, and pCO₂, do not have a single depository but are often included in parameter specific larger data collations. Much of the underway pCO₂ data finds its way into SOCAT (Bakker et al., 2016) and some of the underway temperature and salinity are added to the GOSUD which is planned to become the general GO-SHIP archive for such data. In addition, there are efforts in the United States to place all data routinely acquired on research ships in a depository called rolling deck to depository, R2R⁹.

In addition to submission to centers that accept all specific GO-SHIP measurements, there are specific requirements of national funding agencies for submission to national data centers. The data centers, which are often part of world data centers under auspices of IODE or International Council for Science (ICSU), have mandates to store data in perpetuity. These include, for example, the British Oceanographic Data Centre, which is the United Kingdom facility for preserving and distributing marine data, the German data center PANGAEA, NCEI, which is the United States archive for hydrographic data, and JODC, which is the Japanese archive. These data centers often do not have an efficient way to retrieve data for programs such as GO-SHIP but rather are parameter focused. In the United States there are additional centers that house specific United States GO-SHIP datasets such as the SeaWiFS Bio-optical Archive and Storage System (SeaBASS), which is the publicly shared archive of *in situ* oceanographic and atmospheric data maintained by the NASA Ocean Biology Processing Group (OBPG), and the Biological and Chemical Oceanography Data Management Office (BCO-DMO) that serve data online from research projects funded by the oceanography programs at the United States National Science Foundation¹⁰.

A GO-SHIP Data Assembly Center (DAC) using modern data management and interoperability procedures would facilitate a means to submit and access data in the various repositories. The existing data assembly and archive centers need support to develop new tools and centers to manage the increasing variety of properties observed on hydrographic lines, to coordinate data management activities with programs such as Argo and OceanSITES, and to improve technology and data policies to release data in a timely manner. Linking datasets seamlessly through Global Data assembly centers (GDACs) such as proposed for marine biogeochemistry (GDAC-BGC) at the Bjerknes Climate Data Centre would aid access and discovery. GO-SHIP endorses a central portal and a logical query system where all the data obtained in GO-SHIP can be acquired.

Global Ocean Ship-Based Hydrographic Investigations Program will continue to focus on acquiring the highest quality, documented and referenced data. There is a need for clear documentation of practical information for cruise activities in an updated GO-SHIP manual and easily accessible voyage reports.

This includes rosette sampling order of parameters, sample storage protocols, and cleaning and maintenance procedures for sampling bottles (Niskins). A protocol and recommendation for citation of GO-SHIP data should be developed and provided in prominent locations including all portals for GO-SHIP data, such that it is clearly referenced when used in publications or as reference data in calibration/validation of data from other observing systems such as Argo.

Systems for optimized monitoring of GO-SHIP from early cruise planning to the timely submission of data are needed. Emerging scientific products (including best practices, data synthesis and scientific publications) are presently implemented as coordinated efforts between data portals, data centers, and JCOMMOPS; coordination of these across all GO-SHIP contributors presents a major goal for the next decade.

GO-SHIP EVOLVING TO MEET FUTURE OCEAN OBSERVATION DEMANDS

A Platform for Multidisciplinary Ocean Observations

Global Ocean Ship-Based Hydrographic Investigations Program has advanced since the first global cycle during WOCE in the 1990s and is continuing to develop as requirements and technology are evolving. The evolution in large part consists of measurements of a broader range of variables, many of which are EOVs. These include physical, biogeochemical, and biological/ecosystem variables¹¹. Open ocean research vessels are well suited to measure EOVs and there is a focus on including more EOVs in the suite of variables measured on the GO-SHIP reference sections. This has to be balanced by the feasibility of adding measurements along with the current measurement suite, considering factors such as costs, availability of channels on conducting cable, water requirements, number of berths available, station time and endurance.

Additional variables that are measured during a GO-SHIP cruise involve either Level 2 or Level 3 variables, some of which may be EOVs. The GO-SHIP community encourages and supports these additional observations to the extent possible, subject to limitations just mentioned. The GO-SHIP science committee, in consultation with the GO-SHIP community, shifts variables to a higher priority as feasibility and impact justify this. Conversely, some parameters can be relegated to a lower level when the need to observe them decreases, such as Helium/Tritium measurements given the decay of the atomic testing signal and completion of a global survey of the deeper signal. Decisions regarding additional parameters that should/could be measured on GO-SHIP cruises must include defining suitable observing strategies. This includes all aspects of observations, such as making sure that best practices (Pearlman et al., 2019) are developed and followed, that the data reporting is well defined, and that there is a data center able to accept, serve, and provide long term storage of the data and metadata (Tanhua et al., 2019).

⁹<http://www.rvdata.us/>

¹⁰www.bco-dmo.org/

¹¹<http://goosocean.org/eov>

Sensing techniques have improved recently and can be used to determine diversity and biomass of zooplankton and phytoplankton, making these observations of biology and ecosystem EOVs on GO-SHIP cruises feasible. Techniques include: bio-optical sensors deployed on the rosette frame or in-line for underway sampling (e.g., measuring bulk absorption, attenuation, scattering and/or fluorescence at wavelengths useful to detect plankton pigments and/or their presence and size distribution); bio-acoustic techniques deployed on the rosette frame or on the hull of the research vessels for continuous operation. Imaging techniques such as the Underwater Video Profiler (UVP, Hydroptics) on the rosette, Imaging Flow Cyto-Bot (IFCB, McLane), and discrete samples for shore based analysis from rosette and/or underway surface samples. Observations include variables constraining bulk properties (e.g., POC, HPLC pigments) as well as species/group specific variables (e.g., genetics, flow-cytometry). Many of these observations (other than genetics and imaging) have long established protocols for operation and analysis. Imaging techniques have the advantage that they can be analyzed in the future through open source hosting. One example is Eco-Taxa, a web application dedicated to the visual exploration and the taxonomic annotation of images (Raes et al., 2018). The SCOR working group 154, P-OBS, is dedicated to the identification of plankton relevant technologies that could be incorporated into GO-SHIP (Boss et al., 2018; Lombard et al., 2019).

Additional areas and variables that are being considered to be elevated to Level 1 or 2 for GO-SHIP include: observations of air-sea fluxes and marine aerosols properties; additional biogeochemical EOVs such as N_2O (currently a Level 2 measurement); NCP (e.g., using in-line O_2 -Ar Mass-spectroscopy), and observations of turbulence (currently a Level 3 measurement). Nitrous oxide (N_2O) is routinely measured from bottle samples on United States GO-SHIP by the CFC groups using similar instrumentation and protocols as for CFC analyses.

There is also a need for near real-time data transmission of observations, in particular surface salinity and temperature from underway measurements and profile data from the CTD, for operational services. Currently, CTD profiles are transmitted from the United Kingdom GO-SHIP sections and retrieved by the United Kingdom MET service. The Coriolis data center is used by French and German ships for real-time CTD data transmission <http://www.coriolis.eu.org/Data-Products/Submit-data>. It is necessary to develop protocols to distinguish this near-real time (NRT) data from the delayed-mode calibrated data used for the detection of decadal scale trends that is the core mission of GO-SHIP and the current procedures in Argo are being scrutinized as an effective example.

Global Ocean Ship-Based Hydrographic Investigations Program cruises are also useful for development and validation of new observing techniques. For example, GO-SHIP voyages have supported the validation of pH sensor measurements in underway systems (Takeshita et al., 2018), and turbulent mixing observations using CTD-chipods (Pickering et al., 2016). Given the range of variables observed on GO-SHIP, and the facilities on research vessels in comparison to autonomous platforms,

or ships of opportunity, GO-SHIP cruises can be used to an even larger extent for validation and calibration of new sensors, sampling schemes, and analytical techniques.

Autonomous Ocean Networks and Sensor Development

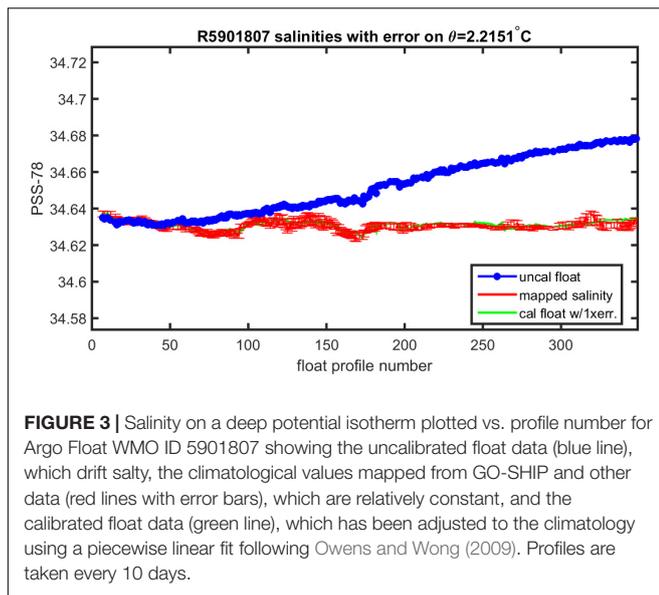

Global Ocean Ship-Based Hydrographic Investigations Program contributes substantially to autonomous ocean observing networks in several ways. GO-SHIP (Talley et al., 2016) provides a variety of high-quality data required for calibration and validation of sensors on autonomous oceanographic platforms such as floats, gliders, and marine mammal tag CTDs. Importantly, GO-SHIP provides the highest-quality reference standard data of salinity for the core Argo array as well as those of oxygen, pH, nitrate, and other biogeochemical data for emerging BGC Argo profiling float program. Now that Deep Argo (Johnson et al., 2015; Jayne et al., 2017) has begun sampling the full ocean depth, GO-SHIP data are crucial for ensuring the high precision and accuracy needed for deep ocean temperature and salinity analyses. GO-SHIP cruises also provide a platform for assessing the performance of new sensors. These sensors are sometimes added to the underwater package, and occasionally integrated into the CTD data-stream for direct comparisons.

High Quality Reference Data for Sensor Calibration

High quality salinity data are essential in understanding the variability and changes in ocean circulation and hydrological cycle. High quality and deep salinity profiles (reaching slightly below the 2000 dbar limit of standard Argo floats) from shipboard CTDs calibrated with bottle samples referenced to the International Association for the Physical Sciences of the Ocean (IAPSO) Standard Seawater are essential to delayed-mode scientific quality control of Argo float salinity data (Wong et al., 2003).

Conductivity sensors on Argo float CTDs are calibrated at the manufacturer prior to deployment, but a variety of factors can introduce biases into the reported salinities once the floats is deployed. Float CTD conductivity cells are occasionally subject to fouling after calibration but prior to deployment, initially biasing reported salinities fresh of actual salinities. Float CTD conductivity cells can also foul owing to biological activity, and become fresh with time. Float CTD salinity data have also sometimes exhibited a salty drift (e.g., **Figure 3**), very recently hypothesized to result from the separation of the protective jackets from the exterior of the cells, increasing the conductivity measured.

CTD data that have been calibrated to bottle salinity data referenced to an international standard (IAPSO Standard Seawater) are essential for validating, and calibrating when necessary, Argo CTD salinity data. Profiles deep enough to sample water masses with relatively temporally stable and laterally homogeneous temperature-salinity relations (such as North Pacific and North Indian Deep Water, or Circumpolar Deep Water) are vital. Profiles contemporaneous and co-located with float deployments are also useful. As Deep Argo is coming on line, profiling to 6000 dbar, high accuracy GO-SHIP CTD data are essential to validate the Deep Argo CTD data.

Global Ocean Ship-Based Hydrographic Investigations Program's decadal global monitoring of all components of the carbonate system is indispensable for being able to relate autonomous measurements from the newly expanding biogeochemical (BGC) Argo to the full carbon system. BGC Argo floats, including oxygen, pH, nitrate, and other sensors, are powerful tools for dramatically better understanding the variability and changes in ocean biogeochemistry including biological production (Johnson et al., 2017a), deoxygenation (Stramma et al., 2008; Sasano et al., 2018), air-sea CO₂ fluxes (Gray et al., 2018), and ocean acidification. GO-SHIP plays two important roles in calibrating and validating these sensors. (1) The recently developed calibration methods for BGC Argo sensors (Johnson et al., 2017b) use the accurate and quality controlled Global Ocean Data Analysis Project (GLODAPv2) profile data set (Olsen et al., 2016), which is heavily based on GO-SHIP data. As the relationships between ocean properties evolve, for instance as acidification progresses and nutrient balances change, continued reference standard measurements collected in GO-SHIP, which are incorporated in the temporally evolving GLODAP synthesis, are essential for global implementation of sustained BGC Argo floats (Carter et al., 2017). (2) For validation of these BGC sensor calibrations in the large pilot Southern Ocean BGC float experiment as part of the Southern Ocean Carbon Cycle Observation and Modeling (SOCCOM¹²) project, shipboard measurements of salinity, oxygen, nitrate, pH, DIC and TALK coincident with BGC Argo float deployments have been required (Williams et al., 2016). For the BGC-Argo bio-optical sensors, which are used to derive chlorophyll-a and POC, concurrent HPLC and POC shipboard sampling in the near-surface have been collected with all SOCCOM deployments. These are currently not GO-SHIP Level 1 measurements, but they

¹²<https://soccom.princeton.edu/>

have been critical for validation of the NASA algorithms for converting satellite ocean color to *in situ* chlorophyll-a and particulate organic carbon (POC) (Haentjens et al., 2017). GO-SHIP cruises, and cruises that are modeled closely on GO-SHIP, are by far the most helpful and highest quality for these validations.

Measurements from marine mammals typically use the Conductivity-Temperature-Depth Satellite Relay Data Logger (CTD-SRDL), developed by the Sea Mammal Research Unit at the University of St Andrews. Marine mammals often sample remote, harsh environments, e.g., the sea-ice edge and the Antarctic continental shelf during winter. However, CTD-SRDL measurements have a random bias in the conductivity cell caused by the marine mammal interfering in the inductive field of the CTD-SRDL (Böhme et al., 2009). Several methods for correcting the individual offsets, which is assumed constant in space and time, have been developed (e.g., Böhme and Send, 2005; Roquet et al., 2011; Frazer et al., 2018). Most of these rely on either little variability in deep ocean measurements from GO-SHIP or delayed mode Argo data (corrected with GO-SHIP data), implicitly placing GO-SHIP as the underlying provider of reference quality data for CTD-SRDL.

Global Ocean Ship-Based Hydrographic Investigations Program provides a platform for assessing new sensors, including BGC sensors, mixing sensors, and biological sensors, inter alia. For instance, to determine their characteristics, oxygen-sensing optodes have been deployed alongside conventional electrode oxygen sensors, allowing both to be compared with bottle oxygen titration data (Sasano et al., 2011). In addition, float CTDs can be strapped onto the shipboard CTD package for *in situ* evaluation of their sensors relative to reference quality shipboard CTD sensors.

Given the importance of GO-SHIP as the provider of the high quality reference data needed by autonomous platforms and other components of the observing system, it is recommended that GOOS endorses GO-SHIP as the ocean reference data set, and that GO-SHIP data be given a unique identifier in the data system to enable users to identify it separate from other observing platforms or sensors.

Deploying Autonomous Vehicles

Global Ocean Ship-Based Hydrographic Investigations Program deploys many autonomous floats for Argo, Deep Argo, BGC Argo, and drifter programs. Deployment of gliders has started on a small scale. GO-SHIP cruises are desirable for autonomous instrument deployment because of the high-quality calibration data they collect, because they are staffed by experienced scientists and technicians who can provide professional support and who recognize the value of the data collected from those vehicles, and because they reach remote locations where deployment opportunities for floats and gliders are limited. For instance, from 2002 to 2019 (Figure 4), GO-SHIP cruises deployed over 7% of Argo floats, which included 70 of the 132 SOCCOM BGC Argo floats deployed up to 2019.

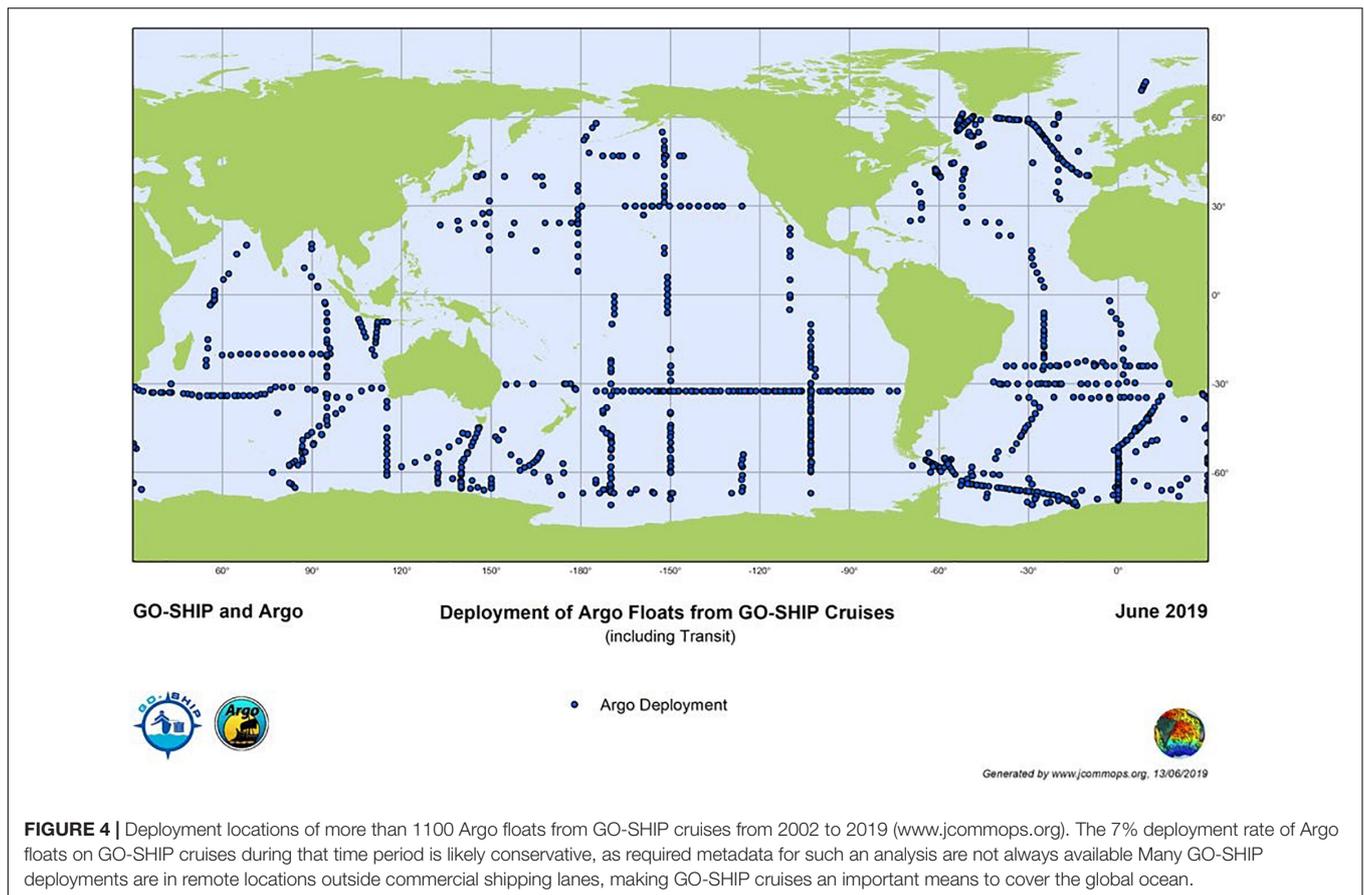

FIGURE 4 | Deployment locations of more than 1100 Argo floats from GO-SHIP cruises from 2002 to 2019 (www.jcommops.org). The 7% deployment rate of Argo floats on GO-SHIP cruises during that time period is likely conservative, as required metadata for such an analysis are not always available. Many GO-SHIP deployments are in remote locations outside commercial shipping lanes, making GO-SHIP cruises an important means to cover the global ocean.

Data Synthesis, Reanalysis Products and GO-SHIP Contribution to Improved Climate Understanding

Data syntheses are important products from GO-SHIP data (Figure 5). After the first decade of WOCE, a major synthesis effort resulted in a gridded data product, the Global Hydrographic Climatology (GHC) (Gouretski, 2018)^{13,14}; print/online atlases for each of the ocean basins¹⁵; and synthesis in a digital atlas, eWOCE¹⁶ (Schlitzer, 2000). The latter utilized the widely used Ocean Data View (ODV) software package (Schlitzer, 2018). These products were focused primarily on the physical properties, oxygen, nutrients and transient tracers, although eWOCE incorporated all of the WOCE data, ranging beyond the hydrographic data sets.

Biogeochemical (BGC) data, with emphasis on the inorganic carbon parameters, were synthesized regionally for the Atlantic (CARINA) (Key et al., 2010) and Pacific (PACIFICA) (Suzuki et al., 2013). The overarching global synthesis of BGC data from ≈1980 to 2000 was the GLODAP project (Key et al., 2004)¹⁷,

involving extensive quality control and cross-over adjustments to yield a globally consistent data set. The recently completed GLODAPv2 2019 represents a major step forward for BGC data synthesis. It includes an iterative inversion process to optimize consistency. GLODAP products include both quality controlled profile data (Key et al., 2015; Olsen et al., 2016, 2019) and a gridded product (Lauvset et al., 2016). GLODAP will be updated bi-annually, using GLODAPv2 as a basis, with a full re-analysis including a new inversion every decade.

The surface water CO₂ measurements performed on GO-SHIP lines are incorporated in surface water CO₂ collations such as the LDEO surface CO₂ climatology (Takahashi et al., 2009) and the Surface Ocean Carbon Atlas (SOCAT)¹⁸ (Bakker et al., 2016). The GLODAPv2 and SOCAT efforts are focused on routine releases, documented submission, and QC procedures. These are labor intensive efforts, and increased automation is being implemented to facilitate uniformity and decrease the personnel time involved. GLODAP and SOCAT have working groups that are represented in the International Ocean Carbon Coordination Project (IOCCP) steering committee. A serious impediment for continuation is that they currently depend on project funds from individual countries that are proposal driven and of finite duration. Entrainment of new younger scientists in these efforts is also critical to maintain them.

quantities based on these repeats would be a useful adjunct to hydrographic data syntheses.

Global Ocean Ship-Based Hydrographic Investigations Program must develop data assemblages by section and/or decade to increase the ease of access and use of all of its Level 1 observations. These data assemblages should follow standard data practices and be provided in a number of file formats that meet users' requirements. Funding of such activities should be a priority of the community. The use of GO-SHIP data in commonly used datasets enhances the use of the data. However, GO-SHIP should develop collaboration with the creators and users of ocean datasets to ensure attribution of the original data source, determine systematic biases in the data, and improve the quality of the observations.

INTERNATIONAL COORDINATION

Long-term funding commitments to sustain and enhance ocean observational efforts such as the activities carried out by the GO-SHIP network remain elusive. Current international efforts rely considerably on contributions from a limited number of countries and a small pool of dedicated scientists. Ship time is often secured 1 to 2 years in advance and is not always guaranteed. GO-SHIP activities are often funded by consecutive short-term research projects. Scientists sometimes struggle to cover the cost and must find multiple funding sources.

Multi-Nation Voyages

To maintain the GO-SHIP program and grow the number of participating nations, a modified operational and funding model should be developed to include multi-nation voyages. Active support and long-term investment from government decision makers and funders of multi-nation voyages has the potential to increase the number of participating countries, enhance capacity, accommodate new measurements of biological and ecosystem variables, and increase awareness of outputs in the form of decision support information products. Capacity building through training a new generation of observational oceanographers is also vital to ensure sustainability. Finally, greater coordination with other ocean observing networks could lead to cost sharing and increased impact within a more coordinated global ocean observing framework.

As the number of variables collected by the GO-SHIP community increases, the demand on human and financial resources becomes difficult to sustain. Multinational efforts offer the potential to share and distribute resource allocations to a wider community. This has occurred in the past. For example Australia has benefitted from United States and Japanese support to undertake tracer (CFC/SF₆) observations. GO-SHIP lines in the Atlantic enjoyed support from European laboratories for variables almost exclusively measured on GO-SHIP such as transient tracers. This approach also empowers new participant nations to take the lead while receiving support from experienced international collaborators. Of course, there are organizational challenges in this approach, but the benefits of shared cost and expertise will widen the pool of countries willing, and able, to lead

GO-SHIP expeditions. The opportunity to extend capabilities, facilitate knowledge exchange, build capacity and future scientific collaboration is huge.

The Irish Example

In 2016, Ireland, led by the Irish Marine Institute and National University of Ireland Galway, committed to complete the 2017 A02 GO-SHIP line on-board the RV Celtic Explorer. While a momentous task, considerable effort to showcase the importance of ocean observing to Irish decision makers and funders proved fruitful. The issue of ensuring the full complement of expertise on-board had to be addressed and the answer lay in an international cooperation. This was a great example of the Galway Statement (signed by United States, Canada and EU May 2013) in action with on-board teams from Canada, Germany, the United Kingdom, and the United States, and additional support from shore teams and experts in Denmark and France. Financial support for partner teams was found through the European Union Horizon 2020 AtlantOS and ATLAS projects, and the Canada Excellence Research Chair in Ocean Science and Technology. The international nature of the 2017 GO-SHIP A02 cruise offered an opportunity for cross-comparison of methods, data quality procedures, and exchange of technical expertise. For example, surface pCO₂ was recorded along the track with the teams from Dalhousie University and the Marine Institute comparing different systems. By using independent systems with frequent multiple point calibration, the RV Celtic Explorer's General Oceanics equilibrator system and Canadian (Dalhousie) team's SubCTech permeable membrane system, there is added confidence in the data produced.

Building Capacity and Training the Next Generation

Global Ocean Ship-Based Hydrographic Investigations Program transects provide an ideal platform to train the next generation of observational oceanographers across the physical, chemical, biological and ecosystem disciplines. Transfer of knowledge and expertise and participation of students and early career scientists is highly encouraged. As commitment and support of international collaborations gain momentum, more opportunities will open to students from developing countries and to scientists in countries without basin and global-class research vessels.

A prime example is the South African floating university. Currently in South Africa, there is a lack of students proficient in mathematics, and by association physics, engineering, statistics, chemistry and computer science, who wish to major in the marine sciences. The majority of students who graduate from a marine science degree program have weak quantitative backgrounds and consequently, battle with understanding the core mathematical or physical dynamics behind open-ocean and coastal processes. "SEAmester" aims to mitigate this problem by introducing marine science as an applied and cross-disciplinary field to students who have shown an affinity for these core science disciplines. In doing so, a new generation of South African marine and atmospheric scientists with a far higher caliber will be trained. "SEAmester" combines traditional classroom lectures with hands-on ship-based deck activities, while providing

students with an opportunity to support scientists specializing in a wide range of marine fields. The South African government's National Development Plan has identified education, training and innovation as being at the forefront of South Africa's long-term development, and specifically states: "*Inadequate capacity will constrain knowledge production and innovation unless effectively addressed.*" The central strategy behind SEAmester is not only of a training program that aligns with South Africa's core Science and Technology objectives, but more importantly, a program designed to fill a growing gap in the capabilities of our current cohort of marine students. It aims to build critical mass within the marine sciences, so as to ensure sustained growth in this field within South Africa and beyond.

Collaborating and Coordinating With Other Observing Networks

Further efforts to consolidate surveys, for example between GO-SHIP transects and deep water data buoy mooring deployment efforts, could lead to cost sharing. There are several examples of this type of coordination in the Prediction and Research Moored Array in the Tropical Atlantic (PIRATA) program and also in Australia. GO-SHIP is an active and dynamic community and keen to strengthen existing links, build new partnerships, and coordinate more closely with other observing networks particularly those focused on biological and ecosystem variables to monitor ocean health. An example to build on is the partnership with Global Ocean Acidification Observing Network (GOA-ON), whereby GO-SHIP is explicitly identified as providing key data for open ocean observing of physico-chemical aspects of ocean acidification, and the active role of GO-SHIP in development of a marine biological and ecosystem observation methods and implementation (Boss et al., 2018). GO-SHIP is involved in the evolution of new regional scale coordinated observing systems, which will bring together the diverse communities of ocean observing networks. These initiatives include the Atlantic Ocean Blueprint, the Tropical Atlantic Observing system (TAOS) (Foltz et al., 2019), Tropical Pacific Observing System (TPOS) (Smith et al., 2019) and European Ocean Observing System (EOOS) together with existing programs such as the integrated ocean observing system (IOOS) and the integrated marine observing system (IMOS).

GO-SHIP Project Office at JCOMMOPS

The Observations Coordination Group (OCG) of JCOMM, part of the World Meteorological Organization (WMO), and UNESCO's Intergovernmental Oceanographic Commission (IOC), coordinates sustained ocean observing networks such as GO-SHIP, Argo, Data Buoy Coordination Panel (DBCP), OceanSITES, GLOSS and the Ship Observations Team (SOT) at the international level. The JCOMM in-situ Observations Programme Support Centre (JCOMMOPS), which is hosted by Ifremer in Brest (France), maintains an information system that allows for monitoring and implementation planning within and across these networks. The JCOMMOPS metadata tools help to set up multi-national and multi-institutional GO-SHIP cruises, and monitor the targets of an ocean observing program in terms

of space, time, quality and availability of the emerging data. Scientific publications based on GO-SHIP data are captured in the GO-SHIP bibliography maintained by JCOMMOPS. Beyond core GO-SHIP activities, the JCOMMOPS system allows for identifying opportunities for other networks that rely on GO-SHIP reference data (e.g., deployment of floats and drifters), or ship time in vicinity of a cruise (e.g., maintenance of a moored buoy). So far, JCOMMOPS monitoring capacity concerns cruise/platform metadata but it is planned to expand this to the observations made available in real-time and delayed-mode. This would allow JCOMMOPS to track cruise progress in real-time and optimize data flow to users.

Costing GO-SHIP, Determining Value, and Securing Sustainable Funding

Efforts to cost ocean observing networks are at an early stage of development and a standard economic methodology has yet to be determined to assess the true cost of ocean observing efforts. As part of the European Horizon 2020 Optimizing and Enhancing the Integrated Atlantic Ocean Observing Systems project (AtlantOS¹⁹) the cost of running the GO-SHIP network in the Atlantic for the period 2012–2023 was estimated at a total of about 100 million Euro. However, the report highlighted that this is a conservative number since many hidden costs exist such as costs of on-land laboratories and equipment required for pre- and post-QC parameter checks on methods. Determining the value of the GO-SHIP network has not been tackled in a quantitative manner due to the lack of economic and socio-economic methods in this area. An important starting point for a clearer definition of the value of GO-SHIP is the definition of value chains describing how the data lead to meeting a variety of end user needs.

Currently, most GO-SHIP cruises are funded through short-term commitments of direct public sector government funding, together with time limited project based research funding. The questions of how to secure sustainable funding for GO-SHIP are echoed by many other ocean observing networks, and by the emerging coordinated observation systems concept. Is a new model of funding based on multi-national voyages and/or increased participation of the private sector the path to sustainability? How can this be achieved? How would such funding models be governed to ensure that scientific independence, quality and open data access is enshrined? Could more coordination and integration of government funding be achieved with commitments that run over periods longer than national political cycles? These are questions to be addressed by GO-SHIP together with the ocean observation community as a whole, policy makers and national funders.

SUMMARY AND RECOMMENDATIONS

Global Ocean Ship-Based Hydrographic Investigations Program has successfully provided the necessary data for estimates of

¹⁹www.atlantos-h2020.eu

decadal trends and changes of large-scale ocean circulation, deep heat uptake and carbon inventories. The contemporaneous collection of a suite of ocean variables has shown the value in simultaneously collecting physical, biogeochemical and biological observations if we wish to fully understand and track the impacts of ocean variability and change within the Earth's System. In the decades to come, GO-SHIP will continue to build the time-series of full-depth repeat ocean measurements capable of resolving decadal and longer time scale changes in the circulation and property storage (including heat, freshwater, oxygen, and carbon) of the global oceans. GO-SHIP will also continue to provide a means to access remote ocean areas for deployment of autonomous observing platforms, including Argo floats, surface-drifters and gliders. GO-SHIP will continue to evolve based on the findings of the previous work and emerging science requirements and technological developments. Future developments will include additional biogeochemistry and biology measurements to enable GO-SHIP to determine trends and variability in marine biogeochemistry, health, and ecosystems. These measurements will be incorporated into the sustained primary objectives of GO-SHIP. As the number of autonomous platforms increases and new sensors are developed, GO-SHIP will be increasingly relied upon as the high quality ocean reference data set required to ensure the accuracy and consistency of a number of EOVS from the increasing diverse range platform/sensors comprising the ocean observing system. While the last decade has seen the establishment of GO-SHIP as a vital component of the global ocean observing system, there is still much work to do to ensure its sustainability and effectiveness. This paper identifies some key points that GO-SHIP needs to address and progress if it is to meet the needs and expectations of the increasingly diverse user community.

Key recommendations for GO-SHIP in the next decade are:

- GOOS should endorse GO-SHIP Level 1 data as a key “surface to bottom” ocean reference data set. GO-SHIP should continue to be the provider of the high quality ocean reference data needed by autonomous platforms and other components of the observing system. GO-SHIP data should be given a unique identifier in the data system to enable users to track and identify it from other ship-based and observing platforms or sensors, and its use in (gridded) products.
- Global Ocean Ship-Based Hydrographic Investigations Program must develop guidelines to evaluate the request of additional variables to the program in order to facilitate incorporation of new variables in the sampling suite. The documentation should include the feasibility, use and importance of the measurement. The logistical issues such as extra ship time, station time, personnel, ship laboratory space, and expertise will need to be considered, as well data management systems for storage and accessibility. Also, the cost needs to be considered for all cruises, including the availability of resources for all the GO-SHIP participating nations.
- Global Ocean Ship-Based Hydrographic Investigations Program needs to focus on establishing and seeking funds for an internationally agreed and adhered to data procedures and management pathways that is still somewhat *ad hoc*. There should be a single mandate/requirement for each GO-SHIP data type in terms of timing, posting, and archiving, and a central data portal. A central data portal tracking and linking all component data sets is essential, including formal agreements on depositories, interoperability, and exchange. This will require the inclusion of data management costs both at the national level and contribution to international coordination within national-led funding proposals.
- The protocol and recommendation for citation of GO-SHIP data²⁰ should be provided in prominent locations including all portals for GO-SHIP data, such that it is clearly referenced when used in publications or as reference data in calibration/validation of data from other observing systems such as Argo.
- Global Ocean Ship-Based Hydrographic Investigations Program must develop data assemblages (by section or decade) to increase the accessibility of the data to the wider community and use of all of its Level 1 observations. These data assemblages should follow standard data practices and be provided in a number of file formats that meet the users requirements.
- A modified operational and funding model should be developed to include multi-national voyages. Programs such as AtlantOS and intergovernmental agreements such as the Galway Statement have been successfully employed by GO-SHIP to increase national participation and share resources. GO-SHIP should work with national funding agencies to formalize these arrangements to increase national participation, capacity building and training of the next generation of skilled sea-going scientists and technicians.
- New models of funding based on multi-nation voyages and/or increased participation of the private sector need to be actively investigated as a means to sustainability. The questions of how to secure sustainable funding for GO-SHIP are echoed by many other ocean observing networks. This needs to be addressed by GO-SHIP together with the ocean observation community as a whole, policy makers and national funders to guarantee the existing ocean observing systems and provide investment to expand the ocean observing systems where required.

AUTHOR CONTRIBUTIONS

BS, RW, and MK led the writing and overall content of the manuscript. GJ, LT, TT, CC, EO'R, EMcG, EB, and KK led sections of the manuscript. All other authors contributed to different sections, to manuscript revision, read, and approved the submitted version.

doi: 10.3389/fmars.2019.00440

Well-founded data management systems are of vital importance for ocean observing systems as they ensure that essential data are not only collected but also retained and made accessible for analysis and application by current and future users. Effective data management requires collaboration across activities including observations, metadata and data assembly, quality assurance and control (QA/QC), and data publication that enables local and interoperable discovery and access and secures archiving that guarantees long-term preservation. To achieve this, data should be findable, accessible, interoperable, and reusable (FAIR). Here, we outline how these principles apply to ocean data and illustrate them with a few examples. In recent decades, ocean data managers, in close collaboration with international organizations, have played an active role in the improvement of environmental data standardization, accessibility, and interoperability through different projects, enhancing access to observation data at all stages of the data life cycle and fostering the development of integrated services targeted to research, regulatory, and operational users. As ocean observing systems evolve and an increasing number of autonomous platforms and sensors are deployed, the volume and variety of data increase dramatically. For instance, there are more than 70 data catalogs that contain metadata records for the polar oceans, a situation that makes comprehensive data discovery beyond the capacity of most researchers. To better serve research, operational, and commercial users, more efficient turnaround of quality data in known

formats and made available through Web services is necessary. In particular, automation of data workflows will be critical to reduce friction throughout the data value chain. Adhering to the FAIR principles with free, timely, and unrestricted access to ocean observation data is beneficial for the originators, has obvious benefits for users, and is an essential foundation for the development of new services made possible with big data technologies.

Keywords: FAIR, ocean, data management, data services, ocean observing, standardization, interoperability

INTRODUCTION

Well-functioning and fit-for-purpose data management systems are essential to the sustained ocean observing system. This quote from the Intergovernmental Oceanographic Commission (IOC) of United Nations Educational, Scientific, and Cultural Organization (UNESCO) Oceanographic Data Exchange Policy articulates the high-level mandate for and the essence of the requirements for oceanographic data flow:

“The timely, free and unrestricted international exchange of oceanographic data is essential for the efficient acquisition, integration and use of ocean observations gathered by the countries of the world for a wide variety of purposes including the prediction of weather and climate, the operational forecasting of the marine environment, the preservation of life, the mitigation of human-induced changes in the marine and coastal environment, as well as for the advancement of scientific understanding that makes this possible.”

It is worthwhile to note that the IOC member states, in this policy, agreed to “provide timely, free and unrestricted access to all data, associated metadata and products generated under the auspices of IOC programs,” and encouraged the member states to do the same also for non-IOC programs. Although this is an excellent aspiration, in practice, this principle has been only loosely enforced by the IOC.

Fit-for-purpose data management systems are of vital importance as they ensure that essential data are not only collected but also retained and made accessible for analysis and application for current and future users. Data management systems that facilitate free and open access, use, and interpretation of data and products must be included as essential elements of the ocean observing system. Effective data management is based on collaboration across activities including observing, metadata and data assembly, quality assurance and control (QA/QC), and data publication. It enables local and interoperable discovery and access and secures archiving that guarantees long-term preservation.

As ocean observing systems evolve with an increasing number of autonomous platforms and sensors being deployed, measuring an increased range of essential ocean variables (EOVs), the volume and diversity of data are increasing dramatically. Automation of data workflows¹ and effective standards will be critical to reduce data friction throughout the whole data life cycle (e.g., Taylor et al., 2006). This increased efficiency is relevant for all data types, from physical observations to biogeochemical

observations and biological and ecosystem observations. With the development of information technologies, researchers expect easy access to a wide range of data and data products. As it becomes easier to aggregate huge amounts of data, the risk of mixing “apples with oranges” increases if the delivery services are not well designed and the data and data products are not clearly described using standardized schemas.

The challenge of enabling optimal use of research data and methods is complex with multiple stakeholders: researchers wanting to share their data and interpretations; professional data publishers offering their services; software and tool builders providing data analysis and processing services; funding agencies (private and public) increasingly concerned with proper data stewardship; and a data science community mining, integrating, and analyzing the output to advance discovery. Computational analysis to discover meaningful patterns in massive, interlinked datasets is rapidly becoming a routine research activity.

The global ocean data system should be designed as an interoperable system of systems that will allow data to be easily findable, accessible, interoperable, and allowing reusability through thematic integrated products and services. The long-term goal is to develop a data system of systems that allows the development of data services at different levels with a guarantee that the best version of the observed data is used at all levels. Data quality, interoperability, and good discoverability can only be assured with a standardized, traceable workflow throughout the lifetime of the datasets. This paper reviews recent developments in technical capacity and requirement setting of a data management system for the Global Ocean Observing System (GOOS). The focus is on EOVs, and the content reflects the increased attention to biogeochemical and biological ecosystem EOVs, building on successes of the physical data system that has evolved the fastest.

THE CHALLENGES

Over previous decades, the requirements for ocean information on an ever-increasingly diverse range of issues have increased. In the past, data management systems have largely developed in isolation and with different objectives to serve particular communities or funding routes. Here, we list some of the main challenges in moving ocean data management toward the FAIR principles of being findable, accessible, interoperable, and reusable (see next section for more details).

¹See, for instance, <https://www.wfmc.org/>

Wide Diversity

The diversity of oceanographic data makes it difficult for the scientist or application developer to find, understand, and use data to optimal benefit. Significant time is invested in these activities before the actual research or data utilization can begin, while provenance and traceability are required for the sake of reproducibility. While automation can bring improved efficiencies to data management for some data types, there is highly variable uptake of these automation methods, and some disciplines will require considerable progress in standardizing observation methods and data management processes before they can take full advantage of these advances.

Multitude of Disparate Data Management Structures

The existence of a multitude of disparate data management infrastructures currently imposes problems for observing systems. These include delayed and duplicated data receipts, versioning issues, missing data and metadata, and undocumented data processing procedures. The interoperability issues resulting from the existence and use of various data management infrastructures are fundamental and wide ranging. Resources are often not available to resolve these issues by wholesale replacement of existing systems. For instance, there are more than 70 data catalogues for the Polar Ocean, see **Box 1**.

Increased Volume of Data

The past 10 years have seen the development of autonomous platforms able to acquire accurate measurements during years-long deployments (e.g., Argo, glider, moorings, and ships-of-opportunity). These platforms are transmitting as much data in 1 year as has been acquired in the past century (**Figure 1**). This rapid increase in data volume puts high demands even on well-organized and interoperable data management systems. Not

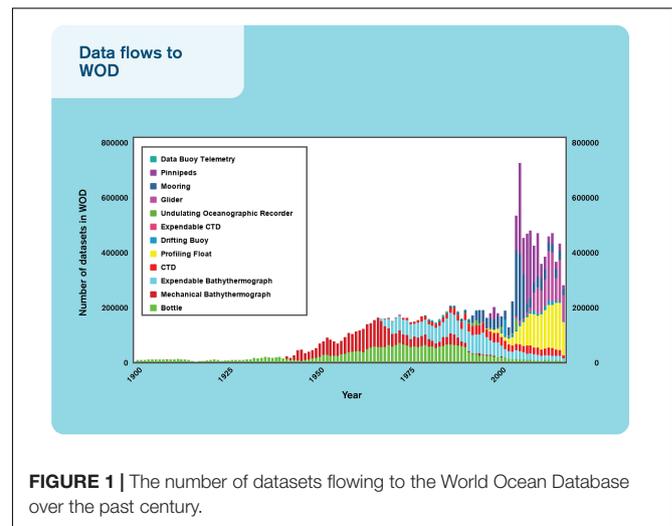

only is the real time (RT) *in situ* data increasing in volume, but also new variables, particularly for biogeochemistry and biology, are frequently being transmitted in RT. This has also resulted in a concomitant increase in the workload for delayed-mode data processing that corrects for biases that accumulate during time spent at sea.

New Sensors Creating New Formats

A major challenge is the management of novel data types produced from new sensors that require mapping to existing standards and conventions or the creation of new ones.

Widely Used Formats Not Universally Applicable

Implementation of widely used standards and formats can be beyond the capabilities of many scientific communities, even

BOX 1 | Polar Oceans.

The Southern Ocean links the world's major ocean basins and the upper and lower levels of global ocean circulation (Meredith et al., 2013). Research in this region is largely conducted under the auspices of the Antarctic Treaty System (<https://www.ats.aq/e/ats.htm>). The polar oceans provide a particular example of the need for global cooperation, given the logistical challenges of working in high-latitude environments and the strategic and scientific importance to nations well beyond those that share geographic borders with the polar regions. The distances and logistical challenges in these oceans mean that much oceanographic research is conducted by national polar research programs rather than purely oceanographic programs. In data management terms, the data centers serving these communities must meet data and metadata standards for both terrestrial and national data communities, in addition to those agreed in the international oceanographic community. Serving 'many masters' as these polar data centers do highlights the need for oceanographic data managers to use agreed standards. More than 70 metadata catalogs hosting polar data have been identified, many of which are not part of metadata federations or aggregations and, hence, put comprehensive data discovery beyond the capacity of most researchers.

In order to achieve FAIR, the Southern Ocean Observing System (SOOS) explicitly accounts for differences in the workflows and levels of technological integration among its scientific communities and seeks to make data available through a variety of paths to "meet each scientist where they are." SOOS, along with the EMODnet Physics group, is making standardized and aggregated *in situ* datasets available for exploration and download through SOOSmap (<http://www.soos.aq/news/current-news/362-explore-southern-ocean-soosmap>). For the long tail of non-standardized data, SOOS is working with Arctic and Antarctic data management groups to investigate the best ways to achieve federated metadata search and to ensure that the EMODnet/SOOSmap infrastructure can be directly linked to virtual labs. SOOS is encouraging scientists in its community to use existing data discovery tools to identify key datasets that should be standardized and federated to publish through SOOSmap. Along this line, SOOS, the Standing Committee on Antarctic Data Management (SCADM), and the Arctic Data Committee (ADC) have founded the POLDER (<http://www.soos.aq/data/federatedsearch>) initiative (Polar Data Discovery Enhancement Research) to identify and advocate the needs of the polar data community in the development of federated metadata search for polar oceanographic and terrestrial data. The activities to date, described above, have largely focused on the findability and accessibility of polar ocean data, and it is likely that these will continue to be significant activities for the next decade. As new observing technologies develop, observing systems are encouraging researchers to standardize formats and QC processing, which should considerably improve on the interoperability and reusability of those datasets.

when the benefits of using those formats are clear. While some progress has been made through tools like the National Oceanic and Atmospheric Administration (NOAA) National Centers for Environmental Information's Network Common Data Form (NetCDF) templates², which help data producers across disciplines create Climate and Forecast (CF) and Attribute Conventions Dataset Discovery (ACDD)-compliant NetCDF, truly comprehensive adoption has not yet been achieved. IT activities are typically funded by science activities, so the requirements of particular science communities may be addressed effectively. However, this can be at the expense of universal interoperability.

Gap Between Data-Producing Scientists and Downstream Users of the Data

It is incumbent upon our community to develop or leverage existing tools that can bridge the gap between data-producing scientists and downstream users of the data, i.e., to remove barriers from “owning data” to “sharing data” for maximal community benefit would require cultural changes. Efficient (FAIR) sharing of data is a social responsibility of scientists, mostly funded by the society, to support the blue economy and ocean information building.

Development of Common Protocols Takes Time

As identified by de La Beaujardière et al. (2010) and Hankin et al. (2010), the development and adoption of common standards for data/metadata (Keeley et al., 2010) and sharing protocols (Pouliquen et al., 2010) take time, coordination, and careful testing.

Best Practices Poorly Defined

At present, best-practice data management (Pearlman et al., 2019) is often largely undefined and is generally left as a decision for the data curator and/or data publisher, although community standards for metadata, data formats, communication protocols, and data server software infrastructure are the foundation for interoperability. Data that are poorly documented can be considered lost and will have little or no value without access to the team that collected the data. Even the research team that collected the data will be challenged to remember details, or find notes, on how the data were collected if it is not properly curated at the time of collection and review.

THE FAIR PRINCIPLES

Open and free data policies are widely encouraged and increasingly required by many organizations, including the IOC and International Oceanographic Data and Information Exchange (IODE), the European Commission, and the Antarctic Treaty System, as well as many funding and operational agencies. Interoperability among data services has become a priority

with the development of the FAIR principles³, a set of guiding principles to make data:

- **Findable**
Each dataset should be identified by a unique persistent identifier and described by rich, standardized metadata that clearly include the persistent identifier. The metadata record should be indexed in a catalog and carried with the data.
- **Accessible**
The dataset and its metadata record should be retrievable by using the persistent identifier and a standardized communications protocol. In turn, that protocol should allow for authentication and authorization, where necessary. All metadata records should remain accessible even when the datasets they describe are not easily accessible.
- **Interoperable**
Both metadata and datasets use formal, accessible, shared, and broadly applicable vocabularies and/or ontologies to describe themselves. They should also use vocabularies that follow FAIR principles and provide qualified references to other relevant metadata and data. Importantly, the data and metadata should be machine accessible and parsable.
- **Reusable**
To meet this principle, data must already be findable, accessible, and interoperable. Additionally, the data and metadata should be sufficiently richly described that it can be readily integrated with other data sources. Published data objects should contain enough information on their provenance to enable them to be properly cited and should meet domain-relevant community standards.
The FAIR data principles are gaining increasing traction across all scientific domains, triggered by an important publication that radically influenced data management and data sharing developments (Wilkinson et al., 2016). The FAIR principles specifically focus on machine use of data and metadata because this is more difficult than achieving FAIR data for human users, whose intuitive sense of semantics and ability to infer meaning from contextual cues assists them in navigating non-standardized datasets and their metadata descriptions. While full implementation of the FAIR principles may rarely be achieved, these principles are designed to encourage data managers to take steps along a continuum from unstructured, undocumented data to fully FAIR data (Wilkinson et al., 2016). As ocean observing systems develop, they will need to account for the patchy legacy of data management approaches. Data management infrastructure—both technical and human—will need to be flexible to assist those disciplines and nations without access to sophisticated data management systems to make their data FAIR, while also encouraging continued development toward the FAIR principles from those disciplines and nations with a strong history of data management.
Oceanographic data systems generally possess a high level of FAIRness compared to many other disciplines. The major, but certainly not only, hurdle today is machine-to-machine aspects

²<https://www.nodc.noaa.gov/data/formats/netcdf>

³<https://www.force11.org/group/fairgroup/fairprinciples>

of interoperability. At the same time, we acknowledge that in some disciplines, it is important to the scientists who collect a dataset that they be given the opportunity to publish their findings before the data are made public. There is nothing in the FAIR principles that precludes data originators from embargoing their data for a limited period, even though the sustained ocean observing system heavily relies on timely availability of data. We believe that giving scientific data originators the option of embargo can be important to maintain confidence in the data management system.

THE PAST DECADE

The process of developing a multidisciplinary, integrated ocean observing system for operational uses, including sustained scientific research, follows the guidelines of the framework for ocean observing (Lindstrom et al., 2012). This framework was a major outcome of the OceanObs'09 conference and was developed through sponsorship of IOC, and the implementation is coordinated by the GOOS. Important aspects of the Framework of Ocean Observing (FOO) are the focus on EOVs and the expansion of GOOS to cover the biogeochemical and biological/ecological domains as well as physical variables. During the last few years, the ocean community has been working toward agreeing on a set of EOVs for physics, biogeochemistry, and biology/ecosystems. As a result, ocean data management systems have put emphasis on servicing the need to observe and report on EOVs for sustained ocean observing systems.

Both the means to acquire these data and the way they are used have evolved greatly in the past 10 years. In the past decade, new Global Data Assembly Centers (GDACs) were set up for some *in situ* networks, applying the OceanObs'09 recommendations (Pouliquen et al., 2010). In their contribution to OceanObs'09, (Hankin et al., 2010) recommended key areas in which oceanographic data managers should focus their attention during the decade that is now coming to a close. Their recommendations focused on what they considered pragmatic and realistic actions to improve the accessibility and interoperability of ocean-focused data. These included (1) working toward adopting common standards for data and metadata building on progress made in the past decade (Keeley et al., 2010); (2) establishment of a single entry point (GDAC) concept to network data or for aggregated products (Pouliquen et al., 2010); (3) the use of common standards that allow systems to interoperate; (4) leveraging the efforts of commercial search engines through the adoption of Web services with tools (Blower et al., 2010); (5) developing and adopting data models based on sampling geometry; (6) developing semantic Web tools to allow straightforward translations between metadata standards; and (7) specific recommendations for meteorological data, data archiving processes, biological data, satellite data, and software toolkits for systems developments. In particular, they advocated for all ocean observations to be made universally accessible through CF-compliant NetCDF files using common vocabularies served through Open Geospatial Consortium (OGC) Web services or commonly used tools such as Open-source Project for a Network Data Access Protocol (OPeNDAP) servers.

At the time of writing, these formats are already widely used for model outputs and satellite products. The last decade has seen the introduction of the discrete sampling geometries (DSG) into the CF standard as of version 1.6, released in December 2011. These geometries are designed to provide representations for *in situ* features such as time series, vertical profiles, and surface trajectories. More mature networks are currently implementing these features in their NetCDF data representations. Recently, these standards have also been embraced by the biogeochemical community, e.g., the Surface Ocean CO₂ Atlas (SOCAT) project uses NetCDF, CF-compliant DSG as the backbone of its data ingest and QC system. The European SeaDataNet community, working on standards for validated, archived data, has adopted Ocean Data View (ODV) ASCII format as well as SeaDataNet NetCDF CF for the observation datasets (profiles, time series, and trajectories), and NetCDF CF for its data products such as climatologies. However, the biological communities have not embraced the CF conventions to describe their data but have converged on different standards; e.g., biological data standards are curated by the Biodiversity Information Standards (TDWG). The most popular standard for sharing biodiversity information is Darwin Core, which enables integration between the two largest communities, the Global Biodiversity Information Facility (GBIF) and Ocean Biogeographic Information System (OBIS). The difference between physical and biological data standards has likely to do with the requirement (RT vs. delayed-mode data delivery), the amount of data to be handled (physical data tend to have significant higher volume), and the methods of data collection.

In addition to developments within the oceanographic community, key interdisciplinary communities have emerged to address data informatics topics common to multiple communities. These include the American Geophysical Union (AGU) and European Geophysical Union (EGU) Earth Space and Science Informatics groups and the Research Data Alliance (RDA). Examples of efforts that have had links to these communities are the FAIR principles and developments in the use of Digital Object Identifiers (DOI).

Progress in information technologies over the past decade with an increase in data services available *via* the internet has led to the emergence of new computing paradigms and technologies such as high-performance and high-throughput computing; cloud, edge, and fog computing; big data analytics; machine learning; and virtual research environments. This opens up significant opportunities but requires FAIR data management practices to be implemented. One example demonstrating how embracing new technologies has improved data access for uses occurred when NOAA's Big Data Project (BDP) partnered with Amazon Web Services (AWS) to provide access to the complete historical archive of the Level-II Next Generation Weather Radar (NEXRAD). NEXRAD data are used for a variety of purposes, including weather forecasting, water management, etc. With these data available in the cloud, the data were accessed 2.3 times as often as the historical monthly access rates⁴, indicating it was much easier to find and use for data consumers. Similarly, within the European H2020 ENVRIplus project, a subscription

⁴<https://www.ncei.noaa.gov/news/noaa-expands-big-data-access>

system was developed, allowing faster subsampling on the full Argo dataset, and semantic search based on FAIR Argo metadata system is under development using Elasticsearch and big data technologies.

Another example is SeaDataNet, which connects in excess of 110 data centers in Europe and gives harmonized discovery and access to a large volume of marine and ocean datasets. For this purpose, SeaDataNet dynamically maintains so-called data buffers for specific parameters. SeaDataNet is also performing data discovery and access as well as data buffer services for several European Marine Observation and Data Network (EMODnet) projects. Several data products are delivered with DOI, OGC Web services, NetCDF (CF), and other formats, depending on their user communities. In addition, all products carry SeaDataNet PIDs and related metadata for the used basis datasets for acknowledging data originators and following FAIRness principles. The experience is that these harmonized and validated data products are popular with users, encouraging more data centers to join the marine data infrastructures for standardized exchange. SeaDataNet is making good progress with developing a collaborative and high-performing cloud and virtual research environment (VRE), configured with tools and services for processing essential marine data. Using OGC, ISO, and W3C standards and incorporating scientific expertise, dynamic workflows are configured for analyzing, processing, and combining subsets of data. The VRE and workflows will allow data product teams to work more efficiently for processing large amounts of input datasets and generating data products collaboratively, while also adopting innovations like machine learning for QA/QC of large data collections. This way, the production cycle for data products can be reduced in duration and higher-quality products can be achieved.

Hankin et al. (2010) provided a series of predictions and recommendations for how oceanographic data management systems would evolve over the past decade. Their prediction that data management would likely improve incrementally rather than in 'heroic leaps' has held true, though some of their other predictions have proved overly optimistic. Despite considerable progress and effort toward the goals outlined by Hankin et al. (2010), oceanographic data are generally not yet managed through independent and interoperable data

management systems, forming a system of systems. Semantic interoperability tools are only patchily translating terminology, codes, conceptual models, and relationships across data and metadata standards. Progress has been made on all of these fronts, but true international interoperability seems only to have been achieved for a small fraction of the kinds of data being collected in the world's oceans. Excellent progress has been made when it comes to many physical and meteorological variables needed by the operational ocean community and on validated archives of marine data *via* metadata standards and semantics like the British Oceanographic Data Centre's (BODC) Natural Environment Research Council (NERC) Vocabulary Server. However, the biogeochemical (BGC) and biological data communities are still striving for improvement and need increased and sustained funding to meet observing systems' needs. There are multiple reasons for the slower progress of BGC and biological communities when it comes to data interoperability. These communities are largely operating more in "research mode," with low requirement for fast and interoperable data exchange and with a large and complex set of variables being measured. The definition of EOVs and wider acceptance of best practices will likely help remedy the situation.

THE CURRENT SITUATION

A great abundance of regularly acquired environmental data exist for a wide range of disciplines derived from both *in situ* and remote sensing observing platforms, available in real-time, near real-time, and delayed modes. These data are acquired within routine monitoring activities and scientific surveys by a few thousand institutes and agencies around the world. A number of projects have been working of improving data management practices for sustained ocean observing, for instance the AtlantOS project (see **Box 2**).

Increasingly, scientists directly consider societal needs and benefits, policy dimensions, environmental health, business needs ("blue economy"), and the operational utility of their research. The societal (both from the public and private sector actors) need of ocean information is increasing as society is relying more and more on the ocean for food, energy,

BOX 2 | AtlantOS.

AtlantOS is an EU-funded project with the aim of enhancing and optimizing the integrated Atlantic Ocean Observing System. The targeted European data system within the AtlantOS project enhances and integrates existing data systems to ingest and deliver more *in situ* data. The existing data systems are diverse, and integrators are charged with integrating the data streams. These integrated system are mature systems with long-term experience and established procedures for data collection and management, often agreed at an international level; trying to implement a sovereign and rigid set of rules would be highly challenging and not in the best interest of the observing system. By relying on sustained infrastructure, AtlantOS has furthered the implementation of the FAIR principles for Atlantic observations, achieved through a system of systems where ocean observations are made available to users on a free and unrestricted basis, ensuring timely, full, and open exchange of data, metadata, and products. This includes improving interfaces with observing networks, European monitoring centers, European nations' oceanographic data centers, and the way exiting integrators exchange data and products using FAIR principles. AtlantOS recommended to integrate existing standards and protocols, rather than reinvent the wheel, by first implementing a minimum set of mandatory information for metadata. Using agreed vocabularies in the data processing and distribution chain allows for traceability of the observations. AtlantOS encourages open and free data policy and focuses on data quality by implementing a set of common near real-time QC procedures for seven EOVs acquired in near real time. AtlantOS enhances access to network data by setting up a unique entry point to discover and download existing data, either by integrating the data in existing Global Data Centers or by setting up new ones, recognizing the importance of existing integrators. The enhancement of monitoring facilities offered by JCOMM *in situ* Observations Programme Support Centre (JCOMMOPS) associated with the documentation of existing services through a unique catalog is an important element for the development of integrator services. They also allow efficient connection to the Global Earth Observation System of Systems (GEOSS).

natural materials, transport, etc. This results in integrative research that includes the social sciences and humanities as part of a much-needed holistic perspective on environmental change. It also introduces the need to ensure that open data policies consider ethical dimensions of such policies. While the default should be fully open data, in some cases (e.g., personally identifiable information, health data, sensitive species information, some indigenous knowledge, etc.), specific management and dissemination methods must be employed to avoid harm (i.e., aggregation, anonymization, etc.).

Data management practices across oceanographic sciences are highly variable in terms of their sophistication and the levels of support they offer to data providers to make their data available in a timely, free, and unrestricted manner. A good practice example is in the Argo program where observations from floats are uploaded by satellite link to national Data Assembly Centres (DACs) where homogeneous automated QC processes are applied, and the data made available rapidly through two Global Data Assembly Centres (GDACs) that synchronize their data holdings many times a day, see **Box 3**. All data from this program are open and free, in a highly standardized format, which allows data users to aggregate it, subset it, and manipulate it with comparative ease. **Figure 2** illustrates typical interfaces between observing networks and data systems, and **Figure 3** illustrates the need for data management systems to cover a variety of scales.

Tools, such as Environmental Research Division's Data Access Program (ERDDAP), that allow scientists to work in their format of choice, but make the data available through interoperable formats, such as NetCDF and Web services, without an added burden on the scientist, are crucial to increasing interoperability. Additionally, tools such as ODV, Thematic Real-time Environmental Distributed Data Services (THREDDS), and ERDDAP can reduce the technical barrier that NetCDF presents. For real-time data, the need for interoperable data streaming (for instance by piping different processes) has been partially borne out of the technological context (i.e., digital sensors)

and of the impracticality of data transformations after the operational time of the sensor. Although real-time data exchange for many EOVS has been operational for decades, facilitated by World Meteorological Organization (WMO) standards, it is still difficult for non-operational users to get access to GTS data (see **Box 4**). In the European context, the EMODnet (Miguez et al., 2019) physics is trying to bridge the gap between real-time and delayed-mode data streams by linking existing data management systems developed in both communities, see **Box 5**. In addition, the Joint Technical Committee for Oceanography and Marine Meteorology (JCOMM) Observations Coordination Group (OCG) has led a successful pilot project to improve both distribution and access of real-time data from the Global

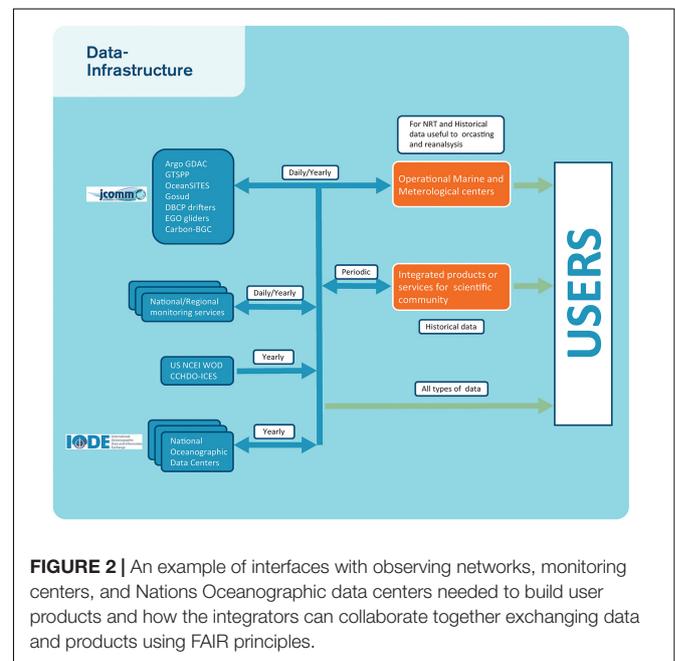

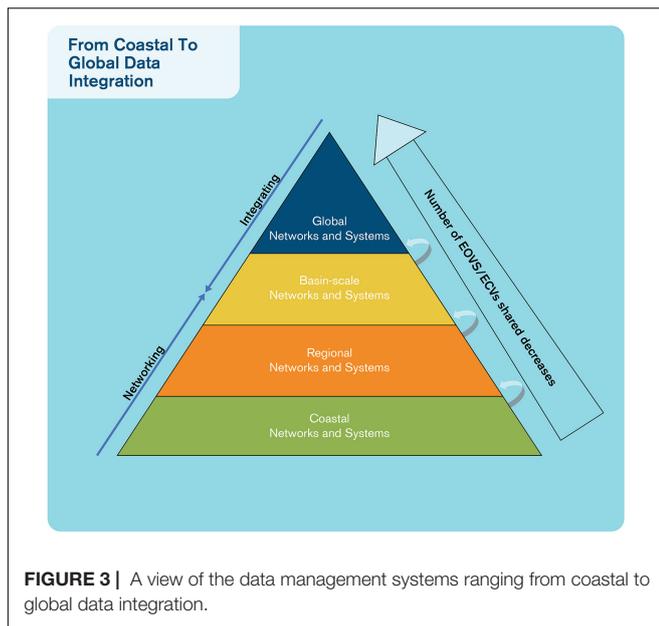

FIGURE 2 | An example of interfaces with observing networks, monitoring centers, and Nations Oceanographic data centers needed to build user products and how the integrators can collaborate together exchanging data and products using FAIR principles.

BOX 3 | Argo.

Since its design in 2001, Argo data have become the dominant source of *in situ* data in the physical oceanographic community. The national DACs receiving data via satellite transmission decode and QC the data according to a set of RT automatic tests. Erroneous data are corrected or flagged and then sent to two GDACs and the GTS. The GDACs collect data from the 11 DACs, synchronize their databases daily, and serve the resulting data products on FTP sites (<http://www.argodatamgt.org/Access-to-data/Access-via-FTP-on-GDAC>). The Argo Information Centre (AIC <http://argo.jcommops.org/>) monitors the status of the Argo program, including data distribution and metadata on float location, model, transmission system, owner, and other variables. The Argo Regional Centers (ARCs) perform a variety of tasks including coordinating float deployments, consistency checks on delayed-mode QC, finding additional reference data for delayed-mode work, adopting floats for delayed-mode QC, and producing Argo data products.

Argo supports FAIR principles with an open and free data policy both in real time and in delayed mode. The FAIR principles are also supported by the Argo team to enhance the interoperability of the Argo data system. Argo was the first network to apply a unique ID for each float in the program (unique WMO numbers) and has worked with the RDA to develop a strategy for managing DOIs for continuously increasing datasets (DOI with a monthly tag for the GDAC monthly snapshots) (<http://www.argodatamgt.org/Access-to-data/Argo-DOI-Digital-Object-Identifier>). The metadata attached to a float, containing information such as serial number of the sensors and other technical information, support analysis from the Argo GDAC, a strategy that has shown its efficiency when anomalies were detected. QC of Argo data involves a complex sequence of both automatic and manual tests to produce delayed-mode data of high quality. With 400 profiles daily, the burden on human resources dedicated to QC is large and Argo is investigating machine learning solutions to improve the process.

While the complete data chain has been developed for the Argo core mission (P/T/S, 0-2000 dbar), the extension to Deep Argo and Biogeochemical (BGC) Argo is under development with a similar philosophy for the data system, realizing the increased need for resources to accommodate new data streams (Roemmich, 2019). Since Argo is often used in conjunction with data from other platforms, an important next step is enhancing the interoperability of Argo data with other data systems by implementing the FAIR principles. Improving the FAIRness of the Argo data system may require updates in data and metadata formats as standards and user requirements evolve. Serving high-quality data is a top priority for Argo, and comparison with other observing systems will help each system improve data quality and services.

Telecommunication System (GTS) Pinarði (2019). Leveraging and ensuring a sustainable and consistent implementation of such tools are also crucial in an era where funding is tight and where data management is often an afterthought. However, increasingly, management planning is obligatory, and funding and allocation of costs for data management and adopting FAIR principles are now encouraged. One example would be Argo (see text **Box 3**).

It is important to recognize that part of the failure to build fully interoperable data systems is that the use of a self-describing and highly effective data format such as NetCDF is beyond the

technical reach of many science groups, even when they see the benefits of using the format.

Data Management for Biology and Ecosystems

In the biological and ecological disciplines, there is often a 5-year lag in data publication so that the majority of effort is still allocated to data archeology rather than uploading more recent observations (Muller-Karger et al., 2018). Much of this delay is inevitable as the processing and identification of samples may take some time due to processing techniques and the consultation of taxonomic experts. Where the oceanographic community started working together in the 1980s on data archeology, standardization, and routine surveys, such cooperation has a much shorter history in many biological disciplines. In areas where this has happened, such as fisheries, the data are often not publicly available due to political and/or economic sensitivities. Development of systems that allow automated collection and/or analysis of samples is in its infancy. An exception may be in the field of aquatic telemetry, where a significant effort has been made to automate data acquisition and publication (Hussey et al., 2015; Treasure et al., 2017; Hoenner et al., 2018).

Continuous biological data acquisition is at an early stage, leading to little standardization and movement toward automated processes. A notable exception is the progress made by the Integrated Marine Observing System (IMOS) in Australia on timely distribution of non-physical data⁵. The vast majority of biodiversity research or monitoring happens by discrete sampling or human observation from a distance, each with their heterogeneous sampling protocols and statistical consequences. Within marine biology data management, the OBIS has contributed toward vocabulary and metadata-level

⁵<https://portal.aodn.org.au/>

BOX 4 | Evolution of the WMO Information System (WIS).

The GTS, implemented by the WMO, has been successful in meeting its primary objective—the cost-effective dissemination of meteorological information in near RT. However, the GTS was developed in a period when teletype communication was the norm and, as such, the capabilities of this system no longer meet the needs of the modern era. While the GTS is well managed, reliable, and effective, it is also limited in capability, expensive, complex, and with restricted access. To address the shortcomings of the GTS and expanding the data services offered by the WMO, the WIS offers three services areas: (1) routine collection and dissemination service for time-critical and operation-critical data and products; (2) data discovery, access, and retrieval service; and (3) timely delivery service for data and products. WIS plans to expand the GTS offerings through the utilization of public networks, including the global Internet. This service area holds great promise to provide greater access to WMO data services⁵. The WIS does present a unique opportunity to increase the dissemination of marine observations and modeling data for use in operational forecasting. One such opportunity is for the WIS to adapt data transmission message standards to accommodate new platforms and current data conventions used in the oceanographic community. Through this evolution, the hope is that the WIS will provide not only greater access to near RT data but also streamlined procedures for data publishing without the procedural overhead now imposed by the GTS.

BOX 5 | European marine data initiatives. At the European scale, enhancing *in situ* data observation and product FAIRness has been identified as a priority, and collaboration between the different actors has been fostered through the EuroGOOS “DATA Management, Exchange and Quality” (DATAMEQ) working group. Within DATAMEQ, close collaboration is fostered between the observing network operators, the regional monitoring systems within EUROGOOS, and the main infrastructures dealing with *in situ* observations Copernicus Marine Service (CMEMS), SeaDataNet, and EMODnet. In particular, important are agreements on vocabularies, agreements on common QC automatic procedures for a selection of EOVs, improvements on interfaces between the different components to facilitate integrated product elaboration like those provided by CMEMS, EMODnet, or SeaDataNet. These three infrastructures have signed a memorandum of understanding (MoU) to strengthen and sustain their collaboration and move toward common products delivered by more than one infrastructure. The success came from a step-by-step approach, focusing first on physics and extending gradually to biogeochemistry, with biology being a new target. Another factor of success was a win-win relation established with *in situ* observing system operators that can use the European services for extending the use of their observations. Improving FAIRness of the European infrastructures is an important objective, and major steps should be achieved in the ENVRI-FAIR H2020 project in the next 4 years with experience that will be shared within EuroGOOS through the DATAMEQ working group within the EuroSea H2020 project.

harmonization. For instance, the release of the Darwin Core Event Core in 2015 enables structured information on the sampling protocol and links a number of observations to a sampling event. This critical addition enables users to model population monitoring, simultaneous counting, and capture–recapture schemes—knowledge of which is essential to use such datasets for Essential Biodiversity Variable (EBV) products. For ingestion of data into OBIS, extensive semiautomated QC checks are employed, including completion of mandatory fields, correct typing and formatting of fields, and basic geographical checks, as well as taxonomical backbone mapping. The Darwin Core data standard means that there is little interest among biodiversity researchers in adopting formats and conventions from other disciplines, such as NetCDF and CF to primary occurrence data (e.g., presence/absence, abundance, and density measurements). To fully achieve interdisciplinary interoperability, current data catalog solutions will need additional interoperability layers, possibly based on those already mature in other domains, rather than building new services.

While some nations have considerable budgets for ocean observing and have significant resources to devote to data management, researchers in other nations have been left without professional data management support to aid them in publishing and curating their data (Parsons et al., 2011). Capacity development in data management and use is critical for a global reach and impact of ocean information. For instance, IOC/UNESCO's IODE are building capacities around the world *via* training and online learning materials⁶. In most countries, most of the time, data management is poorly funded compared to data acquisition, and therefore, the data are often not processed at a level suitable for true interoperability that would allow the full data life cycle to be documented. Internationally comparable numbers to assess this quantitatively could not be found, but personal experience of the authors demonstrates that all oceanographic disciplines and nations lack the sustained resources needed to fully underpin global and regional ocean observing systems.

THE FAIR PRINCIPLES IN PRACTICE

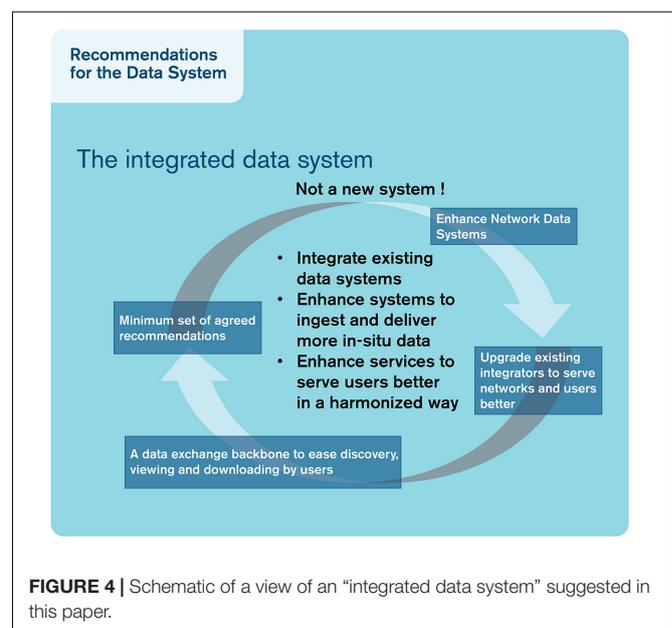

It has become clear that no single data access portal and application will ever fully satisfy the data access and requirements of all users. Rather, individual communities have very specific needs when it comes to how they access and use data, although cross-community data access is becoming more and more important. Rather than try to funnel users to an unfamiliar data portal, it is more valuable to focus on making data available through interoperable platforms. This can include direct access using protocols like the Data Access Protocol (DAP) Buck et al. (2019) or small, agile data portals that can potentially be easily and quickly built using the services provided by the data platform or be the result of thorough and consistent work over the years. A fundamental issue with data portals is their long-term maintenance, especially when they replicate the underlying data.

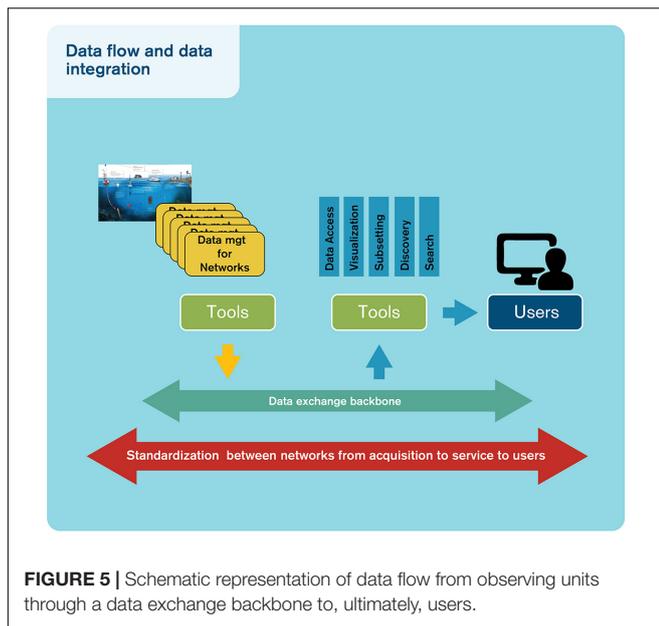

⁶For example, Ocean Teacher, <https://classroom.oceanteacher.org/>

Data portals need to link to or regularly synchronize with the underlying data to avoid decoupled copies of datasets becoming increasingly different over time.

Professional data management is an essential element of the FAIRness of an observing system and should be designed and properly funded as part of the cost of collecting the observations. New data types, especially from autonomous observing platforms, will need to have professional data management streams developed for them. At the same time, the new focus on EOVs means that many older observing platforms will need to have new data management workflows developed and applied to the legacy data. Data management needs to be structured to work across EOVs and from local to global scales (Figure 3). As the volume and diversity of data increase, so does the need for professional data managers. The broader oceanographic community need to follow the path of physical oceanographers in terms of establishing DACs and GDACs to curate observations, along with the necessary standardized data management processes (Figure 4). This cannot be done without providing adequate and sustainable funding for the technical data management, as well as for the necessary coordination needed to define and agree on the best processes to be used.

Since one of the key tasks of data managers is to preserve data for the long term, it is imperative that new data management repositories or data assembly centers have sustainable, long-term funding, with the possible exception of targeted data rescue efforts. A common rule of thumb for scientific data management funding is that at least 5 to 10% of the funding for a science project should be committed to managing the resulting data. While it is difficult to accurately price the global cost of either oceanographic programs or data management efforts, the total cost of a single research voyage, for instance, is considerably higher than the cost of hiring a data manager for a year. For instance, a study by Shepherd (2018) indicate

annual gains in the order of a billion euro within the EU of ocean/marine information being accessible. As an example of a comparatively well-funded data management activity, Australia's IMOS apportions 10% of its budget to building and maintaining the Australian Ocean Data Network (AODN), that is in addition to primary data management performed before the data reach the AODN (Lara-Lopez et al., 2016). Similarly, the TPOS 2020 2nd report recommend that 10% of observing effort should go toward data and information management⁷.

Figure 5 illustrates the principles of our suggestion, where data are delivered to the system from various networks or individual data providers through a data exchange backbone facilitated by appropriate tools and services to serve a wide data flow path from acquisition to user services.

The FAIR Principles and the FOO

In building any data system, a choice must be made between focusing on variables or on platforms/sampling events. It does not, in principle, matter from which platform observations of a variable originates, as long as the appropriate metadata are preserved, including estimation of the observation accuracy. This is in line with the focus on EOVs in the FOO. For RT data, it is essential to work with network operators to ensure complete data transmission and processing, appropriate QC steps, and labeling for practical/operational reasons. The integration of EOV data from different sensor, platforms, and networks require adequate characterization of accuracy and precision so a user can decide which data to use for a specific purpose. For delayed-mode data, a first level of delayed-mode processing, correcting for offset or drift, must be performed at the platform level, as it requires solid technical knowledge on the measurement procedure. A second step must focus again on the data in an EOV perspective, allowing for evaluation of cross-platform coherency.

⁷<http://tpos2020.org/project-reports/second-report/>

This assures the most complete coverage by combining EOV data from multiple platforms and assures the highest possible quality. An interoperable data system should facilitate comparing the data on one EOV coming from different platforms with other products, for instance, surface ocean temperature from satellites or from Argo floats.

The FAIR principles now enjoy broad recognition through the data community, and increasingly in the ocean observing community (e.g., the GOOS 2030 Strategy⁸ and the FOO). The FOO (Lindstrom et al., 2012) draw data and information systems, at the conceptual stage, in the discussion of maturity levels and in the discussion of processes of the Framework. However, it treats requirements, observations, data, and information as sequential, distinct parts of the framework and uniquely associates data and information with the outputs. In reality, those requirements will include data and information characteristics sitting alongside the EOVs. For example, an operational ocean prediction center that requires rapid access to physical data will have requirements in terms of quality, ease of access, and metadata. A climate assessment activity, on the other hand, will usually have a narrower requirement in terms of variables, but will emphasize quality, metadata, continuity, and comprehensive spatiotemporal coverage. The methods of data assembly and QC will be very important.

It is also clear that the requirements from stakeholders (providers and users) occur at both the input side and the output side according to the FOO framework. The observing systems themselves also have requirements; the effectiveness of data and information systems determines the impact of observing elements.

Several oceanographic organizations/projects are already embracing the FAIR principles alongside the consideration of EOVs and requirements, e.g., the Atlantic Blueprint vision document De Young et al. (2019); the latter conclude that "Following the FAIR principles must be a guiding principle for building and maintaining the Atlantic Ocean data management system." This should apply to GOOS and the FOO more generally so that data and information are recognized as essential alongside EOVs, with the variables replaced by a set of static attributes. Requirement setting for data and information systems should be performed alongside requirement setting for EOVs. The requirements will emanate from three levels: (a) from the data users who are specifying needed accuracy and sampling on variables, (b) from operators of observing elements, and (c) from the value chain of ocean observing where delivering fit-for-purpose data and products is paramount.

The essential elements of data and information might include requirements to follow FAIR principles. RT data submission should be as close to real time as possible but delayed enough to assure quality is fit for purpose, and the communication system should be open and accessible. Furthermore, QA/QC should be integrated with the instrument/platform and automated as far as possible. The FOO should also assess access and assembly of

⁸http://www.gooscean.org/index.php?option=com_oe&task=viewDocumentRecord&docID=24590

digital object identifiers and the use of long-term archives in the requirement setting.

The FAIR principles should not need to evolve with technological change, but the essential requirements for data and information almost certainly will. Just as new observing technologies, like gliders or the proposed Surface Water Ocean Topography (SWOT) satellite mission, open up new possibilities for data and products at different resolutions and quality, changing IT capabilities and emerging general standards will provide opportunities for improved solutions for data and information systems, encouraging stricter requirements.

Testing FAIRness

Some oceanographic data types already meet the FAIR principles. These are mostly those data for which international agreements already exist on the observation methods, dataset structures, and an infrastructure to coordinate data aggregation and QC processes. For most *in situ* oceanographic data types, however, the FAIR principles have only been partially implemented. Datasets that have been published through general purpose or national data centers are typically somewhat findable and accessible, though their findability is limited if the data center's metadata holdings are not connected to metadata aggregators or federations. Over the next decade, we anticipate general improvement in the implementation of the FAIR principles, leading to increased accessibility of data.

Many data systems are in the process of becoming FAIR; some even claim to be FAIR. However, it is important to utilize tools to measure FAIRness from a machine perspective. The GO FAIR office, active in the Netherlands, Germany, and France, has taken the initiative to develop metrics for testing FAIR readiness⁹. The metrics will assess the degree to which a data product meets the FAIR principles as accurately as possible. The aim is to give data holders the means to check where improvement is required (Wilkinson et al., 2018). For instance, SeaDataNet is a candidate implementation network, and the first FAIRness assessment has been made using the new metrics, providing a practical test¹⁰. SeaDataNet has made considerable progress in the last decade on metadata and data standardization on both syntax and semantics.

⁹<https://www.go-fair.org/technology/go-fair-metrics/>

¹⁰<https://www.seadatanet.org/Data-Access>

Focus has been given to the development of data access services and Web services to find and access the data.

Integrated Data Services

Integrated data services can be important tools in the FAIR process, facilitating uptake by users. DACs and Thematic Acquisitions Centers (TACs) assemble data from different providers to provide integrated products and services. While a DAC is linked to a network and the DAC process data from acquisition to data delivery, a TAC is a thematic center that aggregates data from other data centers to provide a service for a specific type of users.

The role of TACs is to collect, process, and QC upstream satellite and *in situ* data. The satellite TAC's main functions are to work on homogenization and intercalibration of data from multiple missions (so called L2P processing) and the development of higher-level data products. *In situ* TACs deal with the collection of data from a wide range of networks by the development of homogenized QC and validation procedures as well as high-quality data products. Such an approach can be used at global- and regional-level generating products in near real time as well as reprocessed data.

Such services have been developed in different continents, and collaboration exists between these initiatives through the Global Ocean Data Assimilation Experiment (GODAE) Ocean View for Operational services, RDA, and IODE. Past decades have seen the development of TACs [e.g., CMEMS, SeaDataNet, International Council for the Exploration of the Sea (ICES), or EMODnet] that developed cross-platform services targeted to a wider range of users. Other thematic centers have developed specific data products and services for specific EOVs [e.g., SOCAT for surface ocean pCO₂ data, Global Ocean Data Analysis Project for Carbon (GLODAP) for interior ocean biogeochemistry (see **Box 6**), GEOTRACES for trace element chemistry, or OBIS for biodiversity and biogeography]. Setting up GDACs to provide an interoperable data platform for data access will allow for services on an EOV basis or a network basis. In turn, this will facilitate a rigorous and effective quality assessment service.

Data and Information Products

Data products are also useful ways of avoiding duplicate versions of the same dataset ingested in the analysis. Satellite data

BOX 6 | SOCAT and GLODAP

The SOCAT and GLODAP are two complementary carbon-related data products. SOCAT is a QCed global ocean surface carbon dioxide (CO₂) dataset (Pfeil et al., 2013), and GLODAP is a QCed, internally consistent, global interior ocean data product on carbon-relevant variables.

SOCAT supports the FAIR data principles by leveraging current data standards, archiving the data and providing DOIs as well as providing interoperable Web services to access the data. In addition, SOCAT has implemented a semiautomated data ingestion dashboard that allows the SOCAT data providers to submit data into the SOCAT QC system. Functionally, this means that scientists can work in their native data formats, and the ingestion system will manage the more technical tasks of creating standards-compliant files, associating the proper metadata with the files, providing submission to national data centers, and, finally, making the data available through high-level Web services. This automation of services has allowed SOCAT to evolve from a release every 4 years to annual releases. These annual releases serve to inform global products such as the Global Carbon Project's Annual Carbon Budget (<http://www.globalcarbonproject.org/carbonbudget/>). The automated system used by SOCAT demonstrates a method to efficiently manage the higher volumes of data expected with the future of new ocean observing efforts. The GLODAP (<https://www.glodap.info/>) product (Olsen et al., 2016) has evolved since its first release in 2004 (Key et al., 2004), with improved routines to retrieve data, for primary and secondary QC, and for archiving and viewing results from these processes. However, a large fraction of the work to produce the product is still manual, which places heavy demands on the community. The GLODAP community has begun to look at building SOCAT-like processes to handle future GLODAP releases in a more effective and efficient way.

managers regularly produce higher-level data products that include quality flags and suggested editing features to fully applied QC and regular geolocated gridded data. NASA, NOAA, EUMETSAT, ESA, and other agencies use self-describing file formats [e.g., NetCDF, Hierarchical Data Format (HDF)] and CF metadata conventions. This makes indexing the data easier for the data centers' databases and makes sure that the quality flags are easily paired with their science variable for mid-level products so users can QC the data for their specific research needs. It lends itself to producing higher-level products, usually gridded, for data assimilation into models.

Web services are APIs, typically hosted by the data center. The Physical Ocean Distributed Active Archive Center (PO.DAAC) provides Web services to search on datasets and granule/file metadata and data. From there, the user can discover what files/granules fit their need, either by parameter, region, or time range. The user can then retrieve the entire dataset or subset it. This allows well-informed users to easily access data with their code as well as having smaller specialized data centers supplementing their community with satellite data without the need to archive themselves. As the data follow widely adopted conventions, specialized data readers are not required for the user to analyze the data.

Derived and model data outputs rely on knowing the quality of the data before assimilation by proper metadata. This provides traceability of the data assimilation and easier ingestion because the linkages between data and any quality flags are provided.

Data Discovery for Non-EOVs

Full data interoperability is the appropriate goal for data types that already have agreed standards and processes for collecting, documenting, and QCing the data. However, new variables will be observed and new observing methods are continuously being developed. It will always take time for new observation types to be validated and replicated. There are also historical datasets that gain new perceived value, making them “worth” aggregating in a standardized format (Griffin, 2015). It is important to provide data discovery tools, allowing researchers and data managers to find those datasets not yet entrained in sophisticated data management systems. For those datasets, it may not be possible to achieve all of the FAIR principles, but at least three of them—findability, accessibility, and reusability—can be applied to almost all ocean data.

To date, these non-standardized datasets are principally housed in nation- and discipline-specific data centers, which publish discovery metadata through in-house catalogs and through metadata aggregators. In the past, a common approach has been to ensure that a single master copy of data is preserved, but the accompanying metadata records have been translated among differing standards and republished through aggregating metadata catalogs to increase the visibility of the dataset. Combined with a lack of persistent identifiers on records, this has resulted in a legacy of partially duplicated metadata records across multiple catalogs, with limited capacity to keep those duplicates updated. These partially duplicated records provide a considerable challenge to data discovery, and we are not aware of

any mature deduplication algorithms being applied in federated metadata discovery tools.

Increasingly, oceanographic metadata managers are investigating options to develop federated metadata search tools. Such tools will allow simultaneous searching of multiple metadata catalogs, thus considerably improving the findability and accessibility of non-standardized datasets while reducing opportunities for semi-duplicated metadata records to proliferate.

Federation of metadata search requires a brokering mechanism, which, in turn, requires well-understood crosswalks between the common metadata standards, vocabularies, and profiles in use by a community. This is done by having data that are in self-describing file formats (e.g., NetCDF or HDF) or well and regularly, easy-to-read file formats (e.g., ASCII). Following metadata standards is also a requirement as the brokering mechanisms can recognize the metadata and properly handle the data. The newly launched Google Dataset Search¹¹ (currently as early release while gathering requirements for future iterations) relies on well-formatted metadata and tags following the schema.org definitions, where they see discipline-specific requirements on search and discovery as the responsibility of the discipline to implement. Smaller, more tightly focused federations will pose fewer challenges in terms of brokering these differences and will, hence, likely result in stronger search algorithms. In contrast, global federations will trade off searching power for larger holdings and greater economies of scale in terms of tool development. It is likely that the next decade will see a proliferation of metadata federations as communities balance the relative costs and benefits of small and large federations.

Standards and Best Practices

To achieve optimal use of research data and methods, we recognize the need to follow common community standards and best practices for data systems outlined by recognized international bodies such as IODE and GOOS. Implementing these practices requires that well-defined workflows are followed and that a sustained infrastructure is in place where the chain from data delivery by observing systems, initial QC/QA and feedback from the data center to the primary data producers, integration in data products, and archiving in recognized data repositories are supported (Pearlman et al., 2019). Specialist support from data centers is a relatively small cost with potentially large positive gains in terms of timely data submission and quality. Careful metadata and quality flags are important attributes for ocean data, including information on the level of QC.

Best practices and standards for data management are increasingly being implemented by many observing networks and projects on national or continental scales. Successful cooperation among different operators is important for developing and promoting standards and best practices that facilitate the interoperability of systems.

Credit Through Publication: Data Citation, Persistent Identifiers, Etc.

Credit for developing new datasets, through attribution and citation, has several challenges as the supporting infrastructure needed for this is not fully developed. Journals increasingly require data that support an article to be in a FAIR-aligned repository that is open, uses persistent identifiers, and supports data citation (see the COPDESS Web site⁵).

We recognize that a significant fraction of the ocean data is collected “in research mode,” i.e., from project-based science with limited-term funding agreements; in science, output is largely measured in citable publications rather than in published datasets (Mons et al., 2011). It is imperative that scientists are incentivized to make their data publicly available. Options include using data citation tools, such as DOIs, that make it easier to credit the originating scientist and publishing data reports as peer-reviewed publications [e.g., Earth System Science Data (ESSD)]. Alternatively, a metadata record can contain fields identifying the data provider, giving recognition. To remedy this issue, the Coalition for Publishing Data in Earth and Space Sciences (COPDESS)¹² is working with the scientific data facilities and scholarly publishers “to help translate the aspirations of open, available, and useful data from policy into practice.”

Other efforts helping to automate data citations include a new task force by ORCID to work with repositories in capturing data creator ORCIDs and the necessary linking, and the MakeDataCount project¹³ defining consistent ways to count data usage and providing tools to repositories to consistently show these metrics.

Attribution and credit for data starts with the data repository and the registration of a persistent identifier associated with that data. Included in this metadata are the names and ORCIDs of the data creators. Through the registration process of the persistent identifier and services available through ORCID, a new dataset is made known in the research data infrastructure and linked with the repository and publication. For instance, publishers need to implement the full capability of the CrossRef Citation schema¹⁴ to include the portion about relationships. This identifies, in a machine-readable way, which citations are data and their association with research papers, which is particularly important for persistent identifiers that are not a DOI. Data facilities further need to capture the name of the data creator(s) along with their ORCID and provide that information when registering the persistent identifier for the dataset. This should also be provided to ORCID through the provided API that is created for repositories that have not implemented a globally unique persistent identifier. Similarly, researchers need to identify the best possible repository for their data, preferably one that is familiar with that type of data, providing curation services and is FAIR aligned.

Persistent Identifiers for Data and/or products (PID) is another important piece of metadata for traceability of processing (proper identification and versioning) on one side and traceability of use by end users and organizing feedback to

providers. Such PIDs can be attached to the platform such as a WMO number for Argo, drifters, meteorological moorings, ICES code for vessels, etc. DOIs can also be attached to a version of a dataset, e.g., DOI on data from a research cruise, on one glider mission, on versions of aggregated products like for SOCAT, GLODAP, or the Coriolis Ocean database for ReAnalysis (CORA), or on a periodic snapshot of a GDAC. Different strategies have been developed in the past 10 years, and the PID technology has evolved to be able to manage network data that evolve continuously.

As datasets are aggregated into data products, it is not yet obvious how to give appropriate credit to all of the originating scientists who generated the data, with potentially thousands of scientists contributing to a single research article. Work is needed to develop ways to efficiently and effectively give credit to all those who have contributed. Similarly, data centers that curated datasets integrated into data products need to be efficiently credited as contributors, perhaps by ensuring that the full lineage of a metadata record is maintained through all levels of aggregation and federation, maybe by exploring the blockchain concept in marine data lineage. Certification of repositories (e.g., CoreTrustSeal¹⁵) plays a key role; there is strong alignment between the tenets of FAIR and the elements of certifications to help researchers and publishers make an informed decision on determining which repositories meet criteria and are FAIR aligned. Recognizing that data to support research is valuable as stand-alone products enables the community to work with institutions to enhance promotion and tenure criteria to publish data and data products. The more we cite data from repositories that support data citation, the more we can link that data back to cruises and other research objects from the same research effort and show a more complete view and demonstrate value.

Additionally, unambiguous citation of the underlying data used in the climate assessment is becoming a requirement for transparency. An example of such a policy emerged in the United States under Barack Obama’s presidency with the open government initiative¹⁶ and open data policies on European Commission projects¹⁷.

Implementing FAIR

The *Enabling FAIR Data* project, which promotes mandatory exchanges across all journals to provide data creators the attribution and credit for the effort, building upon COPDESS through the commitment statement¹⁸ and author guidelines¹⁹, addresses this issue:

“Publication of scholarly articles in the Earth, Space, and Environmental science community is conditional upon the concurrent availability of the data underpinning the research finding, with only a few, standard, widely adopted exceptions, such as around privacy for human subjects or to protect heritage field samples. These data should, to the greatest extent possible, be

¹⁴<https://support.crossref.org/hc/en-us/sections/202832803-Crossref-schema>

shared, open, and stored in community-approved FAIR-aligned repositories. Leading repositories provide additional quality checks around domain data and data services and facilitate discovery and reuse of data and other research outputs.”

The recently started *ENVRI-FAIR* project aims to implement FAIR across the European research infrastructures, which include Argo, the European Multidisciplinary Seafloor and water column Observatory (EMSO), and the Integrated Carbon Observation System (ICOS). SeaDataNet is facilitating horizontal synergy between these research infrastructures (RIs) in the marine subdomain, but also toward RIs in the atmospheric, biological, and solid earth subdomains. The time of writing the project was at the stage of assessing FAIRness of the research infrastructures with a total project duration of 4 years.

DATA SERVICES OF THE FUTURE

Generating data that follow FAIR principles can be expensive upfront but generally pays big dividends in the long term. It is easier for the data producer to make data products according to their own needs, but that makes reuse much harder for other users. Those data products may not be formatted according to established standards, making it harder for users to read and access them. The quality of the data is not as obvious if it lacks quality flags or provenance information. This creates more work for the user as they try to understand the best way to read and use the data for their needs. When the data producer creates data that follow metadata standards and are well formatted, they facilitate access and use of the data. This implies some overhead as making the data products comply with standards is not a trivial task. It should, however, be noted that even if the workload for the data product producer is not trivial, we believe that it is a worthwhile endeavor when considering the amount of time that is saved for the users. Well-formatted data can almost act as their own service as there are many tools, software, and protocols that recognize NetCDF and HDF data that follow CF conventions, so less effort is needed by the user for finding, reading, and interpreting the data. Data that follow the FAIR principles also make it easier to attribute credit to the creators.

Information and Communication Technology (ICT) and VRE

One of the grand challenges of eScience is providing machine-readable data as the main substrate for knowledge discovery and to assure that these processes run smoothly and are sustainably.

At all levels of the value-adding chain (observation providers, products developer, and downstream services), we are facing an exponential increase in the volume of data acquired by different means of earth observing (*in situ* or satellites) or products made available to the community (*in situ*, satellite, and model outputs). Progress in the development of Internet and fast telecommunications services; big data capabilities, including machine learning and artificial intelligence; and standardized Web-services have and will continue to revolutionize the services available to users. VREs allowing users to remotely conduct processing not possible on desktop systems and to retrieve only the outputs (data/products) that are needed for

their applications are being facilitated through cloud systems. These are providing important storage space and computing facilities through high-performance computers and are under development in most regions.

The addition of cloud and VRE as mainstream tools introduces opportunities and challenges. As a community, we must now consider “cloud-to-cloud” interoperability. This will build on standards and methods already in place and evolving for service-to-service interoperability. We must now consider how to ensure that data and application code (e.g., model code) developed on different platforms can be effectively integrated (e.g., Zacharewicz et al., 2017; Chang and Reinsch, 2018). Interoperability between the different elements of the Earth data management system is becoming a necessity driven by research and operational user requirements, and this will continue to evolve as cloud and VREs become more prominent and numerous. While big data and cloud tools will change the way services to users evolve in coming years, they will require sustainability in their development and in the funding scheme by member states.

Web Services and Smart Sensors

The acceleration of data production, diversity, and RT availability will increasingly demand machine-based processing of data flows. Data processing will require that machines (algorithms) be provided with properly structured metadata and data to discover and have access to services for catalogs, observations, and alerts on the Web. These Web services should be provided *via* uniform and compatible encodings, using community-adopted standards. Availability of open standards, supported by open-source software developers, and the advent of smart sensors, e.g., equipped with standard metadata on-board their communication interface and capable of data preprocessing, will support the FAIR principles for real-time data. Examples of such standards are the OGC sensor Web enablement (SWE)²⁰ with the community-specific marine SWE profile²¹ or the use of services such as data streaming²². While still on the path to maturity and with limited uptake in the marine community, these technologies should soon enable the transition to real-time machine-based processing and production of data products.

SUMMARY AND RECOMMENDATIONS

We have pointed out some challenges to support sustained and efficient ocean data management and pointed to the FAIR principles to guide future directions, and have shown some examples where the FAIR principles have started to demonstrate added value. Here, we try so summarize some of the main recommendations moving forward for the next decade, without going into technical details.

To progress toward increasing FAIRness of ocean data, there is a need to introduce the why and how of FAIR data to early career scientists in marine science so that adoption of

²⁰<http://www.opengeospatial.org/ogc/markets-technologies/swe>

²¹<https://odip.github.io/MarineProfilesForSWE/>

²²<https://aws.amazon.com/streaming-data/>

these principles and this approach to data management becomes second nature and a natural part of doing ocean observations. We realize that future graduate students might not even go to sea but receive the data they need from autonomous platforms delivered through various integrated data services (Vance et al., 2019).

Hodson (2018) outline several recommendations to foster the FAIR principles in a recent EU report. For instance, they state that research facilities should be incentivized to follow FAIR principles by reviewing the FAIRness of data management processes. They also suggest that FAIR data practices should be included in the assessment of research contributions and career progression and that infrastructure and services that enable FAIR data must also be recognized and rewarded accordingly. A FAIR data policy is essential to enhance the accessibility of data, foster reuse of existing data, and turn observation data into information needed by end users. The FAIR principles should be embraced in assessing the technical readiness level for data and information. They should be an integral part of assessing requirements in the framework for ocean observing, and the principles should be backed up by appropriate investment in data and information management. Both pilot and mature systems should comply with the FAIR principles. Although there is great heterogeneity among oceanographic disciplines in terms of their progress toward the FAIR principles, considerable progress over the next decade can, and should, be made.

When data are not FAIR, access is limited to researchers in tight-knit networks. When data are FAIR, access is opened to people who are working outside their main discipline and outside the academy. The corollary of this is that there is an overhead in making data FAIR, which may be beyond the capacity of data creators working outside academia. It is therefore crucial that those organizations with the resources to develop data sharing tools do so in ways that are accessible to those outside their institutions.

Among the data lifetime models available, there are certain commonalities in the sense that they describe a series of steps in standardizing the handling of data from discovery to publication. These steps include (a) data acquisition, processing, and QA; (b) data description and representation; (c) data cataloging and dissemination; and (d) repository services and preservation (Crowston and Qin, 2011). Modern data management infrastructures are needed to support the ocean observing system so that all these activities along the data flow pipeline are more automated and fault tolerant. Progressively, the systems should advance toward interoperability; this serves both the routine data exchanges within and between the observation networks, as well as user-friendly tools for data/products discovery viewing and access.

It is worth considering that the large majority of oceanographic ocean observations are funded by public funds; there are almost always requirements from the funding agency to make the data public, realizing that the exact requirements and the level to which they are imposed vary greatly from country to country. Submitting ocean data to a repository do not automatically mean that the data follow the FAIR principle. An important aspect is the latency of the process and the level of FAIRness of the data portal to which the data have been

submitted. A FAIR data policy should be a priority for all marine datasets and should be supported by nations and stakeholders.

In chapter 2, we listed some challenges; here, we suggest actions to mitigate those.

Large Diversity

A high level of interoperability is required to harmonize these dispersed data systems to allow for easy access by users. Improving metadata services will be key at many steps in the data life cycle. For non-standardized datasets, better metadata search tools will be crucial. Leveraging the research infrastructures data systems to provide infrastructure for data of all EOVs at the same level of accessibility should be a priority. Data centers and scientific funding agencies should make international coordination an explicit part of data management staff's job description in order to achieve these outcomes.

Multitude of Disparate Data Management Structures

These existing systems need to be used as the 'building blocks' for an interoperable framework of data management systems. As an example on how this can work is the EMODnet effort in Europe, improving free, timely, and unrestricted access to interoperable European marine data, building on existing database, and open sharing infrastructures such as SeaDataNet, CMEMS, European Ocean Biogeographic Information System (EurOBIS), ICES, and EGDI (Shepherd, 2018). Similarly, open source data platform tools, such as ERDDAP, can reduce the burden of providing interoperable data services for users and improve data uptake by consumers.

Increased Volume of Data

As a consequence of increased data volume, it has become clear that it is beneficial to spread the data processing workload across many institutes and that harmonization of data processing and distribution is a priority. The data management systems must also be able to grow with the increasing volume of data expected in the future, leveraging on the IODE network of National Oceanographic Data Centres (NODCs), Associate Data Units (ADUs), online information sources, repositories, and learning objects. Based on robust FAIR data systems to deliver observation data and products, service development will drastically change in nature with the development of Big Data infrastructure and machine learning techniques that should foster reusability of existing observation and products exponentially.

New Sensors Creating New Formats

For all sensors, more complete metadata that are captured early in the data life cycle will improve the reusability of observations for many purposes. In communities that struggle to meet FAIR principles, leveraging existing tools can help those communities significantly increase their level of data interoperability with a minimum of resources. In addition, working more closely with sensor manufacturers to provide metadata directly from

the sensors in community-accepted standards and conventions will make it much easier to properly document data further downstream in the data life cycle.

Widely Used Formats Not Universally Applicable

IT solutions need to meet the needs of particular science communities while at the same time facilitating the universal interoperability we desire. Both open source tools and services with community governance and commercial solutions are potentially possible.

Gap Between Data-Producing Scientists and Downstream Users of the Data

Modern data management architecture and infrastructures are needed so that all activities along the data pipeline are understood and efficient and progressively advanced toward interoperability. This serves the routine data exchanges within and between the observation networks, as well as user-centered tools for finding, accessing, analyzing, and (re)using data/products. Community standards for metadata, data formats, communication protocols, and data server software infrastructure are the foundation for interoperability. A key component is close monitoring and QC of data streams with communication between the observing system operators and data managers. Data centers need to give high priority to the use of modern information and communication technologies.

Development of Common Protocols Takes Time

These efforts, along with best-practice elaboration, should be organized and properly funded to develop new standards and enhance existing ones to meet the needs of the community in a reasonable timeframe.

Best Practices Poorly Defined

There is a growing need to identify the most efficient and systematic strategy for processing data all the way from the initial planning of data collection to the availability of the data products and their dissemination, i.e., development of a data management plan that evolves throughout the life cycle of the data. Data management for large, dispersed datasets benefits significantly from a well-established and standardized approach starting even before the data are collected. The FAIRness of the data system will rely on continuously updated standards and best practices for metadata and data harmonization as well as QA/QC common procedures; such activity should be properly funded at national, continent, and international level. This also includes support, training, and outreach to the teams that will develop data systems for networks or thematic services. Data can be more easily found and utilized if they are properly managed, follow best practices, are described with exhaustive and structured meta information, and are assigned persistent identifiers. These goals can be achieved by following internationally agreed standards and protocols for file

formats, “content” (vocabularies/conventions), and “packaging” (metadata standards) and ensuring the data are preserved and curated in a sustained repository. Investing in the development and maintenance of freely available software utilities will pay dividends by assisting data producers in publishing data that meet community standards. Support for the implementation of standards and best practices by the research infrastructures is key to enhance interoperability and reusability of existing data and to avoid duplication of efforts.

Taking these steps will not only allow the scientist or developer to download the data and apply traditional data analysis techniques but will also enable the use of modern tools to transform, manipulate, visualize, and utilize the data in novel ways. These tools and platforms help ensure that true data interoperability is achieved, enabling interdisciplinary studies with a range of data from different domains. In addition, they promote reusability by making sure data can be understood by those who did not produce the data. These capacities are vital for international, interdisciplinary ocean observing systems.

AUTHOR CONTRIBUTIONS

TT, SP, JH, KO'B, and PB helped to conceive the study, coordinated the author contributions, wrote and edited the manuscript, and contributed to tables and figures. TdB, JB, EB, TC, KC, SD, AG, HG, VH, DK, JM, AN, BP, PP, AVdP, ER, DeS, AS, NS, DiS, TS, SS, MT, PT, ST, TV, MW, LW, and ZZ contributed to the manuscript ideas and text.

FUNDING

We thank the funding agencies and the data management projects that have made this work possible through dedicated funding for the data management activities and improvements. TT and JB acknowledge support from the EU Horizon 2020 project AtlantOS (grant agreement 633211). JM acknowledges support from the Integrated Oceanography and Multiple Uses of the Continental Shelf and the Adjacent Ocean Integrated Center of Oceanography (INCT-Mar COI, CNPq, Proc. 565062/2010-7). DS acknowledges support from the H2020 project SeaDataCloud (grant agreement 730960). SP acknowledges support from the EU Horizon 2020 project ENVRIplus (grant agreement 654182). AN acknowledges support from the EMODnet Physics (grant number EASME/EMFF/2016/1.3.1.2-Lot3/SI2.749411). HG acknowledges funding from the EU H2020 Ocean Data Interoperability Platform (ODIP) project (Grant No: 654310). JH acknowledges that funding came from the National Aeronautics and Space Agency as managed by the California Institute of Technology under task number 80NM0018F0848. AVdP acknowledges support from Belpo in the framework the EU Lifewatch ERIC (grant agreement FR/36/AN3). KO'B acknowledges that his publication is partially funded by the Joint Institute for the Study of the Atmosphere and Ocean (JISAO) under NOAA Cooperative Agreement NA15OAR4320063, Contribution No. 2018-0175.

Climate change and variability are major societal challenges, and the ocean is an integral part of this complex and variable system. Key to the understanding of the ocean's role in the Earth's climate system is the study of ocean and sea-ice physical processes, including its interactions with the atmosphere, cryosphere, land, and biosphere. These processes include those linked to ocean circulation; the storage and redistribution of heat, carbon, salt and other water properties; and air-sea exchanges of heat, momentum, freshwater, carbon, and other gasses. Measurements of ocean physics variables are fundamental to reliable earth prediction systems for a range of applications and users. In addition, knowledge of the physical environment is fundamental to growing understanding of the ocean's biogeochemistry and biological/ecosystem variability and function. Through the progress from OceanObs'99 to OceanObs'09, the ocean observing system has evolved from a platform centric perspective to an integrated observing system. The challenge now is for the observing system to evolve to respond to an increasingly diverse end user group. The Ocean Observations Physics and Climate panel (OOPC), formed in 1995, has undertaken many activities that led to observing system-related agreements. Here, OOPC will explore the opportunities and challenges for the development of a fit-for-purpose, sustained and prioritized ocean observing system, focusing on physical variables that maximize support for fundamental research, climate monitoring, forecasting on different timescales, and society. OOPC recommendations are guided by the Framework for Ocean Observing which emphasizes identifying user requirements by considering time and space scales

of the Essential Ocean Variables. This approach provides a framework for reviewing the adequacy of the observing system, looking for synergies in delivering an integrated observing system for a range of applications and focusing innovation in areas where existing technologies do not meet these requirements.

Keywords: observing system evaluation, observing system design, sustained observations, observing networks, observation platforms, climate, weather, operational services

SOCIETAL REQUIREMENTS FOR OCEAN OBSERVATIONS

That the ocean plays a central role in the Earth system is well known. Planetary scale transport of heat, freshwater and carbon by the ocean rivals that of the atmosphere, and the ocean's storage capacity for these quantities leads to slow modes of propagation that extend the predictability of climate conditions and have enabled the development of practical climate forecasting systems on seasonal to decadal time scales (e.g., Smith et al., 2012; Doblas-Reyes et al., 2013; Kirtman et al., 2013; Meehl et al., 2014). Much of the information that underpins these prediction systems comes from globally coordinated ocean basin scale observing systems.

For example, impacts of a predicted weakening of the Atlantic Meridional Overturning Circulation (AMOC) (e.g., Caesar et al., 2018) may already be evident in changing patterns of summer atmospheric circulation and heat waves in Europe (Duchez et al., 2016; Frajka-Williams et al., 2017) and in accelerating rates of sea level rise on the U.S. East Coast (e.g., Yin et al., 2009; Caesar et al., 2018). In the South Atlantic Ocean, numerical models have shown that low-frequency AMOC variations may influence decadal variability of global atmospheric circulation patterns (e.g., Lopez et al., 2016). The tropical Pacific's El Niño-Southern Oscillation (ENSO) dramatically affects global climate including regional temperature, precipitation, severe weather, marine and terrestrial ecosystems, fisheries and human activities (Timmermann et al., 2018; Smith et al., 2019). In Australia the severe droughts of 1982, 1994, 2002, and 2006

were all associated with ENSO, while in South America reduced precipitation is observed in north/north-eastern South America and enhanced precipitation is found in south-eastern South America during ENSO events, with the opposite during La Niña events (Tedeschi et al., 2016).

At the coasts, rising sea level is increasing the probability that storm surge, or even the regular cycle of the tides, will produce sea level extremes that damage property and infrastructure, and present an immediate risk to human safety. This may be exacerbated by damage wrought by more frequent tropical storms of increasing duration and severity (Webster et al., 2005; Vecchi and Soden, 2007; IPCC, 2014). Coastal areas are densely populated, with about 27% of the global population living along the coastal fringes as of 2010 (Kummu et al., 2016). Many of these communities depend on the ocean for subsistence, livelihood, and general well-being through food provision, tourism, recreation, transportation services, water supply, and energy. In addition, for communities living by the sea, the ocean is also frequently a key aspect of their cultural identity (e.g., Marzeion and Levermann, 2014).

Ocean temperature extremes, commonly referred to as marine heatwaves (Hobday et al., 2018), impact marine habitats and ecosystems through thermal stress. There is a risk of increased frequency of marine heatwaves, which imperil coral reefs due to increased bleaching events. The marine heatwaves off Australia in 2016 has been linked to coral bleaching in the Great Barrier Reef (Hughes et al., 2018). In addition to natural variability and human-induced climate trends, ocean ecosystems are also vulnerable to direct anthropogenic forcing from overfishing, pollutant contamination, pathogens, coastal development, and maritime operations related to resource use and tourism.

In climate prediction (seasonal to decadal) and projection (centennial), demonstrating the veracity of coupled climate models with respect to future climate conditions relies on the ability to show meaningful skill in reproducing past climate variability by comparison to long observational time series. Seasonal and decadal prediction systems will rely principally on accurately forecasting the slow ocean modes and their role in modulating the fast atmosphere (Kirtman et al., 2013). In order to predict climate, models (coupled or ocean only) must be initialized with the ocean observations. Timely and sustained ocean observations, both satellite and *in situ*, will be crucial for the development of skillful climate predictions that meet societal expectations and needs (Smith et al., 2012).

The decades of oceanographic observation by research vessels, ships of opportunity, research and operational satellites, and experimental platforms and sensors, have contributed immeasurably to our knowledge of the ocean and our ability

to respond usefully to calls for information regarding the important societal needs noted above. The ocean observing system remained relatively sparse and regionally-focused until the 1990s (Gould et al., 2013). These human pressures also need to be observed and monitored if their influence is to be placed in proper context compared to change driven by climate variability and change. In the decade since OceanObs'09, the use of autonomous *in situ* platforms has revolutionized the ocean observing system. Yet despite these successes, it remains that many of these data sets are brief relative to the time scales of natural variability (e.g., Jones et al., 2016) and trends or long-term cycles. Nevertheless, the data that the present observing system has delivered have been crucial in developing our understanding of the oceanic state, change and their underlying processes and their relation to observed climate variability to the extent that we can offer actionable guidance to users and stewards of the ocean environment. Sustained full-depth monitoring of ocean physical and biogeochemical parameters is required to deliver this information in order to determine our human influence upon the observed changes in the ocean.

It is anticipated that further technological advances in platforms and physical and biogeochemical sensors will continue to improve our ability to observe the ocean. Ensuring that the suite of ocean observations is adequate for the many uses to which they are put, and truly global in scope, demands a coordinated approach to using vessels, the deployment of instruments in the ocean, and satellite remote sensing in a manner that is complementary to their respective capabilities and meets agreed requirements for data quality, sampling frequency and geographic coverage. There are still many gaps and the observing system requires expansion into many regions that are poorly sampled or have simply never been visited (e.g., some shelf areas, marginal seas, sea ice covered oceans and the deep ocean below 2000 m) to further improve assessments of the status of the global climate (e.g., von Schuckmann et al., 2016; Johnson et al., 2018).

Even for fundamental physical observations such as temperature and sea level, these requirements are difficult to quantify because of the diversity of potential users and observing technologies, and inevitable practical limitations on resources. As new observing technologies arise and analysis methods advance, the requirements for sustained observing should adapt and evolve if the system is to remain efficient and effective. Given the preponderance of pressing societal needs related to food supply, water quality and environmental health, coupled with emerging capabilities for observing the ocean's chemistry and key biological variables for ecosystems, it is becoming increasingly important to move beyond ocean physical variables to develop coordinated multidisciplinary observing technologies and systems to monitor and assess the status of marine ecosystems under different stressors. To date, this is only possible for a restricted number of variables and limited to regional scales (Miloslavich et al., 2018).

Given the increasing complex mix of observing platforms and sensor technologies, and the ever expanding users and their differing and sometimes divergent requirements, the Ocean Observations Physics and Climate panel (OOPC) faces new

challenges. These challenges included the expanded role of OOPC to provide science-based recommendations for a fit-for-purpose, sustained and prioritized ocean observing system, that maximizes support for fundamental research, climate monitoring, forecasting on different timescales, and society. In this paper we take stock of progress to date; OOPC achievements and anticipated future challenges and opportunities to develop an integrated and consistent ocean observing for the future.

OCEAN OBSERVATION COORDINATION EFFORTS

The history of OOPC is linked to major milestones in the development of the sustained ocean observing system. The predecessor to the OOPC was the Ocean Observing System Development Panel (OOSDP), convened in 1990 under the Committee on Climate Change and the Ocean (CCCO) of the Scientific Committee on Oceanic Research-Intergovernmental Oceanographic Commission (SCOR-IOC) and the International Council for Science-World Meteorological Organization (ICSU-WMO) Joint Scientific Council (JSC). Building upon the successful internationally coordinated World Climate Research Programme (WCRP)'s World Ocean Circulation Experiment (WOCE), and also motivated by the Tropical Oceans Global Atmosphere (TOGA) Experiment, OOSDP was established and charged with the design of an ocean observing system for climate.

While WOCE and TOGA advanced understanding of the ocean and ocean-atmosphere dynamics and the accuracies needed in the observing system, they also promoted mechanisms for the development of internationally coordinated global-scale ocean observations including standardized quality control procedures and open and timely data sharing protocols (Siedler et al., 2001). Building on this legacy, OOSDP met for 5 years and produced a series of in-depth background reports addressing the challenges and capabilities of different elements of the ocean climate system and of the role of models in a global ocean observing effort. The work of the OOSDP culminated in a realistic but aspirational plan for ocean observations, which was assessed on the basis of feasibility versus impact, a central theme of the Framework for Ocean Observing today. The OOSDP, as the name indicates, provided the required systems development plans and gave the foundation and terms of reference of a continuing ocean observations panel.

The OOPC met for the first time in 1996, as a panel of the Global Climate Observing System (GCOS), the Global Ocean Observing System (GOOS) and WCRP. OOPC took on the mantle from OOSDP to coordinate the respective capabilities of various observing approaches (National Research Council, 1997). Given the history of its development, the focus of OOPC within GOOS was the open ocean; other panels and groups were given charge of the enclosed and shelf seas and near-shore coastal seas. The initial tasks undertaken by OOPC were a number of reviews including: the global sea level observing system given the capability of satellite altimetry, and a review of the Ship-of-Opportunity Programme (SOOP) expendable BathyThermograph (XBT) program given plans

for the International Argo program. These reviews were thus prompted by the advent of new technologies and observing capability. The panel was also involved in forming the Global Ocean Data Assimilation Experiment (GODAE; succeeded by GODAE OceanView), which placed new demands on the ocean observing system.

The panel's early work culminated in the OceanObs'99 conference, which cemented the foundations of what we know now as the sustained ocean observing system for climate. From OceanObs'99 there emerged a consensus within the ocean observing communities to undertake an internationally coordinated sustained global ocean observing effort for ocean physical and carbon variables with respect to climate applications, the details of which were subsequently agreed and presented in the first GCOS Implementation Plan.

During the 2000s OOPC, with other partners, supported the establishment of a number of sustained observing networks building on the OceanObs'99 recommendations. These included the establishment of the OceanSITES moored time-series initiative in 1999, and development of the International Argo array of profiling floats in 2000. OOPC's involvement was critical to brokering data agreements and incorporating these new networks into existing programs such as SOOP and the global XBT network, and connecting to the expanding satellite missions (e.g., Sea Surface Temperature and Ocean Altimetry). In addition, OOPC co-sponsored a workshop on the Indian Ocean held in Perth, Australia, that led ultimately to the creation of a regional alliance to support GOOS in the Indian Ocean (IOGOOS). In 2001, OOPC conducted a review of the Tropical Moored Buoy Array. During this period OOPC established close and strong collaborations with WCRP including their Climate and Ocean: Variability, Predictability and Change (CLIVAR) project and other panels, ensuring both the development of a sustained ocean observing system and providing input to regional and basin process-studies. Building on the OOPC input to the establishment of GODAE, in 2002 OOPC's indirect sponsorship was vital to bringing climate-change consideration into the plan for the development of what is now the Group for High Resolution Sea Surface Temperature (GHRSSST) project.

The consolidation of the OOPC activities and oversight of the ocean observing networks and sensor development culminated in the OceanObs'09 [OOPC co-led with CLIVAR and the Integrated Marine Biosphere Research (IMBeR)] conference. OceanObs'09 recognized the utility of ocean observations beyond climate and the need to expand beyond physical variables to include biogeochemical and ecosystem variables within the ocean observing system. To this end there was strong engagement with the various ocean communities involved in ocean observations and end users. Leading up to OceanObs'09, OOPC in collaboration with the International Ocean Carbon Coordination Project (IOCCP) and CLIVAR developed a strategy for a sustained global repeat hydrography program as a contribution to the OceanObs'09 Conference (Hood et al., 2010). Arising from this strategy, in 2009 the Global Ocean Ship-based Hydrographic Program (GO-SHIP) was established as a component of GOOS. A further outcome of the conference

was the development of the Framework for Ocean Observing (FOO) (Lindstrom et al., 2012; Tanhua et al., 2019). The FOO provides guidelines for evolving the observing system in the service of a broad range of applications and users. To support expansion of the ocean observing system, GOOS expanded to include three disciplinary panels; OOPC became the physics and climate panel, IOCCP provides oversight of ocean biogeochemistry, and a new biology and ecosystems Panel (BioEco) was formed. OOPC retains, importantly, the dual roles as the ocean panel of GCOS and physics panel of GOOS. Delivery to GCOS requires OOPC to work across all components of GOOS.

OOPC has the demanding role of coordinating ocean input to GCOS and interacting with its sibling Terrestrial (TOPC) and Atmosphere (AOPC) GCOS panels, while also working with the other panels of GOOS. OOPC is the steward of the ocean Essential Climate Variables (ECV) of GCOS and the physical Essential Ocean Variables (EOVs) of GOOS, and hence must consider the requirements for observations across multiple time and space scales to meet users requirements from marine weather to climate, including both real-time and delayed mode data, while being mindful of complementing biogeochemistry and ecosystem observing at all scales. Since the OceanObs'09 Conference, GOOS has developed and articulated the need for ocean observation around application areas which cut across the disciplinary panels: climate, operational services, and ocean health. OOPC leads on delivery to Climate and Operational Services, and supports Ocean Health through articulating requirements for underpinning physical information. OOPC is also a panel of the WCRP, and provides scientific guidance and evaluation to observing networks through the Joint WMO IOC Technical Commission on Oceanography and Marine Meteorology (JCOMM) Observation Coordination Group.

These many responsibilities to GCOS, GOOS, WCRP, and JCOMM, spanning a broad spectrum of scales and including multiple disciplines, are demanding roles. Fundamental to delivering on these responsibilities, OOPC's, in conjunction with other programs, is undertaking regular assessments of elements of the observing system in order to provide objective guidance on the continued evolution of the system that will meet current and future user requirements.

We argue that the role of OOPC in the assessment and evolution of the observing system is becoming increasingly important given the expansion of ocean observing technologies, increased user dependency for sustained and timely ocean observations and expanding user groups. Given this, questions OOPC needs to consider are:

- How do we evolve the observing system to meet a broader range of applications, ranging from extreme events (e.g., cyclones, storms, marine heat waves, and coastal inundation forecasting) to climate monitoring and supporting ecosystem services?
- How do we maintain the interest and momentum for sustaining observations, when much of the funding is on short term cycles?

- What actions do we need to take to keep exercising the system through reviews; engaging users, innovation, broadening participation?
- How do we continually evaluate and innovate the observing system to ensure it performs as an integrated system?

DEFINING REQUIREMENTS FOR SUSTAINED OBSERVATIONS – THE ESSENTIAL OCEAN VARIABLES

The challenge of measuring the ocean to meet the range of application needs discussed in section Societal Requirements for Ocean Observations may seem insurmountable. The Essential Ocean Variables are a tool to describe and communicate the “essential” requirements for sustained ocean observations and enable for evolution of the observing system with time. Essential Ocean Variables were inspired by the success of the Essential Climate Variables concept for articulating the critical variables that must be observed to meet user requirements (Bojinski et al., 2014).

The Framework

The Framework for Ocean Observing (Lindstrom et al., 2012) identifies lessons learned from the successes of previous and existing ocean observing efforts and provides an internationally-accepted common language and guidance for expanded collaboration in sustained ocean observations. It is focused on:

- Delivering a system based on common requirements, coordinated ocean observing elements, and common data and information streams;
- Essential Ocean Variables (EOVs), a common focus for requirements defined based on feasibility and impact on societal and scientific drivers; and evaluation of readiness levels of sensors, platforms and data management procedures.

EOVs are identified by the GOOS Expert Panels, based on the following criteria:

Relevance: The variable is effective in addressing the overall GOOS Themes – Climate, Operational Ocean Services, and Ocean Health.

Feasibility: Observing or deriving the variable on a global scale is technically feasible using proven, scientifically understood methods.

Cost effectiveness: Generating and archiving data of the variable is affordable, mainly relying on coordinated observing systems using proven technology, taking advantage where possible of historical datasets.

When EOVs are identified, a series of recommendations are created and disseminated by the Expert Panels, including what measurements are to be made, various observing options, and data management practices. The adoption of EOVs is not intended to replace existing ocean observing networks and international coordination groups, but to provide a

mechanism to bring them together to develop a holistic ocean observing system and strengthen the ocean observing communities ability to grow and best meet current and future user requirements.

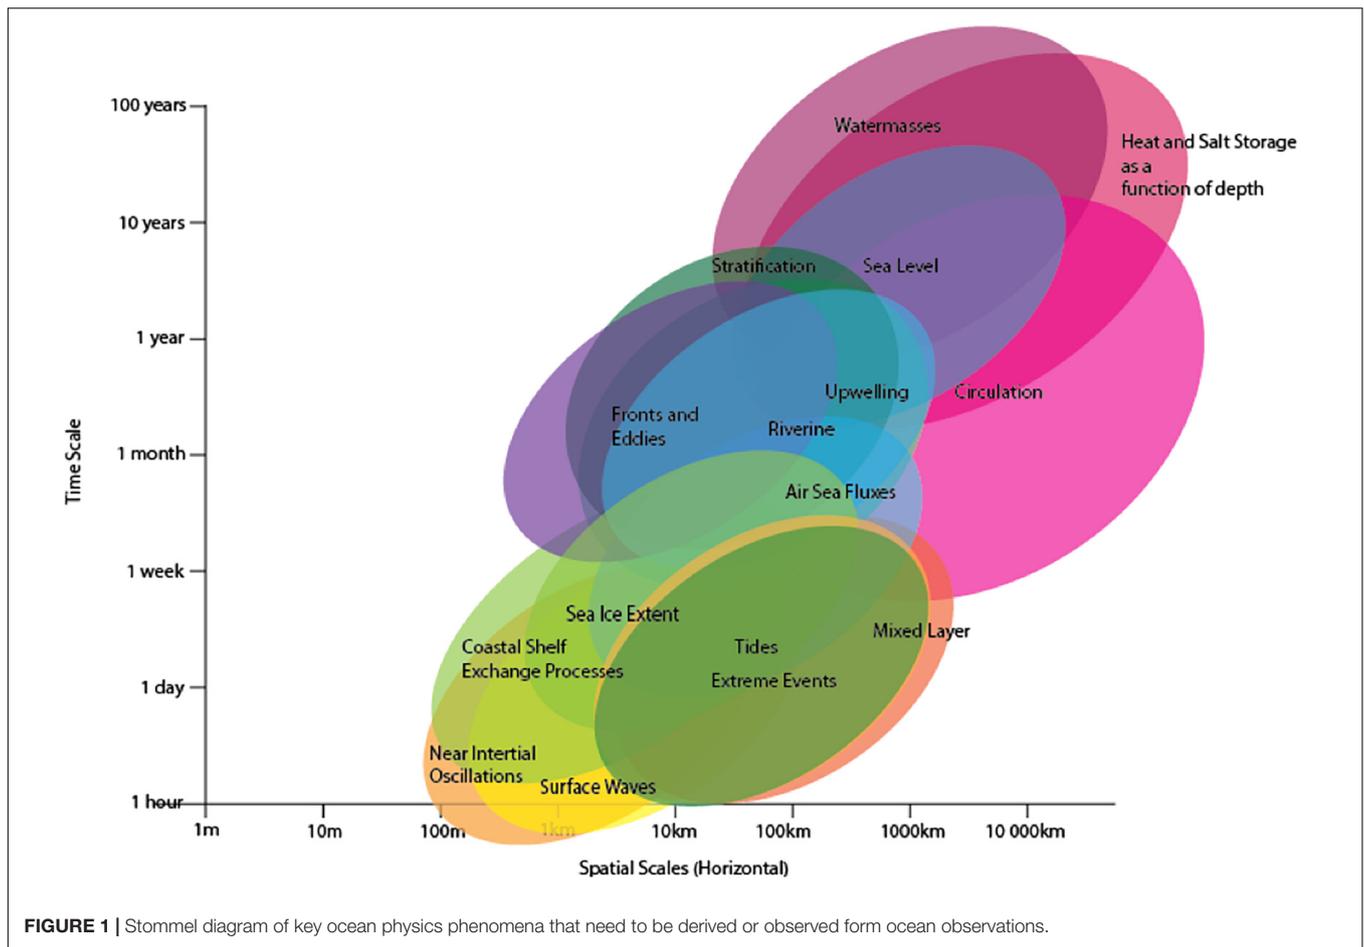

Key Ocean Phenomenon

To help with the identification of scales (spatial and temporal, global, regional) and parameter spaces for a certain observing objective, OOPC has determined key or overarching ocean physical phenomena that the observing system should be able to resolve. In identifying these phenomena OOPC, considered the GOOS definition of a phenomenon as an observed process, event, or property, with characteristic spatial and timescales, measured or derived from one or a combination of EOVs, and needed to answer at least one of the scientific questions asked in order to address relevant societal need.

The list of phenomena, needed to be captured by EOVs, defined by OOPC (OOPC-19 Report) are:

- Heat storage;
- Salt storage;
- Water mass (i.e., Water properties and characteristics);
- Ocean Circulation;
- Sea level;
- Fronts and eddies;
- Stratification;
- Mixed layer;
- Sea ice;
- Air-sea fluxes;
- Upwelling;
- Coastal processes (encompassing a wide range of dynamics including, but not limited to, shelf-open ocean exchange of momentum, heat and salt);
- Tides;
- Riverine input;
- Surface waves;
- Near inertial oscillations;
- Extreme events (i.e., marine heatwaves, tsunamis, cyclones, storms).

Measurements of these key phenomena occupy a large spatial and temporal domain to meet the requirement of users (**Figure 1**). The phenomena span a spatial scale of 100's of meters to 1000's of kilometers and timescales of hours to centuries. These phenomena have different spatial and temporal measurement requirements from large basin-scale at annual resolution to coastal and weekly resolution. A diverse range of observing platforms are required to deliver this information including satellites, research and volunteer vessels, moorings, and surface and subsurface floats, and gliders. In addition, it is anticipated that as technologies (platform and sensors) advance, improved ocean observing techniques will be employed and these coupled with advances in telecommunications, will fill current gaps in the observing system and lead to improved impact of the observing system relative to investment (Sloyan et al., 2017).

Essential Ocean Variables (EOVs)

The set of key physical phenomena and processes are determined/estimated from observable ocean variables. OOPC, in conjunction with the GOOS Biogeochemistry and Biology and Ecosystem panels, motivated by the GCOS work on Essential Climate Variables (ECVs) and the strategic plan for integrated ocean observing “Framework for Ocean Observing” (FOO), have developed lists of Essential Ocean Variables (Table 1). The EOVs are judged to be the priority variables required to determine these key physical phenomena and meet most of the needs of the diverse user community. The EOVs also reflect the technical readiness to collect the observation. The selection of EOVs is based on key variables that are found to be required to describe the ocean state. They are also relevant in the context of UN Sustainable Development Goals, notably 13. Climate Action, 14. Life Below Water and 15. Life on Land. In general there are a number of observational platforms or methods used to measure an EOv. These platforms or methods may vary in their readiness level from concept to mature.

GOOS provides detailed information for each EOv including the spatial and temporal sampling requirements, identification of the key ocean processes and phenomena that require measurements of the variable, and characteristics of the observing platforms or programs that measure the variable

(see www.gooscean.org for more information). The detailed EOv specification sheets demonstrate the interdependencies amongst EOVs and unique characteristics of observing platforms and programs to deliver the observations of the key ocean phenomena or process required by the diverse users of the ocean observing system. The selection of EOVs is based on their need to support improved scientific understanding and also societal needs; at the same time the mature status reflects technical readiness and feasibility of the observing methods. The importance of connecting the major drivers and themes with the societal benefits informed by scientific issues and applications, is moreover ensuring consistent identification of the EOVs and their corresponding observing element. In turn, strengths and deficiencies, synergies and interdependencies can be objectively tracked and evaluated.

The OOPC panel (and likewise the other GOOS panels) shall moderate such communication by informing the observing community. In that context, the panels have created EOVs specification documents that provide guidance on input variables, their definitions, observing platforms that sample the variables, information on accuracy, and examples for utilization of the data in the ocean observing value chain.

New scientific challenges may arise, as may societal needs. Observing technology will also evolve and improve. Thus, the

EOVs specification sheets and EOVs will change with time to reflect need and readiness. At the same time, inclusion of the metric of readiness in the selection of mature EOVs, makes it clear that development of scientific understanding requires more progress in observation technology. For example, challenges of quantifying the large-scale heat budget of the Earth have been highlighted through the international WCRP/CLIVAR research focus “CONCEP-THEAT” (von Schuckmann et al., 2015). Quantifying the heat budget requires, for example, observation of the exchange of heat between the atmosphere and ocean at the sea surface. Ocean surface heat flux is also critically important for understanding and predicting climate variations on time scales of days to decades. The need for this observation was brought to the attention of the OOPC, and recently added ocean surface heat flux as an EOV. Ocean surface heat flux is one of the most complex EOV as it comprises both radiative and turbulent components. While ocean surface heat flux is considered an ocean ECV/EOV, its radiative components are considered atmospheric ECVs, with networks that extend over both land and ocean. Likewise, for many applications, the turbulent latent and sensible heat fluxes are estimated using a bulk algorithm applied to state variables, some or which are atmospheric ECVs, while others are oceanic ECVs. Ocean surface heat flux thus requires close coordination between all GCOS panels; Ocean, Atmosphere and Terrestrial. OOPC has thus initiated an ocean surface heat flux expert panel, with members from other GCOS panels, that will work to assess and improve capability and readiness. As one of the first activities of this group, Cronin et al. (2019) developed a strategy document for making breakthrough improvements to the gridded ocean surface heat fluxes. The ambitious strategy involves optimizing satellite-based observations for boundary layer measurement of humidity and air temperature, sea surface temperature and wind stress; and expansion of the *in situ* flux network. OOPC will continue to be active in evaluating this strategy and its roadmap.

CONCEPT-HEAT was also involved in highlighting the importance of observing the deep ocean. As they developed the Deep Ocean Observing Strategy under GOOS, they felt that additional observables should be considered as EOVs. To follow this up, three physical quantities were put forward to the OOPC by Deep Ocean Observing Strategy (DOOS) for consideration: notably bottom pressure, ocean mixing, and flux through the seafloor. OOPC assessed the requirements for each as well as the technical readiness and feasibility for observing on a global basis. As a result DOOS was encouraged to complete the documentation to advance bottom pressure as a potential EOV; ocean mixing and seafloor fluxes were judged to not yet be ready for identification as EOVs.

The expert panels for GOOS biogeochemistry (IOCCP) and biology/ecosystem (GOOS BioEco) follow a similar strategy to OOPC in providing structural elements as EOV and phenomena and estimating the relevant time/space and parameter space that is linked to a specific application. Ocean physics and its interaction with the marine ecosystem also plays a major role in understanding and predicting marine biology and biogeochemistry and in probably almost all of the ocean observing design for marine biology

and biogeochemistry the physical processes (transport, thermodynamics) have to be considered as well. In other words, an apparently monodisciplinary experiment in marine biology or biogeochemistry is typical a multidisciplinary one involving ocean physics (and the associated sampling). Hence as we move toward an increasingly multidisciplinary observing system new challenges in a fully integrated system will need to be identified and eventually solved.

The EOV (and ECV) process very much focuses on observational quantities, meaning the sensor data and its combination with other variables. However, for the observing system and in particular for providing guidance on the individual observing networks it is mandatory to introduce a mechanism to trace each data point from the sensor mounted on an observing platform to a certain product that has been generated by the downstream services (e.g., a sea surface temperature map). Such an start-to-end evaluation is required if the complete value of the observations or observing system is required. This “value” assessment is further complicated by the interdependencies that exist in the observing system (e.g., GO-SHIP provides the highest quality observations of a suite of EOVs used by autonomous platforms for calibration). Thus assessment and attribution of value of the observing system is not a simple task.

As a common language for multi-platform global observing for the diverse user community, EOVs are fundamental to the implementation of FOO. In response to the advances in research and observing technology, OOPC will continually update specification sheets for each EOV and consider the addition of new EOVs. Moreover, increasing participation of private sectors in the ocean observing systems suggests the need to set target uncertainties for each EOV (Weller et al., 2019). The challenge that OOPC faces in keeping the EOV specifications relevant is formidable. EOV sampling requirements must acknowledge applications that span real-time weather and climate and maritime operations, fundamental ocean dynamical understanding to global climate, as well as requirements in support of ocean health applications. These are informed through strong liaison between GOOS, GCOS and JCOMM, and by the scientific and technical expertise and experience of the membership of the GOOS panels and steering committee.

DATA INTEGRATION, DERIVED PRODUCTIONS AND INFORMATION DELIVERY

Effective data management demands group collaboration across activities that include observation collection, metadata reporting and data assembly using community accepted standards, quality assurance and control (QA/QC), data publication that enables interoperable discovery and free, open access (both interactively and via machine to machine through standard protocols), and archiving that guarantees long-term preservation. Some sustained ocean observing networks are quite successful in accomplishing these data management functions, while others that are less centrally coordinated or are supported largely by research projects with short-term funding are challenged to

TABLE 1 | GOOS essential ocean variables.

Physics	Biogeochemistry	Biology and ecosystems
Sea state	Oxygen	Phytoplankton biomass and diversity
Ocean surface stress	Nutrients	Zooplankton biomass and diversity
Sea ice	Inorganic carbon	Fish abundance and distribution
Sea surface height	Transient tracers	Marine turtles, birds, mammals abundance and distribution
Sea surface temperature	Suspended particles	Live coral
Subsurface temperature	Nitrous oxide	Seagrass cover
Surface currents	Stable carbon isotopes	Macroalgal canopy
Subsurface currents	Dissolved organic carbon	Mangrove cover
Sea surface salinity	Ocean color	Microbe biomass and diversity (*emerging)
Subsurface salinity		Benthic Invertebrate Biomass and Diversity. (*emerging).
Ocean surface heat flux		

OOPC is responsible for physics variables.

operate consistently. They may employ varying data policies and submission requirements, and may lack the resources to engage experienced staff to review and QA/QC data flowing from disparate providers or to offer cyberinfrastructure services that achieve the level of service to match more mature networks. Recent publication discuss many aspects of data management (e.g., Moltmann et al., 2019; Pinardi et al., 2019; Snowden et al., 2019); here we address the need for EOVs data collections.

Where EOV data are handled by a multitude of disparate data management infrastructures this imposes problems for the global observing system. These include, but are not limited to, delayed and duplicate data receipts, versioning issues, missing data and metadata, and undocumented data processing procedures, and data recovery. If data quality and supporting metadata are to carry over from observers to products then modern data management infrastructures are essential at every step along the data flow pipeline, from data recovery, collection through assembly and to preservation. The more automated and fault tolerant these steps are, the more they embrace community standard practices and the more efficiently and swiftly will systems advance toward the levels of reliability and interoperability that user communities seek. The Committee on Earth Observations Satellites (COES) and the International Quality controlled Ocean Database (IQuOD) are examples of groups that are focused on providing the community with high quality data that has a consistent and unified quality control standard applied. OOPC needs to support and promote these activities and products, respectively.

Interoperability serves both routine data flow within and amongst the networks, and user discovery and access. Community standards for metadata, data formats, communication protocols, and data server software infrastructure are the foundation for interoperability. These are not new considerations for the ocean data management community. The technical aspects have been demonstrated and successfully deployed in many regions and specific parts of the global networks. Expanding on these successes is important, and is being guided by various ocean observing

programs led by individual national efforts, regional and international groupings, as well as by coordinating organizations independently and jointly in the WMO and IOC. The time is right to improve interoperability across the observing system networks and enable sustainable process that can create integrated datasets for the EOVs.

A data collection for EOVs must ensure the following:

- Data are quality assured and controlled according to agreed international standards;
- Feedback is given to the data sources as needed;
- Duplicates are identified and resolved;
- Metadata are complete and meet agreed best practices and existing standards;
- Data and metadata are discoverable and accessible through interoperable services;
- Data requests and searches from users can be reproduced;
- Data and metadata are electronically published with protocols for citation and acknowledgment;
- The complete provenance and lifecycle of data processing is traceable for each ECV/EOV dataset.

In addition to cataloging and preserving data and enabling effective delivery to users, these practices help ensure that observing programs/platforms and organizations get credit for data they make available and that users and reviewers can repeat precise requests for data referenced in scientific publications for the purposes of reproducing, verifying or expanding upon and enhancing prior work.

By providing interoperable access, and adhering to standards and conventions, this framework makes data synthesis efforts more efficient than with the less-integrated data management systems that exist in many quarters. It is such data synthesis efforts, founded on quality assured observational products, that deliver integrated assessments of regional and global ocean climate change and variability.

We note that the periodical re-calculation of integrated gridded climatologies or model-data ocean and coupled atmosphere-ocean reanalysis products, such as is performed to inform State of the Ocean reports (e.g., von Schuckmann et al., 2018) and the IPCC process, are greatly facilitated by the existence of a stable, robust and interoperable data management and delivery system. Every effort should be made to sustain and enhance this data stream following the guiding principles, and for the reasons, noted above.

PERIODIC REVIEWS OF THE OBSERVING SYSTEM

From OOPC's perspective, a virtue of the EOVS concept is that it helps guide global coordination of the ocean observing system through articulating requirements in a platform/sensor agnostic way. The EOVS specification sheets emphasize requirements for accuracy, sampling resolution and frequency, and the timeliness of data delivery, without immediately calling out how these requirements might be met in terms of existing sensor types or scope of deployments. The actual deployments will always be the domain of the various expert observing networks (both *in situ* and satellite) and the national and international agencies that fund them. OOPC should advocate for national investment in the observing platforms.

Increasing use of the ocean observing system has driven OOPC to lead, support or provide substantive input to a number of systems-based-reviews of the observing system, some of which are developing into finite-lifetime development projects:

- 2011: The Deep Ocean Observing Strategy (DOOS) (Levin et al., 2019);
- 2014: The Tropical Pacific Observing System (TPOS) 2020 project (Smith et al., 2019);
- 2019: Ocean heat and freshwater review (Palmer et al., 2019);
- 2019: Air-Sea fluxes with focus on heat and momentum (Cronin et al., 2019);
- 2019: Boundary Currents (Todd et al., 2019);
- 2019: AtlantOS and the Atlantic blueprint (deYoung et al., 2019).

OOPC has also advised on two reviews led by the CLIVAR expert panels:

- 2019: Indian Ocean Observing System Review;
- 2019: Tropical Atlantic Observing System Review.

These system- or regional-based reviews are driven from the need to observe various targeted phenomenon, science questions and expanded user requirements. In this context an ongoing challenge for the stakeholders of the ocean observing system is designing, implementing and sustaining critical observations required by the diverse users groups. In addition, it is a significant challenge for OOPC to draw on these regional and thematic review and development activities to facilitate advancing the global observing effort in a consistent way.

To this end it would be valuable to turn to the community of global and regional modeling systems that formally meld data from the full suite of observing platforms with models using advanced data assimilation to derive ocean state estimates in support of reanalysis applications and weather-scale and sub-seasonal to seasonal and decadal prediction. For these groups, observations are vital to constraining the ocean state, and are the fundamental metric against which forecast skill is evaluated. Many such groups are also advanced service providers, and are important links in the value chain that translates observations into information products and OOPC needs to liaise with major institutions providing operational climate and environmental services. Where the observing network falls short in informing the analyses that underpin derived products generated by the service providers, it is important that this is communicated back to OOPC and GOOS to establish priorities for observing system enhancement.

The ocean modeling and analysis research communities and many operational centers have formulated and prototyped quantitative tools for rigorous assessment of the impact that individual observations or networks have on analysis and forecast skill. Though their use is not routine, such tools have the potential to systematically identify observational gaps and to evaluate new or revised deployment strategies or platforms to more effectively meet user requirements. More widespread analyses of observation gaps and EOVS requirements by modeling groups would be a welcome addition to the OOPC-sponsored or coordinated network reviews. Modeling groups that emphasize product delivery to stakeholder communities are also well placed to advise on changing EOVS requirements to inform new data uses, including beyond physics variables to multi-disciplinary EOVS.

Additionally, assimilation of similar data from multiple platforms, each with its estimate of accuracy, can help identify biases or inconsistencies in the data. Where models and data frequently disagree also identifies needs for improved model dynamics and parameterizations. By delivering formal expected errors of the merged analyses, these systems highlight where the observing network is sparse and in need of expansion. When executed with hypothetical data sets, these systems can offer rigorous assessments of observing system design and significantly inform and prioritize the need for new observations.

There remain many unanswered questions on the fundamental nature and drivers of the oceans on climate processes and feedbacks amongst the components of the Earth's climate system; atmosphere, terrestrial, cryosphere, oceans, and biosphere. Improved dynamical understanding of the ocean, land, ice and atmosphere, and the ocean-atmosphere-ice-land coupling and teleconnections will lead to more reliable and skillful multi-year to decadal climate forecasts. Key to improved knowledge are intensive process studies that integrate both observation and models and target specific key knowledge gaps. Leveraging existing components of the sustained observing system with short-period intensive process studies may prove an effective mechanism to achieve significant advancement of ocean and earth sciences.

As we look to the next decade, OOPC must ensure that ocean observations are sustained and evolve to best meet the needs of our sponsoring programs GCOS-GOOS-WCRP and other user requirements. The assessment and recommendation of the evolution of the observing system should balance user requirements such as, providing improved knowledge of underpinning ocean dynamics, ocean state monitoring for assessment, and adaptation and mitigation, marine services operational weather and marine forecasting that encompass regional, basin and global scales and seasonal to decadal predictions systems. In addition, with the establishment of the biogeochemical and biological/ecosystem panels, GOOS has recognized that ocean observing in the service of existing and emerging users ultimately requires a multi-disciplinary approach. As such, the physics component will increasingly be integrated with biogeochemical and ecosystem observing sensors and platforms. This will require close collaboration amongst all GOOS panels.

We suggest that expanding model-based assessments of the accuracy and effective resolution of observing networks would be a valuable step in refining the guidance in the EOVS specifications with respect to sampling resolution and frequency. There is an increasing need to assess the current and future observing system capabilities in light of the climate variability and potential climate change response that we can anticipate from both climate modeling systems and our existing knowledge and oceanographic theory. For example, closure of global energy and sea level budgets will increasingly demand improved sampling below 2000 m as the global warming signal propagates downward (Gleckler et al., 2016; von Schuckmann et al., 2016).

AN INTEGRATED, SUSTAINED AND PRIORITIZED OCEAN OBSERVING SYSTEM FOR THE FUTURE

Despite century-long efforts, observations are still limited for many parts of the global ocean. The ocean observing system must continue to evolve to maximize support for climate monitoring, process understanding, development of improved numerical models, and prediction of weather and climate on a range of timescales. Meeting societal needs will require more reliable ocean data for prediction of extreme events and their intensity and frequency distribution, monitoring of Earth's climate cycles (heat, water, and carbon) to inform discussion and development of mitigation and adaptation policy, marine forecasting, and weather to climate predictions and projections.

The OceanObs'09 Framework for Ocean Observing (Lindstrom et al., 2012) sets a foundation for how the GOOS – a multiplatform, multidisciplinary and multifunctional ocean observing system – might evolve. However, it is recognized that the implementation of the observing system relies heavily on champions at the national level to bring the plan to reality. OOPC enables connections between the various observing systems/platforms and national implementers of the observing system to leverage the necessary funding from national agencies. OOPC's advocates for and endorsement of the ocean

observing systems, through scientifically-informed assessments of stakeholder needs and observing system capabilities. Thus, OOPC's role is to provide objective advice, representing a wider community view of the observing system as a whole and acts as a broker between stakeholders, national agencies and intergovernmental constructs.

It is expected that through OceanObs'19, many community-driven ideas will be voiced for improving the GOOS. Some of these recommendations may be readily implemented by new and current operators, while others may require trade-offs and/or international support and coordination. Transitioning to new observing system designs, for example, can be disruptive to long climate records that seek to minimize artifacts associated with changes in the measurement techniques and sampling characteristics that may mask the underlying climatic signals. Indeed, the next decade will present a number of opportunities that may enable genuine growth of the ocean observing system and the potential to provide a more secure funding mechanisms in future. The recent declaration of the United Nations Decade of Ocean Science for Sustainable Development (2021–2030) aims to provide ocean science, data and information to inform policy for a well-functioning ocean in support of all sustainable development goals of the Agenda 2030. This will generate scientific knowledge, underpinning infrastructures and partnerships and will require a cohesive GOOS across the coastal/shelf seas to the open ocean. OOPC's international coordination will be integral to building an integrated, sustained and prioritized ocean observing system and fostering cooperation with the GOOS biogeochemistry and biological/ecosystem expert panels, the JCOMM Observations Coordination Group, and GCOS.

SUMMARY AND RECOMMENDATIONS

OOPC, over the last 3 decades, has provided international guidance and a collaborative framework for the global ocean observing efforts that support fundamental research related to understanding and monitoring ocean physics and climate. More recently we have witnessed an acceleration in the technical capacity to deliver high quality observations in near-real time. This capacity for real-time data delivery has resulted in increasing demands for ocean observations in support of operational weather and maritime forecasting. Meteorological and ocean operational service providers have demonstrated how expanded ocean observations support the provision of improved forecasts and novel derived products of value to numerous user communities. OOPC needs to develop an inclusive partnership with these users to ensure support for the development and maintenance of the observing system.

Designing and operating a multidisciplinary observing system that goes beyond the physical ocean state into biogeochemistry and ecosystems will demand an even greater level of coordination and an expanded view of the phenomena that drive requirement specification. This will be accomplished by strong connections and collaborations between OOPC and the other GOOS panels, and it will fall on OOPC to provide informed consensus

leadership on the expanding requirements for multidisciplinary ocean observing.

The heterogeneous nature of observing technology and the expanding sensors and platforms used, present great opportunities and challenges for the observing system. Coordination amongst disparate networks has the potential to offer efficiencies or enhanced complementarity of platforms. OOPC, with its responsibility to consider the observing system as a whole and its platform agnostic stewardship of the EOJ/ECV requirements, is the natural forum to foster this coordinated evolution of the observing system. OOPC needs to ensure the observing system develops in a coordinated way and that data remain openly accessible in a timely manner. The synthesis and delivery of higher-level derived products based upon direct observations in support of research, operational and climate applications is a major scientific undertaking that demands significant added investment of both money and people. It is only through the coordinated synthesis of *all* observations for a given EOJ that integrated observational datasets that meet user requirements and expand the use of the data will be achieved.

OOPC oversight and endorsement of ocean observing system reviews (e.g., TPOS2020, TAOS, IndOOS) and design studies for future systems (DOOS) is not currently undertaken in a consistent way. To ensure that these interconnected components of a global observing system are consistent, OOPC needs to provide a set of common guidelines to frame these review or design studies. Inevitably, there remain knowledge gaps in our understanding of how the ocean influences Earth's weather and climate across the full spectrum from daily to interannual and multidecadal time scales. Intensive short-term hypothesis-led observing studies targeted at specific processes are vital contributors to advancing our understanding of the oceans' influence on climate processes. Support for intensive ocean process studies will stand on their own intrinsic scientific merits, but may identify shortcomings in the global observing system, its design, its operation, or its fitness to deliver multidisciplinary objectives, OOPC should support the need for specific process studies wherever these emerge.

Key recommendations for OOPC to ensure that the ocean observing system delivers a globally integrated and consistent fit-for-purpose ocean observing system are:

1. OOPC should enhance links between observing networks and operational services that use data to generate higher level information products. Because of their dependency on these data, operational and modeling communities have a significant interest in supporting sustained ocean observing, and in offering guidance to ensure the system delivers data that meet evolving user needs.
2. OOPC should formulate a set of common principles for observing system evaluation and design. These will draw on the FOO and provide a consistent set of guidelines for the conduct of reviews, their terms of reference, and the reporting of their outcomes. It would be appropriate for OOPC to assume an oversight role in

monitoring adherence to these principles to ensure that the guidelines are implemented consistently.

3. Under OOPC leadership, regular reviews of the EOJ/ECV requirements should be undertaken to ensure they meet existing and emerging user needs. OOPC, with OCG, will work with observing networks to build unified data management practices to build consistent and findable data systems. OOPC must be a strong advocate that enables national implementers of the observing system to secure funding from national resources.
4. OOPC will support the coordination of EOJ data collections, and production of synthesis and higher level products that users value. OOPC will publicize these products to increase data update and demonstrate to funders the value of these synthesis projects and need for ongoing resourcing of such efforts.
5. OOPC, in coordination with research partners (e.g., WRCP), will advocate for intensive process studies to address knowledge gaps.

CONCLUSION

The ever increasing complexity of the Ocean Observing System both in terms of the observation techniques and users requirement calls for a strong and robust management and evaluation process. OOPC provides an internationally recognized and supported mechanism for coordinating the review and evolution of existing observing systems that is essential to meeting the wide range of current and future user requirements.

Providing leadership on the continual assessment of the observing and data system, identifying gaps, risk and user needs is a central task of OOPC. We will continue these efforts reviewing existing observing systems and recommending unified data management and formats, all the while keeping in mind how their integration and expansion into multifunctional, multidisciplinary systems will meet an expanding range of user requirements. These review processes and the proposal of new observations require input and collaboration amongst the observing platforms/programs (satellite and *in situ*), research and user communities and insights from climate models and other modeling systems. Where reviews of regions or themes suggest continuation or expansion of observations, OOPC will be a strong advocate for continued support of the ocean observing system.

AUTHOR CONTRIBUTIONS

KH, JW, and BS led the conception and writing of the manuscript. MPC, MFC, JJ, JK, MK, TL, EO, MP, BR, SS, KvS, RW, and WY contributed to the text.

FUNDING

BS received support from the Centre for Southern Hemisphere Oceans Research, a collaboration between the CSIRO and

the Qingdao National Laboratory for Marine Science and Technology and the Australian Government Department of the Environment and CSIRO through the Australian Climate Change Science Programme and by the National Environmental Science Program. JK was supported by the European Union's Horizon 2020 Research and Innovation Programme under the grant agreement no. 633211 (AtlantOS). MP was supported by the Met Office Hadley Centre Climate Programme funded by the BEIS and Defra. SS was supported by the Ecole Normale Supérieure, CNRS, and Ifremer funded by the European Union's Horizon 2020 Research and Innovation Programme

under the grant agreement no. 633211 (AtlantOS), CNES, and ANR grants.

ACKNOWLEDGMENTS

We thank the scientific experts and observing programs who contributed to the development of the EOVS specification sheets. We also thank David Legler for his valued contribution to OOPC activities. Comments from the reviewers improved the manuscript.

There is a growing need for operational oceanographic predictions in both the Arctic and Antarctic polar regions. In the former, this is driven by a declining ice cover accompanied by an increase in maritime traffic and exploitation of marine resources. Oceanographic predictions in the Antarctic are also important, both to support Antarctic operations and also to help elucidate processes governing sea ice and ice shelf stability. However, a significant gap exists in the ocean observing system in polar regions, compared to most areas of the global ocean, hindering the reliability of ocean and sea ice forecasts. This gap can also be seen from the spread in ocean and sea ice reanalyses for polar regions which provide an estimate of their uncertainty. The reduced reliability of polar predictions may affect the quality of various applications

including search and rescue, coupling with numerical weather and seasonal predictions, historical reconstructions (reanalysis), aquaculture and environmental management including environmental emergency response. Here, we outline the status of existing near-real time ocean observational efforts in polar regions, discuss gaps, and explore perspectives for the future. Specific recommendations include a renewed call for open access to data, especially real-time data, as a critical capability for improved sea ice and weather forecasting and other environmental prediction needs. Dedicated efforts are also needed to make use of additional observations made as part of the Year of Polar Prediction (YOPP; 2017–2019) to inform optimal observing system design. To provide a polar extension to the Argo network, it is recommended that a network of ice-borne sea ice and upper-ocean observing buoys be deployed and supported operationally in ice-covered areas together with autonomous profiling floats and gliders (potentially with ice detection capability) in seasonally ice covered seas. Finally, additional efforts to better measure and parameterize surface exchanges in polar regions are much needed to improve coupled environmental prediction.

Keywords: polar observations, operational oceanography, ocean data assimilation, ocean modeling, forecasting, sea ice, air-sea-ice fluxes, YOPP

INTRODUCTION

Over the last 10 years, there has been a significant maturing of ocean prediction systems, led by efforts such as GODAE OceanView (GOV; Bell et al., 2015; Davidson et al., 2019) and the European Union Copernicus Marine Environmental Monitoring Service (CMEMS; Le Traon et al., 2017). Numerous operational global and regional ocean analysis and forecast systems are now in place providing services for a range of applications including search and rescue, short- and long-range atmospheric and coupled prediction systems, aquaculture, energy sector activities and environmental management including environmental emergency response.

We have also seen the implementation of high-resolution operational ice-ocean prediction systems for polar regions providing forecasts on timescales of hours to days. These include the CMEMS Arctic Monitoring and Forecasting Centre (ARC MFC), the U.S. Navy Global Ocean Forecasting System, Environment and Climate Change Canada's Global and Regional Ice Ocean Prediction Systems among others (Carrieres et al., 2017). While these systems are intended to provide support for marine operations and related applications, there has been a growing acceptance of the importance of including coupled interactions across the marine surface in numerical weather prediction systems (Brassington et al., 2015). Indeed, operational medium-range weather forecasting systems in Canada and at the European Centre for Medium Range Forecasting (ECWMF) now include a dynamic coupling with ice-ocean models (Mogensen et al., 2017; Smith et al., 2018). As a result, polar ocean observations may now have impacts beyond the polar regions on mid-latitude weather predictions (Jung et al., 2015). Moreover, coupled atmosphere-ice-ocean models have been shown to provide skillful forecasts at monthly-to-seasonal time scales in the polar regions, especially for the Arctic sea ice cover (e.g., Guémas et al., 2016a; Sigmond et al., 2016). The

importance of polar sea ice initial conditions in affecting skill of monthly-to-seasonal predictions at lower latitudes in the atmosphere has also been discussed (e.g., Guémas et al., 2016b). These advances are also fostering a coupled modeling approach in the context of Earth system reanalyses for climate monitoring (e.g., Buizza et al., 2018).

Environmental prediction systems rely heavily on ocean observations from a variety of platforms (both *in situ* and from remote sensing). Indeed, Observing System Experiments (OSEs) have shown the delicate balance and complementarity provided by the current basket of observations (Oke et al., 2015; Fujii et al., 2019). However, polar regions present a number of unique observing challenges (see Calder et al., 2010). For short lead-times (hours to days), forecast skill depends strongly on initial conditions, which in turn depend on real-time observations ingested through data assimilation. The lack of real-time Argo profiling floats in polar regions due to the sea ice cover (Roemmich and Gilson, 2009) therefore creates a significant gap. This gap is compounded by additional errors in satellite products in polar regions, for example, due to difficulties in distinguishing snow and ice from clouds (Castro et al., 2016). The relative remoteness and harsh environmental conditions in polar regions further hinder efforts to provide *in situ* measurements. Moreover, the increasing use of coupled models noted above requires collocated observations of the atmosphere, ice and ocean, including flux estimates (Bourassa et al., 2013). This is all the more important because of the role of the Arctic region in particular in shaping the heat and freshwater transports at global scales, thus having a crucial remote impact on the mid- and low- latitude climate as well (Serreze and Barry, 2011; Jung et al., 2015).

Additionally, the rapidly receding summer ice cover in the Arctic is leading to both an increase in the demand for accurate ice-ocean and weather forecast products (Jung et al., 2016), as well as challenges in how to adapt prediction systems to

accurately forecast conditions that may not have an existing analog in the historical record (e.g., the 2012 record low Arctic sea ice cover; Parkinson and Comiso, 2013). Similar issues apply in the Antarctic: rising temperatures and reports of both expanding and reduced sea ice have led to uncertainties about changes in the system (Maksym, 2019), while at the same time growing demands from Antarctic tourism and research logistics have driven a need for improved forecasts (Hoke et al., 2018).

Here, we outline the status of existing near real-time ocean observational efforts in polar regions, discuss gaps, and explore perspectives for the future. The first section is dedicated to *in situ* observations of temperature and salinity and several projects underway to further extend these efforts. Section “Satellite Observations” focuses on satellite observations of sea surface temperature (SST) and height (SSH), along with information on the sea ice cover. Section “Air-Sea Flux Measurements in Polar Oceans” discusses issues associated with surface flux measurements in polar regions. Section “Forecasting System Experiments” presents several impact studies in different prediction systems demonstrating the importance of ocean and sea ice observations to forecasting skill. Section “International Efforts to Address Gaps in Polar Ocean Observations” discusses several international projects working to address the gap in ocean observations in the polar regions. Finally, recommendations and an outlook for the future are presented in Sections “Recommendations” and “Outlook.”

IN SITU OBSERVATIONS OF TEMPERATURE AND SALINITY

In the polar oceans there are several methods for collecting ocean and sea ice data and sending the data in near real-time via the Global Telecommunications System (GTS) or other transmission systems. In ice-free areas various methods are used, including ships, Argo floats, surface drifters, gliders, etc., while in ice-covered areas, only ice-borne instrument systems can operate throughout the year and transmit data in near real-time. Owing to their significant deployment and maintenance costs, the number of these platforms is very limited, resulting in large gaps in the data coverage in the ice-covered Arctic Ocean. Antarctic sea ice is largely single-year (or first-year) ice, which makes it ill-suited for ice based measurement systems. A significant fraction of the ocean data from the Arctic, as well as under-ice Argo profiles from the Antarctic seasonal ice zone, are only available in delayed mode, because underwater platforms in ice-covered areas cannot transmit data via satellite communication. This limits the access to ocean data available in near real-time, which is required by monitoring and forecasting services.

In the following section, the most common observing systems for the Arctic Ocean and Antarctic marginal sea are described briefly. Sections “The WHOI Ice-Tethered Profiler,” “ALAMO and Arctic Heat,” “Deployment of Argo Floats in Canadian Marginal Ice Zone by CONCEPTS,” “Under-ice BGC Argo Floats in the Canadian Arctic,” and “Surface Drifters and IABP” detail several specific observing efforts as exemplars of each class of technology.

Overview of Current Observing System Profiling Floats

Argo floats are the backbone of the global ocean observing system developed over the last two decades with more than 3500 units currently in operation (e.g., Roemmich et al., 2009). In the north, Argo floats are used in ice-free areas of the North Atlantic/Nordic Seas, Baffin Bay and Bering Sea. In the North Atlantic/Nordic Seas about 10–20 Argo floats are deployed each year sustaining an operational array of about 40 – 50 Argo floats in these regions. These floats are provided mainly by national efforts (e.g., NorArgo) and coordinated at the European level by EuroArgo. The funding of these Argo floats is relatively secure, and provided for by the countries that participate in EuroArgo.

There is ongoing development to adapt Argo floats to operate under ice, using ice-sensing algorithms as well as acoustic and optical techniques. In the Southern Ocean, the Argo program has demonstrated success with under-ice profiling floats that delay data transmission until the float is in open water, typically in summer (e.g., projects SOCLIM, RemOcean, SOCCO Bio-argo and ReMOCA). In particular, the Southern Ocean Carbon and Climate Observations and Modeling project (SOCCOM) has made an effort to deploy a significant number of under-ice Argo floats in the Southern Ocean. Moreover, RAFOS floats (Klatt et al., 2007; Reeve et al., 2016) provide the capability to triangulate their position using sound signals from nearby moorings for periods when they are not able to surface. In the Arctic, the ice-sensing algorithm is starting to become more mature and is being complemented with additional detection methods currently being tested by Takuvik (see Under-ice BGC Argo Floats in the Canadian Arctic).

Ice-Borne Observing Systems

Many types of ice-borne ocean measurement systems have been developed and fielded in the last 2–3 decades. Ice-based platforms are the only autonomous systems that can presently deliver near-real-time subsurface ocean observations year round from ice-covered areas. Early examples consisted of discrete sensors mounted on a floating mooring that drifts with the sea ice. More recent examples employ a drifting surface buoy deployed in the ice with a Conductivity-Temperature-Depth (CTD) sensor that is repeatedly transported along the mooring cable over the upper 800–1000 m of the water column. Ice-Tethered Profiler (ITP) systems from the Woods Hole Oceanographic Institution (WHOI, see The WHOI Ice-Tethered Profiler for details) have been fielded since 2004. Similarly, investigators from Laboratoire d’Océanographie et du Climat (LOCEAN) have developed and deployed IAOOS (Ice-Atmosphere-Arctic Ocean Observation System) buoys¹. In addition to CTD profile observations, the IAOOS buoy includes ice mass balance measurements (snow and sea ice temperature and thickness), as well as a variety of meteorological sensors (Provost et al., 2015). Other similar platforms include the JAMSTEC Polar Ocean Profiling system (POPS; Kikuchi et al., 2007), the NPS Autonomous Ocean Flux

¹See <http://iaaos.ipev.fr/> for more details.

Buoy² (AOFB), and the UpTempO ice-tethered buoy developed by APL-UW (Castro et al., 2016). The Arctic University of Norway has recently developed and field tested a new platform called the Ice-Tethered Platform Cluster for Optical, Physical, and Ecological Sensors (ICE-POPE) that will be deployed operationally in 2019 (Berge et al., 2016). The Polar Research Institute of China is also developing ice-tethered platforms, which are being tested during Arctic expeditions of the I/B Xuelong. In comparison to Argo-type profiling floats, ice-based platforms are rather expensive (>100–300 k€ per unit). To date, funding to construct and field these systems and provide data to the community has derived from individual PI-led research projects. There are no operational programs to support the ice-tethered platforms at the moment, but there is a clear requirement from the Arctic Ocean modeling and data assimilation community that 10+ such platforms need to be deployed every year and supported operationally.

It is widely known that sea ice in the Arctic is shrinking in areal coverage, thinning, and becoming more mobile. All of these changes present complications to an ice-based observing system. Although diminished, the sea ice will remain critically important to earth's climate and ecosystems as well as transportation and tourism, making ice-following observing platforms necessary into the future. However, future ice-borne instrument systems must be able to float and demonstrate resilience during fall freeze-up. Thinner, more mobile ice can be more prone to ridging that can damage ice based buoys. It has not proven feasible to maintain the array of 20 ice-based observatory systems in the Arctic that was envisioned at the turn of the century. Nor have these technologies been used extensively in the seasonal ice zone surrounding Antarctica, where sea ice typically melts completely every summer. Nevertheless, ice-based observatories have and are continuing to return valuable year-round upper ocean data from the central Arctic. Buoy clusters sampling various elements of the atmosphere, sea ice and upper ocean have proven particularly valuable.

Ice/Snow Surface Drifters

A reasonable number of low-cost ice buoys operate in the Arctic, providing ice motion, air pressure and surface temperature data. At present, most of these buoys are drifting in the western part of the Arctic, whereas the eastern part, including the Eurasian Basin and the Russian shelves, has very few buoys. The drifter data are transmitted via the Argos or Iridium satellite systems then posted on the WMO/IOC GTS and provide baseline data for weather and ice forecasting in the Arctic (see Section Surface Drifters and IABP for more detail). Drifters are also routinely deployed throughout the Southern Ocean, providing important information (e.g., SST and sea level pressure) to forecast systems from extremely data sparse regions.

Sea ice mass balance buoys (IMBs) provide information on temperature within snow and ice as well as ice thickness and its motion. Development and use of these buoys have continued for several decades with more than 100 IMBs deployed

from 1957 to 2014. The data are transmitted in near real-time, but processing of the temperature profiles is mainly done manually. There are ongoing efforts to develop automated methods for retrieval of snow and ice thickness (Liao et al., 2018; Zuo et al., 2018). It is a challenge to develop robust algorithms that give accurate retrievals through the melting and freezing seasons.

Currently, three different systems are deployed in the Arctic including the CRREL-Dartmouth IMB (Richter-Menge et al., 2006), the SRSL Sea Ice Mass Balance Array (SIMBA; Jackson et al., 2013) and the TUT ice-tethered buoy developed by PRIC and TUC in China (Zuo et al., 2018). Some of the Ice-tethered platforms described in Section “Ice-Borne Observing Systems” are also equipped with SIMBA instruments.

Other Systems

- (1) Ferrybox systems: The Norwegian Institute for Water Research (NIVA) operates a ferrybox between Tromsø and Longyearbyen/Ny Ålesund. Data are obtained every 2 weeks year-round. This system is fairly sustainable through support from a new infrastructure project led by NIVA.
- (2) Ship-based CTD data during scientific cruises and fishery management cruises: Several research vessels in the North Atlantic/Nordic seas deliver CTD observations in near real-time. The data are provided more or less regularly, depending on the schedule of the research vessels.
- (3) Profiling gliders: Several institutions conduct ocean glider experiments in the Arctic (e.g., Nordic Seas, David Strait, Fram Strait, north of Svalbard, Beaufort Sea) providing CTD data in near real-time. These experiments are mainly in the summer season, however, acoustically navigated ice-capable Seagliders (developed by APL-UW) were successfully used for the year-round missions in Davis Strait and in the Beaufort Sea including under ice measurements in winter (Curry et al., 2014; Lee et al., 2016). Glider experiments are also conducted with growing frequency in the Southern Ocean. These provide valuable data and upper ocean process understanding from winter through summer (e.g., Swart et al., 2015; Thomson and Girton, 2017; du Plessis et al., 2019 – in review).
- (4) Autonomous surface vehicles: Wave Gliders have been deployed in both the Arctic and Southern Ocean, providing rare surface flux (heat, momentum and CO₂) information over multiple months at a time and with high resolution (Monteiro et al., 2015; Schmidt et al., 2017; Thomson and Girton, 2017). Many of these platforms are reporting or being adapted to report real-time surface observational data.
- (5) Sea-mammal borne instruments (CTD data) are becoming the most numerous *in situ* observations at high latitude in the Antarctic and also more recently in the Arctic, and may improve forecast skill and circulation patterns (Fedak, 2013; Roquet et al., 2013; Carse et al., 2015).
- (6) Acoustic tomography: Acoustic sources and receivers have been deployed in the Arctic in the past (Mikhalevsky et al., 2015) and offer the unique capability to measure

²See <https://www.oc.nps.edu/~stanton/fluxbuoy/> for more details.

large-scale changes in temperature and heat content of the Arctic Ocean over long periods (Howe et al., 2019). New deployments of this technology were conducted under the CANAPE project (led by Scripps); CAATEX programs (led by NERSC) have been approved. While no observations are currently available in real-time, nor assimilated in delayed mode, acoustic tomography nonetheless presents an interesting possibility for constraining ocean state-estimate/prediction systems.

- (7) **Moored Arrays:** Several long-term observatories have been running in both ice-covered and open-water areas with the capacity to provide real-time data. Examples include the German long-term observatory FRAM (Frontiers in Arctic Marine Monitoring; Soltwedel et al., 2013) and the Barrow Strait Observatory (Richards et al., 2017).

The WHOI Ice-Tethered Profiler

Historically, the Arctic Ocean has been poorly sampled relative to waters at low- and mid-latitudes, especially in winter time. To address this observing shortfall, the WHOI ITP was designed to sample the upper ocean below drifting sea ice throughout the year and to return data in near real time (Krishfield et al., 2008; Toole et al., 2011). As noted earlier, there are now a variety of systems with similar capability now being fielded; the ITP is detailed here as exemplar of the group. The expendable ITP consists of a surface buoy that supports a weighted wire-rope tether extending through the ice and down to (at most) 800 m depth (**Figures 1A,C,D**). The heart of the ITP system is a cylindrical vehicle fitted with sensors (similar in size and shape to an Argo float) that travels up and down the tether. ITPs are equipped with CTD instruments for observing the ocean's thermohaline stratification and may also include sensors that sample, for example, dissolved oxygen (Timmermans et al., 2010), bio-optical properties (Laney et al., 2014), and ocean currents (Ice-Tethered Profiler with Velocity – ITV-V; Thwaites et al., 2011; Cole et al., 2015). In addition, instruments measuring temperature-conductivity, pCO₂, dissolved O₂ and pH have been affixed to the tether above the profiling interval (e.g., Islam et al., 2017). Deployments may be done from ice camps (supported by fixed-wing aircraft or helicopters) or ships. The majority of deployments have been through holes augured through ice floes but a handful of systems have been installed in open water (the buoy has sufficient buoyancy to support the system); most of those have survived fall freeze-up.

The basic ITP system was designed for an operational lifetime of more than 2 years assuming approximately 1500 m of profiling per day (e.g., 2 one-way profiles of 750 m span). Actual lifetimes of the full ITP system are often less than this, **Figure 1B**. There are two major failure modes of ITPs: crushing of the surface buoy and/or breaking of the tether in ice ridging events and dragging of the tether in shallow water. As is evident in **Figure 1B**, ITP surface buoys frequently transmit position data for an extended time after communication with the underwater unit is lost.

ITP data, available from the project website³, the National Environmental Data Center and the Arctic Data Center, support a

³<http://www.whoi.edu/itp>

range of scientific investigations and student projects. The basin-wide and year-round coverage facilitates studies of seasonal-to-interannual physical and biogeochemical processes (e.g., Rabe et al., 2011; McPhee, 2013; Laney et al., 2014, 2017; Islam et al., 2017) and basin-scale phenomena (e.g., Timmermans et al., 2014), as well as supporting the initialization (data assimilation) and/or validation of numerical models. Smaller-scale processes may also be investigated with ITP data, including meso- and sub-mesoscale variability (e.g., Timmermans et al., 2011; Zhao et al., 2014, 2016), near-inertial internal waves (Cole et al., 2014; Dosser et al., 2014) and double diffusion (e.g., Timmermans et al., 2008; Shibley et al., 2017). Notably, the range of sensors able to be supported on ITPs provides a wide-ranging view of the evolving Arctic Ocean system.

ALAMO and Arctic Heat

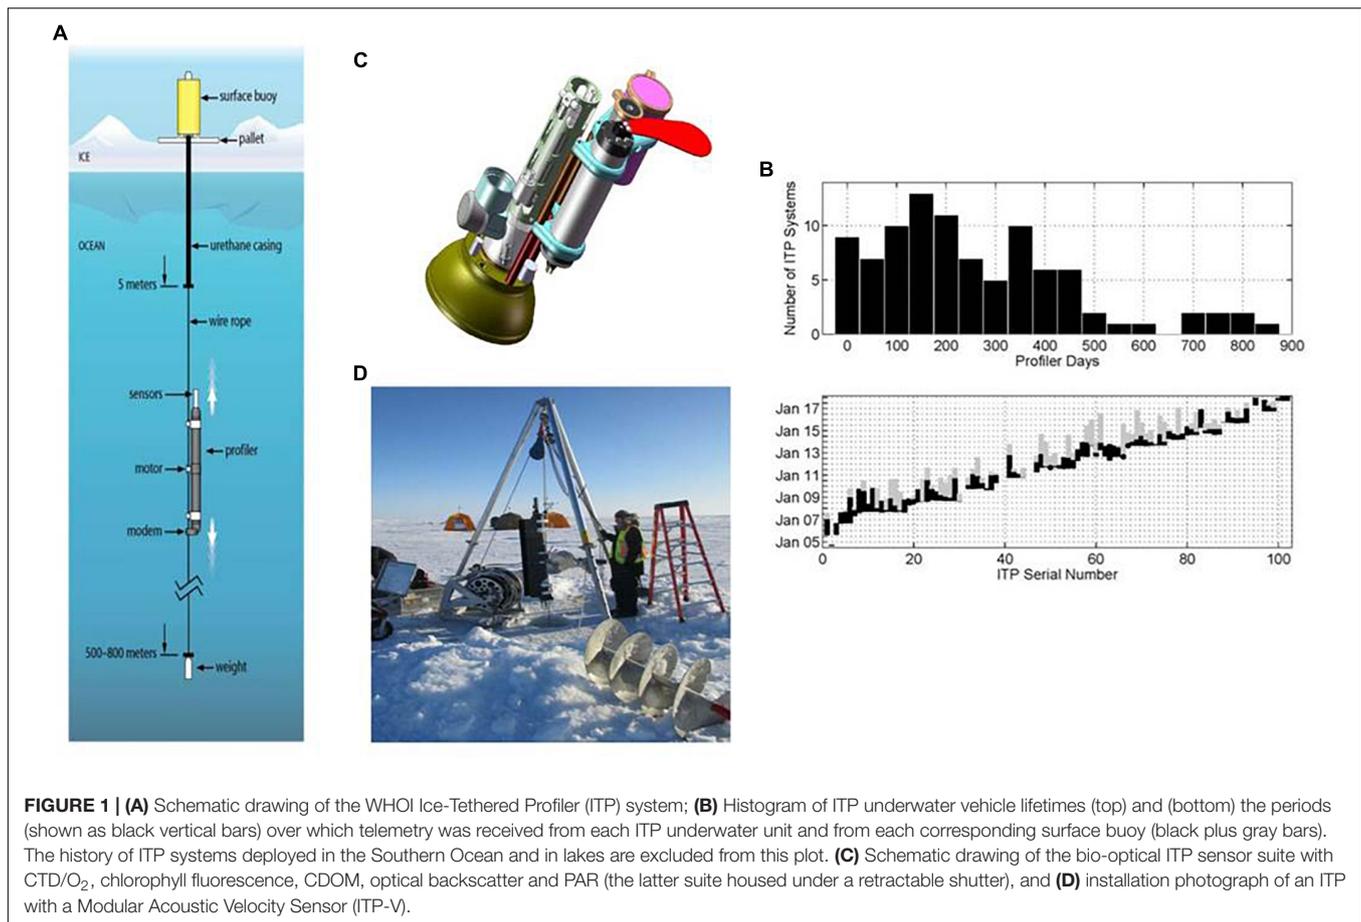

Since 2014, NOAA Pacific Marine Environmental Laboratory (PMEL) and the University of Washington's Joint Institute for the Study of the Atmosphere and Ocean (JISAO) have been developing and field testing a series of autonomous marine systems designed for Arctic applications. This work has been carried out in collaboration with scientists, forecasters, and industry, primarily under the auspices of the Innovative Technologies for Arctic Exploration (ITAE⁴) program. Fifteen new types of technology have been developed or advanced for Arctic use under this program, including the Air-Launched Autonomous Micro-Observer (ALAMO), the Sailer drone autonomous marine vehicle, and the Oculus Coastal Glider.

An example of a multi-platform experiment along these lines is the Arctic Heat Open Science Experiment (Wood et al., 2018). Here a NOAA Twin Otter research aircraft (NOAA-56) has been equipped with a range of weather and ocean-sensing instruments, which in 2018 included flight-level weather and radiometry, an A-size sonobuoy deployment tube used for a range of air-deployed probes – including AXBT/AXCTD/AXCP, atmospheric dropsondes, ALAMO autonomous profilers, and experimental UAS (Unmanned Aerial Systems) platforms – LIDAR and thermal imaging camera. Arctic Heat deploys an array of ALAMO floats in the Chukchi Sea between May and September; floats deployed later in the season are active into winter (**Figure 2**), and are used to develop an experimental seasonal freeze-up projection, in combination with satellite-derived SST and historical sea ice extent/concentration. In 2018 a combination of more than two dozen profiling floats of various types were deployed by three collaborating research groups in the Chukchi and Beaufort Seas⁵.

The dense array of floats in 2018 provides an opportunity to thoroughly investigate the potential gain in predictive skill provided by enhanced real-time ocean observations. Understanding how assimilating more observations will impact modeled analyses and short-term forecasts is of fundamental importance as new coupled models are developed. For example, sensitivity experiments with the NOAA-Earth System Research

Laboratory Coupled Arctic Forecast System (CAFS) (see NOAA-ESRL/CIRES Coupled Arctic Forecast System) are being pursued.

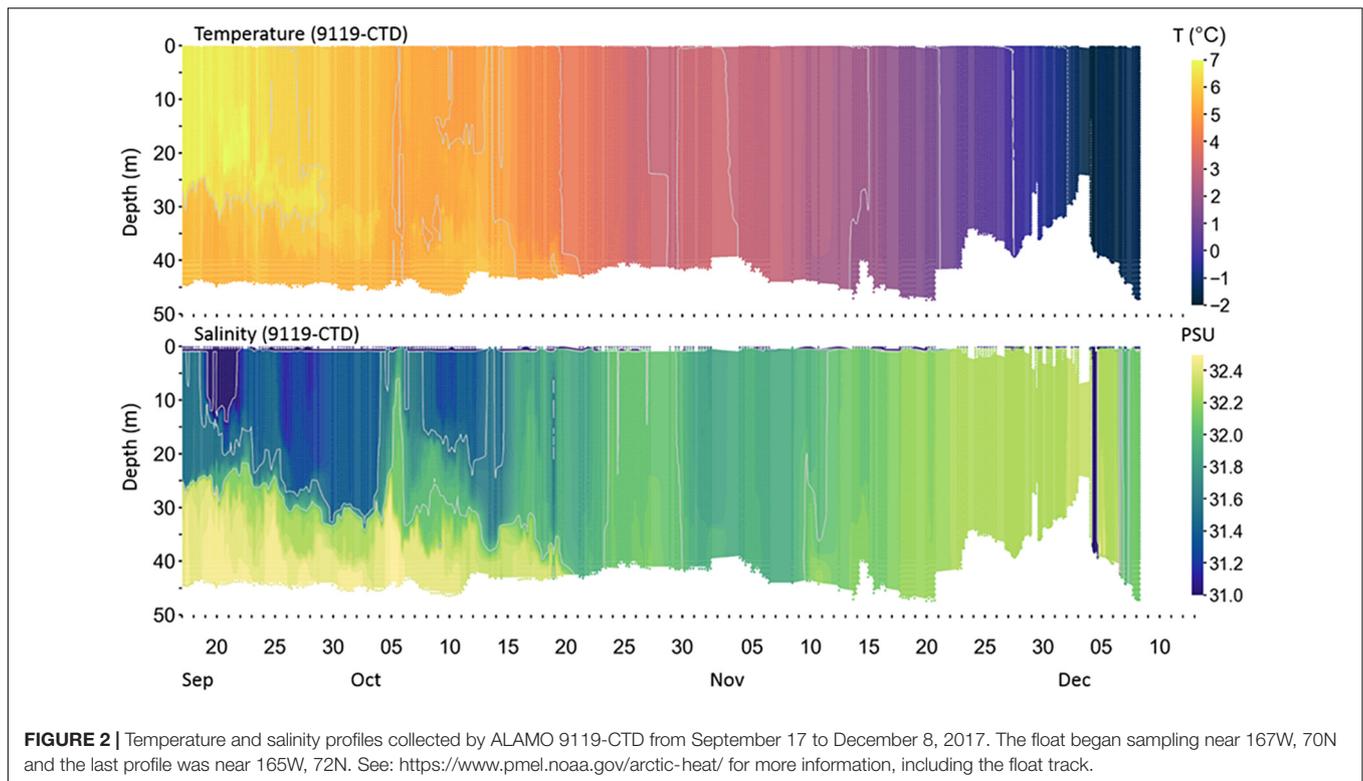

Deployment of Argo Floats in Canadian Marginal Ice Zone by CONCEPTS

A Government of Canada initiative called CONCEPTS (Canadian Operational Network of Coupled Environmental Prediction Systems; Davidson et al., 2013) has implemented global and regional environmental prediction systems over the last few years. A particular need has been identified to complement the existing observing system with additional real-time observations to better constrain water mass properties in the ocean analyses, in particular in Canadian seasonally ice-infested seas. As a result, a project is underway to test the implementation of different observing technologies for their ability to provide reliable measurements of ocean temperature and salinity at a low cost. A first step was the deployment of a standard Argo float in the Gulf of St. Lawrence, configured with a shallow profiling and parking depth (200 m). The objective was to provide observations over the spring-to-fall ice-free period and to allow the float to remain subsurface in winter when ice forms. The use of existing technology (i.e., without any particular ice detection capability) reduced costs and increased feasibility. This initial

effort was quite successful and provided an excellent complement to existing (and more costly) moorings deployed in the Gulf of St. Lawrence.

A second effort included the deployment of an Argo float on the Labrador shelf, again with a shallow profiling depth of 200 m. This depth was greater than the local bathymetry allowing the float to rest on the sea floor and reduce lateral drift. Despite the presence of ice in winter, this float was able to breach the surface periodically (roughly every 10 days) and transmit ocean measurements. Additionally, the float observed temperature and salinity measurements during winter that deviated significantly from climatological conditions (**Figure 3**). As these climatological values are typically used by various applications in the absence of other data, the Argo float observations filled an important gap. Moreover, their availability in real time permits their use in data assimilation systems that can allow the detected anomaly in water mass conditions to be propagated over suitably correlated water masses (i.e., along the Labrador Shelf).

As part of the YOPP (see Year of Polar Prediction), this effort has been expanded to include the deployment of 7 Argo floats during the Arctic summer Special Observing Period (July–September 2018). If successful, and found to provide adequate benefit for the cost, this effort could become part of the Canadian Argo Program, and also contribute to the newly forming

Canadian Integrated Ocean Observing System (CIOOS). The use of air deployable ALAMO floats and floats with ice-detection capabilities is also being investigated.

Under-Ice BGC Argo Floats in the Canadian Arctic

As part of project Green Edge⁶, Takuvik deploys Biogeochemical Argo floats (BGC Argo; manufactured by NKE⁷) in the Arctic Ocean to study the dynamics of ice-edge phytoplankton spring blooms as controlled by sea ice dynamics, vertical mixing, light and nutrients. BGC Argo floats are more specialized profilers, equipped with sensors capable of sampling additional essential ocean variables (Claustre et al., 2010). The study focuses on Baffin Bay, which involves navigational challenges for floats in terms of bathymetry, ice coverage and circulation. Simulations of trajectories to choose the best dropping zones, combined with observations from ice charts (climatology and real-time charts) are necessary for safe deployments. An ice-covered ocean presents a real challenge for Argo floats that must surface for geo-localization and to use satellite networks for data transmission and command reception (Riser et al., 2016), see **Figure 4**. Therefore, some technical refinements have been needed to make the floats operational in the Arctic Ocean (Fennel and Greenan, 2017).

The development of a new generation of floats (PRO-ICE) to be operated under ice, was founded by the French project

NAOS⁸. If sea ice is present at the surface, Argo floats need to postpone surfacing. It will perform several consecutive profiles without sending stored data. PRO-ICE have additional non-volatile memory and are able to record data from all profiles including those performed during wintertime. Because of the need to transmit a high volume of data, communications are performed via a two-way Iridium link, which is faster than the older ARGOS link. This minimizes time at the surface and allows instructions to be transmitted to the float. In addition, floats to be deployed in Arctic seas need to be able to deal with a wide range of seawater salinity/density. Some Argo floats, like PRO-ICE, do not require pre-ballasting as a function of mean seawater density. This is a huge advantage since they can surface easily in a low-density surface seawater layer (Riser et al., 2016).

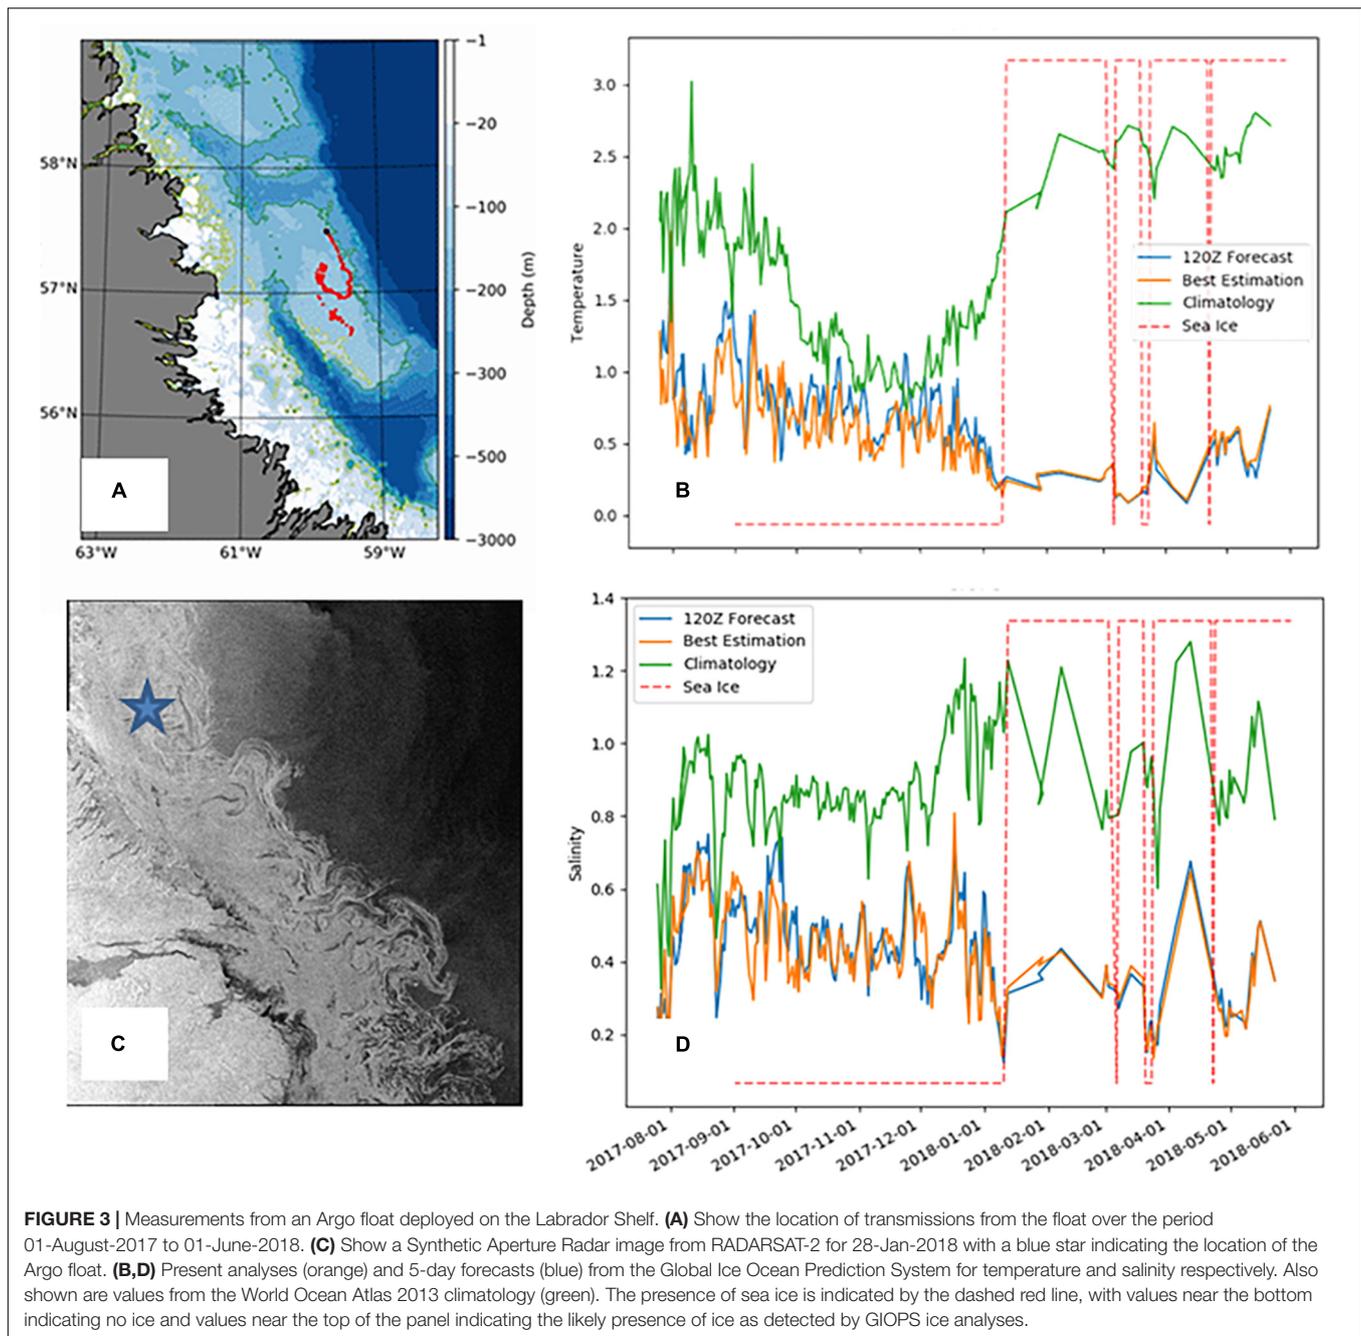

The PRO-ICE floats use a combination of three technologies to detect ice: a reversed altimeter (active acoustics), an Ice Sensing Algorithm (Klatt et al., 2007) (ISA) based on seawater freezing temperature and an optical sensor. In the Arctic Ocean, the threshold of the ISA algorithm is difficult to determine because of the high levels of variation in salinity (seasonal and regional), compared to the homogeneous salinity present in Antarctica. Takuvik gathered a substantial data base of temperature and salinity data in Baffin Bay, linked to ice cover information in order to locally adapt the threshold of ISA.

Furthermore, the resolution provided by an altimeter is not sufficient to detect a thin-ice layer. For this, Takuvik has

⁶<http://www.greenedgeproject.info/>

⁷<http://www.nke-instrumentation.com/>

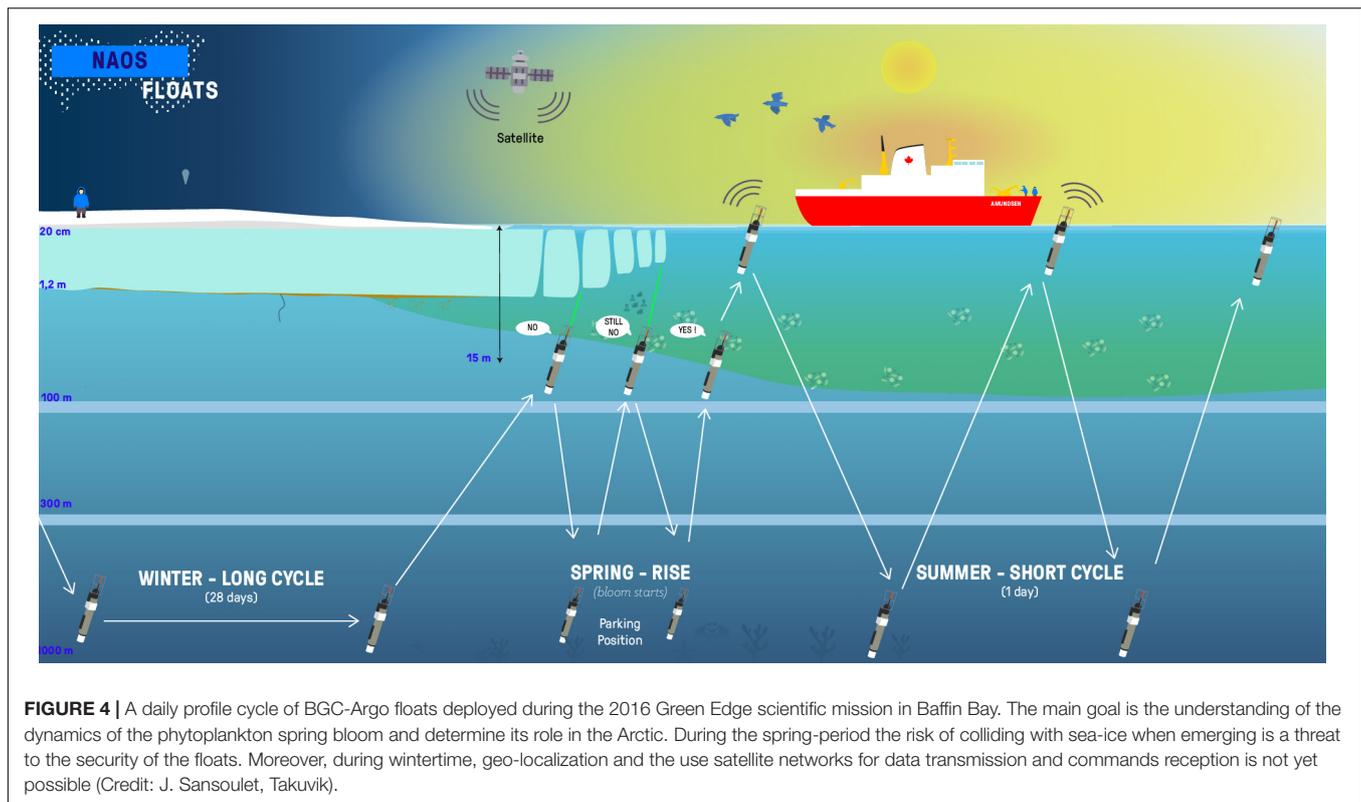

⁸Naos, "Equipex Naos." <http://www.naos-equipex.fr/>.

developed an ice-detection system based on laser polarimetry (Lagunas et al., 2018). Since sea-ice is a strong light depolarizer, this characteristic was used as an indicator of the presence or absence of ice. This ice-detection system has been installed on several PRO-ICE BGC-Argo floats deployed yearly in Baffin Bay since 2016.

A potential solution to data transmission issues caused by an inability to surface under the ice cover may be provided by underwater acoustic networks. Multipurpose underwater acoustic networks can provide under-ice positioning (“underwater GPS”; Lee and Gobat, 2008) and low bit-rate

communication services (Freitag et al., 2015) to AUVs fitted with low-power acoustic receivers. Acoustic positioning systems have been deployed for under-ice navigation of Argo floats in the Weddell Sea (Klatt et al., 2007). Challenges for designing basin-scale acoustic systems include modeling the time-varying nature of the Arctic sound channel, for which measurements of annual variations of under-ice sound profiles and ice-bottom roughness are scarce (Rehm et al., 2018). The role of multipurpose acoustics networks as key components of polar observing systems is explored further in a complementary article (Howe et al., 2019).

Data acquired by Takuvik's PRO-ICE floats are available in the Argo database at the CORIOLIS Global Data Assembly Centre⁹ (GDAC). The data policy set for Argo mandates free access to the data for all interested scientists, research groups and operational agencies. The data management is designed to facilitate easy and immediate access to data not only in real time, but also in delayed mode.

Surface Drifters and IABP

Surface air pressure, temperature and ocean/ice circulation in the polar regions (Figure 5) are observed by a network of drifting buoys maintained by participants of the International Arctic Buoy Programme (IABP¹⁰, Figure 6) and the International Programme for Antarctic Buoys (IPAB¹¹). Over the Arctic Ocean and its peripheral seas (north of 60°N), there were about 120 buoys reporting as of August 2018. Most of these buoys were located in the North American sector, with only a handful reporting in the Eurasian sector of the Arctic. This gap in the Arctic Observing Network creates a significant uncertainty in the analyzed fields of sea level pressure, temperature and winds (Inoue et al., 2009, Figure 7).

In the Southern Ocean (south of 40°S) there were about 50 buoys as of August, 2018. Although over 100 buoys were deployed during the Austral summer near the coast of Antarctica, most of

these buoys were destroyed by the sea ice during freeze up or have been blown north, away from the coast by the prevailing winds.

Maintaining the polar observing networks near the coasts around most of Antarctica, and in the Eurasian Arctic is an ongoing challenge, since the prevailing winds and ocean currents quickly transport the buoys away from the coast. Ideally, the IABP and IPAB networks should be reseeded during the winter, but it is difficult to deploy buoys from ships and aircraft during the polar night and extreme cold and harsh conditions of winter.

The participants of the IABP and IPAB strive to release their data onto the WMO/IOC GTS in near real-time by both the global research and operational weather and ice forecasting communities.

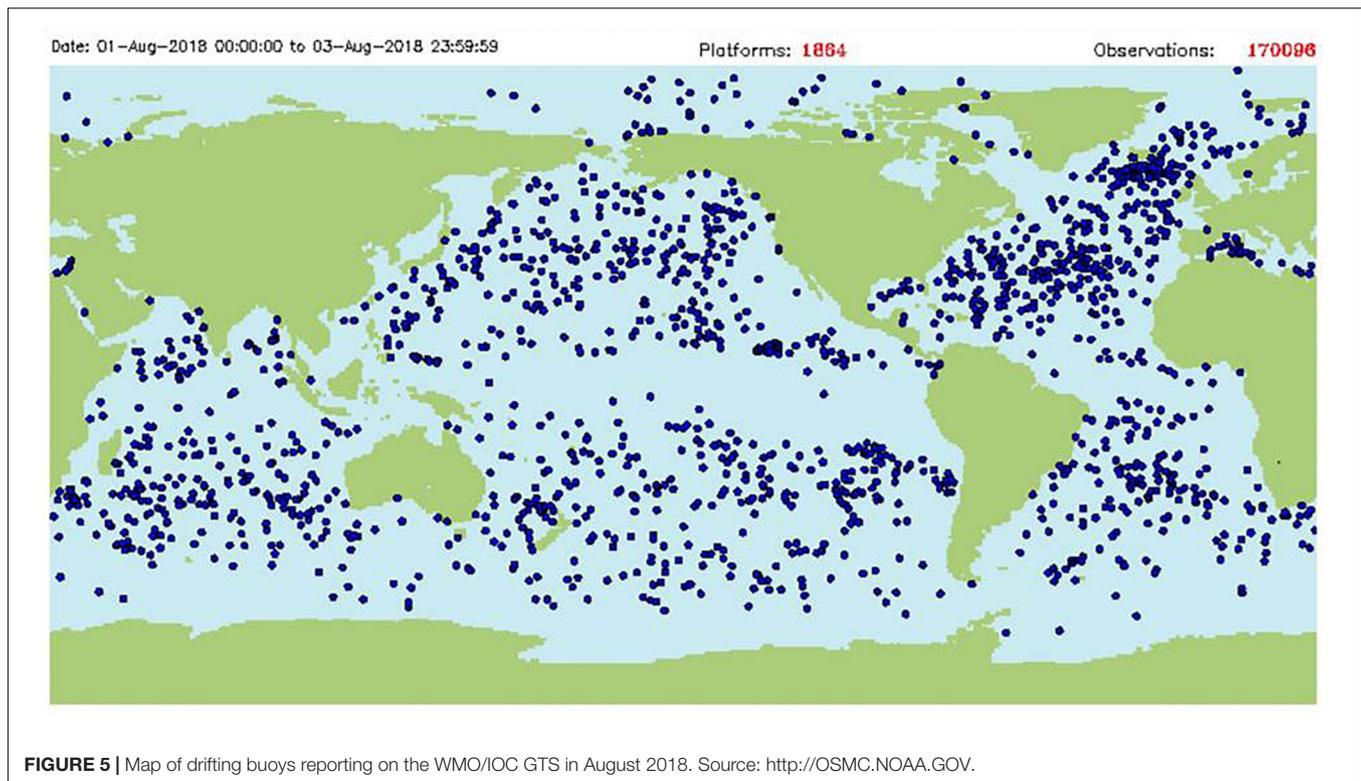

SATELLITE OBSERVATIONS

Satellite observations of polar oceans have been acquired for more than four decades by different measuring systems. The most prominent record comes from microwave radiometers that have been documenting the reduction of sea ice extent (Cavalieri and Parkinson, 2012; Osborne et al., 2018). Remote sensing systems also provide valuable information about other parameters of the sea ice (concentration and thickness) or about the underlying ocean (temperature and circulation). However, despite continuous technological advances and progress in data processing, several weaknesses can be pointed out and should be considered in the future for improving the observing system of polar regions.

Sea Ice Concentration

Satellite-based sea ice observations are required for assimilation to provide accurate polar environmental forecasts. These observations have been proven beneficial in improving prediction skill at different temporal scales when assimilated (e.g., Lisaeter et al., 2003; Lindsay and Zhang, 2006; Stark et al., 2008; Massonnet et al., 2013; Tietsche et al., 2013). In addition, it has also been shown that summer sea ice thickness (SIT) can be constrained to some extent by assimilating sea ice concentration (e.g., Yang et al., 2015). However, there is a significant spread in sea ice concentration products obtained through different retrieval algorithms (Ivanova et al., 2014), which affects the consistency of ocean-sea ice analyses that assimilate those products (Chevallier et al., 2016; Uotila et al., 2018), and the skill of seasonal predictions initialized from those reanalyses (e.g., Bunzel et al., 2016).

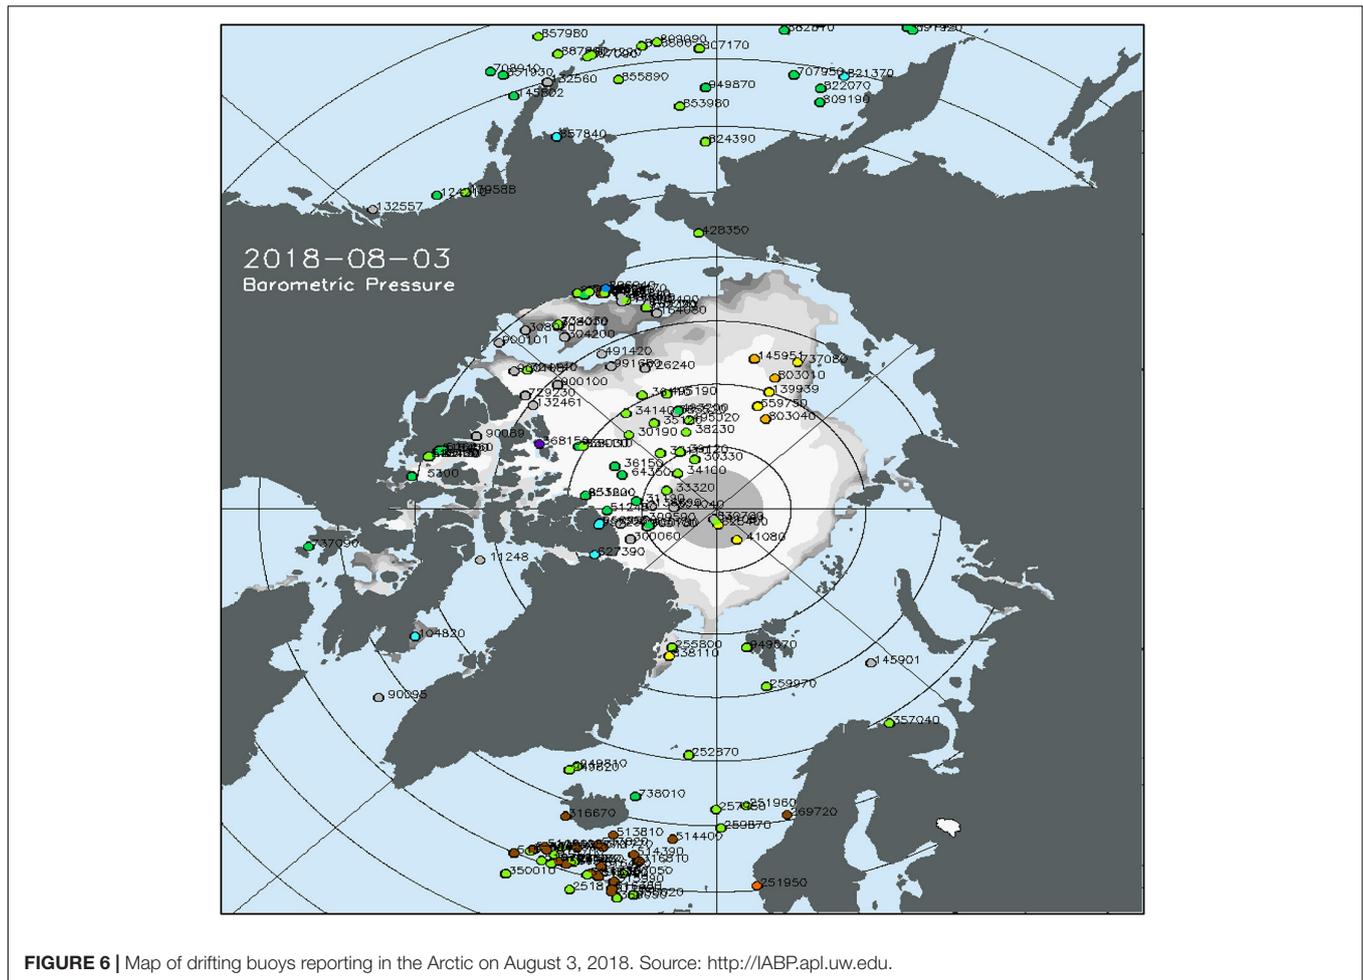

Sea Ice Freeboard and Thickness

Observing SIT from space is a challenge (Kwok and Sulsky, 2010), and gridded data are sparse. Recently SIT has been estimated using altimetry (CryoSat-2; Kwok and Cunningham, 2015), or the L-band radiometers of SMOS (Kaleschke et al., 2012; Tian-Kunze et al., 2014) and NASA's SMAP (Pařilea et al., 2019) satellites, for thinner ice. The ICESat-2 laser altimeter satellite, which was launched in September 2018, is also starting to provide polar SIT estimates.

Sea ice thickness is typically derived from radar altimetry observations of freeboard using the hydro-static equilibrium assumption (e.g., Alexandrov et al., 2010). Both the freeboard

retrieval from altimeter measurements (e.g., Ricker et al., 2014) and the freeboard to thickness conversion are active fields of research. The freeboard to thickness conversion is constrained by the limited availability of auxiliary information (sea ice type, density and snow parameters). Snow thickness on sea ice is still poorly known and is a major source of uncertainty. Snow depth models are not yet satisfactory, and alternative strategies will need to be defined to permit improving snow thickness estimation over sea ice. The joint use of Ku and Ka frequencies may facilitate estimates of the snow load above the ice pack. Studies based on AltiKa (Ka-band about 35.7 GHz) and CryoSat-2 (Ku-band about 13.5 GHz) satellite data have shown that differences in penetration of Ka- and Ku-band are correlated with snow loading on sea ice (Armitage and Ridout, 2015; Guerreiro et al., 2016). Although AltiKa only provides measurements up to 81.5°N and thus cannot provide pan-Arctic data. The combination of laser (ICESat-2) and radar altimetry is also promising for this purpose. A better estimation of freeboard and then thickness would greatly benefit from such measurement complementarity. Data editing is also important on heterogeneous surfaces such as sea ice, where melt ponds act as bright targets in the radar footprint resulting in peaky waveforms that look very similar to returns from leads. As a result, radar altimeter ice thickness products based on CryoSat-2 (e.g., Hendricks et al., 2016) are not available in summer months.

Previous studies showed that assimilation of SMOS ice thickness significantly improves the first-year ice estimates (Yang et al., 2014; Xie et al., 2016). Furthermore, assimilating CryoSat-2 and SMOS SIT leads to a reliable pan-Arctic SIT estimates (Mu et al., 2018; Xie et al., 2018), and also has the potential to

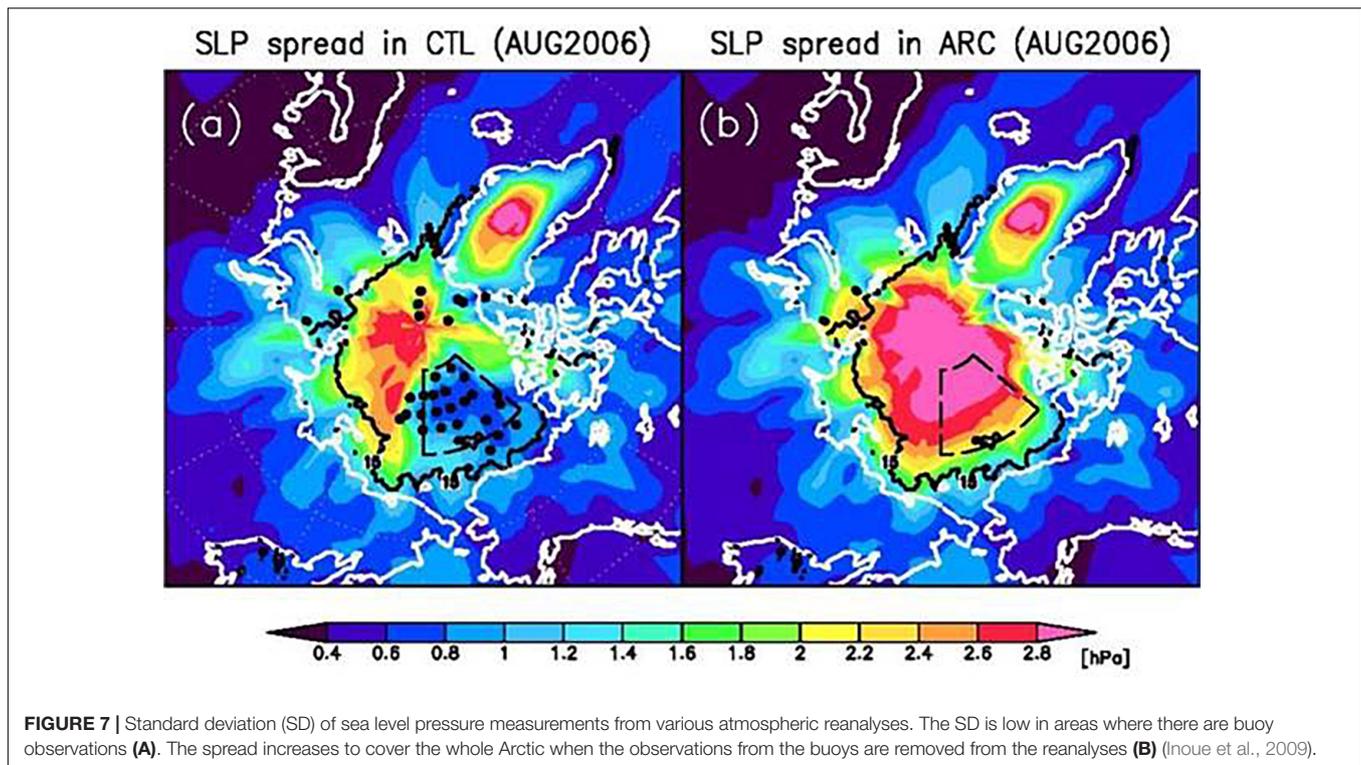

improve seasonal forecasts of Arctic sea ice (Chen et al., 2017; Blockley and Peterson, 2018). The Cryorad mission has been proposed by Macelloni et al. (2017) as a microwave radiometer at very low frequency (down to 500 MHz, lower than SMOS) which longer wavelengths would penetrate through thicker SIT. A critical difficulty related to this mission is the contamination by Radio-Frequency Interference.

Sea Surface Temperature

Satellite SST retrievals in polar regions are challenging. SST is estimated from instruments operating in the infrared (IR) and microwave regions of the spectrum through the so-called atmospheric window regions. IR retrievals in polar regions are often limited by the observed abnormal (often very dry) atmospheric conditions (Vincent et al., 2008). In addition, there are issues in detecting clear-sky ocean conditions that are free from cloud and sea ice, issues which are compounded during polar nights and in areas of persistent cloud. Consequently, frequent measurements of SST at high latitudes rely on microwave imaging instruments. Although not impacted by cloud (unless precipitation), microwave retrievals are impacted by issues in detecting sea ice, especially at the edges of the instrument footprint.

Many SST retrieval algorithms for both IR and microwave rely on *in situ* data to account for both deficiencies in their calibration as well as correcting for atmospheric attenuation. The lack of *in situ* data should be addressed and new innovative approaches are needed (e.g., Castro et al., 2016). The Group for High Resolution Sea Surface Temperature (GHRSSST) coordinates the production of multi-satellite merged SST products. However, the lack of accurate satellite and *in situ* data means there is little consistency between products, especially at high latitudes (Dash et al., 2010).

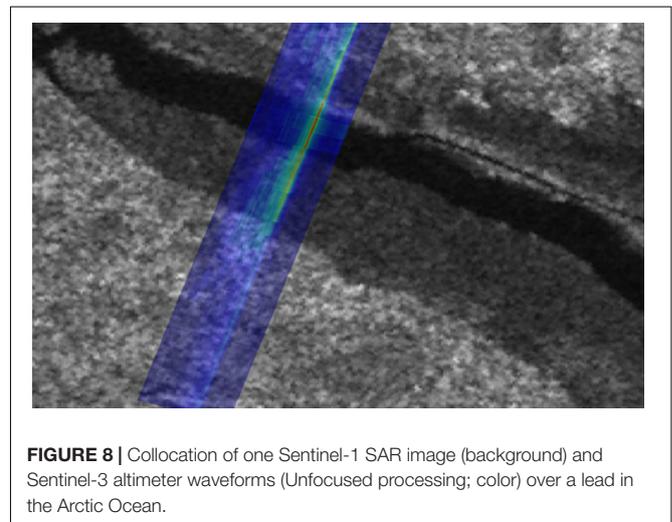

The current lack of continuity of microwave imagers that can be used to derive global SST is a major concern. For polar regions this requires the inclusion of a channel around 6.9 GHz (Gentemann et al., 2010). Currently, the only approved future instrument with this capability is the Chinese Microwave Radiometer Imager (MWRI) onboard the HaiYang-2B (HY-2B). A Copernicus Imaging Microwave Radiometry (CIMR) is currently being studied by the European Space agency (ESA) and JAXA is planning a follow-on to the Advanced Microwave Scanning Radiometer (AMSR2). The AMSR3 and CIMR missions are highly complementary and in combination would provide improved coverage and sampling in polar regions.

Sea Surface Height

Satellite observations of sea level are required to constrain surface geostrophic currents in ocean forecasting systems, and several teams try to tackle the issue (Prandi et al., 2012; Andersen and Piccioni, 2016; Armitage et al., 2016). However, sea level observations from altimetry over polar regions suffer from three main issues:

1. First, the altimeter constellation has mainly been created to fulfill ocean requirements for the ice-free regions, in particular with regard to orbit coverage/inclination. With the exception of the CryoSat-2 mission, which covers the Arctic Ocean up to 88°N, altimetry missions do not cover poleward of 82°, leaving a vast region without any measurement.
2. Second, although significant progress has been made to distinguish whether measurements correspond to open ocean, ice floes or leads within the sea ice, further progress is still needed to unambiguously identify the different returns, in particular in complex mixed water/floe areas. Exploitation of close match-ups between SAR imagers and altimeter measurements as the potential for improving the identification of leads and the editing of ambiguous measurements coming from melt ponds or polynya in the melt season. An example of such collocation between a Sentinel-1 image and Sentinel-3 measurement is provided in **Figure 8** (Longépé et al., 2019).
3. Lastly, the accurate retrieval of absolute SSHs, and therefore currents, in polar regions also suffers from degraded corrections. Tide models show higher

inter-model variability in polar regions than anywhere else, mean sea surfaces are not as accurate. An effort to refine the geophysical corrections applied to altimeter measurements is needed to improve polar SSH accuracy levels and make them useful for assimilation in operational oceanography systems.

As a result, there is currently no dedicated operational Arctic sea level product for assimilation in models. Efforts to provide Arctic sea level information in CMEMS, following the current SL-TAC products are ongoing.

Other innovative concepts such as SKIM's (Sea surface Kinematics Multiscale monitoring, Arduin et al., 2018) rotating radars at different angles offer opportunities to monitor waves, surface currents and possibly sea ice drift. The Surface Water Ocean Topography (SWOT) mission also has the potential to provide innovative new observations for sea level and sea ice cover, although its orbit is lower than 70 degrees.

Sea-Ice Drift

Sea ice drift data are now obtained all year round both in the Arctic and Antarctic by pattern cross-correlation of scatterometers and passive microwave images. For global information, Scanning Multichannel Microwave Radiometer (SMMR), the Special Sensor Microwave/Imager (SSM/I) and SSMI/Sounder (SSMIS), and the Advanced Very-High-Resolution Radiometer (AVHRR) are used. Currently, daily products (e.g., Lavergne et al., 2010; Tschudi et al., 2019) typically use data acquired at Day D-1, with span of 24 or 48 h. In addition, buoy observations of the International Arctic Buoy Program (IABP), and ice motion derived from NCEP/NCAR surface wind vectors can be used. Low resolution ice drift products are calculated daily from aggregate charts derived from radiometers (e.g., SSMIS, AMSR2) or scatterometers (e.g., ASCAT). The typical resolution of these input images is 12.5 km. The large acquisitions, the repetition of the acquisitions, and their independence with respect to the weather conditions allow a daily polar coverage.

Sequences of SAR images can be used to derive higher resolution drift information. Algorithms have been developed to calculate ice drift from successive pairs of SAR images covering a common area. They are generally based on a spatial correlation calculation between these images, at several resolution scales (from the coarsest to the finest). In Europe, Sentinel-1 is used by DMI to produce an operational sea ice drift product as part of CMEMS (Pedersen et al., 2015). SAR data from Sentinel-1 A/B constellation allow the derivation of daily fields of sea ice deformation at 2 km resolution (Korosov and Rampal, 2017). The algorithm developed by FMI has been operational in the Baltic Sea since early 2011 (Karvonen, 2012), using the wide Radarsat-1 ScanSAR mode and the wide swath ASAR Envisat mode data.

Revisit is the key here: higher revisit of SAR images is naturally required. Algorithms often use image tracking features between consecutive images. This type of algorithms perform better if the images are taken with the same frequency, short interval, and ideally same geometry. Joint acquisition of multi-frequency SAR would enable accurate sea ice drift products, which is not possible with stand-alone current mono-frequency SAR missions. Cross-pol channel is often preferred as it is less sensitive to incidence angle variation (at least for C-band SAR). Drift cannot be calculated in areas without characteristics (i.e., so-called "level ice" and open water areas). These are of course only estimates of the integrated ice trajectories between the time instants corresponding to the SAR acquisition times. Lagrangian drift products are typically 2-day trajectories with coarse resolution (62.5 km) and are not often assimilated even though the accuracy is satisfactory (3 km for 2-days drift).

The TOPAZ4 system does assimilate these sea ice drift operationally, although the effect is relatively weak (Sakov et al., 2012). A different sea ice rheological model, more sensitive to winds, may be more adapted to assimilate this data (Rabatel et al., 2018). More precise (500 m for 1-day drift) and detailed (10 km resolution) sea ice drift products are now obtained year-round from Sentinel-1 SAR images, which cover about 70% of the Arctic as of February 2019.

AIR-SEA FLUX MEASUREMENTS IN POLAR OCEANS

The Need and Challenge for Air-Sea Flux Observations in Polar Regions

Air-sea fluxes quantify the exchanges of heat, momentum, freshwater, gases and aerosols between different components of the polar climate system (i.e., atmosphere, water column, sea ice). Flux observations are essential for understanding the global energy budget (Trenberth and Fasullo, 2010), for evaluating forecasting and climate models, and for evaluating processes such as ocean heat uptake and mixed-layer temperature and SST variability (e.g., Dong et al., 2007). However, *in situ* air-sea or air-ice flux observations are extremely sparse in polar regions (e.g., Bourassa et al., 2013), with almost no winter observations in the Southern Ocean (e.g., Gille et al., 2016; Swart et al., 2019) or in ice-covered ocean domains in both the Arctic and Antarctic (e.g., Taylor et al., 2018). Quantifying air-sea exchange in regions with sea ice requires specialized approaches that must account for spatio-temporal heterogeneity. This has led to significant gaps in our knowledge of both air-sea and air-sea-ice exchanges.

Since there are few reliable near-surface atmospheric observations to serve as constraints, reanalyses and satellite derived surface flux products have major errors and vary considerably between products (Josey et al., 2013; Bentamy et al., 2017; Schmidt et al., 2017; Taylor et al., 2018). For example, in the Southern Ocean, atmospheric models (and reanalyses) have large air-sea heat flux biases, including substantial short-wave errors related to their inability to adequately represent super-cooled liquid cloud water (Bodas-Salcedo et al., 2014, 2016), and these errors appear to bias coupled model SST (Hyder et al., 2018), sea ice, and wind (Bracegirdle et al., 2018). Moored-buoy flux observations or year-round ice camps are required to evaluate and ultimately improve these products but to date buoys have been deployed in only two locations in the Southern Ocean (Schulz et al., 2012; Ogle et al., 2018) and in only a few instances in the Arctic, (Taylor et al., 2018). The Surface Heat Budget for the Arctic Ocean (SHEBA) program offered the only year-round ice camp in the Arctic (e.g., Persson et al., 2002), although Multidisciplinary drifting Observatory for the Study of Arctic Climate (MOSAiC; see MOSAiC) will soon extend this. The Southern Ocean Observing System (SOOS) working group on Southern Ocean air-sea fluxes (SOFLUX; Swart et al., 2019) has been working to coordinate observing system capabilities and requirements for high-latitude air-sea fluxes.

Impact of Flux Uncertainty on Forecasting/Prediction

There are significant advantages to forecasting with a coupled atmosphere-ice-ocean system, especially on longer timescales. The intrinsic turbulence of the atmosphere limits predictive skill to timescales of days to weeks (Mariotti et al., 2018), whereas the large-scale ocean is predictable on monthly time scales. This provides a mechanism by which the predictability of atmosphere may be extended allowing skillful seasonal predictions.

A particular limitation in this regard is with respect to the significant uncertainty in the atmosphere-ocean boundary layer, made even more egregious when considering sea ice. Boundary layer dynamics involve vertical scales unresolved by coupled forecasting systems, which must be parameterized (e.g., Pullen et al., 2017). The exchanges between components are parameterized by so-called bulk formulae, which estimate air-sea-ice exchanges based on near-surface large-scale properties. Currently, the uncertainties in bulk formulae are a primary bottleneck to seasonal prediction (Penny and Hamill, 2017). In other words, even if we had a perfect ocean model with perfect initial conditions, the information retained in the monthly ocean prediction would be degraded when propagated to the atmosphere due to uncertainty in estimating the true exchanges (Vecchi et al., 2014). Therefore, a priority in the coming decade must be to gather *in situ* estimates of air-sea-ice exchanges in the context of large-scale properties informing how to minimize errors in the bulk formulae parameterizations. Efforts such as YOPP, MOSAiC and ONR Marginal Ice Zone (MIZ) project are examples of projects aiming to address this gap.

We recommend further research to determine how best to represent these exchanges in a coupled forecasting system, with a focus on determining what aspects of boundary layer physics need to be resolved and what can be skillfully parameterized. For parameterized physics, we require that process studies be carried out to determine parameterizations and parameterization coefficients, including identifying the observations that should be sustained to validate estimated fluxes. Addressing these areas are primary goals to enable weekly-to-seasonal skillful predictions in the polar regions.

FORECASTING SYSTEM EXPERIMENTS

Understanding how assimilating more observations will impact modeled analyses and short-term forecasts is of fundamental importance as new coupled models are being developed. For instance, preliminary results using a regional coupled model [CAFS from the NOAA Earth System Research Laboratory (ESRL)] demonstrated that current ocean reanalyses do not include realistic representation of subsurface water masses relative to observations taken in 2015 and 2016 (including Arctic Heat data). Forecast experiments using a high-resolution fully coupled regional model show that these water masses impact sea ice evolution on synoptic time scales through upper-ocean mixing and heat flux at the ice-ocean interface. It is expected these effects will increase as sea ice continues to decline and surface heat flux processes increase. In addition, assimilating

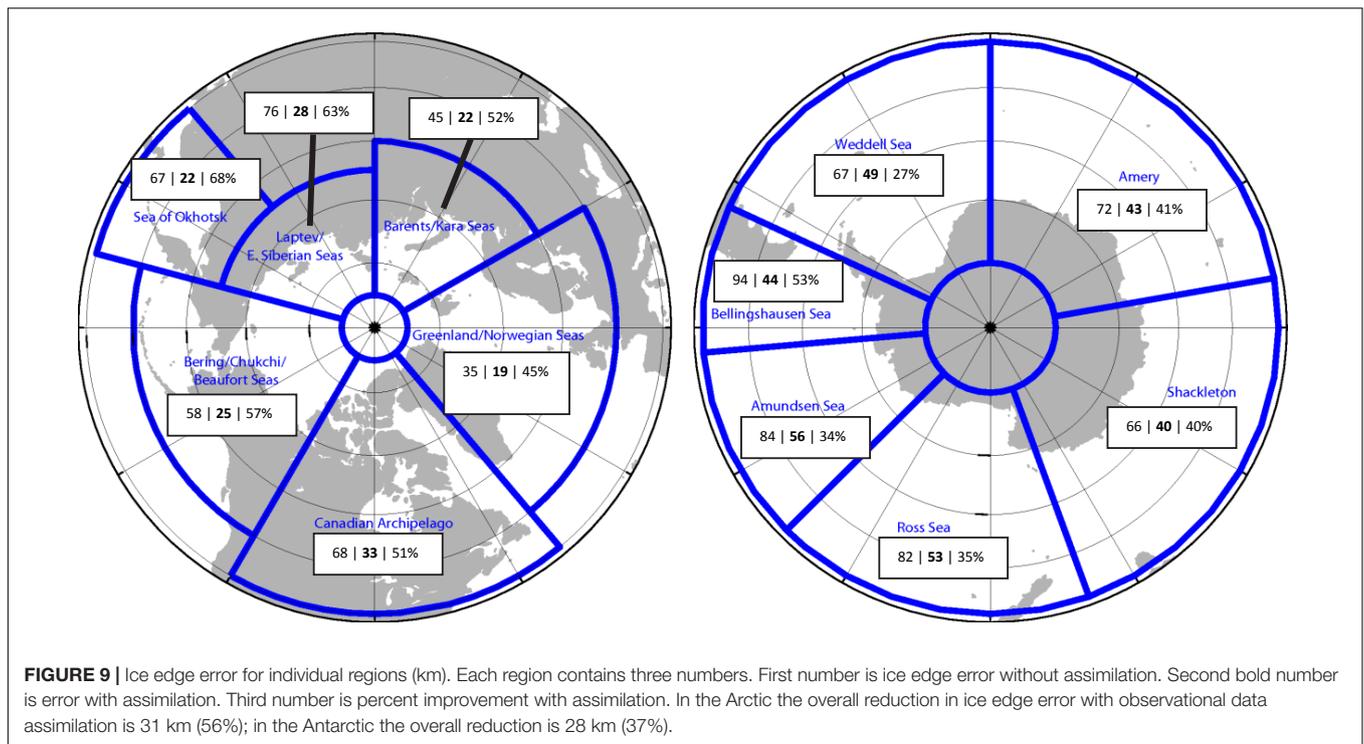

real-time ocean observations in the initial forecast conditions allows for the identification of biases in the coupled system, which are difficult to isolate when the ocean is allowed to drift away from the observed state. Some studies (e.g., Inoue et al., 2015; Lien et al., 2016; Xie et al., 2017) have begun to show the important potential impact of assimilating enhanced observations on model-based analyses and short-term sea ice forecasts. Additional focused research in this area would allow us to explore coupled model data assimilation issues, better understand physical processes, and assess model performance in comparison to non-coupled (atmospheric) model frameworks. In the next sections, we review a few results from operational centers.

Impacts of Arctic and Antarctic Observations in U.S. Navy Coupled Ice-Ocean Models

The ability to forecast sea ice conditions is of crucial importance for maritime operational planning (Greenert, 2014). The current U.S. Navy operational sea ice forecast system is the Global Ocean Forecast System (GOFS) version 3.1. GOFS utilizes the Los Alamos Community Ice Code (CICE) version 4.0 (Hunke and Lipscomb, 2008) sea ice model, which is two-way coupled with the HYbrid Coordinate Model (HYCOM) (Metzger et al., 2014) ocean model. The grid resolution is $1/12^\circ$, with horizontal resolution approximately 3.5 km at the poles. Atmospheric forcing is provided by the NAVY Global Environment Model (NAVEM; Hogan et al., 2014). The precursor to GOFS 3.1 was the Arctic Cap Nowcast/Forecast System (ACNFS; Posey et al., 2015). ACNFS is a coupled ice/ocean model similar to GOFS with two main differences: (1) ACNFS only covered areas north of 40°N , and (2) in ACNFS HYCOM has 32 ocean layers compared to 41 in GOFS. An important part of both GOFS and ACNFS is the assimilation of observational data, which is accomplished using the Navy Coupled Ocean Data Assimilation (NCODA) system (Cummings and Smedstad, 2014).

Assimilation of observational data is performed to reduce errors in model forecasts that can result from many factors including non-linear processes that are not deterministic responses to atmospheric forcing, poorly parameterized physical processes, limitations in numerical algorithms, and limitations in model resolution. Polar observational data assimilation is an essential part of GOFS forecasts. Sea ice concentration observations are currently assimilated from the Defense Meteorological Satellite Program (DMSP) SSMIS and AMSR2. These observations are used in conjunction with the Interactive Multi-sensor Snow and Ice Mapping System produced by the U.S. National Ice Center (NIC; Helfrich et al., 2007). A full description of the assimilation process in GOFS and ACNFS can be found in Hebert et al. (2015).

The impact of data assimilation in the U.S. Navy models is significant. One measure that the U.S. Navy uses to determine the accuracy of the modeled sea ice edge (defined in Hebert et al., 2015) is the distance between it and the sea ice edge determined daily by analysts at NIC. The sea ice edge error over six regions in each hemisphere is shown in **Figure 9** as well as the entire Arctic/Antarctic. GOFS was run for 1 year (2014) without data assimilation and compared to the current GOFS

system with ocean and sea ice data assimilation, including sea ice concentration. The impact of assimilating these observations was to reduce the sea ice edge error in the Arctic by 56% (31 km) and in the Antarctic by 37% (28 km), with a reduction in sea ice edge error for each region ranging between 27 and 68%.

As model resolution increases, so does the need for high-resolution observations. SSMIS and AMSR2 are relatively coarse resolution (25 and 10 km, respectively) compared that of GOFS. Higher resolution (less than 1 km) sea ice concentration observations are available from the Suomi NPP Visible/Infrared (VIIRS). Although VIIRS observations can be obstructed by clouds, including high resolution VIIRS ice concentration into our data assimilation further reduced GOFS ice edge error by 19% (5 km) in the Arctic and 11% (4 km) in the Antarctic. This result points to the need for higher resolution sea ice concentration observations to use in model applications.

In an earlier study using ACNFS to examine the impacts of sea ice concentration observations in ship routing and planning in boreal winter (January–March), assimilating satellite ice concentration observations reduced the projected track an ice breaker would take to a ship near the sea ice edge by an average of 150 km versus not assimilating sea ice concentration observations. This improved the time for planning operations by 12 h and reduced the distance a ship needs to prepare to encounter ice by 212 km.

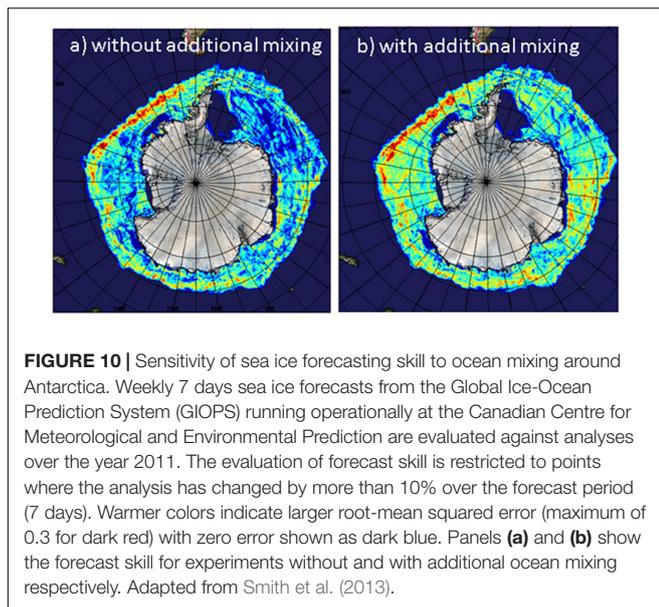

SIT observations are also important. Currently, pan-Arctic SIT observations on a daily basis are not available. Only limited satellite tracks per day are available that are aggregated on a monthly basis. In a recent study by Allard et al. (2018), ACNFS was re-initialized on March 15th using the March 2014 monthly CryoSat-2 thickness observations and integrated for 18 months.

It showed a reduction in SIT bias by 0.75–0.97 m compared to ACNFS SIT without CryoSat-2 initialization. The impact of this one-time re-initialization was significant and work is underway to assimilate daily satellite track SIT observations on a daily basis.

Sensitivity of Sea Ice Forecasting Skill to Ocean Mixing Around Antarctica

The rapid evolution of the sea ice cover can have important impacts on coupled environmental predictions through a variety of processes (Smith et al., 2013). These include the formation of leads and coastal polynyas, as well as changes in the ice cover along the marginal ice zone (MIZ). In these regions, the rapid formation, melt and advection of the sea ice cover can modify atmosphere-ocean fluxes on relatively short timescales. Interestingly, small-scale ocean variability has a role to play here as the timing and intensity of changes will be sensitive to the surface ocean mixing layer depth, water mass properties and mesoscale ocean circulation (e.g., Zhang et al., 1999).

As an illustration of the sensitivity of sea ice evolution to ocean mixing, an evaluation of the skill of two sets of sea ice forecasting experiments is shown in **Figure 10**. The first set uses the standard configuration of the Global Ice-Ocean Prediction System (GIOPS; Smith et al., 2016) running operationally at the Canadian Centre for Meteorological and Environmental Prediction. GIOPS combines the Système Assimilation Mercator (SAM2) ocean analysis system with a 3DVar ice analysis (Buehner et al., 2013) to produce daily 10-day forecasts using the NEMO ocean model at 1/4° resolution coupled to the CICE ice model. The second set of experiments is identical to the first with the parameterization for surface wave breaking deactivated. **Figure 10** shows the 7-day forecast skill evaluated

against 3DVar ice analyses from weekly forecasts over 2011. The verification method used here (Lemieux et al., 2016) restricts the error evaluation to areas where the ice concentration analysis has changed by more than 10% over the forecast lead time (i.e., 7 days). This verification method has the advantage that it focuses the evaluation on ‘hot spots’ of activity, predominantly in the marginal ice zone.

From **Figure 10** it can be seen that a small modification to the ocean vertical mixing can have a first order impact on the ice forecast errors. Interestingly, while the surface wave breaking parameterization degrades ice forecast skill, it does lead to an improvement in water mass properties over ice-free waters (as evaluated against Argo profiles; not shown). This is perhaps not surprising given that the mixing regime in polar regions is quite different from that at lower latitudes. This highlights the need for an expanded under-ice ocean monitoring program to be able to adequately model vertical mixing and constrain water mass properties and mixed layer depths.

Impact of Temperature and Salinity Profiles in the CMEMS Arctic MFC

There have been special observing periods of the Arctic and Antarctic in the past, in particular the successive International Polar Years (IPYs), the latest of which took place in 2007–2009 (with a gradual ramping up of ocean observing systems in the preceding years). Looking back at the impact of a recent IPY in a period with similar low-ice-coverage conditions in the Arctic, expanded sea ice in the Antarctic, and similar satellite coverage as today can provide another measure of the expected impact of the YOPP Special Observing Periods.

In the Arctic, the TOPAZ4 reanalysis is based on a regional configuration of the HYCOM model coupled to an early version of the CICE model at 12 km resolution. It assimilates both satellite and *in situ* observations using an Ensemble Kalman Filter (Sakov et al., 2012). As of 2018, the TOPAZ4 reanalysis system is almost

identical to the real-time physical forecasting system used in the Copernicus Arctic MFC and operated by MET Norway (Melsom et al., 2015; Xie et al., 2017). It assimilates the same types of ocean and sea ice observations: along-track sea-level anomalies from altimeters, sea surface temperatures, sea ice concentrations and drift and *in situ* temperature and salinity profiles.

Ocean models have well-known limitations in simulating the advection of Atlantic Waters into the Arctic (Ilıcak et al., 2016), which for a model like TOPAZ4 results in a typical cold bias of the 300–800 m water temperature by 0.5 K (see **Figure 11**, blue line) and regional differences by 1.5 K typically (green line). During the IPY time period, the assimilation of ITPs is able to constrain this bias down to 0.1 K and reduce the regional differences below 1 K. The end of the IPY in 2009 relaxes the constraint and the bias and RMS errors return to larger values, although slightly lower than before the IPY (i.e., there is no “dynamical shock” after the IPY stops). Even though the quantitative impact on the TOPAZ4 system is dependent on the practical setup of the model and its assimilation scheme, the qualitative behavior may apply to other forecasting systems based on similar types of models and data assimilation schemes and indicates that a density of ITP profiles at least equal to that of the IPY should be sustained continuously to constrain efficiently the Atlantic Water properties in the Arctic.

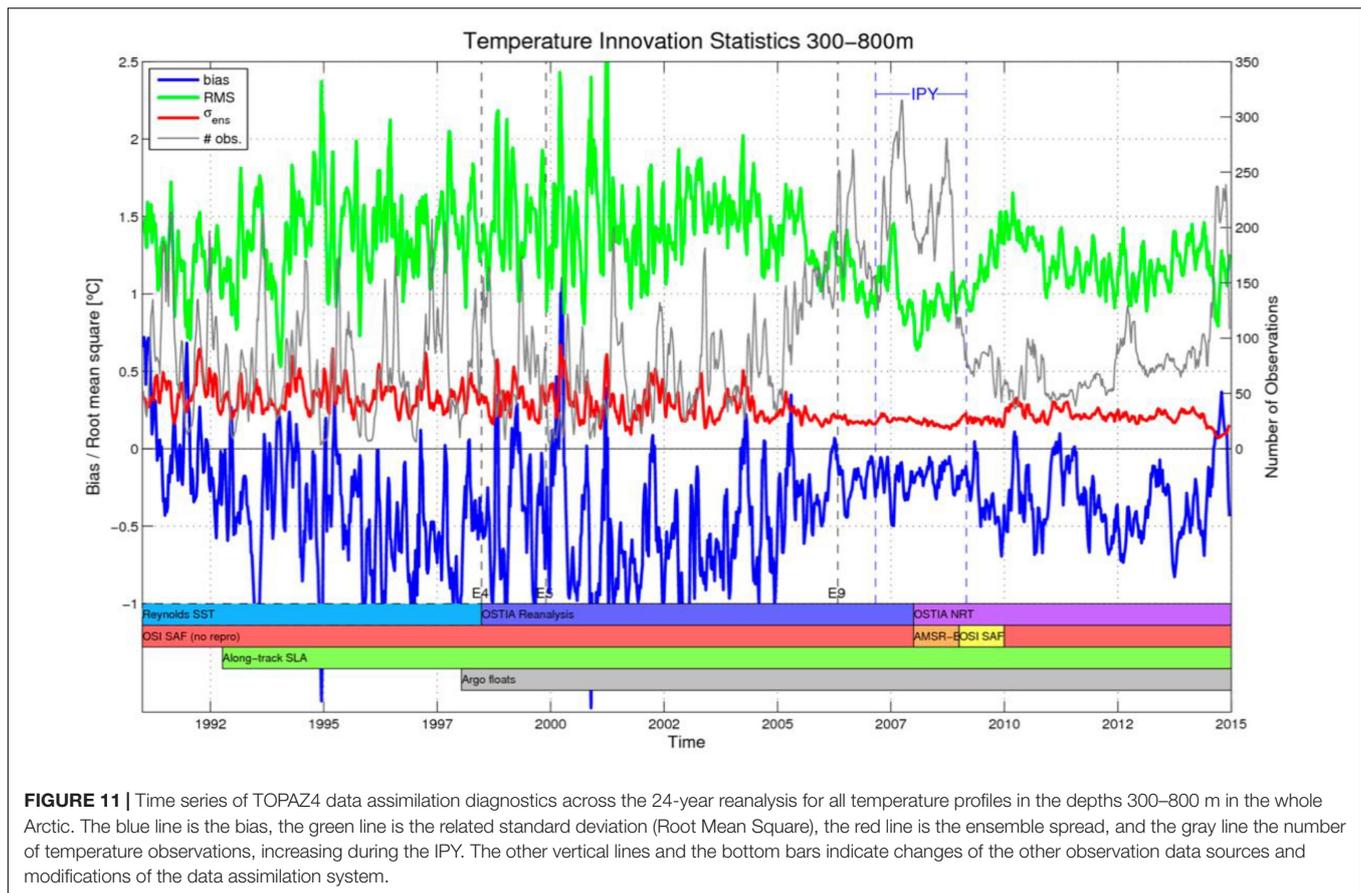

NOAA-ESRL/CIRES Coupled Arctic Forecast System

NOAA ESRL has provided experimental, daily, 10-day forecasts of Arctic weather and sea ice evolution to stakeholders during freeze-up seasons since 2015 and daily forecasts year-round starting on February 14, 2018. CAFS produces high-resolution (10 km) regional coupled-model Arctic forecasts using global 0.5° GFS forecast fields for lateral forcing. The current configuration of the model includes the POP2 dynamical ocean model (adapted from Maslowski et al., 2012), the CICE5 sea ice model (Hunke et al., 2015), the NCAR CLM4.5 land model, and the WRF3.6 ARW atmospheric model, coupled by the NCAR CPL7 coupler. The domain is the Arctic basin and surrounding coastal regions, including Bering Strait, to provide model guidance for the National Weather Service (NWS), and Fram Strait, to include the complete planned Multidisciplinary drifting Observatory for the Study of Arctic Climate campaign (MOSAiC) domain.

The CAFS forecasts are being used by NOAA ESRL to identify sources of skill on sub-seasonal time-scales due to coupled ocean-ice-atmosphere processes and by stakeholders as model guidance for sea ice forecasts. Real-time CAFS products are made available to the community¹². Figures and animations from the 10-day forecasts are provided for sea ice, atmosphere, and ocean variability, as well as, an archive of model output for users to download. These forecasts are being used for model guidance by the NWS Alaska Sea Ice Program, the NOAA Arctic Testbed, the U.S. National Ice Center, and by the U.S. Navy and NOAA for operations during Arctic campaigns.

Coupled Arctic Forecast System forecasts use initial conditions that ingest SIT measurements from ESA’s CryoSat-2 and SMOS satellites and the NASA Jet Propulsion Laboratory Multi-Scale Ultra-high Resolution Sea Surface Temperature

¹²<https://www.esrl.noaa.gov/psd/forecasts/seaice>

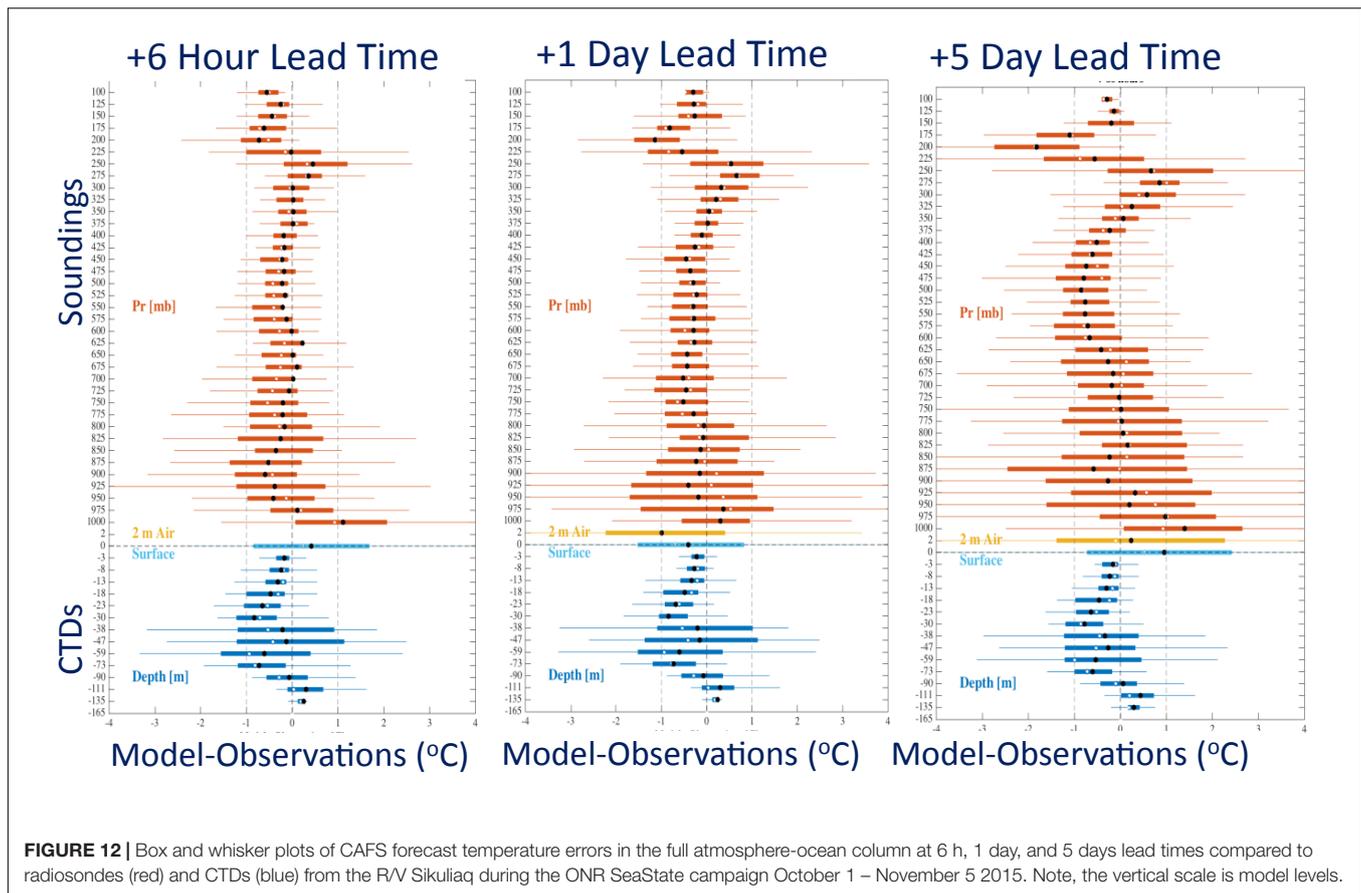

(MUR) SSTs and sea ice concentration. The MUR SSTs are used to initialize the ocean mixed layer with a mixed-layer depth diagnosed from the model. In order to identify whether using these satellite products in the initial conditions increases the skill of the 10-day forecasts, a series of 10-day hindcasts were performed for the time period of the ONR SeaState DRI, Oct. 1–Nov. 5 2015. The hindcasts are setup exactly like the real-time forecasts except the lateral boundary conditions are the GFS analyses instead of the GFS forecasts, in order to identify potential model biases. In addition, similar to the forecasts, hydrometeor mass and number are initialized with fields from the first day of the previous day's hindcast to reduce spin-up time of cloud fields.

Intensive measurements were taken of the ocean, surface, and atmospheric state during the SeaState campaign. This provides for a comprehensive observational database for model validation. **Figure 12** shows the model error of the ocean-atmosphere state at the location of the R/V Sikuliaq over the 6-week campaign at lead times of 6 h, 1 day, and 5 days. At a 6-h lead time, there are equivalent errors in the ocean and atmosphere, less than 0.5°C . Due to the initialization of the ocean mixed-layer with satellite SSTs, errors in the ocean grow slowly up to 5-day lead times. However, differently in the atmosphere, errors in the lowest 2 km grow rapidly with errors greater than $+1^{\circ}\text{C}$ in the near-surface temperatures and errors greater than -1°C at the top of the atmospheric boundary layer. This is an indication that the model

is unable to maintain the observed boundary layer stratification and rapidly evolves into a less-stable state. It would not have been possible to identify this model bias without initialization of the ocean/ice state. Process studies are currently underway to identify if this bias is due to cloud processes or boundary layer parameterizations.

Quantitative Network Design

The Quantitative Network Design (QND) approach constitutes a computationally efficient alternative to Observing System Experiments (Fujii et al., 2019). The approach can be used to inform the design of observing networks or space missions. QND evaluates a set of observations (network) in terms of its constraint on a target quantity, i.e., a quantity of interest. This evaluation is performed in a modeling system that is capable of simulating counterparts of the observations and of the target quantity from a set of unknowns in the system (control variables). For a detailed description of the formalism we refer to Kaminski and Rayner (2017). Briefly, it proceeds in two steps: In the first step, the observational information is used to infer the uncertainty in the posterior control vector, $C(x)$, that is consistent with the observational uncertainty, $C(d)$, and the prior uncertainty of the control vector, $C(x_0)$ [Equation (1)]. In the second step the uncertainty in the control vector is mapped onto an uncertainty in the target quantity, $\sigma(y)$ [Equation (2)]. Both steps use appropriate sensitivities (linearizations/response

functions) of the modeling system. The first step, an inversion step, is formalized by

$$C(x)^{-1} = M'^T C(d)^{-1} M' + C(x_0)^{-1}, \quad (1)$$

and the second step by

$$\sigma(y)^2 = N' C(x) N'^T + \sigma(y_{mod})^2, \quad (2)$$

where M' (N') denotes the sensitivity of the vector of observations (the target quantity) with respect to the control vector, as simulated by the modeling system, and $\sigma(y_{mod})$ is the residual uncertainty in the simulation of the target quantity that remains even for a perfect control vector. The approach represents a network through observational locations and times and the observational uncertainty, but does not require real observations. Consequently, it can evaluate hypothetical networks/space missions based on assumed instrumental specifications and space-time coverage. Observations can range from point-scale (*in situ*) to gridded data sets or level-1 satellite data, if appropriate forward models/observation operators mapping the model's state variables onto the respective data stream (Kaminski and Mathieu, 2017) are available.

Historically, QND was first applied by Hardt and Scherbaum (1994) to optimize the locations of a set of seismic sensors. Rayner et al. (1996) applied the approach to the *in situ* sampling network for atmospheric CO_2 . For the physical sea ice-ocean system in

the Arctic domain, Kaminski et al. (2015) applied the approach to evaluate idealized flight transects derived from NASA's Operation IceBridge airborne altimeter ice surveys. Target quantities were 10-day to five-month forecasts of snow and ice volumes over areas relevant for maritime traffic (along the Alaskan coast) and offshore resource exploration (Chukchi Sea). The control vector was composed of physical constants in the model's process representations as well as initial and boundary conditions.

In an activity funded through ESA's Support to Science Element as a contribution to YOPP, Kaminski et al. (2017) constructed the Arctic Mission Benefit Analysis (ArcMBA) system. The system exploits the fact that model sensitivities at observational times and locations as well as the target quantities can be pre-computed, so that the actual assessment of a data set requires only matrix multiplications and inversions [Equation (1) and Equation (2)]. This means the assessment can be performed so fast that the ArcMBA system could be used as an interactive tool to assist decision makers, for example, in a meeting. Currently the system uses pre-computed model sensitivities M' for observations of SIT, sea ice freeboard, radar freeboard, laser freeboard, and snow depth along with precomputed model sensitivities N' for forecasts of snow and ice volumes for three regions along the Northern Sea Route (North-East Passage) respectively denoted by West Laptev Sea, Outer New Siberian Islands, and East Siberian Sea. These sensitivities were computed with the Max-Planck-Institute Ocean Model

(MPIOM, Jungclaus et al., 2013) in a global configuration with high resolution over the Arctic (Niederrenk, 2013). The control vector is composed of physical constants in the model's process representations as well as initial- and boundary conditions.

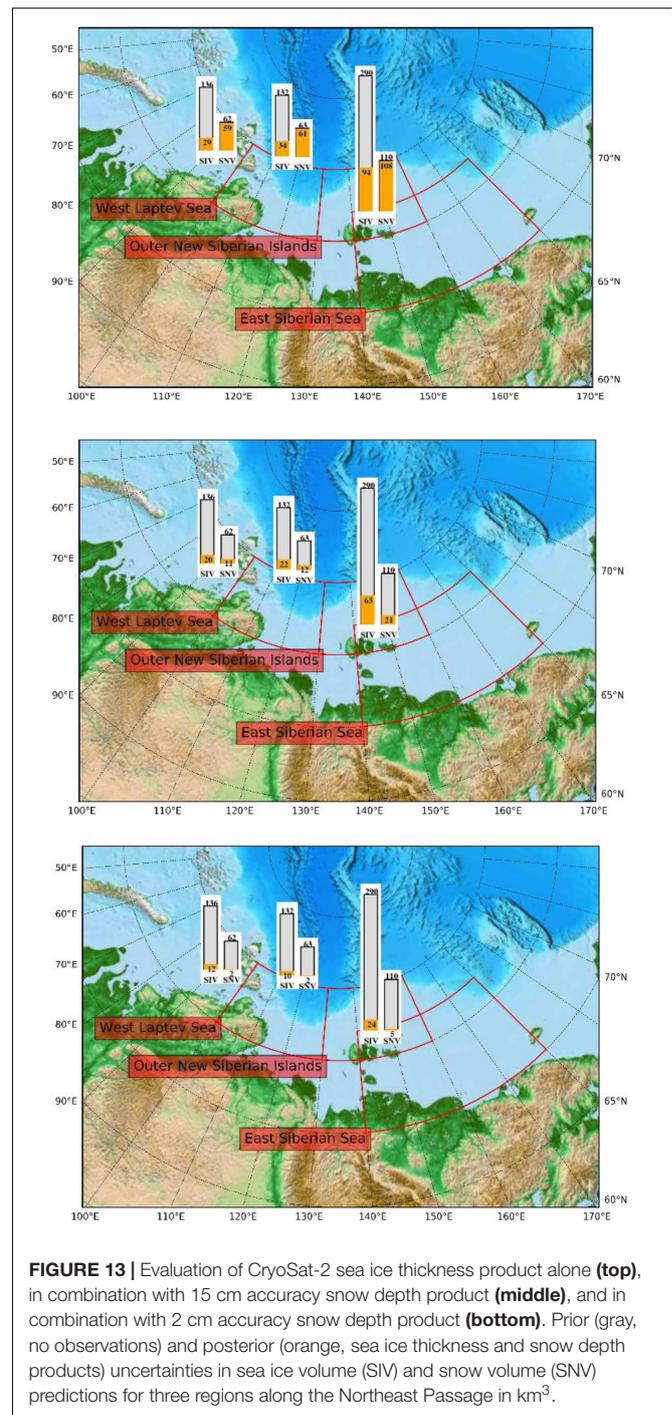

Kaminski et al. (2017) applied the system to evaluate real and hypothetical remote sensing products. The real products were monthly SIT, sea ice freeboard, and radar freeboard, all derived from CryoSat-2 by AWI. These real products were complemented by two hypothetical monthly laser freeboard products (2 and 20 cm accuracy, respectively), as well as two hypothetical monthly snow depth products (2 and 15 cm accuracy, respectively). Target quantities are 4-week forecasts of snow and ice volumes over three target regions along the Northern Sea Route.

As an example, **Figure 13** shows the posterior uncertainty in snow and ice volumes over the three target regions, when the CryoSat-2 SIT product (Ricker et al., 2014) is used alone, in combination with the hypothetical snow depth product with 15 cm accuracy, or in combination with the hypothetical snow depth product with 2 cm accuracy. To sharpen the contrast between the observational scenarios, $\sigma(y_{\text{mod}})$ (which acts as an offset) is set to zero (perfect model scenario). Comparison of the top and middle panels shows the added value of the hypothetical snow product, not only for the snow volume forecast but also for the sea ice volume (SIV) forecast. SIV is sensitive not only to initial SIT but also to initial ice concentration and snow depth, which are both constrained by the snow depth product. SIV is also sensitive to some of the process parameters that are constrained by snow depth, notably the ice strength, see Kaminski et al. (2017) for details. Comparison of the middle and top panels shows the added value of a higher accuracy in the snow depth product. Increasing the accuracy from 15 to 2 cm results in a reduction in uncertainty of the SIV forecast for the East Siberian Sea target region from 63 to 24 km³.

The ArcMBA can be extended to cover further Earth Observation (EO) products and further target variables. In the setup used here, the model can simulate a range of sea ice-ocean variables in addition to those considered in the present study (e.g., ice drift, mixed layer depth, freshwater/sea surface salinity, SST, circulation). Switching to a more comprehensive model configuration would enable the investigation of yet further variables. For example the model can be operated with its biogeochemistry module HAMOCC activated (Ilyina et al., 2013) or in a mode coupled to an atmospheric general circulation model and thus enable the analysis of biogeochemical products/target quantities or Arctic mid-latitude linkages. The extension of ArcMBA by a terrestrial biosphere component is planned, which will allow joint assessment of ocean and land observations.

INTERNATIONAL EFFORTS TO ADDRESS GAPS IN POLAR OCEAN OBSERVATIONS

Various international efforts contribute to coordinate and support the vast and complex polar observing networks. These networks are maintained by a collection of national and international efforts and scientific projects. These include

national efforts outlined above, such as IAOOS, FRAMs and NorArgo as well as diverse multi-platform observing projects such as the US SODA (Stratified Ocean Dynamics of the Arctic) program (Lee et al., 2016) that include many of the types of platforms described in Section “*In situ* Observations of Temperature and Salinity” (WHOI ITPs, ALAMO floats, drifters, gliders). In the south, these efforts are coordinated through the Southern Ocean Observing

System (SOOS; Newman et al., 2019) supported by the Scientific Committee on Ocean Research (SCOR) and the Scientific Committee for Antarctic Research (SCAR).

A clear need for a coordinated approach for the Arctic has arisen following the International Polar Year (IPY) and is being developed through a series of bi-annual Arctic Observing Summits (Murray et al., 2018). These summits contribute to a broad initiative by Sustaining Arctic Observing Networks (SAON) that has arisen from the International Arctic Science Committee. Recently, a framework for the development of an Arctic Region Global Ocean Observing System (ARGOOS) has been proposed by Lee et al. (2019). Additionally, the CLIVAR/CliC Northern Oceans Panel serves as an international forum for coordinating and strategizing activities on the role of the Arctic Ocean in the context of the global climate system from a coupled perspective and facilitates progress in developing new tools and methods to observe the Arctic Ocean and neighboring seas.

While these efforts aim to address a broad range of societal needs, in this section we describe several particular initiatives that work to address specific gaps in the observing system important for environmental prediction.

INTAROS (INTEgrated ARctic Observation System)

INTAROS is a research and innovation project under the European Union Horizon 2020 program, running from 2016 to 2021, with objective to build an efficient integrated Arctic Observation System in the Arctic. This requires collaborative efforts among many institutions to extend, improve and unify existing systems, which in many cases are designed and developed for specific scientific disciplines. INTAROS focuses on the *in situ* part of the observing systems, which represent the largest component of the integrated observing system. Satellite Earth Observation programs provide the most developed and operational components of the system, which are run by space agencies and satellite monitoring services such as Copernicus¹³. The satellite systems provide data for near real-time monitoring as well as for long-term climate observations. Validation of the satellite-derived variables is an important part of the operational services. *In situ* observations play an important role for this validation, but there is very limited access to such data from the Arctic Ocean. Furthermore, most of the ocean observations are only available in delayed mode, because they are provided by underwater moorings and seafloor observatories. Some platforms that operate at the surface can transmit data in near real-time and can therefore contribute to operational monitoring of sea ice and ocean variables.

INTAROS is multidisciplinary, implying that the observing systems encompass atmospheric, marine and terrestrial systems in the different regions of the Arctic. Marine observing systems are also divided into physical and biogeochemical components of the ocean surface (including sea ice), the water column and the seafloor. INTAROS contributes to all these components in collaboration with other observing programs and projects, by

deploying new sensors and platforms to enhance the observing capacity in different Arctic regions. The collection of new *in situ* data under INTAROS started in 2017 and will continue through 2020, coinciding with and contribute to the extensive data collection in the MOSAiC program (see MOSAiC). Examples of INTAROS supported platforms include: IMBs deployed in the Central Arctic Ocean by the Finnish Meteorological Institute during Chinese Arctic expeditions (Lei et al., 2018); a network of Argo floats in the Nordic Seas in ice-free areas; bio-Argo floats in Baffin Bay together with Takuvik; and the Ferry-box transect between Norway and Svalbard¹⁴. INTAROS also supports data collection from the cargo vessel NORBJØRN that runs between Tromsø and Longyearbyen throughout the year. Data can be transmitted to land in near realtime and is available for operational monitoring. Ship of Opportunity is promising method to collect oceanographic data in Arctic waters, since there is a growing number of ships operating in the Arctic, especially tourist ships.

Arctic observing systems will benefit greatly from collaboration with local communities (Johnson et al., 2018). INTAROS is therefore working with Community-Based Monitoring (CBM) systems which are under development in many places in North America, Greenland and Russia. CBMs can be supplementary to scientific observations when indigenous and local people collect scientifically relevant data and made them available via websites¹⁵. Community-based monitoring can also provide valuable data that cannot be obtained from normal research and monitoring programs. In the circumpolar Arctic region there are a number of observing programs addressing sea ice, oceanographic data and observations of marine mammals and fish which are very important for the communities.

EMODNET

Observations of the ocean are usually made for specific purposes. In order to save costs and improve marine knowledge, the European Union is now moving to a new paradigm where data are collected once and then used for many purposes. This paradigm is being implemented as part of the European Marine Observation and Data Network (EMODnet) consisting of a variety of organizations working together to assemble marine data and products, and to facilitate the dissemination of these resources to both public and private users. EMODnet is currently in its third development phase with the target to be fully deployed by 2020. Six Sea Basin Checkpoint programs were initiated as part of EMODnet, including the Sea Basin Checkpoint Arctic¹⁶, with the objective to examine the current status of Arctic data and to assess how fit-for-purpose the Arctic data are.

The project (2015–2018) aimed to identify problems and knowledge gaps and was organized in 10 challenges: wind farm siting, marine protected areas, oil platform leak, climate change, coasts, fisheries management, fisheries impact, river input, bathymetry and alien species. Within the project, each dataset found (292 in total) was assessed on its spatial and temporal

¹³<https://www.copernicus.eu/en>

¹⁴<https://www.niva.no/en/projectweb/norsoop>

¹⁵<https://mkp28.wixsite.com/cbm-best-practice>

¹⁶<http://www.emodnet-arctic.eu>

coverage, its accessibility and cost to access, the responsiveness and the temporal and vertical resolution. Also, each assessment report using a dataset (840 in total) was assessed on its adequacy for the project. For the oil spill challenge an oil accident was simulated. This demonstrated the necessity for rapid acquisition and inspection of ocean current and wind data in order to provide a reliable response capacity.

MOSAIC

An important Arctic observing project called MOSAiC (Multidisciplinary Drifting Observatory for the Study of Arctic Climate; Shupe et al., 2018) is planned for 2019–2020. The German research icebreaker *Polarstern* will be frozen into the pack ice and over-winter in the Transpolar Drift to obtain measurements over a complete annual cycle. The MOSAiC sea ice platform provides an opportunity for greatly enhanced deployment of autonomous instrumentation and coordinated intensive field studies from research vessels, manned and unmanned aircraft, and distributed surface stations.

MOSAIC observations have been designed specifically to characterize the important coupled processes within the atmosphere-ice-ocean system that impact sea ice melting and freezing. These processes include heat, moisture, and momentum fluxes in the atmosphere and ocean, water vapor, clouds and aerosols, biogeochemical cycles in the ocean and ice, and many others.

The MOSAiC central observatory will be a manned, icebreaker ship-based ice camp with comprehensive instrumentation to measure coupled processes within the atmosphere, ice, and ocean. This intensive observatory will be embedded within a constellation of distributed measurements made by buoys, ice-tethered profilers, remote meteorology stations, underwater drifters, unmanned aerial systems, aircraft, additional ships, and satellites. These distributed observations will provide critical information on the spatial context and variability of key parameters, and allow for limited measurements in environments with sea ice of differing age, thickness, and concentration.

The additional observations from MOSAiC together with other sources during YOPP provide an ideal opportunity to assess the impact on forecast skill in environmental prediction systems through OSEs and process studies. Results will provide a quantitative baseline for use in decisions regarding how to configure a sustained Arctic observing system appropriate for the needs of environmental prediction.

Year of Polar Prediction

The need for improved environmental predictions (i.e., atmosphere, ice and ocean) has motivated an international effort called the Polar Prediction Project (PPP¹⁷). The PPP was created under the auspices of the World Meteorological Organisation's World Weather Research Programme (WWRP) to "promote cooperative international research enabling development of improved weather and environmental prediction services for the polar regions, on time scales from hourly to seasonal." YOPP is a PPP flagship activity (Jung et al., 2016) with

¹⁷<http://www.polarprediction.net>

a core phase during 2017–2019, with the overarching goal to "Enable a significant improvement in environmental prediction capabilities for the polar regions and beyond, by coordinating a period of intensive observing, modeling, verification, user-engagement and education activities." In particular, there are a series of Special Observing Periods for both the Arctic and Antarctic to improve the polar observing system to provide better coverage of high-quality observations in a cost effective manner, primarily by carrying out Observing System Experiments. The Southern Hemisphere SOP occurred from November 2018 to February 2019, and included deployment of extra radiosondes and drifting buoys, as well as the prolongation of the Ocean Observatories Initiative surface mooring at 55°S. The Arctic SOPs were conducted for winter (February–March, 2018) and summer (July–September, 2018). A more comprehensive list of research activities is given by PPP Steering Group (2013, 2014). Additional observations gathered through field programs will also be used to improve our understanding of key polar processes relevant for improving prediction skill. A third Arctic SOP is planned for February–March 2020 as part of YOPP to capitalize on the MOSAiC observational effort.

The additional observations from MOSAiC together with other sources during YOPP provide an ideal opportunity to assess the impact on forecast skill in environmental prediction systems through OSEs and process studies. Results will provide a quantitative baseline for use in decisions regarding how to configure a sustained Arctic observing system appropriate for the needs of Environmental Prediction.

RECOMMENDATIONS

The scarcity of observations, the unique balance of physical processes, the key importance of sea ice, and the rapidly evolving climate of the Arctic, and the uncertainties in Antarctic sea ice trends and carbon uptake lead to a number of scientific challenges for observations in the context of a polar prediction system. Addressing these challenges motivates the following recommendations:

1. The presence of a seasonal ice cover limits the availability of real-time *in situ* data in polar regions to assist operational requirements. While several technologies have been developed (e.g., ITPs, gliders communicating via acoustic modems) a comprehensive real-time ocean observing network able to supplement Argo for polar regions has yet to be put in place, hindering progress toward coupled polar prediction. It is therefore recommended that a network of ice-borne measurement systems be deployed and supported operationally in ice-covered areas. These platforms represent well-proven technologies for year-round data collection and near-real time data transmission via satellites.
2. Antarctic measurements are also needed, in particular, to evaluate changes that could be harbingers of continental ice melt. Recent studies also highlight the importance of measuring and understanding the intra-hemispheric ocean interactions on numerical weather prediction to climate time-scales (Foppert et al., 2017). Ice-borne observing

systems that have proven their utility in the Arctic should now be adapted and tested in the Antarctic marginal ice zone.

3. Conditions are changing rapidly with the loss of summer sea ice extent in the Arctic and changing ice-cover patterns in Antarctic marginal seas. Phenomena long considered negligible in the Arctic and Antarctic may be becoming important (e.g., ocean waves – Cavaleri et al., 2012; Massom et al., 2018). The observing system needs to be reevaluated with this in mind. The retreat of the Arctic ice cover increases the area where open-water (or seasonally ice free) observing systems (e.g., gliders, Argo) can operate providing the possibility in future to provide a substantial amount of near-real time data for polar prediction systems.
4. Ships of opportunity present a promising method to collect oceanographic data in polar waters, since there is a growing number of ships operating in these regions. Moreover, community-based monitoring can also provide valuable data that cannot be obtained from normal research and monitoring programs. These atypical observing methods should be encouraged and enhanced to provide a low-cost expansion to the *in situ* observing system.
5. *In situ* observations are routinely used for the calibration of remote sensing products over much of the globe, with fewer such calibrations made in polar regions due to lack of *in situ* observations. Studies have shown the large benefits that such calibrations can have (e.g., Castro et al., 2016; Kwok et al., 2017). The availability of near-real time *in situ* measurements could be used to improve the quality of satellite products and thus on downstream environment predictions that assimilate them. Additional efforts involving multi-platform calibration are needed to improve the quality of remote sensing products.
6. The increasing maturity of satellite sea-ice thickness winter-time products merging several sensors (e.g., CryoSat-2 and SMOS) and its positive impact in preliminary assimilation experiments call for symmetrical efforts in the Antarctic ocean, where such products do not exist at the moment.
7. Polar surface properties are often dominated by various forms of ice that vary rapidly on small spatial scales. Some remote sensing methods of ice properties (ice cover, ice thickness, snow depth on ice, albedo, crystal structure) are not mature and offer little and/or coarse-resolution information from within the ice, whereas *in situ* methods provide poor spatial coverage. Neither is currently able to address the need for high spatial and temporal resolution observations of sea ice deformation over large regions. Observations providing information regarding ice deformation and redistribution during ridging are also lacking. There is a need for high-resolution (km-scale) remotely sensed snow and ice property data for both the Arctic and Southern Ocean with sufficient temporal resolution to address these relevant features.
8. The value of polar observations for multi-range environmental prediction emerged during the last decade from a variety of impact studies. The importance of SIT initialization for seasonal forecasting, the significance of sub-surface initialization in ice-covered areas, are non-exhaustive examples that call for coordinated efforts (including QND, OSEs and Observing System Simulation Studies) to enhance the Arctic and Southern Ocean observing networks.
9. To date, few data withholding experiments (OSEs) or observation design experiments (OSSEs) have been undertaken for polar regions using real-time prediction systems. Performing such experiments using additional observations available during YOPP (or other periods of additional observational coverage such as IPY) is suggested to provide valuable information to guide the design of a sustainable real-time observing system for polar regions suitable for environmental prediction. In particular, multi-system exercises shall be encouraged to gain robustness in the observation impact assessments.
10. Polar environmental prediction using coupled atmosphere-ice-ocean models is strongly sensitive to errors in fluxes across the surface interface and thus requires collocated information about the state of the atmosphere, sea ice and ocean, to be used for improving interface fluxes (i.e., coupled model validation) and eventually data assimilation. Direct flux covariance measurements, in particular, would be immensely valuable in constraining bulk parameterizations used to represent fluxes in models.
11. Open access to data, especially real-time data, is a critical capability for improved sea-ice and weather forecasting and other environmental prediction needs. The optimal observing system will no doubt include a suite of different instrument types, since no single platform can be optimized for the full range of observing needs (i.e., sub-surface and lower atmosphere), and hence multi-platform coordination will be necessary, including coordination with local community-based observatories. This means that real-time dissemination of *in situ* observations in polar regions to global data assembly centers must be prioritized in order to make the observational efforts suitable for environmental prediction applications.
12. International collaboration will continue to be key for facilitating deployment of polar ocean instrument systems, including the fielding of drifting and anchored buoys, floats and gliders and free, rapid dissemination of the resulting data.

OUTLOOK

The relative remoteness and harsh environmental conditions over polar regions will always hinder efforts to provide adequate observations for polar prediction. Over recent years, we have seen improvements in observing technology and capabilities that create new possibilities for how to construct and maintain the polar ocean observing system. The technologies make an adequate polar ocean observing system feasible, but the question remains, is it worth the cost? YOPP aims

to help address this question by coordinating international observing activities and fostering efforts to assess the impact of additional observations on environmental prediction skill, including impacts on downstream users and products. Following the YOPP core period (2017–2019), there will be a consolidation phase to assess these impacts and develop recommendations toward sustained polar observation. This effort will culminate in a YOPP Final Summit planned for summer 2022, providing an ideal opportunity for funding and implementation agencies to benefit from this community effort.

FUNDING

The development of the new generation of floats (PRO-ICE) to be operated under ice was funded by the French project NAOS. Twelve PRO-ICE were funded by NAOS and nine by the Canadian Foundation for Innovation (FCI-30124). The GreenEdge project is funded by the following French and Canadian programs and agencies: ANR (Contract #111112), CNES (project #131425), IPEV (project #1164), CSA, Fondation Total, ArcticNet, LEFE and the French Arctic Initiative (GreenEdge project). The INTAROS project has received funding from the European Union’s Horizon 2020 Research and Innovation Program under grant agreement No. 727890. The setup of the ArcMBA system and the experiment described in section “Quantitative Network Design” were funded by the European Space Agency through its support to science element (contract #4000117710/16/I-NB). SSw was supported by a Wallenberg Academy Fellowship (WAF 2015.0186). The work at CLS (GL, PPr, and PT) has been funded by internal investment, in relation with on-going CNES and ESA funded studies making use of radar data over Polar regions. EMODNET (BK) is funded by the European Commission. NRL Funding (for RA, JC, DH, EM, PPO, OS) provided by NRL Research Option “Determining the Impact of Sea Ice Thickness on the Arctic’s Naturally Changing Environment (DISTANCE), ONR 6.2 Data Assimilation and under program element 0602435N (JC, RA, DH). JT’s Arctic research activities are supported by the U.S. National Science Foundation and ONR. SG was funded by NSF grants/awards PLR-1425989 and OCE 1658001. IR is funded by contributors to the US IABP (including CG, DOE, NASA, NIC, NOAA, NSF, ONR). CAFS is supported by the NOAA ESRL Physical Sciences Division (AS and JI). LB and JX are funded by CMEMS. The WWRP PPP Steering Group is funded by a WMO trust fund with support from AWI for the ICO. The publication fee is provided by ECCC.

ACKNOWLEDGMENTS

We would like to acknowledge the valuable suggestions made by both reviewers that has improved the quality of this manuscript. Contributions to the PPP Trust Fund are acknowledged as well as AWI’s financial contribution to hosting the ICO. For work done for section “Under-ice BGC Argo Floats in the Canadian Arctic,” we thank E. Leymarie and C. Penkerch (LOV Laboratoire d’Océanographie de Villefranche sur Mer) for their contribution in the development of the PRO-ICE. We also thank officers and crew of CCGS Amundsen for their help during our deployments of floats.

The ocean is key to understanding societal threats including climate change, sea level rise, ocean warming, tsunamis, and earthquakes. Because the ocean is difficult and costly to monitor, we lack fundamental data needed to adequately model, understand, and address these threats. One solution is to integrate sensors into future undersea telecommunications cables. This is the mission of the SMART subsea cables initiative (Science Monitoring And Reliable Telecommunications). SMART sensors would “piggyback” on the power and communications infrastructure of a million kilometers of undersea fiber optic cable and thousands of repeaters, creating the potential for seafloor-based global ocean observing at a modest incremental cost. Initial sensors would measure temperature, pressure, and seismic acceleration. The resulting data would address two critical scientific and societal issues: the long-term need for sustained climate-quality data from the under-sampled ocean (e.g., deep ocean temperature, sea level, and circulation), and the near-term need for improvements to global tsunami warning networks. A Joint Task Force (JTF) led by three UN agencies (ITU/WMO/UNESCO-IOC) is working to bring this initiative to fruition. This paper explores the ocean science and early warning improvements available

from SMART cable data, and the societal, technological, and financial elements of realizing such a global network. Simulations show that deep ocean temperature and pressure measurements can improve estimates of ocean circulation and heat content, and cable-based pressure and seismic-acceleration sensors can improve tsunami warning times and earthquake parameters. The technology of integrating these sensors into fiber optic cables is discussed, addressing sea and land-based elements plus delivery of real-time open data products to end users. The science and business case for SMART cables is evaluated. SMART cables have been endorsed by major ocean science organizations, and JTF is working with cable suppliers and sponsors, multilateral development banks and end users to incorporate SMART capabilities into future cable projects. By investing now, we can build up a global ocean network of long-lived SMART cable sensors, creating a transformative addition to the Global Ocean Observing System.

Keywords: ocean circulation, ocean cabled observatories, submarine telecommunications cables, tsunami early warning, ocean observing, UN Joint Task Force, SMART subsea cables

THE SMART CABLES CONCEPT

Deploying oceanographic sensors on new undersea telecommunication cables is a promising solution for obtaining the extensive, longitudinal, real-time data that are critical for understanding and managing urgent environmental issues such as climate change and tsunami hazard mitigation. Such sensors can provide important environmental data from sites in the deep ocean that are otherwise difficult and expensive to obtain in real-time and over decadal time scales. Suitable sensors are already deployed on dedicated cabled ocean research observatories, and with modest non-recurring engineering expenses, such sensors can be integrated in future telecommunications cables to create SMART cable systems (Science Monitoring And Reliable Telecommunications; **Figure 1**).

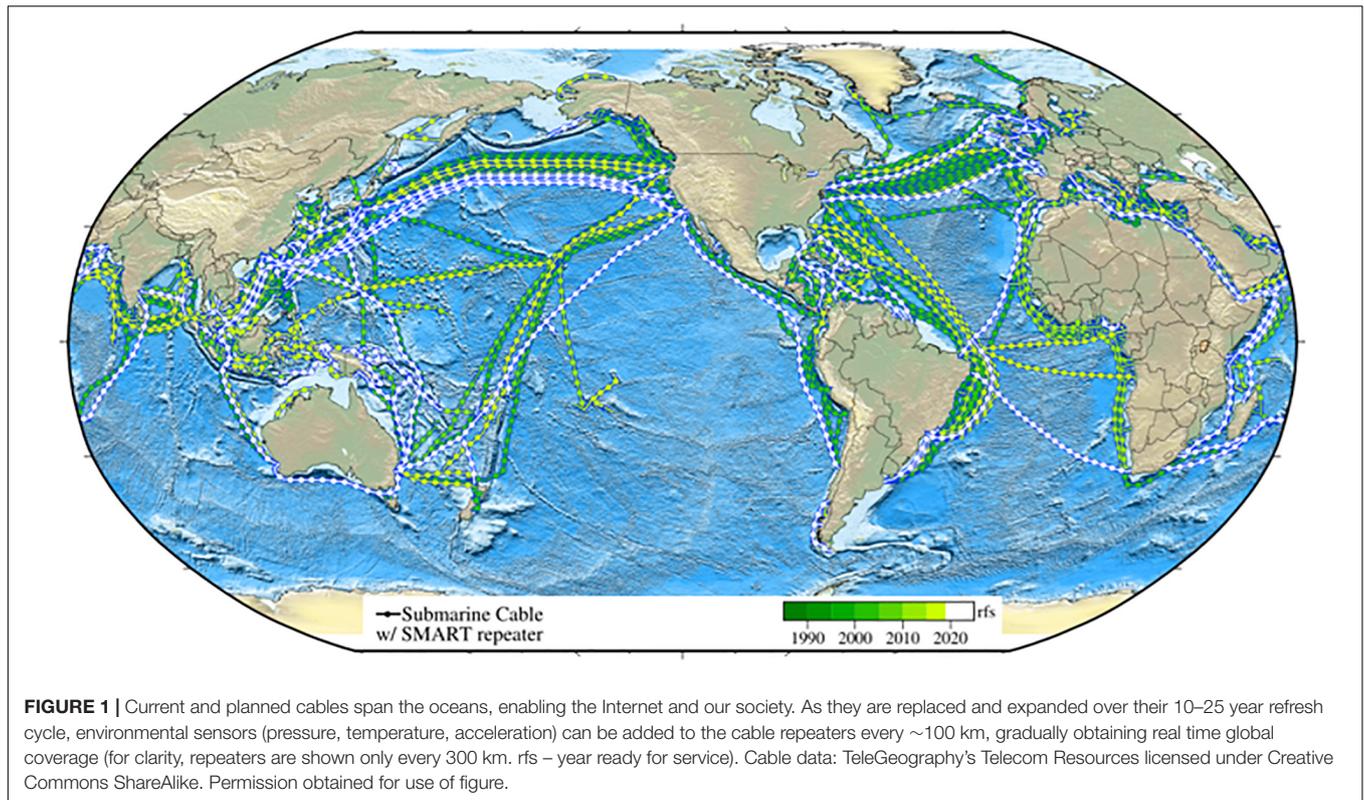

The SMART cables concept originated decades ago and has been demonstrated on a small scale by placing a few sensors at the end of disused cables, such as off Japan in the 1990s for detecting earthquakes and tsunamis. Modern fiber-optic cables, capable of delivering power and high bandwidth, have been used as part of dedicated sustained cabled observatories to obtain data on complex ocean systems beyond what is available from conventional methods, such as research vessels and fixed buoys (Favali et al., 2010). The first such cabled observatories were the 2006 coastal VENUS system (Tunnicliffe et al., 2008) and the regional NEPTUNE observatory operational in 2009 (Barnes et al., 2015; Best et al., 2015), now within Ocean Networks Canada (ONC). Similar observatories, tailored to national, scientific, and geographical needs, have included Japan – DONET and S-net (Kawaguchi et al., 2015; Kanazawa et al., 2016), United States – Ocean Observatories Initiative (OOI) and others (Massion and Raybould, 2006; Kelley et al., 2014; Howe et al., 2015), China (Lu et al., 2015), and Europe (Best et al., 2014; Person et al., 2015). These developments have in turn fostered the evolution of progressively smaller, more precise

and reliable sensors (Schaad, 2009; Paros et al., 2012; RBR, 2017; Delory and Pearlman, 2018).

Advocacy for the SMART cables concept began in earnest with a paper by You (2010). In 2012, following workshops in Rome (2011) and Paris (2012), three United Nations agencies established the Joint Task Force (JTF) to facilitate development of the concept (the International Telecommunication Union (ITU), the World Meteorological Organization (WMO), and the Intergovernmental Oceanographic Commission of the United Nations Educational, Scientific and Cultural Organization (UNESCO/IOC). The initial few years of development of JTF were described by Barnes (2018) and details of the various workshops and publications are provided on the JTF web site: <https://www.itu.int/en/ITU-T/climatechange/task-force-sc/Pages/default.aspx>.

Science Monitoring And Reliable Telecommunications cables represent a potential major new element in the Global Ocean Observing System (GOOS), and JTF, as it develops SMART cables, is engaging closely with the GOOS Framework for Ocean Observing (FOO¹; Lindstrom et al., 2012). A core concept of GOOS FOO is “Essential Ocean Variables” (EOVs): high impact, discrete, feasibly monitored observable attributes of the global oceans. SMART cables, by their nature as extensive, deep-ocean, high-data-rate observatories, directly address several of the GOOS EOVs. For example, ocean bottom pressure (OBP) was recently accepted as an emerging EOV, and SMART cables are potentially the most extensive and cost-effective source for such measurements. SMART cables also measure subsurface temperature, and the tsunami-measurement capabilities of SMART cables would address one aspect of the Sea Surface Height EOV. GOOS prescribes a phased approach for new ocean observing technologies, from concept to regional pilots through to global implementation. JTF is following this approach, taking steps to ensure that SMART cables and the

¹<http://www.oceanobs09.net/foo/>

data derived from them can be seamlessly incorporated in GOOS as part of a comprehensive Deep Ocean Observing Strategy (DOOS; Levin et al., 2019).

A central feature of the SMART cables concept is that it brings together two key themes of the 21st century: the increasing pressure for global connectivity and the urgent need for coherent, concerted global effort on climate change and ocean management. The market-driven investment in information infrastructure can be harnessed to achieve tangible, social benefits in climate and ocean science. The relatively modest suite of proposed instruments will help address many of the basic science and societal needs, and will also facilitate the monitoring of the physical integrity of the cable itself. The importance of such synergy is reflected in the themes of OceanObs'19 (e.g., the “Blue Economy” and “Ocean Discovery,” particularly in the deep oceans) and the United Nations’ Sustainable Development Goals (SDG 13 – Climate and SDG 14 – Oceans).

Joint Task Force and its industry partners recognize the need for funding sources to bear the development costs of integrating sensors into existing submarine cable components and the incremental capital expenditures associated with adding SMART capabilities to a telecommunications cable system. JTF's next step is a wet demonstration/pilot project, in which sensor packages are included on a relatively short submarine cable using standard industry practices, with data retrieved in real-time over a minimum of 1 year. Multiple suitable cable projects are in the planning stages in the South Pacific, where JTF can validate not only the technical elements, but also the data management, regulatory

clearances, and funding mechanisms (e.g., multilateral development banks).

This paper first explains how SMART cables can improve our understanding of myriad ocean and geophysical processes, including ocean temperature, circulation, sea level rise, tides and wind waves, as well as tsunami modeling and seismology (see section “Improvements in Ocean Observing with SMART Cables”). The paper then details the practical aspects of creating such a network: what sensors SMART repeaters will use and how will they integrate into subsea telecommunications cable systems (see section “Technical Approach”); how the resulting data will be managed, distributed, and used (see section “Data Management and Users”); how the international SMART cables program will be overseen (see section “Program Management”); what legal and permitting considerations are relevant to SMART cables (see section “Legal Outlook”); what the costs of a SMART cable system are and what sources of financing there are to meet those costs (see sections “Cost Estimate” and “Financing”). Recommendations for OceanObs'19 to consider are given in section “Summary.” Cost elements and projections from year 1 through 25 are provided as a supplement.

IMPROVEMENTS IN OCEAN OBSERVING WITH SMART CABLES

The data collected by the SMART cables would greatly enhance and complement multiple observation networks already in place today. The variables measured by the SMART cable repeaters

are temperature, pressure, and seafloor seismic acceleration. Importantly, as discussed in the previous section, the direct measurements and their derivatives respond directly to the GOOS need for greater attention to EOVs and the UN imperative to contribute to the SDGs. More broadly and in the future, the SMART cable infrastructure will provide a general interface into the deep ocean.

Oceanography

Oceans are currently monitored by *in situ* (ships, buoys, moorings, or floats) and remote sensing (satellite) techniques, yet the deep ocean and the important processes occurring remain undersampled and unobserved. Data from SMART cables would fill critical gaps in our existing monitoring systems, complement existing observations, increase our current level of understanding of the ocean, and improve our capability to predict its future evolution.

Ocean Temperature

Antarctic Bottom Waters, which fill much of the deep oceans (Johnson, 2008) are warming, absorbing substantial amounts of heat, and contributing to sea level rise (Figure 2; Purkey and Johnson, 2010). In addition, the Atlantic meridional overturning circulation (AMOC) is changing (Smeed et al., 2018), and those changes are associated with variations in ocean temperature, air-sea heat flux, and sea level, suggesting that this full-depth ocean circulation feature is important in modulating regional and global climate.

There are now several trans-basin moored arrays monitoring the AMOC at different latitudes (McCarthy et al., 2015; Lozier et al., 2017; Meinen et al., 2017), but outside of the Atlantic, oceanographers currently rely primarily on Global Ocean Ship

(GO-SHIP) repeated transoceanic hydrographic sections (Talley et al., 2016) to monitor the deep ocean water properties and circulation variations, along with a few time series stations (Lukas et al., 2001) and deep instruments on moorings both regional (McKee et al., 2011) and global (Send and Lankhorst, 2011) in scope. Deep Argo floats capable to a depth of 6,000 m have been developed, with a few regional pilot arrays already deployed or planned (Jayne et al., 2017), and a global network envisioned (Johnson et al., 2015). Changes in the deep ocean, however, remain undersampled (Johnson et al., 2015). SMART cables, with transoceanic sampling of temperature in the bottom boundary layer at roughly 50 km resolution, would complement other data sets that facilitate investigation into water temperature variability, trends, and circulation (together with SMART cable pressure sensors). SMART cable temperature sensors would provide much closer spatial sampling than either Deep Argo at 500 km nominal density (Johnson et al., 2015), transoceanic arrays moorings that are often much farther apart in the ocean interior (McCarthy et al., 2015; Lozier et al., 2017; Meinen et al., 2017), or the even sparser OceanSites moorings (Send and Lankhorst, 2011). They would provide much better temporal resolution than either the 10–15 day Deep Argo sampling or the decadal repeats of GO-SHIP transoceanic hydrographic sections (Talley et al., 2016).

Ocean Circulation, Sea Level Rise, and Mass Distribution

Since 2004, the RAPID/MOCHA array has been providing estimates of the AMOC at 26.5°N by estimating the pressure gradient between the western and eastern continental slopes (McCarthy et al., 2015). From the AMOC strength, the climate-relevant meridional heat transport and its variation can

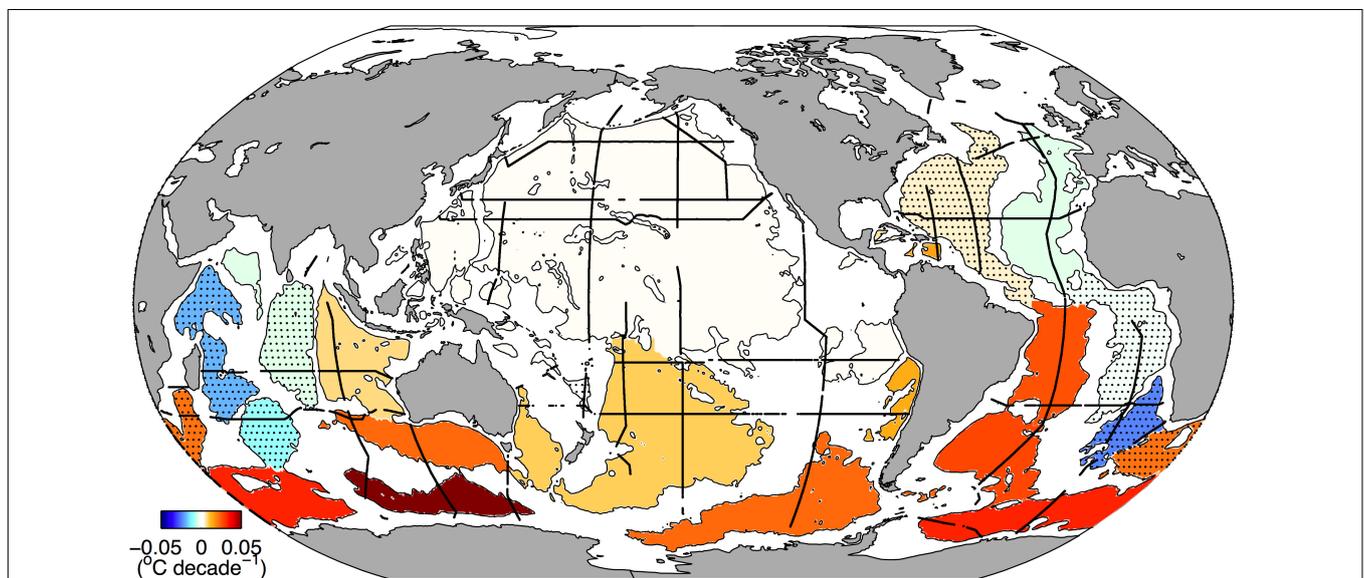

FIGURE 2 | Deep basin (thin solid lines) average warming rates below 4,000 m from the 1990s to the 2000s ($^{\circ}\text{C decade}^{-1}$, colorbar) based on data from Purkey and Johnson (2010). Estimates are based on data from decadal repeats of hydrographic sections (thick solid lines) first occupied during the World Ocean Circulation Experiment (WOCE) (King et al., 2001) and subsequently by the Global Ocean Ship-based Hydrographic Investigations Program (GO-SHIP) (Talley et al., 2016). Stippled basins have average warming rates that are not statistically significantly different from zero at 95% confidence. Permission obtained for use of figure.

also be inferred, because a strong linear relationship exists between ocean volume and heat transports, at least at 26.5°N (Johns et al., 2011). SMART cables would complement and extend the existing AMOC estimates in two ways. First, OBP measurements on cables spanning an entire ocean basin could measure the pressure differences at many depths between the western and eastern boundaries of the basin. The pressure differences are directly related to the transports at those depths, as illustrated in **Figure 3**. Both the upper and lower limbs of the dominant geostrophic component of AMOC transport can be estimated in this way (Hughes et al., 2013, 2018; Elipot et al., 2014). Second, multiple cross-basin transects by SMART cables at different latitudes would allow a division of major ocean basins into boxes. Geostrophic transports across box boundaries could then be estimated from OBP observations as just described, allowing the mass balance of individual boxes to be calculated. These box models would finally allow a quantification of the long-term mass evolution in an ocean basin, based on unaliased measurements.

Global warming has caused global mean sea level to rise at a rate of 3.0 ± 0.4 mm/year since 1992 (**Figure 4**), with an estimated current acceleration of 0.084 ± 0.025 mm/year² (Nerem et al., 2018). This will lead to a sea level rise of approximately 65 cm by 2100. Because individual contributions to sea level change, such as barystatic (mass changes, e.g., due to melting land ice) and steric (expansion of water, e.g., due to warming) effects in the ocean, as well as Earth-produced eustatic (changes in ocean volume) and isostatic (changes in height of land) effects, vary considerably across the oceans, sea level rise is not homogeneous. Sea level variability patterns can be determined by various measurement techniques and sensors, e.g., radar altimetry and tide gauges. The identification of individual contributing effects, however, requires complementary observation methods at each location. OBP observations provide the amount of local barystatic sea level change. SMART cables would provide a network of long-lasting, temporally unaliased OBP sensors that could be quite dense in some basins and unaliased along the cables. In conjunction with sea level observations by altimetry, or density field observations by Argo floats, for instance, the OBP measurements would enable

separation of the steric and barystatic contributions to sea level change at a particular location, whose differentiation is required to understand the causes of sea level rise and thus for reliable sea level projections.

The satellite gravity missions – GRACE (Tapley et al., 2004) and its successor GRACE-FO (Flechtner et al., 2016) – provide measurements of the temporally varying gravity field, which can be interpreted as OBP and ocean mass. Such satellite data, however, are aliased by short-scale processes that cannot be resolved in a global gravity field due to the horizontally integrating nature of the space-based gravity measurement itself, and the characteristics of the satellite orbits, e.g., orbit period, repeat period, inclination, and ground distance between successive orbits. Hence, the data have to be “corrected” by a de-aliasing procedure, involving parameters for oceanic tides, Earth tides, short-term atmospheric pressure variability and short-period oceanic barotropic oscillations (Rietbroek et al., 2006). The quality of the resulting products is one of the main limiters of current and future gravity field missions (Panet et al., 2013). Local alterations of gravity are caused by changes in the vertically integrated mass distribution and a consequence of mass transport in the solid Earth, cryosphere, atmosphere, and ocean (Kelley et al., 2014; Dobslaw et al., 2017). Variations of oceanic mass are reflected *in situ* by OBP changes. Thus, OBP observations from SMART cables can significantly contribute to the improvement of the GRACE-derived oceanic products in two complementary ways.

First, the observed gravity signal is considerably “contaminated” by contributions from continental hydrology as far as 1,000 km from continental coasts. These contaminants are estimated and removed during post-processing by applying numerical models of the sub-systems with results that are useful, if not remarkable (Chambers and Schröter, 2011; Makowski et al., 2015). SMART cable observations from near-coastal areas are expected to substantially improve this signal separation by providing constraints for the determination of the oceanic contribution, especially over continental slopes where strong bottom pressure variations from boundary currents are common.

Second, SMART cable observations have the potential to improve simulations of OBP. Although observations by SMART cables are not yet available, observation system simulation experiments (OSSEs) can estimate these potential improvements. Assimilated synthetic OBP observations along possible SMART cable OBP routes from a global high-resolution version of the regional ocean modeling system (ROMS; Song and Hou, 2006) into a global coarse resolution version of the Max-Planck Institute-Ocean Model (MPIOM; Marsland et al., 2003) with an ensemble Kalman filter (Nerger et al., 2007). According to these model simulations, the root-mean-square difference between the OBP from ROMS and MPIOM is reduced by up to 40% in the Indian Ocean and up to 20% in the Pacific and Atlantic Oceans (**Figure 5**). The advantages of SMART cables compared to other observing systems considered in the study are the large number of instruments, the near-real-time availability, the high accuracy, and the global distribution of the network. The last is especially important for obtaining global improvements with the data assimilation approach.

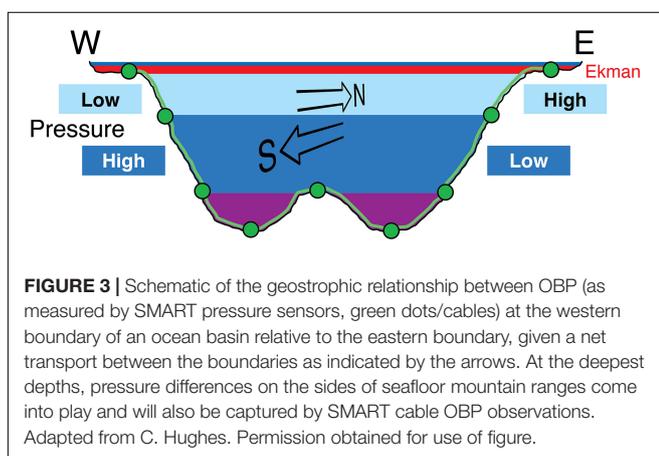

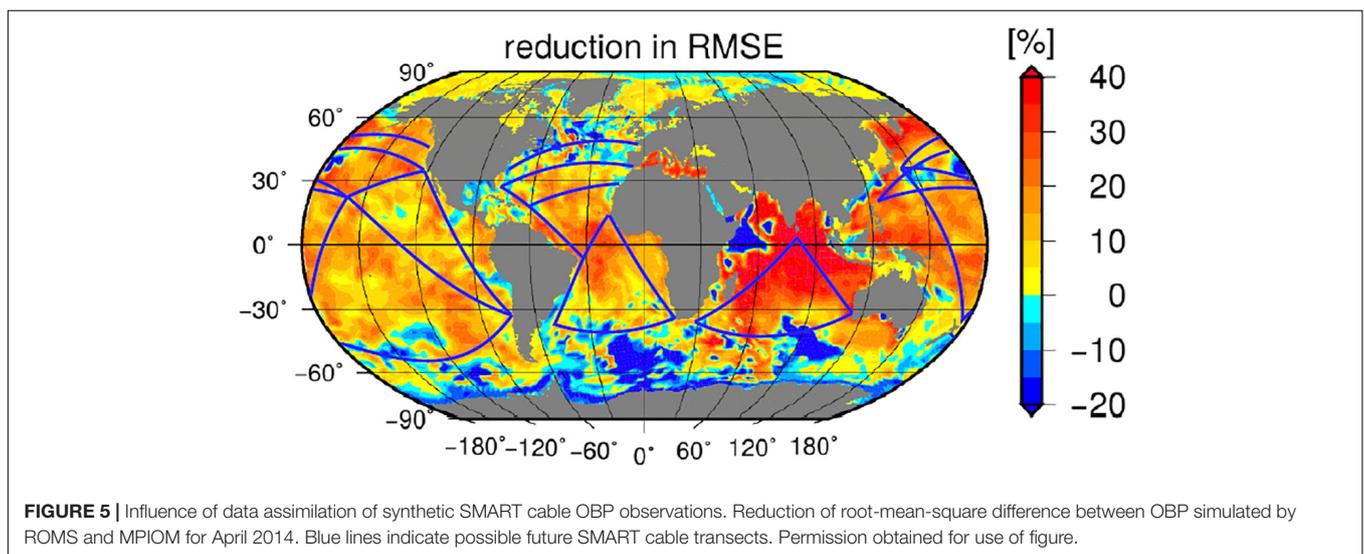

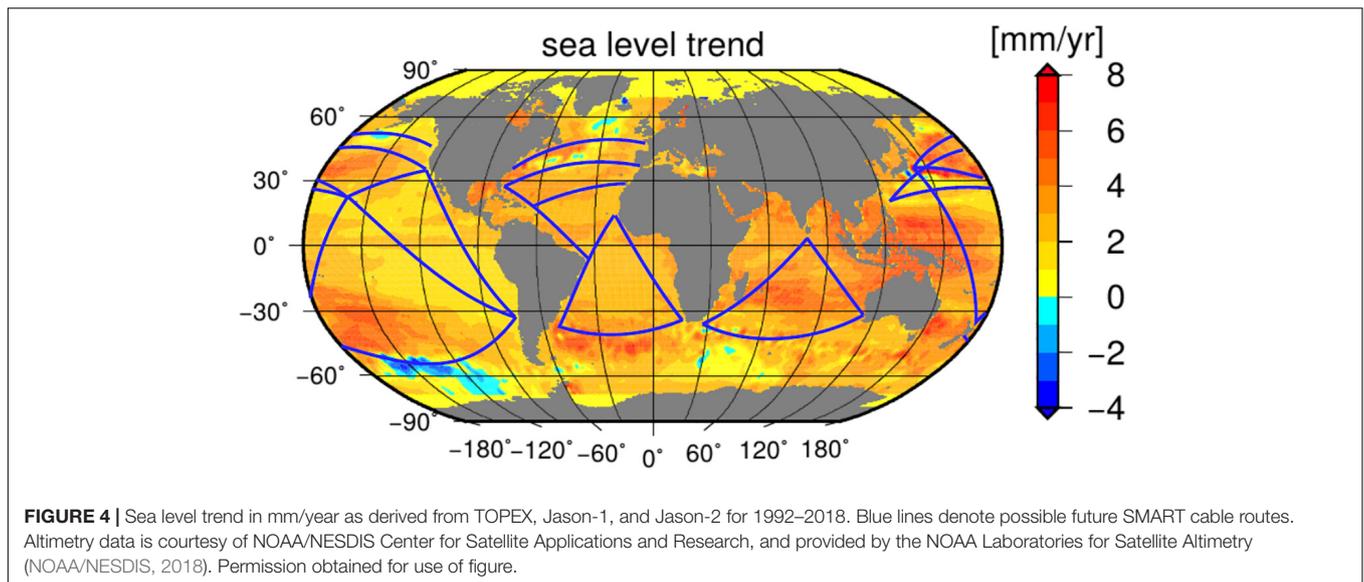

FIGURE 3 | Schematic of the geostrophic relationship between OBP (as measured by SMART pressure sensors, green dots/cables) at the western boundary of an ocean basin relative to the eastern boundary, given a net transport between the boundaries as indicated by the arrows. At the deepest depths, pressure differences on the sides of seafloor mountain ranges come into play and will also be captured by SMART cable OBP observations. Adapted from C. Hughes. Permission obtained for use of figure.

Ocean Surface (Barotropic) Tides

Simulation of the gravitationally forced surface (barotropic) tides has now become quite accurate even without assimilation of satellite altimetric data. Forward tide models now routinely capture 90% or more of tidal sea surface height variance (Arbic et al., 2004; Egbert et al., 2004).

This success does not mean that further study of the tides is now of minimal value. On the contrary, there are still a number of poorly understood or poorly described tidal phenomena, such as the lesser tidal constituents, seasonal variability of all constituents, non-linear constituents, rapid variation of constituent structure in shallow water, and shifting sinks of energy as the global environment changes. Although these factors exhibit small amplitudes, their global distributions are sought due to their impacts on such phenomena as internal tide generation, deep ocean mixing, paleotide descriptions, and Earth structure, as well as due to their utility in defining the tidal “correction”

that must be applied to satellite altimetry data to extract the sub-diurnal variability of ocean circulation features as well as long period sea level rise.

Ocean bottom pressure observations provide one of the better tools for exploring the finer details of the barotropic tides, because the broad band, non-tidal “geophysical noise” within which the tides are embedded is much weaker at the seafloor than at the sea surface (Ray, 2013). The geophysical noise that limits the utility of satellite observations and *in situ* coastal sea level observations arises from surface-intensified processes such as internal waves, mixed-layer currents, and coastal-trapped edge waves.

Furthermore, although the astronomical gravitational potential that gives rise to the ocean tides is precisely known, tides are embedded in, and interact with, a three-dimensional ocean circulation that varies on seasonal and longer time scales, in ways that are not easily predicted. Recent results show that

barotropic tides do vary on seasonal timescales (Müller et al., 2014), and even on secular timescales at the continental coasts (Ray, 2006; Müller et al., 2011). Detection of secular changes in the open ocean tides is less clear (Müller et al., 2011; Zaron and Jay, 2014; Schindelegger et al., 2018).

As an example of time-varying barotropic tide signals that could be seen by SMART cables, we can estimate tidal seasonal variability along the cable paths, using simulated hourly OBP samples from high-resolution global ocean models that are forced simultaneously by atmospheric fields and the astronomical tidal potential (Arbic et al., 2010, 2012, 2018; Müller et al., 2012, 2014; Rocha et al., 2016). The amplitude of the seasonal variability of the principal lunar semi-diurnal tide M_2 from the Müller et al. (2014) simulation is given in **Figure 6**. The range is from 0 to 0.5 cm, which is measurable by the OBP sensors envisioned within the SMART cable repeaters. There are currently no global-scale measurements for models of seasonal tidal variability. SMART cable measurements of OBP would allow unique, basin-scale quantification of barotropic tidal variability over a wide range of timescales, thus providing ground truth for secular and seasonal changes to tidal correction models used in altimetry and gravimetry.

Wind Generated Waves, Microseisms, and Infragravity Waves

Wind-generated waves at periods shorter than 30 s are ubiquitous at the ocean surface. In the open ocean, they play a crucial role in the exchange of heat and gases between the ocean and the atmosphere (Hasselmann, 1991), and they can be a major

natural hazard at the coast (Hoeke et al., 2013). Because the wind-generated waves have wavelengths far shorter than the average ocean depth, these waves cannot be measured at the seafloor deeper than 1,000 m and satellites or floating buoys are used to measure them. The popularity of real-time wave observations from near-coast anchored buoys to mariners and surfers (such as the Coastal Data Information Program; Thomas et al., 2015) suggests that OBP observations on SMART cables on the continental shelves and upper slopes could provide useful information on wave amplitudes, periods, and even directions to the local coastal populace, especially in regions where wave buoys have not yet been deployed.

Microseisms constitute the principal seismic noise source on Earth. Wind waves breaking and interacting in the shallow waters of the continental shelves, as well as in the open ocean, generate seismic noise in the period band of the wind waves and at shorter periods (2–20 s). The larger, but termed “secondary,” microseism generation mechanism (Longuet-Higgins, 1950) in the deep ocean is from opposing trains of ocean waves, which interact and generate a pressure signal at the seafloor with half the period of the interacting waves. This pressure signal generates seismic waves in the seafloor that can be observed and used for analysis even at the farthest reaches from the oceans in central Asia (Bromirski et al., 2005; Arduin et al., 2011; Chen et al., 2015; Butler and Aucan, 2018). These observations improve our understanding of both seismic waves in the seafloor and waves at the ocean surface.

Infragravity (IG) waves are surface waves with periods ranging from minutes to hours. Nonlinear interactions between wind

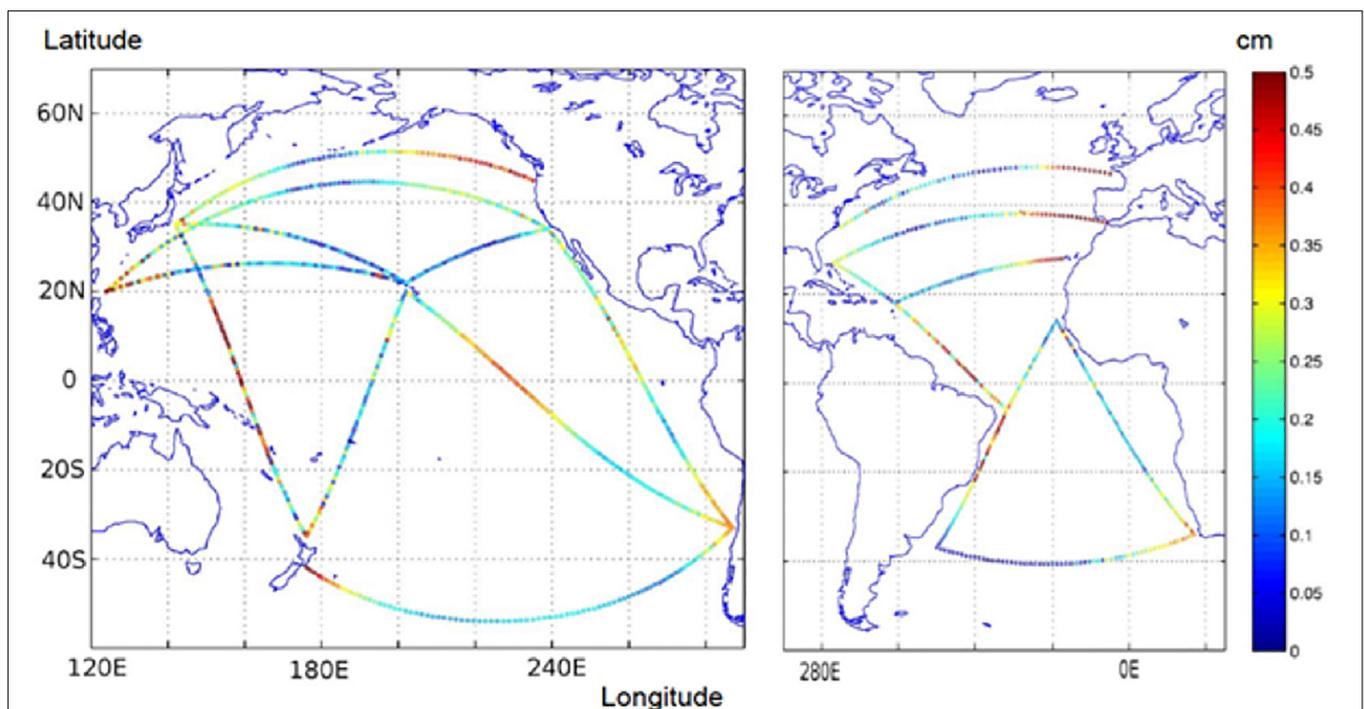

FIGURE 6 | Seasonal amplitude (cm) of the principal lunar semi-diurnal tide M_2 along cable routes simulated with the STORMTIDE model forced by both atmospheric fields and the astronomical tidal potential (Müller et al., 2014). Permission obtained for use of figure.

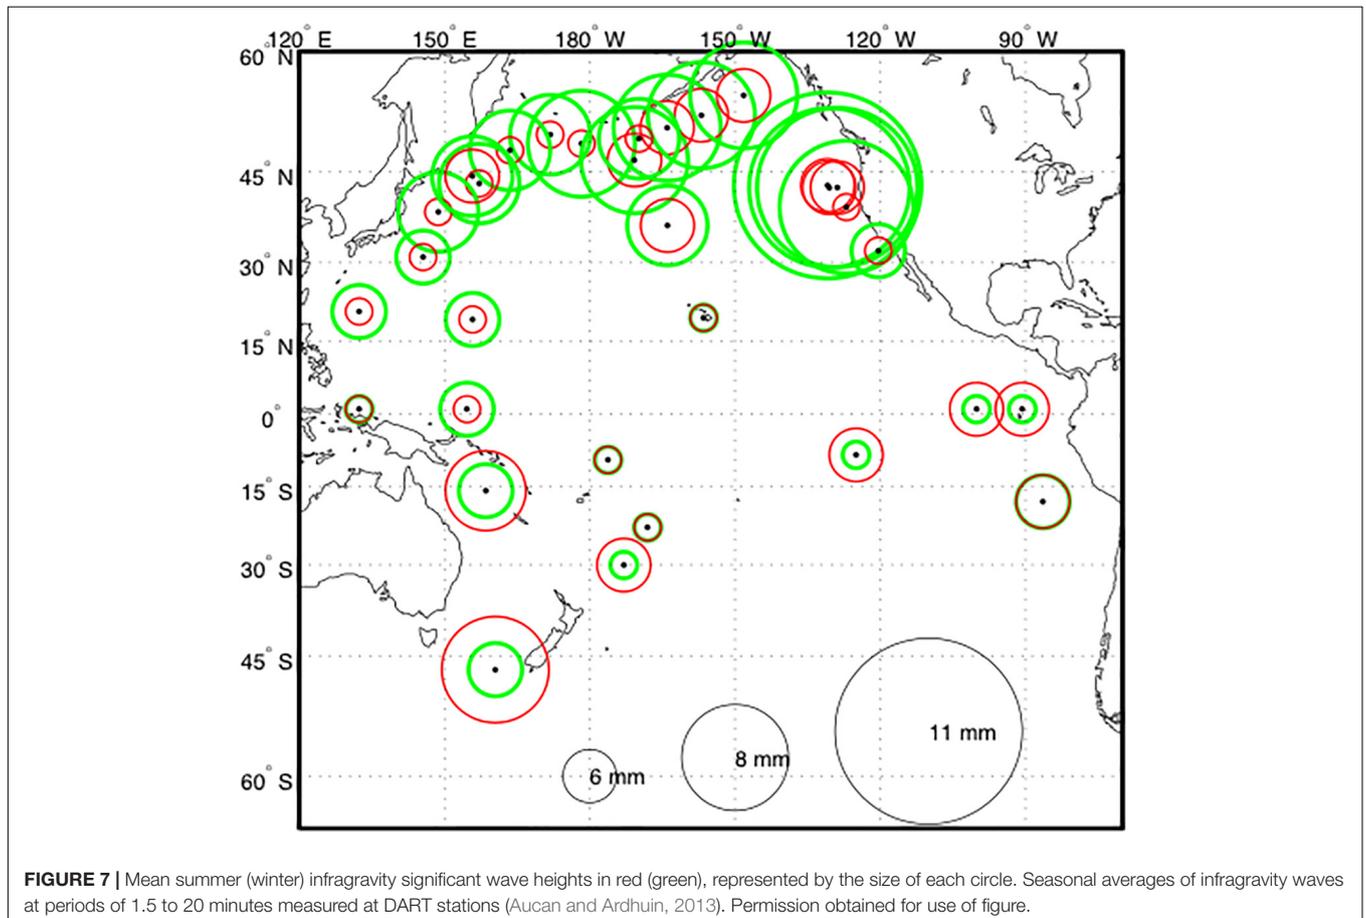

waves in the open ocean and at the coasts generate IG waves at periods from 0.5 min to many tens of minutes. IG waves appear as either “free” or “bound” waves (Herbers and Guza, 1994; Herbers et al., 1995), where the bound waves are tied to underlying groups of wind waves and become free at the shoreline where the short wind waves break (Bertin et al., 2018). A small fraction of the resultant free IG energy leaks into the open ocean where it can spread for thousands of kilometers, with horizontal wavelengths of up to 10s of kilometers and heights of up to 10s of centimeters with significant seasonal variability, as seen in **Figure 7** (Aucan and Ardhuin, 2013). IG waves at longer periods up to hours have also been identified and appear to be forced by the surface barotropic tides and solar modes of oscillation (Chave et al., 2019). Given the size and wavelength of these IG waves, they are a source of alias noise in satellite measurements of sea surface elevation. Thus, a better understanding and modeling of the temporal and spatial variations of the IG waves could improve the processing of satellite altimetry data (Ardhuin et al., 2014).

Observations on wind-generated waves on the shelves, together with observation of IG waves and microseisms in the deep ocean on SMART cables have the potential to inform us about energy flow from the wind and tides into the deep ocean, as well as the source of Earth’s “hum” at the same frequencies, a topic of considerable interest to seismologists using

Earth’s vibrations to explore its structure (Nawa et al., 1998; Rhie and Romanowicz, 2004; Webb, 2008). OBP measurements on SMART cable repeaters would contribute significantly to this purpose since the number of ongoing OBP sensors is so small (currently tens of sensors versus the potential of many hundreds of sensors on SMART cables).

Tsunami Monitoring and Warning

One of the most pressing issues in the tsunami warning community concerns the ability to distinguish destructive tsunamis from those measurable on sea-level gauges but which do not pose a hazard along distant coastlines (Angove et al., 2019). Since the US tsunami warning system began in 1949, 75% of the evacuations of Hawaii’s coastlines have been unnecessary, with direct and indirect costs of millions or tens of millions of dollars per event. This is also true for other coastlines in the Pacific basin and elsewhere. In an attempt to alleviate this problem, NOAA’s Pacific Marine Environmental Laboratory (PMEL) developed the Deep-Ocean Assessment and Reporting of Tsunamis (DART) system (Paros, 2011; Bernard and Titov, 2015) which consists of an OBP sensor that communicates via an acoustic modem with a surface buoy that in turn relays the pressure measurements through the IRIDIUM satellite constellation. Prior to the development of the DART system, warning systems had to rely on tide gauges and coastal

observations when evaluating the potential destructiveness of a tsunami on distant shores. As tsunami height can be strongly affected by nearshore bathymetry and harbor resonance, reliance on coastal observations coupled with the assumption of worst-case scenarios made unnecessary evacuations inevitable. The main limitations of the DARTs are that they require their own power source, need maintenance every 2–3 years, and their availability is reduced significantly by destructive weather and, in some regions, vandalism. Compared to DARTs, SMART cable-based pressure sensors offer much denser sampling and effectively zero maintenance costs after deployment.

An even greater challenge is warning in the near field, i.e., coastal areas directly adjacent to the earthquake rupture. The time between the occurrence of the earthquake and the arrival of the tsunami wave can be as short as 5 min, and in many cases, the tsunami is exacerbated by a sudden co-seismic subsidence of the coast by up to 1–2 m. In all recent catastrophic tsunamigenic earthquakes, fatalities due to the near field tsunami have dominated the overall death toll. Third generation and older DART buoys have to be placed too far from the coast to be helpful for near field warnings due to the necessity of separating in time the pressure fluctuations caused by the tsunami wave from the seismic disturbance caused by the seismic (seafloor) surface wave. SMART cables and fourth generation DART buoys offer higher sample rates, which can separate these two types of disturbances by frequency filtering.

Perhaps the largest uncertainty tsunami warning systems face is in the determination of the source. As some 72% of tsunamis in the historical record are generated by the static seafloor displacement associated with large submarine earthquakes (the remainder by landslides, volcanoes and others), tsunami warning systems have focused on real-time seismology to facilitate rapid tsunami hazard warnings. Until the last decade, the Pacific Tsunami Warning Center (PTWC) based such warnings purely on the earthquake's location and magnitude. However, these quantities alone are not sufficient to precisely assess the effects of a tsunami. As a result, over-warning or unnecessary warnings have been a flaw of whole-ocean warning systems since their inception. Recent advances in computational seismology, such as the ability to rapidly obtain the centroid moment tensor (CMT; Kanamori and Rivera, 2008; Duputel et al., 2012), have enabled the PTWC and other tsunami warning centers to generate whole-ocean forecasts with sufficient accuracy to be of service to emergency management systems. A robust CMT yields an authoritative assessment of the earthquake's magnitude and rupture orientation, subject to an inherent ambiguity between the fault and auxiliary plane (perpendicular to the fault plane and slip vector). It also helps fix the fault geometry for a finite-fault model (Ammon et al., 2005; Weinstein and Lundgren, 2008) which gives the distribution of displacement on the fault plane. From this it is normally straightforward to calculate the sea-floor displacement, which is crucial for determining the overall size of the tsunami and the areas worst affected. A special case is represented by so-called tsunami earthquakes, which are earthquakes that produce tsunamis much larger than expected from their moment magnitude (Kanamori, 1972). Recent examples include the 2006 Java and the 2010 Mentawai

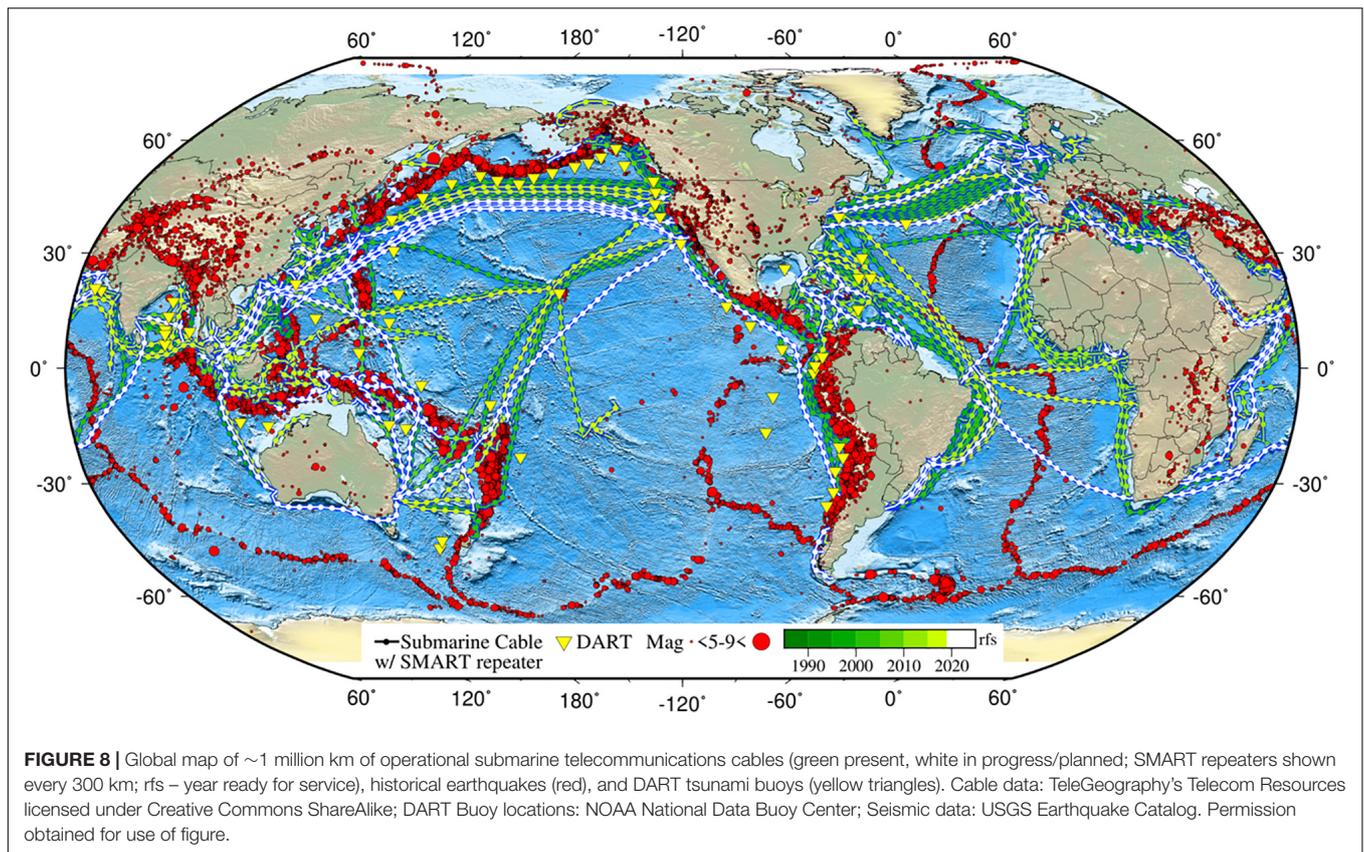

earthquakes. Shaking in these earthquakes is strongly subdued, meaning that the tsunami hits an unprepared population if there is no systematic warning.

The tsunami excitation can be further exacerbated by displacement along splay faults and triggered submarine landslides (e.g., Tappin et al., 2014) which are very difficult to detect by seismology alone. SMART cables can help mitigate this issue by providing arrays of pressure sensors, which allow an accurate assessment of the tsunami wave field as it propagates. Currently there are only some 70 or so deep ocean sensors (e.g., DARTs and DONET, S-net, ONC and OOI cabled observatories) permanently in operation and the vast majority of them are in the Pacific Basin. Placing pressure sensors on SMART cables could increase that number well into the hundreds or thousands (Figure 8). This additional near-real-time information can be used to validate and/or revise forecasts making tsunami warnings for areas >1,000 km from the earthquake more precise and greatly reducing the potential of unnecessary warnings and evacuations.

In addition to pressure sensors, SMART cables are envisioned to include strong-motion instruments (accelerometers), which measure the motion of the seafloor during an earthquake. With a few exceptions, currently all seismometers and strong-motion instruments are land-based, resulting in a one-sided view of subduction zone earthquakes. Accelerometers on SMART cables would fill in the gaps in the global seismic network (GSN) by acquiring data all along their routes, including in some cases, as they cross subduction zones, the source of the great earthquakes that generate ocean-crossing destructive tsunamis. Having a SMART cable with accelerometers near a submarine earthquake (i.e., having at least one sensor package within 100 km, although more distant sensors also significantly contribute) would allow for faster, more accurate hypocenter locations, magnitude estimates, CMT calculations, and finite-fault determinations. This additional information will speed up the process and improve the precision of tsunami wave height propagation models.

The PTWC has performed preliminary calculations as to how SMART cables can improve the tsunami warning system. Figure 9 shows the routes of five hypothetical cables that contain OBP sensor/seismometer packages and the division of the world's subduction zones into potential epicenters of great earthquakes. The routes chosen are hypothetical SMART cable routes and are not specifically based on any existing telecommunication cable route. The instrument packages are spaced 500 km apart and the calculations assume 688 potential earthquake centers located every 120 km on the world's subduction zones.

Pacific Tsunami Warning Center has estimated the potential impact of SMART cables on the speed with which an earthquake hypocenter might be determined. Five stations must detect the P-wave and the largest azimuth gap between any two (azimuthally) neighboring stations with respect to the hypocenter must be less than 180°. The calculation assumes an earthquake at each epicenter and then computes the minimum time required to meet the five station and azimuth gap requirement. The calculations are performed based on the seismic station distribution available to PTWC (as of 2016) with and without the

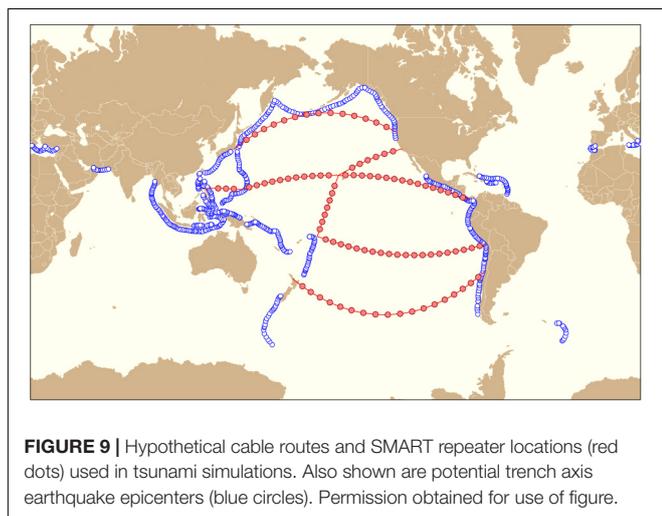

SMART cables in **Figure 9**. The resulting distribution of time-to-detection is shown in **Figure 10** (left). The inclusion of just five SMART cables has the potential to speed up Pacific-wide earthquake epicenter determinations by an average of ~21%.

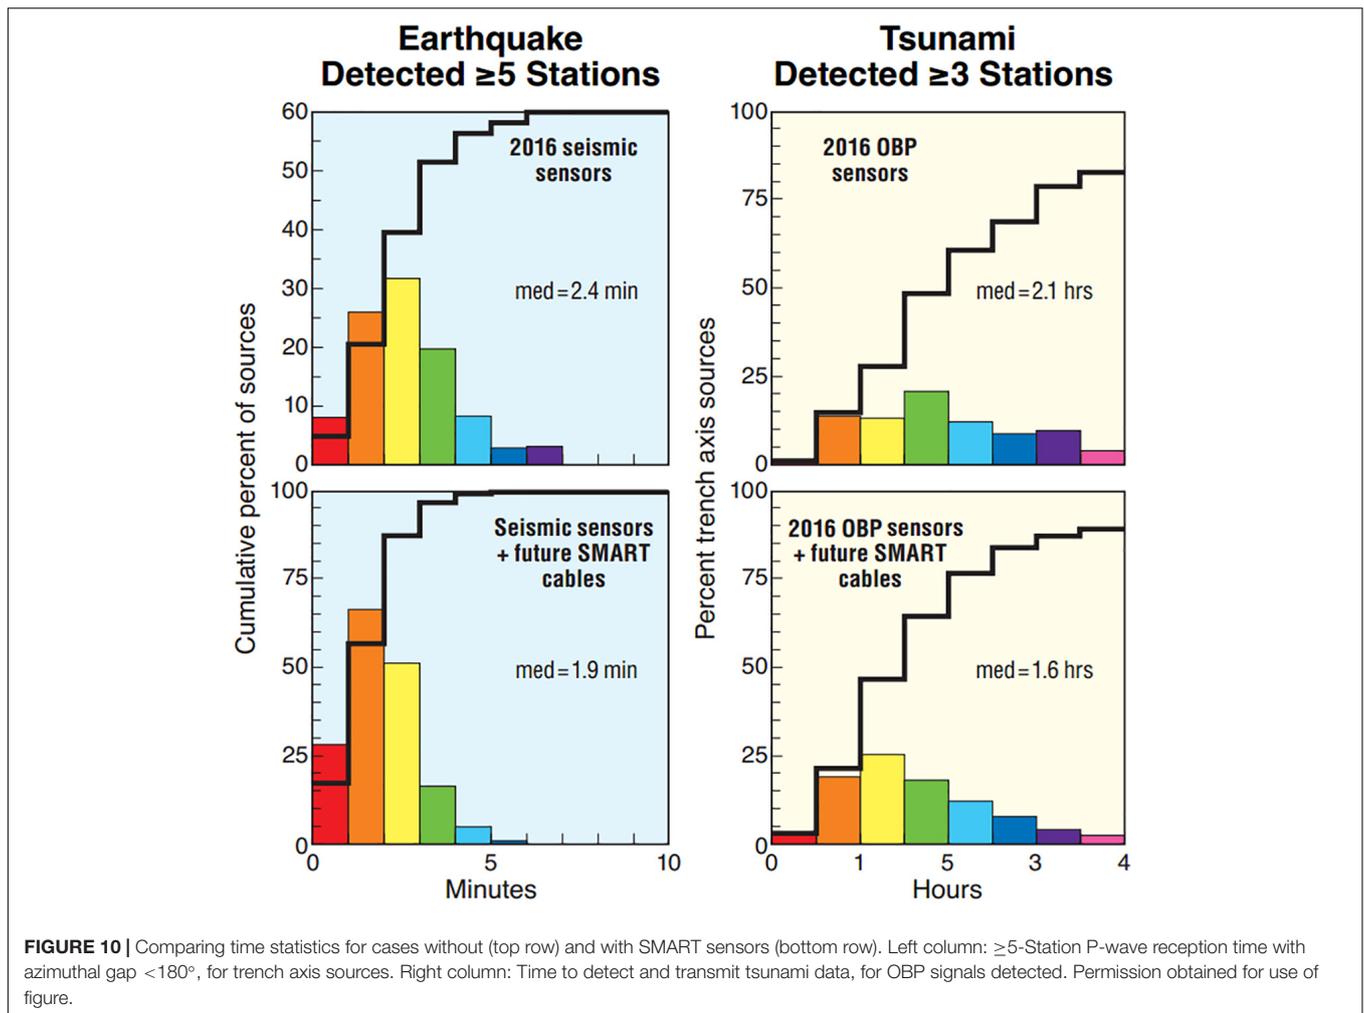

Similarly, we calculated the reduction in latency in tsunami detection that is achievable with OBP sensors, following a tsunamigenic earthquake. Using the 688 epicenters in **Figure 9**, tsunami travel-times are computed from each epicenter to the set

of OBP sensors received by PTWC with and without the OBP sensors associated with the SMART cables. With SMART cables in place, the time required to observe the tsunami arrival at three or more OBP sensors is reduced by ~25% (**Figure 10**, right).

Specifically, the four charts in **Figure 10** compare detection time for earthquakes (left) and tsunamis (right), first using only those sensors available in 2016 (top), and then using existing sensors augmented with simulated data from future SMART cable sensors (bottom). Detection of an earthquake – meaning reception on ≥5 seismic instruments – is reduced from 2.4 to 1.9 min, or from an average of 2 min 24 s down to 1 min 54 s, which is a 21% reduction. Thirty seconds is an eternity in earthquake detection and warning.

Tsunami detection at ≥3 pressure sensors showed a similar percentage improvement, dropping from 2.1 to 1.6 h, for a 24% improvement. Although wide-area tsunami warnings are already helping save lives, unnecessary or overbroad warnings and evacuation orders have significant financial and safety costs. The reduction in detection time coupled with a better description of the wave field will help better characterize the source and improve forecasts in both the near and far field. This will help reduce unnecessary evacuations, which are a longstanding criticism of tsunami warning systems. Thus, SMART-cable augmented tsunami detection will help reduce the direct and indirect costs associated with tsunami warning and evacuation programs, as well as likely improving confidence in the warning system and compliance in the event of a necessary evacuation.

The minimum time required for earthquake location and time required to observe a tsunami at three or more pressure sensors would be further reduced if more repeaters were equipped with SMART capability, reducing the interval between sensors from 500 to 50 km. To balance detection speed and cost, SMART-enabled repeaters could be deployed more densely near the coast and at greater intervals farther away.

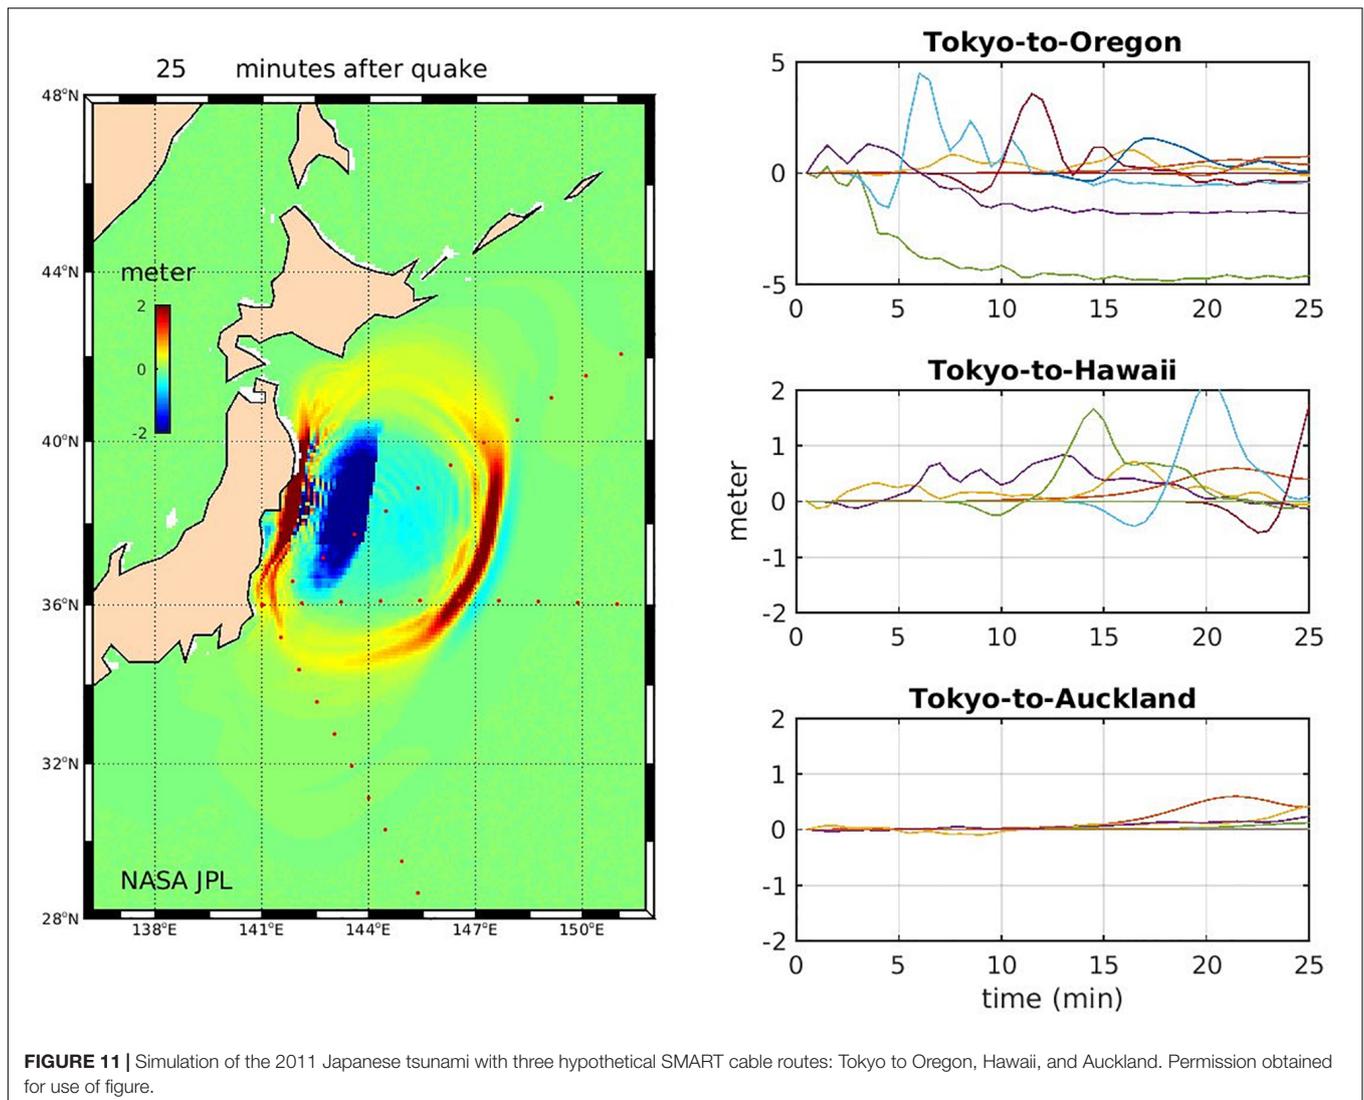

Even larger gains, particularly for the near field, are possible for telecommunications cables running parallel to the coast, as they would provide several measurements from the near-source region, and immediately would constrain the lateral extent of any rupture. Even essential improvements in earthquake early warning, e.g., alerts ahead of strong shaking, might become feasible, depending on the exact position of the cable. The coast-parallel cable does not need to run in close proximity to the coast on the continental shelf but can be in deep water seaward of the trench.

To demonstrate the feasibility of SMART cables for tsunami early warning, the 2011 Tohoku-Oki earthquake and tsunami have been simulated with three hypothetical SMART cables from Tokyo to Oregon, Hawaii, and Auckland, respectively (Figure 11). We show that with these hypothetical cables, the

2011 Japanese tsunami could have been detected and its height confirmed within a few minutes after the earthquake and about 20 min earlier than was possible with the nearby DART buoy (Song et al., 2012). This would have provided enough time for warning the coastal communities. While the S-net early warning cable system mentioned above was specifically built to do this, this could apply just as well to other similar regions, such as the margin of South America.

Seismology

The inclusion of high-sensitivity accelerometers on SMART cables holds great potential for significant advances for the field of seismology by improving our capacity to detect and locate small earthquakes below the ocean floor by improving our ability to determine the rupture type and dynamics for larger offshore earthquakes and by enhancing our ability to image the interior of the Earth. Accelerometers are generally tuned to measure the strong ground motion occurring during large earthquakes, but modern instruments with exceptional sensitivity are available (Paros et al., 2012) that can capture the weak motions associated with distant or small earthquakes. Pressure sensors also provide very useful information to

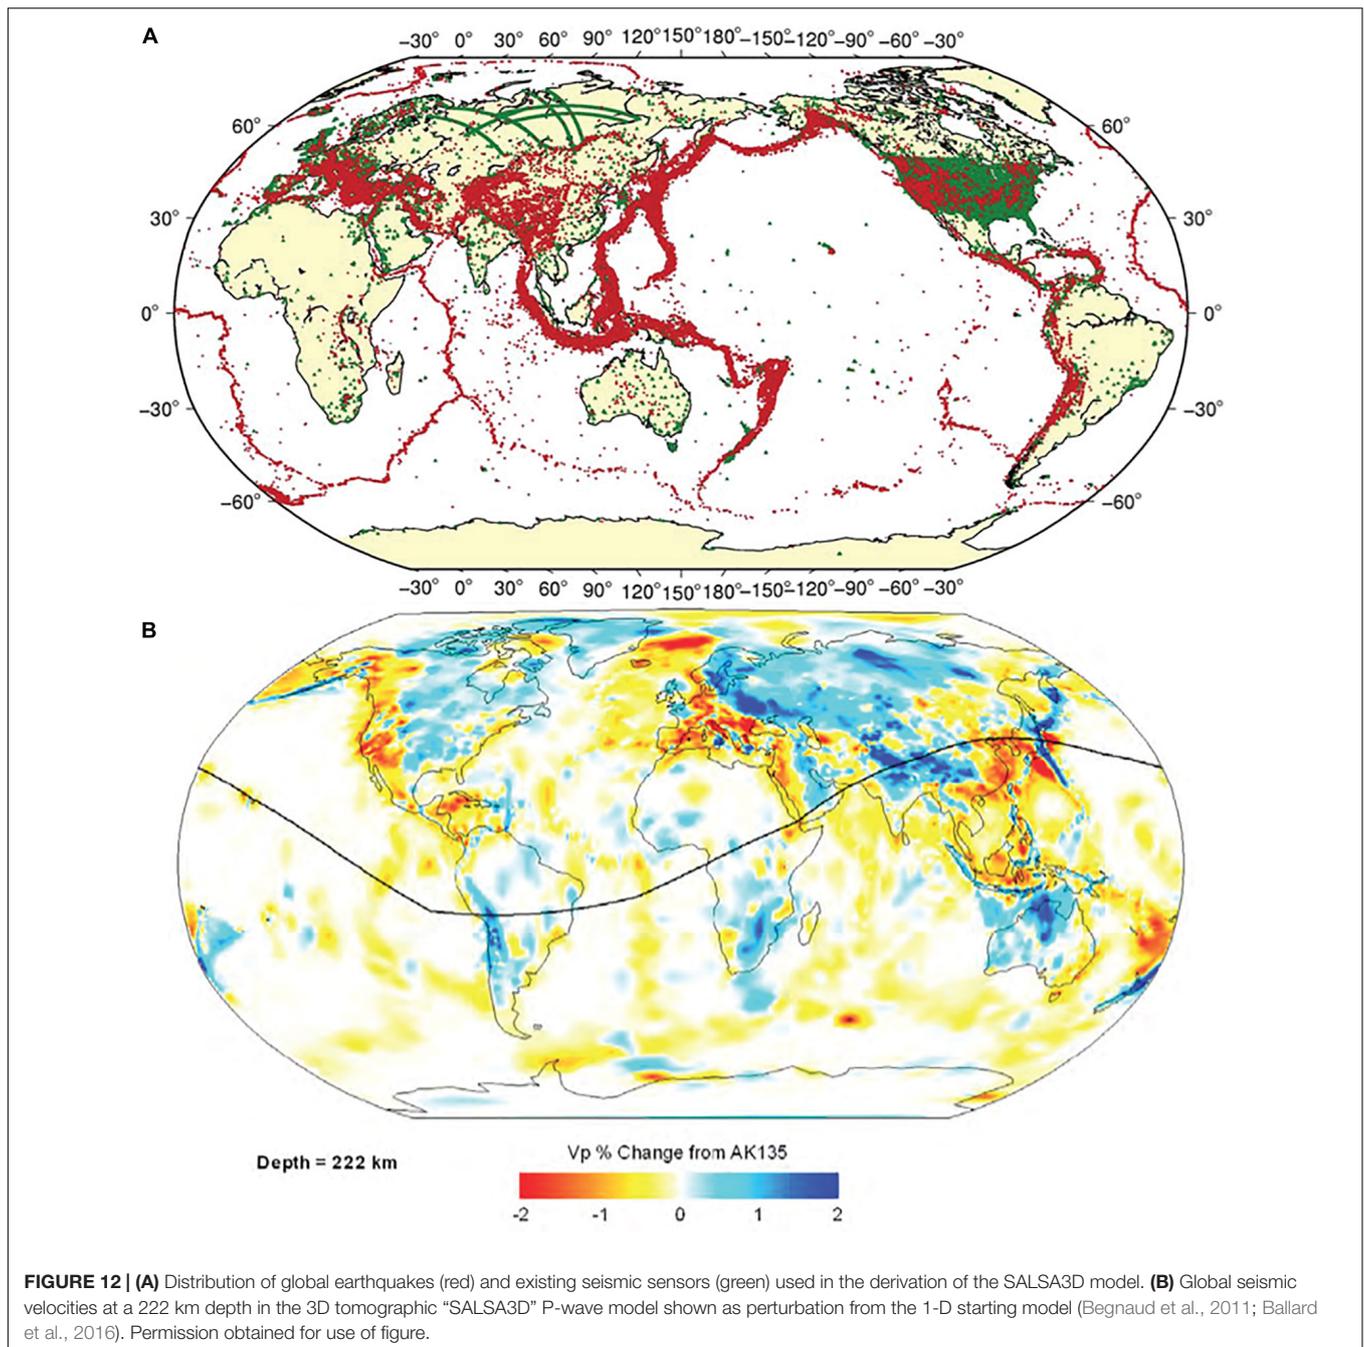

seismologists, as the elastic waves in the solid Earth easily couple into the water layer. They are particularly suitable for studying lithospheric structure and lithosphere-asthenosphere interactions with seismic surface waves.

As an example of the many possible applications, we focus on global body wave tomography as an example to illustrate the potential of data collected from SMART cables for improved sampling of parts of the Earth structure previously poorly illuminated due to the heterogeneous distribution of both earthquakes (largely at the margins of tectonic plates) and sensors (mostly on-land or near shore) (**Figure 12A**). **Figure 12B** depicts a slice through a 3D global model of seismic velocities, derived through tomographic inversion of travel times from the sources to the receivers illustrated in **Figure 12A**. Here, the intensity of color indicates a change in the velocity model, driven by the data, from the 1D radial ak135 reference model (Kennett et al., 1995). White regions indicate no change from the starting model. Because of reduced coverage below the oceans, it is difficult to say whether these are due to (expected) greater homogeneity

below the ocean plates or because of lack of data in these places, hampering our ability to make robust geodynamic interpretation. The addition of SMART cable seismic sensors will significantly enhance the sampling of the Earth by augmenting existing ray paths of seismic propagation.

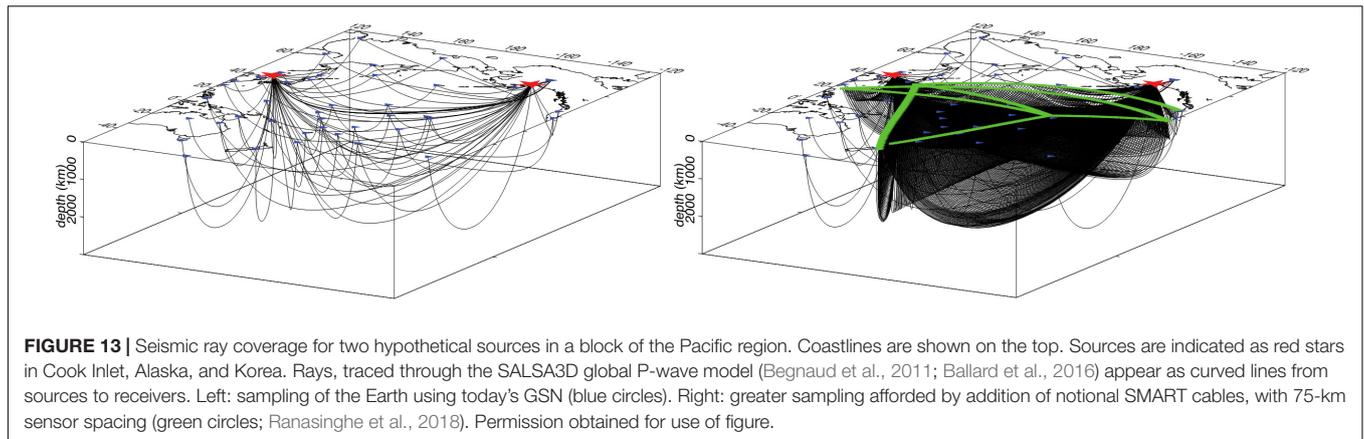

Figure 13 shows a likely sampling improvement for two example earthquakes, for which we performed raytracing to notional receivers along northern Pacific proposed SMART cable positions. We compare ray coverage for these sources using the existing GSN (left) with that possible with these notional SMART cables (right). Full global forward modeling using 20 years of earthquakes demonstrates over 300% improvement in some suboceanic regions, where SMART cables would be deployed (Ranasinghe et al., 2018). This improved coverage will facilitate higher-fidelity 3D global models of both seismic wave speeds and attenuation, improving insight into the physical properties of the Earth mantle beneath the oceans and thus enabling better understanding of geodynamic processes. Improved models of the Earth's interior improve location estimates of seismic sources and

their sizes, which can retrospectively even benefit older events. The SMART cables will reduce detection thresholds not only for small events in proximity to the cables, but also for distant events whose signals can be enhanced by linear array methods using the new sensors.

Many large, destructive earthquakes occur in nearshore environments, where oceanic and continental lithosphere converge. Such plate interactions often occur offshore, hence on-shore seismic networks are some distance from the source, and provide a one-sided distribution of receivers, poorly constraining the location. If a nearby SMART cable exists, it

would significantly enhance earthquake location estimates by reducing the azimuthal gap of sensors near the epicenter, as discussed in section “The Global Subsea Fiber Optic Network.” SMART cable sensors may enhance early earthquake warning for offshore events via faster detection of first seismic waves at closer sensors. This could not only provide some seconds of additional seismic warning time for earthquakes occurring near a deployed SMART cable, but also the improved detection capability could be brought to bear on the analysis of moderate and small earthquakes occurring frequently at these margins. Based on their study we can determine the position of faults

and then, by applying tomographic analysis at a much smaller scale than described above estimate the material properties in the forearc. In turn these can help us to enhance our understanding of the seismogenic potential of the margin.

TECHNICAL APPROACH

SMART Cable Concept Requirements

The fundamental premise of SMART cables is integrating environmental sensors into commercial submarine telecommunications cables. The crucial objectives are: (a) to obtain long term measurements of ocean bottom temperature, pressure, and three-axis seismic acceleration, (b) to have little or no impact on the operation of the telecommunications system that hosts the sensors, (c) to require no special handling or deployment methods, and (d) to be sufficiently reliable that 95% of all sensors operate for a minimum of 10 years.

The Global Subsea Fiber Optic Network

More than 1.1 million km of cable and 400 independent subsea cable systems are operated, maintained, and periodically renewed by the telecommunications industry. A full technical description of modern cable systems is given by Chesnoy (2016). Cables are installed across the North Atlantic, North Pacific, through the Mediterranean and Indian Oceans, through the Middle East, around South America and Africa, and throughout Oceania. Replacement or expansion cables are installed at intervals ranging from a few years on major routes to 10–15 years on minor routes. Thus, there is an opportunity on most or all cables to introduce sensor capabilities within the next 5–10 years.

Subsea Cables

A subsea fiber optic communications system comprises the cable (with varying layers of protection depending on water depth, seabed conditions, and potential risks), pressure housings containing erbium doped fiber amplifiers (EDFAs) (referred to as “repeaters”) spaced at intervals from 60 to 150 km, power feed equipment (PFE) that delivers a controlled direct current to the repeaters through the cable’s single electrical conductor, and terminal station equipment (TSE) to transmit and receive

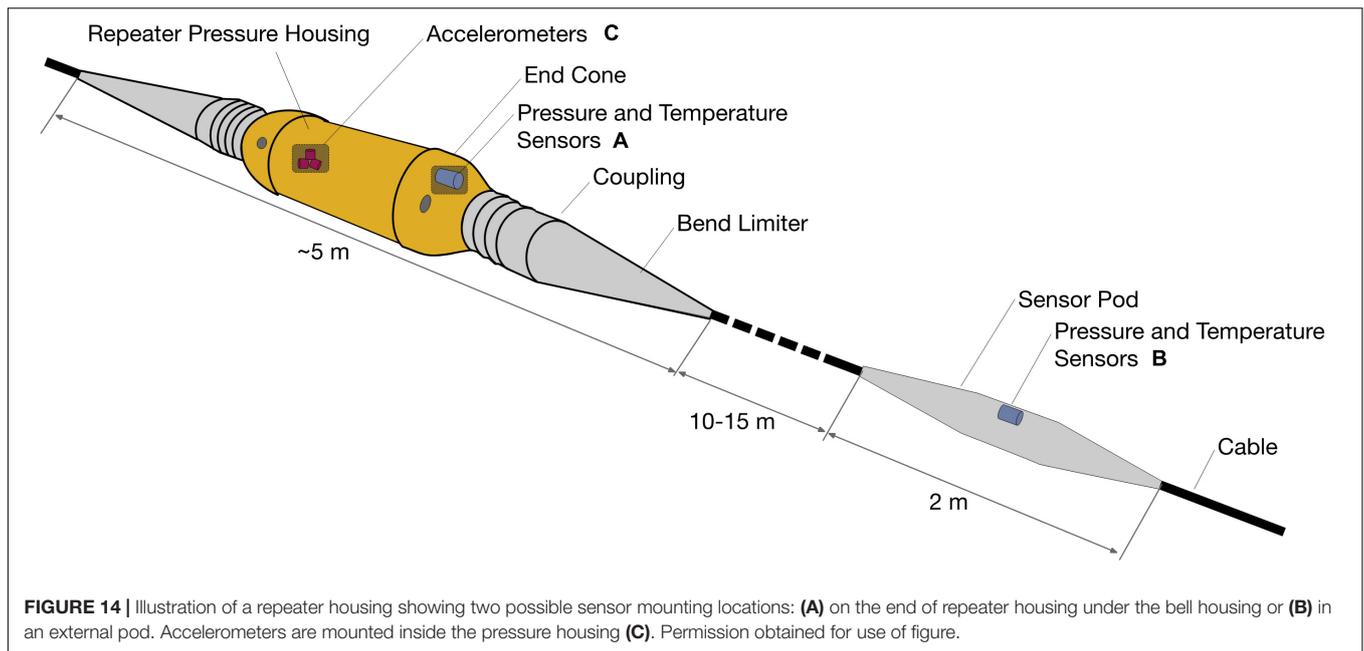

signals on the optical fiber strands within the cable. Systems may include branching units (BUs) to provide connections to locations along the main cable route. Lengths range from less than 100 km to greater than 10,000 km. Regional systems with lengths up to 2,500 km are ideal for the inclusion of sensor capabilities because these systems have sufficient design margin and can usually accommodate additional fibers to carry sensor data. Ocean spanning cables of 6,000 km or more are the most challenging. Successful operation of shorter SMART cables will be needed before sensor functions can be introduced into the longest cables.

The repeater is housed in a cylindrical pressure vessel typically 30 cm in diameter and 60–120 cm in length. Together with couplings and strain relief, the entire repeater assembly is 3–5 m long (Figure 14). The repeater houses EDFAs, which provide signal gain. The current generation of cable systems can have up to 16 fibers (eight bi-directional pairs) and work is underway to allow higher numbers of fibers.

From Single-Purpose Cables to SMART Cables

Functional elements to be added into the repeater include the sensors themselves, digital signal processing, an embedded processor, an Ethernet data switch, fiber optic transceivers, and power supplies. The most feasible way to transmit sensor data is to dedicate one fiber pair, although this reduces the overall capacity of the cable system. Options for embedding sensor data into the signal on a fiber pair dedicated to telecommunications are also under consideration.

To successfully incorporate sensors into a repeater, a number of engineering challenges must be addressed (Joint Task Force, 2015a; Lentz and Howe, 2018). Accelerometers will be mounted inside the repeater housing. The coupling characteristics between various types of seabed and the repeater housing are a subject for further study, although similar housings for ocean bottom seismometers are being used in systems such as Japan’s S-net (Kanazawa et al., 2016). Temperature and pressure sensors must be placed outside the repeater housing, in contact with the environment, necessitating a penetration of the housing to connect these sensors to the internal circuitry (Figure 14). The

sensors must be isolated from high voltages present within the repeater and must be fail-safe so that the normal operation of the repeater cannot be impacted by faults in the external sensors. All of this must be done in a manner that is consistent with the 25-year expected operating life and 8,000 m deployment depth of a commercial repeater. Work is underway to identify and address these issues but will ultimately require the involvement of repeater manufacturers' development teams. Pressure sensor drift remains problematic and although a method of correction has been demonstrated (Wilcock et al., 2017), the resulting form factor is not yet suitable for incorporation into a repeater. The use of quartz pressure sensors without correction remains the best solution currently available.

An alternative, interim solution for adding SMART capabilities to commercial cable projects is to attach a set of SMART repeaters to a backbone cable by means of a BU. The backbone cable contains conventional telecommunications repeaters from which optical fibers and a power feed conductor "branch off" to a dedicated science cable that is independent of the telecommunications system. This arrangement has essentially no impact on the design of the backbone telecommunications system. The only non-standard component is the dual conductor cable required between the BU and shore station, although such a cable has been successfully deployed on multiple prior projects. The BU approach is attractive as an interim SMART cable demonstration because it avoids planning and technical complications of integrating SMART capabilities into tightly designed, standardized telecommunications repeaters. In a BU system, the power utilization, mechanical size, and reliability of the SMART sensors need not conform to the constraints of a fully functioning repeater. This flexibility can be used to prove SMART repeater designs, try other types of sensors, and demonstrate the data gathering and data management processes prior to approaching telecommunications and cable providers with the

proposal for integration into the repeaters of the backbone cable. This interim variant is called a "wet demonstrator" (Joint Task Force, 2015b; Joint Task Force Engineering Team, 2016a,b). The chief drawback of this approach is the SMART functions are not hosted directly on the repeaters but rather are connected to a separate cable which does not provide telecommunications functions; while some costs can still be shared, this reduces the synergy between the telecommunications and science investment.

Previous Work

The earliest example of a submarine cable-based observatory is the Geophysical and Oceanographical-Trans Ocean Cable (Geo-TOC), which was installed in 1997 midway between Guam and Japan using the retired TPC-1 communications cable (Kasahara et al., 1998). The Geo-TOC system anticipated the development of SMART cables by almost two decades yet included all essential SMART cable features: a three-axis accelerometer, pressure sensor, and precision thermometer. These were incorporated into an in-line pressure housing which was deployed from a cable ship in a conventional manner.

In the first decade of the 2000s, attention shifted to regional scale observatories such as NEPTUNE/ONC in Canada, DONET in Japan, and the OOI Regional Cabled Array (RCA) in the United States (Hazell et al., 2007; Kawaguchi et al., 2008; Consortium for Ocean Leadership, 2010; Barnes et al., 2015). Each of these employed telecommunications cable and repeaters; bespoke housings were developed for interconnection, power delivery, and communications. Sensors are installed on separate platforms outside the main pressure housings. These projects demonstrate the usefulness of commercial telecommunications technology in the realm of ocean observing but do not incorporate the close integration needed to create a true SMART cable.

Following the Tōhoku earthquake and tsunami of 2011, Japan undertook rapid development of a large-scale network of subsea seismic and pressure sensors (Kanazawa, 2013; Kanazawa et al., 2016). The resulting S-net system incorporates many of the functions essential to a SMART cable. The overall deployment consists of 150 observation nodes along 5,700 km of cable divided into six independent subsystems. Each observation node consists of an underwater housing containing seismometers and pressure sensors connected in-line with a telecommunications cable. The result closely resembles a telecommunications repeater, however, as the rigid case has a length 1 m greater than that of a typical repeater, modifications to conventional cable laying equipment are required. Nevertheless, S-net provides evidence that SMART cables are close to being feasible using currently available technology.

Another in-line ocean bottom seismometer was developed by the University of Tokyo (Shinohara et al., 2014). This design is more compact than the S-net observatory at 50 cm long and 13 cm in diameter. A total of four units and 25 km of cable were deployed off the west coast of Awashima in 2012 using conventional cable laying equipment. Ethernet switches and optical transceivers are employed, an approach which could also be applied to SMART cables. In 2015, this was commercialized using an industry standard repeater housing and deployed off Sanriku with three nodes and a length of 105 km. This design is commercially available and could be employed as an initial demonstration to build further confidence in the feasibility of SMART cables (Shinohara et al., 2016).

Sensors

The SMART cable sensor suite is comprised of just three sensors for temperature, pressure and acceleration, chosen based on the science described above and for engineering simplicity, especially important in facilitating the overall acceptance of the SMART concept by industry. These are well proven sensors, long used in oceanography and cabled observatories and early warning systems. Temperature is a local measurement while pressure and acceleration provide remote sensing of the entire water column and remote events and the intervening media. Detailed requirements for the SMART sensors are given in the several white papers (Lentz and Phibbs, 2012; Joint Task Force, 2015a).

Temperature sensors can meet the required initial accuracy of 1 mK and stability of 2 mK/year. They need to be mounted some distance from the repeater, a “heat island” dissipating ~50 W; this can be done in a sheath meters from the repeater (**Figure 14**).

Three-axis accelerometers, also called strong motion sensors or seismometers, reside inside the repeater housings; indeed, simple accelerometers are included in one supplier’s repeaters for engineering purposes (Xtera, 2016). The key requirements for SMART accelerometers are a noise level less than 2 ng at 1 Hz and a sample rate of 200 Hz.

Pressure sensors also need to reside external to the repeater housing (see **Figure 14**) with access to local ambient pressure; there is typically a dedicated internal temperature sensor immediately next to the sensing element to account for temperature dependence. The main requirements are: depth rating to 7,000 m (with overpressure tolerance to 8,000 m,

the standard telecom rating); short term accuracy 1 mm water relative to recent measurements; 0.01% of full range absolute; and maximum allowable drift during a settling-in period of 20 cm/year.

Sensors meeting these requirements will be used for the first SMART systems. It is recognized though that sensors are continually improving, and different observables may be desired. In the first category, much effort has been devoted to removing long term drift from pressure sensor data with linear and exponential terms (Watts and Kontoyiannis, 1990; Polster et al., 2009). A new *in situ* calibration method has been devised that largely removes sensor calibration drift, reducing it from ~10 cm/year (initial) to ~1 mm/year, less than the nominal 3 mm/year sea level rise. In this “A-0-A” method, the pressure sensor is occasionally switched from Ambient water pressure to “0” internal case pressure, the latter nominally 1 atm measured with a barometer (Wilcock et al., 2017). While the current prototypes are too bulky, and the mechanical valving is cumbersome, it is worthwhile to monitor the development of the technology.

In the second category of other observables and sensors, many have been suggested, including hydrophones, conductivity sensors, inverted echosounders, acoustic modems, etc. Given that the SMART repeater will provide a general interface, it should be possible in principle to add these and others. In a different class is a new distributed sensing technology based on using optical fibers themselves as sensors. Any strain (stretch) in the fibers can be detected by Brillouin optical correlation domain reflectometry (BOCDR; currently to 50 km; Galindez-Jamioy and López-Higuera, 2012), Rayleigh backscatter interferometry (Lindsey et al., 2017), or a combination of forward transmission optical interferometry and absolute time measurement (Marra et al., 2018). The latter, based on connecting the world’s ultra-stable optical clocks over all-optical networks, opens the possibility of passively using existing trans-ocean fibers as continuously distributed seismic sensors. We strongly emphasize that these additional sensor concepts are for the future. The first, essential step is to achieve successful deployments of the initial three chosen sensor types.

Design and Development

The design and development of SMART cables will require an unprecedented level of cooperation between scientific organizations, cable system suppliers, and cable system operators. The deployment of seismic observatories in Japan demonstrates that many of the necessary components and capabilities are already available. Achieving integration with telecommunications systems will require further refinement of the sensors, design and development of the signal processing and data transmission circuits, and mechanical integration into the repeaters. A full set of technical requirements is proposed in a whitepaper prepared by the Joint Task Force Engineering Team (2016a).

Integration of the SMART functions into cable systems requires a substantial investment on the part of the cable system suppliers. Despite similarities in function, each supplier has different mechanical arrangements and manufacturing processes.

Development of a reference design and standard interfaces for the sensors, signal processing boards, and data communications should be pursued to lessen the burden on each potential supplier and to ensure the science objectives are met consistently. This reference design would incorporate, at a minimum, circuit diagrams and functional code; one or more working benchtop prototypes would be assembled. Individual suppliers could then use this to create functional circuit boards which are compatible with their repeater design.

Reliability is a chief concern for telecommunications cables. A rate of no more than one internal failure per 25 years in 5,000 km of cable is a typical objective for telecommunications-only cables. As a matter of principle, the sensor functions of a SMART cable must not reduce this reliability figure. Because the sensor functions are unlikely to achieve this same level of reliability, the integration must be designed to “fail safe” such that any sensor failures have no effect on the telecommunications function.

The initial design goal for the reliability of the sensor functions embedded within a SMART cable is to ensure 95% of all sensors are still operable after 10 years. This goal is chosen because it is reasonably expected that a newer cable system would be installed alongside any existing cable within 10 years, providing a new source of data to first complement and then replace the original SMART cable. Initial review indicates this goal is achievable using currently available technology, with the main limitation being the reliability of laser diodes used to transmit the signals carrying the sensor data from each repeater. SMART cables are expected to use existing, off-the-shelf components, including laser diodes, which have been widely used in industry for decades and have well characterized reliability that meets or exceeds the 10-year design goal.

Commercial cable system operators must be persuaded to support SMART cables. Submarine cable systems represent a significant investment and a critical piece of strategic network infrastructure (Rauscher, 2010). Any interruption in operations has the potential to cause costly disruptions. For this reason, system owners are reluctant to accept anything new or unproven. Smaller projects, particularly those serving island nations that are most at risk from climate and sea level change and tsunamis, are expected to be initially most receptive to SMART cables. Regional systems are more likely to have surplus capacity or unused fiber pairs, thus eliminating the objection that adding SMART functions reduces the cable's overall capacity. Addressing the concerns of the telecommunications industry will require a series of projects that demonstrate that all technical issues have been fully addressed.

DATA MANAGEMENT AND USERS

Data from SMART cables is expected to be open and freely accessible. The overarching principle of data management for SMART cables is to leverage existing infrastructure in the oceanographic research and operations community rather than developing an independent data management system from scratch. As with any large-scale data stewardship program,

findability, accessibility, interoperability, and reusability (the “FAIR” principles) are key (Tanhua et al., 2019a). Management of SMART cable data will require the ability to handle multiple variables at varying temporal resolutions and a system that can scale to handle the large volumes of data that will be generated by a mature cable network. In particular, SMART cables will resolve processes ranging in temporal scale from earthquake seismic signals and tsunamis to secular climate trends and will need to support both real-time and delayed-mode applications to facilitate hazard monitoring and research.

Data generated by SMART cable sensors will be transmitted along the underlying cable to a shore station where it may be stored in raw form, processed, and transmitted onward to data repositories, national agencies, and academic institutions (Figure 15). Seismic and pressure sensor data that will be used for early warning functions must be forwarded immediately, with minimal latency. Data will be processed and transmitted in recognized formats, such as SeedLink, to ensure compatibility with existing data processing and archival systems.

The Incorporated Research Institutions for Seismology (IRIS) has volunteered to receive, curate, and disseminate all of the data from SMART cable sensors through its well-developed data collection and dissemination process. Particularly valuable is IRIS' capability to ingest high-temporal resolution data, such as output from accelerometers at 100 Hz. This early commitment by a world-leading data management cooperative ensures that SMART cable data products will have an immediate user, as well as being available to myriad other institutions that are not otherwise associated with SMART cable projects.

In addition to distribution through IRIS, SMART cables data products may be managed by a dedicated consortium. A close analog to such a network-specific data management consortium is the global tide gauge network. Like SMART cables, tide gauges are multi-purpose instruments that are also tasked with supporting both tsunami monitoring and climate research applications.

The global tide gauge network comprises approximately a thousand individual instruments organized within a multitude of small, regional networks maintained by independent international agencies in much the same way that SMART cables will be operated by an array of government and industry partners. To facilitate international coordination, the global tide gauge network is overseen by the Global Sea Level Observing System (GLOSS). While it is not possible for GLOSS to absorb SMART cables into its mission outright, there is a clear opportunity for partnership involving exchange of data management platforms and best practices, as well as leveraging existing GLOSS contacts within governmental hydrographic and oceanographic services.

The University of Hawaii Sea Level Center (UHSLC), a primary GLOSS datacenter, will foster collaboration between the SMART cables and GLOSS communities and will leverage existing resources to host first-generation versions of delayed-mode datasets. This effort includes ensuring that these data are available to researchers via standard interfaces such as OPENDAP, ERRDAP, etc. The UHSLC will also work with the SMART cables community to establish standardized formatting

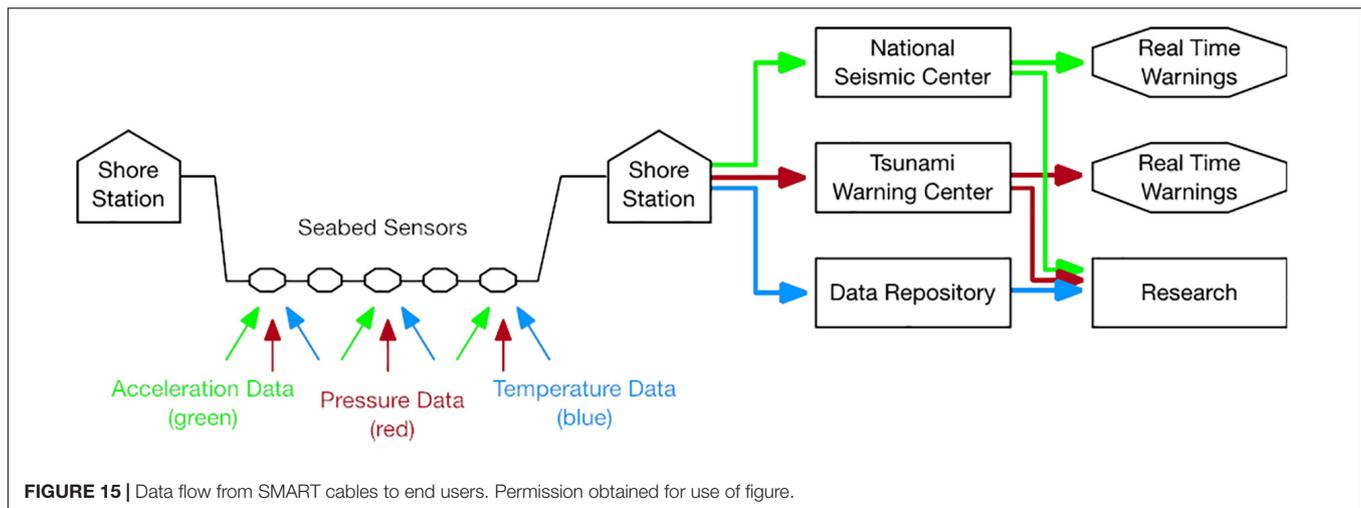

FIGURE 15 | Data flow from SMART cables to end users. Permission obtained for use of figure.

and transmission of real-time SMART cable data over the WMO Global Telecommunication System (GTS). Once on the GTS, tsunami and seismic monitoring facilities will have real-time access to the data and delayed-mode datacenters will be able to retrieve, process, and archive SMART cable data.

Researchers and institutions worldwide have already identified uses for the data products derived from SMART cables. As discussed in section “Technical Approach,” the unprecedented volume of real-time, deep ocean data has the potential to advance oceanographic and seismic understanding across multiple and varied domains. The cable industry itself will be a user of the data, as cable systems necessarily evolve to smart infrastructure, monitoring for threats from trawling, anchors, submarine landslides, and earthquakes (Butler et al., 2014; Huchet and Brenne, 2018).

PROGRAM MANAGEMENT

Joint Task Force has about 130 members representing 80 organizations, almost entirely volunteer. It is sponsored by ITU, WMO, and IOC within the context of GOOS. ITU provides Secretariat support, and IOC provides modest support for reports (with some industry contributions), meetings, workshops, and travel. Major activities at this time include: building relationships with relevant stakeholders, presenting and obtaining support at meetings and conferences, working with multilateral development banks to secure funding, and interacting with candidate cable projects. JTF is not set up to directly participate in specific projects, but rather to facilitate the formation of the appropriate groups to accomplish the necessary tasks. Indeed, after a few fully operational systems are installed, JTF expects to transition into an international project office. The JTF terms of reference can be found on the web page: <https://www.itu.int/en/ITU-T/climatechange/task-force-sc/Pages/default.aspx>.

For the management of the wet demonstration project (based on the scenario of adding a BU to a new system with SMART modules), it is expected that the management structure will

be prescribed by the participants. One wet demo provider would be the recipient (after competition) of a subcontract with the main supplier of the cable system. A project management consultancy would participate. Part of this would include setting up mechanisms for data transfer, quality control, and use.

Following this phase, the first pilot systems with SMART repeaters in active telecom cables would be established. For each system, there would be a local/regional science/early warning working group representing the countries involved that would interface with the cable industry partners, arrange funding, provide oversight of the SMART component of the project (e.g., participation in relevant factory acceptance tests), and arrange for the data management and use. During this phase, it is expected that the provision of the SMART components is handled by the main telecom supplier. JTF would provide advice and facilitate as necessary.

After the first pilots are operating, an international project office will evolve, initially formed by the associated working groups and then expanding to provide oversight and an international and global perspective as additional pilots and then standard systems are installed and operated, following, for example, the International Argo project structure. The latter includes a Project Office with Director and Technical Coordinator, a Steering Team, a Data Management Team, and Information Center, and Oversight Committee. An important responsibility of the project office will be to coordinate education, outreach, and capacity building activities. This international project office would take over the activities of JTF, i.e., the ongoing implementation of the SMART concept within the context of GOOS and the FOO.

LEGAL OUTLOOK

Because SMART cables combine science and telecommunications into a single cable, they do not fit neatly into the international legal frameworks that developed while these were separate maritime activities. Fortunately, the current lag between international legal definitions and research innovation

is unlikely to have a practical impact on near-term SMART cable projects, which will be carried out exclusively in the Exclusive Economic Zone (“EEZ”) of cooperating nations and the high seas. As the dual-use cables concept turns from development to deployment, the collective international understanding of their legal status will be refined, and based on concrete examples, routes, and uses. The following discussion summarizes and updates JTF’s comprehensive legal analysis conducted in 2012 (Bressie, 2012).

The Legal Regime Governing Telecommunications Cables

The laws regarding passage and usage of the seas are established by the United Nations Convention on the Law of the Sea (UNCLOS; United Nations, 1982), other treaties, and customary international law, which establish certain sovereign and jurisdictional rights for coastal states, depending on the distance from their coasts. These rights are generally most extensive in a nation’s territorial waters, and diminish with distance through the contiguous zone, EEZ, continental shelf, and high seas.

International treaties dating back to 1884 guarantee unique freedoms to lay, maintain, and repair submarine cables not only on the high seas, but on the continental shelf and in the EEZ, making them among the most protected of marine activities (Convention, 1884; United Nations, 1958a,b). As the most comprehensive oceans-related treaty, UNCLOS is the applicable legal regime governing submarine cables and treated as customary international law, even by states that have not ratified them, including the United States (Presidential Proclamation No. 5030, 1983; Presidential Proclamation No. 7219, 1999). As a result, undersea telecommunications cables hold a “privileged place in international law, reflecting their status as an essential public good” (Davenport, 2013).

The Legal Regime Governing Marine Data Collection

By contrast, certain types of marine data collection are subject to varying levels of coastal state jurisdiction and regulation. There are several categories of marine data collection: (1) marine scientific research (MSR); (2) survey activities; (3) collection of marine meteorological data; (4) operational oceanography; and (5) exploration for and exploitation of natural resources (Roach, 2007). For SMART cables, the most relevant categories are MSR, marine meteorological data, and operational oceanography.

Importantly, UNCLOS does not define MSR. Its discussion in Article 243 is limited to references to scientists “studying the essence of phenomena and processes occurring in the marine environment and the interrelations between them” and in Article 246(3) to projects “exclusively for peaceful purposes and in order to increase scientific knowledge of the marine environment for the benefit of all mankind.” Ultimately, UNCLOS Article 251 tasked signatories with defining MSR through practice, which has occasionally resulted in tension as different coastal states assert different definitions or scopes of MSR.

Article 87(1)(f) of UNCLOS recognizes MSR as one of the freedoms of the high seas and Article 245 categorizes it as subject

to coastal State sovereignty in the territorial waters and EEZ. Article 246(1-2) set out that MSR in EEZ and continental shelf waters is in general subject to coastal state consent. Although the terms are not specified in UNCLOS, some states divide MSR into categories of “pure scientific research” (essentially activities encompassed by Article 246(3)) in which consent should in normal circumstances be given, and “applied scientific research” [those activities named in Article 246(5)], in which the coastal State may exercise their discretion to withhold consent. States wishing to conduct MSR (whether “pure” or “applied”) in other States’ EEZs or continental shelves are also subject to a number of duties, such as those laid out in Articles 248 and 249.

Other sub-divisions of MSR, which are also commonly used but do not appear in UNCLOS, are marine meteorology and operational oceanography. Marine meteorology generally refers to the collection of meteorological information from equipment such as voluntary observing ships, buoys, and other ocean platforms, and is treated by many coastal states as exempt from coastal State consent requirements applicable to MSR in the EEZ/continental shelf (Davenport, 2013). Operational oceanography is generally defined as an activity of systematic and long-term routine measurements of the seas and oceans and atmosphere, and their rapid interpretation and dissemination to assimilation centers (EuroGOOS, 2018). Some states view operational oceanography as exempt from the MSR regime, while other states view it as a type of MSR and subject to coastal state consent (Roach, 2007).

A Pragmatic Approach: Dual-Use Cables in Cooperating Regions

Thus, JTF, cable projects, and governments have noted the concern that combining science sensors and telecom cables could create uncertainty as to the legal status of such dual-purpose cables, potentially delaying cable deployment.

Fortunately, however, nothing in UNCLOS requires dual-purpose to be classified as MSR or operational oceanography, nor does customary international law reflect such a classification. Thus, individual coastal states have discretion regarding the treatment of dual-use cables, and their practice will form the precedent of how dual-use cables should be treated under international law. More importantly for practical purposes, any current uncertainty would not affect SMART cable projects operating in the high seas or within the EEZ of cooperating nations. Because all JTF projects are expected to be carried out in close cooperation with the national governments with coastal jurisdiction over the areas that the cables land on or transit through, JTF does not expect to encounter any well-founded legal objection.

In this regard, SMART cable projects for the foreseeable future should involve even less legal process than the Argo float system, which itself is well established among coastal states and the international legal community. The Argo system, consisting of nearly 4,000 ocean profiling floats, collects temperature and salinity data mostly in the upper 2,000 m of the ocean, and releases this data freely through the IOC and WMO. In recognition of the value of such measurements, as well as the

absence of specific legal instruments relevant to the project, the IOC concluded that the Argo project must inform affected coastal states when Argo floats might drift into waters of their jurisdiction (i.e., within their EEZ) (International Oceanographic Commission, 2000).

Joint Task Force near term pilot projects are explicitly intended to validate the technology and business case for dual-purpose cables and create a climate where oceanographic sensor-enabled telecommunications cables are a recognized part of maritime infrastructure. In doing so, they will also habituate the industry to such projects and reduce the perceived legal and business risk of this maturing concept.

The scientific community and its vendors can assist this process by developing specifications and standardized components to be included on telecommunications cables. This will provide all parties involved with a clear understanding of the capabilities of dual-purpose cables, thus reducing the potential for concerns by otherwise cooperative nations that such projects could stray from their stated scientific goals.

COST ESTIMATE

The anticipated costs to enable widespread use of SMART cables have been calculated based on known costs for submarine cable systems and sensor sets combined with estimates for development and operational costs. Assumptions regarding the number of cable systems and number of SMART enabled repeaters are a significant factor in establishing the overall costs. To achieve global coverage of 2,000 SMART repeaters, 200 repeaters must be deployed each year. We estimate it will take 10 years to achieve the widespread acceptance necessary to support this deployment rate. Full global deployment is projected to be achieved after 18 years at which time the rate of retirement will equal the rate of new deployments. Costs are separated into three broad categories: development, deployment, and operations.

Development costs include the cost of a demonstration system, the cost to develop a reference design, and non-recurring costs to support the first deliveries of SMART repeaters from cable system suppliers. The demonstration system consists of three prototype sensor sets and up to 300 km of cable. These sensor sets will be installed either as an independent system or as the branching unit off a commercial telecom cable. In either case, the incremental cost associated with the science functionality will be supported by science funding. The reference design is envisioned as an open-source project to develop circuit board schematics, digital signal processing methods, communications protocols and related micro-code which can be reused by each repeater supplier. Some professional input is expected to be required to complete this design, although a large portion of the work should be performed by academia. The final aspect of development costs are non-recurring costs incurred by the cable system suppliers. The first system delivered by each supplier will incur non-recurring development costs. We anticipate that funding will have to be allocated to the first three suppliers that participate in the SMART cable program for this purpose.

Any further participating suppliers will need to bear their own development costs. Development costs are the smallest portion of the overall budget and are incurred only during the first 5 years.

Deployment of fully developed SMART repeaters begins in year three. Deployment costs are calculated based on the number of SMART repeaters deployed times a unit cost, plus some costs for each cable system. We estimate a cost of US\$207,000 per repeater, which includes an allowance for additional fiber in the cable. The cost model assumes this target price will be achieved in the fifth year. For prior and subsequent years, a 10% inflation/deflation factor is applied on the basis that lower volumes will incur higher costs but as delivery volumes and experience increase, the cost will decline to \$175,000 per repeater. Deployment costs ramp from \$6M in year three to a steady state of \$36.5M in year nine. Deployment costs are the largest portion of the overall budget.

The final cost area is operational costs. Operations costs include program administration, data transmission, and data processing costs. Operational costs are about 10% of annual deployment costs but are an essential aspect of the overall program. **Supplementary Table 1** shows the projected approximate system cost. Note the large initial development cost that decreases after approximately year 5, with deployment volume and costs increasing year over year until a steady state in approximately year 10.

For comparison, the US NOAA DART program budget is \$27M/year, comparable to the incremental cost for a SMART cable that spans the Pacific region where most of the US DART buoys are located. The Argo program, with 4,000 expendable floats, costs about \$32M per year to maintain. The NSF funded OOI cost approximately \$400M for the fabrication phase, with operating costs of approximately \$44M annually. NOAA estimates it spends approximately \$430M annually to operate and maintain its ocean, coastal, and Great Lakes observing systems.

FINANCING

Today's submarine cable projects fall into three major categories: consortium, private, and government. In consortium cables, a group of established carriers join to share costs on large projects. Consortium systems are difficult for SMART cables because of the need to get approval from many consortium members. Private cables are undertaken by a single developer using seed financing followed by full project financing with equity and debt. SMART cables in private systems are a reasonable option because the system developer is typically a small cadre of individuals who can be dealt with directly. Because these cables are focused on time to market and profits, however, introducing SMART technology must not cause undue delay or added costs to the owners. Government cables, or government-backed cables, seek to improve a country's link to the global network. With longer timelines and a broader range of goals, these cables represent a good opportunity for SMART cables. This section summarizes and extends a comprehensive funding study undertaken by JTF (OCI Group, 2015).

Early engagement with potential projects is important for influencing the configuration to incorporate SMART requirements and to arrange funding. Because early awareness of a project is not always possible, the SMART efforts must be able to quickly react and introduce SMART requirements into the project technical requirements effort. Equally important at that time is that the SMART effort must clearly demonstrate funding is available for this integration.

Multiple funding options for SMART cables have been summarized in a previous ITU study (OCI Group, 2015). During the course of this investigation it was determined that the potential funders fell into the following categories:

- International Development Agencies
- Foundations
- Government Agencies
- Private Companies

International Development Agencies: Regional multilateral development banks have indicated their support for SMART capabilities in cable projects they are involved with. As of this writing, Asian Development Bank (ADB) supports including SMART capabilities on the Manatua cable in part because the landing point nations of Cook Islands, Niue, Samoa, and Tahiti are acutely exposed to tsunami and climate change risks. ADB expects science capabilities on the East Micronesia Cable for similar reasons. The InterAmerican Development Bank (IADB) is likewise interested, and the IOC Intergovernmental Coordination Group/Pacific Tsunami Warning System (ICP/PTWS) committee is preparing a report for the IADB to facilitate their participation. JTF is also in contact with the World Bank.

Foundations: Only large foundations can support grants of the size anticipated for SMART. JTF is in contact with these major foundations, including the Schmidt Ocean Institute, Schmidt Marine Technology Partners, Simons Foundation, Paul G. Allen Philanthropies, Moore Foundation, Packard Foundation, and Keck Foundation.

Government Agencies: All government agencies are bureaucratic and will require extensive effort to develop funding support, relationships, and consensus. In addition, all government agency funding will be contingent on appropriations and the government budget cycle.

There are a number of candidate government organizations that should be further investigated for funding or to facilitate funding, including in Canada the “Environment and Climate Change Canada” and “Natural Resources Canada”; in Europe the European Commission’s Directorate for Research and Innovation-Research Infrastructures Unit, with the involvement of the Institute for Environment and Sustainability and the European Multidisciplinary Seafloor and Water Column Observatory (EMSO); in Japan the Japan Agency for Marine Earth Science and Technology (JAMSTEC); and in the United States several agencies including the Department of the Interior, the US Geological Survey, the Environmental Protection Agency, the Department of Defense, the Office of Naval Research, and the Department of Commerce, Economic

Development Administration and National Oceanic and Atmospheric Administration (NOAA). In the case of NOAA, funding may be facilitated by the Tsunami Warning, Education and Research Act 2017 (TWEREA; Public Law 115-25) which gives NOAA the responsibility to consider “...integration of tsunami sensors into Federal and commercial submarine telecommunication cables.”

Funding may most readily be obtained from a government that wishes to have its country connected with a new submarine cable and appreciates the value to its country of having SMART technologies as part of the solution. Further, developing countries may be able to arrange funding from the Ministry of Foreign Affairs, or other, of developed country partners for the purposes of community/international connectivity and climate and disaster monitoring.

Private Companies: The previous study effort concluded that commercial entities would be unlikely to allocate funding toward SMART technology because internal research and development dollars are a scarce resource and because such developments may indirectly assist a competitor’s development efforts. However, JTF provides an avenue for commercial entities supportive of JTF’s mission to provide in-kind support through engineering assistance, technical review, or establishing standards. As leading digital technology companies (e.g., Alibaba, Alphabet, Amazon, Apple, Facebook, Microsoft) become more involved with cable systems and more socially conscious, they may become more receptive to dual-purpose cables.

IMPLEMENTATION PLAN

The first deployment of SMART cables is anticipated to be a demonstration system that does not interface with the telecommunications portion of a cable, but instead focuses solely on sensor functionality (Joint Task Force Engineering Team, 2016b). Off-the-shelf components may be used to reduce development costs, even if these are physically larger than would be for a fully developed SMART cable. The demonstration system could be deployed as a branch of a commercial cable system, connected to an existing cabled observatory, or re-use a portion of an out-of-service cable. A minimum of three repeaters need to be included to fully demonstrate sensor functionality. It may be necessary to have more than one demonstration system, as the prototypes come closer to the final version, for instance to demonstrate the power isolation between the external sensors and the internal electronics. If the wet demonstration system was a branch off a commercial telecom system, it would demonstrate the coexistence of telecom and science with no interference.

Following the demonstration system, full development of SMART enabled repeaters must be undertaken by one or more system suppliers. The resulting repeater design will undergo qualification tests and sea trials after which it will be available for use in commercial telecom systems. To increase confidence, it may be necessary to deploy several fully developed repeaters as a further demonstration or in a situation that does not demand high reliability telecommunications services. At this stage of its

development, the SMART repeater could also be used to create a dedicated earthquake/tsunami warning system.

After these confidence-building measures, deployment of the first true SMART cable system will take place. A regional cable, 1,500–2,500 km in length and containing 10–20 repeaters, is ideal as it is manageable both in scope and cost. Successful operation on this scale will provide a final demonstration of the value of SMART cables and ensure they have no impact on the telecommunications performance of the cable system. SMART cables could then be deployed with confidence on trans-Atlantic and trans-Pacific routes. Other cable routes, including the Indian Ocean, South Atlantic and South Pacific, South America, and the Arctic, will be addressed as opportunities arise. An achievable goal for SMART cables is to be generally accepted within 5–7 years and to serve all major ocean routes within the decade.

RELATIONSHIP TO OTHER PROGRAMS

There are natural scientific connections between the SMART program and many other ocean observing programs. There is an urgent need for deep ocean measurements of any type (Levin et al., 2019). Deep ocean temperatures intermittently and coarsely sampled in time and space by deep Argo and by the GO-SHIP program (Meyssignac et al., 2019; Sloyan et al., 2019) will benefit from cross comparison with the fixed high rate Eulerian cable-based measurements and those made by OceanSites moorings (Frajka-Williams et al., 2019), for improved estimates of heat content and deep ocean variability. SMART cable OBP observations will directly feed into the analysis of altimetry and gravity satellite data, as well as contribute to large scale ocean circulation and flux estimates, such as AMOC (Hughes et al., 2018). They are directly relevant to time and space dependent sea level rise estimates, measuring the component associated with increased water mass from melting land ice (Stammer et al., 2013; Ponte et al., 2019). The pressure data will feed directly into tsunami warning centers to improve early warning with better spatial and temporal sampling and array availability (Angove et al., 2019).

From the beginning, the SMART cables initiative has benefited for the sponsorship of its UN organizations – ITU, WMO, and UNESCO-IOC – with the associated imprimatur. With endorsements from the Joint Technical Commission for Oceanography and Marine Meteorology (JCOMM), Data Buoy Coordination Panel (DBCP), the ICG/PTWS, and more recently by the Partnership for Observing the Global Ocean (POGO), the SMART cable project is aligning itself within the FOO (Lindstrom et al., 2012; Snowden et al., 2019; Tanhua et al., 2019b).

SUMMARY

Science Monitoring And Reliable Telecommunications cables fill scientific and societal needs. The science described above and reviewed in multiple workshops – climate,

ocean circulation and sea level rise, and tsunamis and earthquakes – requires the unique data that SMART cables can provide. SMART cables respond to the United Nations Sustainable Development Goals for Climate (SDG 13) and Oceans (SDG 14). Within the context of the OceanObs19 conference, SMART cables address observing technologies and networks, discovery, climate variability and change, and hazards and maritime safety. SMART Cables is an ocean observing technology that needs to be implemented during the UN Decade of Ocean Science for Sustainable Development (2021–2030).

Science Monitoring And Reliable Telecommunications cable systems will directly contribute to the measurement of the EOVs of subsurface temperature and OBP. OBP is an emerging EOV which, through the real-time, global scale sample enabled by SMART cables, can be elevated to full EOV status. Acceleration can be regarded as a supporting variable as it is needed to separate near field pressure and seismic signals for tsunami detection, as well as providing much seismic data, filling the gap of the 70% of the Earth's surface that is ocean. More modeling is required to quantify the benefits, not just for SMART cable scenarios but to the GOOS in general.

Science Monitoring And Reliable Telecommunications cable systems are technically achievable. There are no known technical obstacles, but clearly the engineering development must be performed and all related practical issues addressed. All of the essential components exist today in some form and projects such as DONET, S-net, and Sanriku, demonstrate the capability of the telecommunications industry to deliver ocean observing systems that meet nearly identical goals. Industry partnership and acceptance of the SMART functionality are commercial, rather than technical, challenges to be solved. A reference design that clearly separates the telecommunications and SMART functionality of a subsea cable system will help to address these concerns.

Science Monitoring And Reliable Telecommunications cable systems are allowable within legal and permitting frameworks. JTF is concentrating for the foreseeable future on cable systems in the EEZs of countries that support the SMART cable concept, where there will be strong legal support and few ongoing legal requirements.

Science Monitoring And Reliable Telecommunications cable systems are financially feasible. Cost estimates are similar to other observing system components. The best opportunities for funding appear to be in select development banks, government agencies, and private foundations. Discussions are underway with leading candidate entities, and JTF regularly briefs the others.

Initially, we are relying on development bank funds, with the business case based on combining community connectivity with climate monitoring and disaster mitigation, as encapsulated at the 2018 Global Infrastructure Forum, where “the leading multilateral development banks (MDBs)...expressed their condolences following the tragic loss of lives and livelihoods in Sulawesi, Indonesia and reaffirmed their commitment to

work together to deliver infrastructure that is resilient, inclusive, and sustainable.” (Asian Development Bank, 2018). Nonetheless, governments will have to supply funding as part of their ocean observing efforts. Smaller countries with short chains of command are preferable.

At this point in time, JTF SMART cables is in negotiations to include a wet demonstration component in a commercial system in the South Pacific, with the involvement of the ADB. Other cable systems in the same region are under consideration that include the World Bank. After the Sulawesi earthquake and tsunami of September 28, 2018, the Indonesian government recognizes the need for “cable-based tsunameters” (Kompas Press, 2018). We are engaging in smaller systems that have significant government and/or multilateral development bank involvement for initial wet demonstration and pilot systems. In addition, we are pursuing funding within Europe for the same. Once wet demonstrations and pilots are underway and a SMART repeater is offered “off-the-shelf,” then longer cable system crossing major ocean basins can be considered.

These findings lead to the following recommendations for OceanObs19 to include in the conference outcomes.

Recommendation 1: OceanObs19 recognize the utility of Science Monitoring And Reliable Telecommunications (SMART) subsea cable systems, both in terms of contribution to the observing system and efficiency of effort and investment, and encourages all stakeholders – sensor and system suppliers, system owners, multilateral development banks, other sponsors, and governments and their funding, permitting, early warning, and ocean observing agencies – to participate in the development of the SMART capability, so that it becomes a ubiquitous feature of future cable systems and an integral component of GOOS.

Recommendation 2: OceanObs19 and GOOS support the continuing evolution of OBP as an EOVS.

Recommendation 3: GOOS develop a community capability to evaluate the current observing system and proposed additions thereto and apply the same to evaluating the benefits of data obtained using SMART subsea cable systems.

JOINT TASK FORCE FOR SMART CABLES

The Joint Task Force for SMART Cables is sponsored by the International Telecommunication Union (ITU), the World Meteorological Organization (WMO), and the Intergovernmental Oceanographic Commission of the United Nations Educational, Scientific and Cultural Organization (UNESCO/IOC), with members from academic, government, and industry institutions worldwide.

AUTHOR CONTRIBUTIONS

BH provided the overall guidance and executive editing for the manuscript, and wrote the sections “Sensors,” “Program

Management,” “Relationship to Other Programs,” and the “Summary.” PNT provided the detailed editing and organization, as well as writing the section “Legal Outlook.” CB wrote the section “The SMART Cables Concept.” JA led the writing of the section “Improvements in Ocean Observing with SMART Cables.” Contributions to this latter section: GJ wrote the section “Ocean Temperature.” DL, MT, and TW wrote the section “Ocean Circulation, Sea Level Rise, and Mass Distribution.” TW contributed **Figure 5**. BA, DL, and MM contributed to the section “Ocean Surface (Barotropic) Tides.” JA and DL contributed to the section “Wind Generated Waves, Microseisms, and Infragravity Waves.” SW, NB, YS, and KP wrote the section “Tsunami Monitoring and Warning.” NB contributed **Figures 9, 10**. YS contributed **Figure 11**. CR contributed to the section “Seismology.” SL wrote the sections “Technical Approach,” “Cost Estimate,” and “Implementation Plan.” PT and PNT wrote the section “Data Management and Users.” JM and PNT wrote the section “Financing.” RB, SE, and FT edited throughout. All authors provided input and edited the manuscript.

FUNDING

BH and PNT were supported by the NASA (via JPL) NNN13D462T for the writing of this manuscript. DL received support from NSF OCE-1460022. GJ is supported by the NOAA Research. PMEL Contribution Number 4854.

ACKNOWLEDGMENTS

D. Arcas, K. Bressie, C. Moore, T. Davenport, M. Gutscher, H. Kopp, D. Meldrum, N. Rakowsky, and D. Sieber all helped with various aspects of this paper. B. Bay and M. Izumi worked on illustrations and technical editing. Maps in **Figures 1, 8** were provided by M. Chandler using GMT. Altimetry data were provided by NOAA Laboratory for Satellite Altimetry. Numerical simulations for section “Ocean Circulation, Sea Level Rise, and Mass Distribution” were carried out on the supercomputing system of the German Climate Computing Centre (DKRZ) in Hamburg, Germany. J. You is acknowledged for providing the initial vision for the SMART cables concept. Authors’ and contributors’ individual contributions and the support of their respective institutions is gratefully acknowledged. SOEST Contribution Number 10738. HIGP Number Contribution 2387. The Argo Program has been implemented and sustained for almost two decades, as a global array of about 4000 profiling floats. Argo provides continuous observations of ocean temperature and salinity versus pressure, from the sea surface to 2000 dbar. The successful installation of the Argo array and its innovative data management system arose opportunistically from the combination of great scientific need and technological innovation. Through the data system, Argo provides fundamental physical observations with broad societally-valuable applications, built on the cost-efficient and robust technologies of autonomous profiling floats. Following recent advances in platform and sensor technologies, even greater opportunity exists now than 20 years ago to (i) improve Argo's global coverage and value beyond the original design, (ii) extend Argo to span the full ocean depth, (iii) add biogeochemical sensors for improved understanding of oceanic cycles of carbon, nutrients, and ecosystems, and (iv) consider experimental sensors that might be included in the future, for example to document the spatial and temporal patterns of ocean mixing. For Core Argo and each of these enhancements, the past, present, and future progression along a path from experimental deployments to regional pilot arrays to global implementation is described. The objective is to create a fully global, top-to-bottom, dynamically complete, and multidisciplinary Argo Program that will integrate seamlessly with satellite and with other *in situ* elements of the Global Ocean Observing System (Legler et al., 2015). The integrated system will deliver operational reanalysis and forecasting capability, and assessment of the state and variability of the climate system with respect to physical, biogeochemical, and ecosystems parameters. It will enable basic research of unprecedented breadth and magnitude, and a wealth of ocean-education and outreach opportunities.

Keywords: Argo, floats, global, ocean, warming, circulation, temperature, salinity

INTRODUCTION

The Argo Program is a major component of both the Global Ocean Observing System (GOOS) and the Global Climate Observing System (GCOS), providing near-real time data for ocean and atmospheric services and high quality data for climate research. The Argo Program began its implementation in 1999 and has provided global coverage of the upper 2000 m of the oceans since 2006. By November 2018, Argo had provided 2,000,000 profiles since the program began, and a comparable number of velocity drift estimates at 1000 m depth. Although originally designed to provide temperature and salinity profiles in the upper 2 km of the ice-free oceans, the array has been expanded into seasonal ice zones using floats equipped with ice avoidance algorithms. Argo profiling floats also are sampling in many marginal seas. In addition, ongoing regional pilot programs have demonstrated that Argo floats can now (1) measure biogeochemical parameters to address oceanic uptake of carbon, acidification and deoxygenation (Biogeochemical, BGC, Argo) and (2) make measurements throughout the water column to 6000 m depth (Deep Argo). Notification through the

Argo Information Center (AIC), following Intergovernmental Oceanographic Commission (IOC) guidelines to protect the rights of Coastal States, has enabled global coverage. Presently the number of functioning Argo floats remains steady, with total float count around 4000. This has been possible, despite relatively flat funding, through a collaboration of international partners and significant technological innovation. The Argo Data System provides real-time data within 24 h of collection through the Global Telecommunications System (GTS) and via the internet for use at global prediction centers. The Argo Data Management Team (ADMT) also oversees delayed-mode quality control of the data and the availability of Argo data at the Argo Global Data Assembly Centers.

To meet future needs, Argo should (1) support continuing innovation in float technology, (2) enhance coverage in critical regions such as the equatorial band, where higher temporal resolution is needed and the western boundary regions where mesoscale 'noise' is high, (3) implement Deep Argo and Biogeochemical Argo in the global array, (4) assess the technical readiness and scientific value of experimental measurements for possible future inclusion in Argo, for example those used to

estimate small scale mixing, and (5) collaborate with our end-user community to improve the use of Argo data in prediction systems and services. This review lays out the motivation, development, and present status of the Argo Program, and addresses the five issues mentioned above. It is important to note that Core Argo has reached and maintained full implementation through innovation and broad community support. Only a small fraction of the funding needed to support the ambitious community requests for an expanded Argo Program can be identified at present. It is important for Argo to meet its future challenges as a single integrated program. The present elements of Argo – Core, Deep, and BGC – and of its data management system are not separable, and any other future enhancements will similarly be considered as contributions to the unified effort.

MOTIVATION, DEVELOPMENT, TECHNOLOGY

Core Argo

During the 1990s, the World Ocean Circulation Experiment brought increased understanding of important oceanic roles in climate variability and change (Siedler et al., 2001). The need to observe the global subsurface ocean, together with a fit-for-purpose revolutionary autonomous technology (Davis et al., 2001), led to a multinational proposal for a global subsurface ocean observing system (Argo Steering Team, 1998). The proposed 'Argo Program' would be comprised of over 3000 profiling floats, obtaining a snapshot of the physical state of the ocean from 0 to 2000 m every 10 days. All data would be freely shared in near-real time (NRT, within 24 h) to support forecasting, and with a highly quality-controlled delayed-mode (DM) version delivered within 12 months for climate research and assessments. Argo floats were deployed in regional arrays beginning in 1999 and then globally from 2004 to the present. Argo has fulfilled its promise to complement and integrate across many satellite and *in situ* elements of the GOOS and across many regional observational networks (deYoung et al., 2019; Foltz et al., 2019; Hermes et al., 2019; Lee et al., 2019; Newman et al., 2019; Palazov et al., 2019; Smith et al., 2019; Todd et al., 2019).

A number of key elements that contributed to Argo's success over the past 20 years are evident. The underpinning profiling float technology is simple, robust, and cost-effective. A strong international consensus on the high value of Argo, by agencies and the science community, contributed to Argo's rapid roll-out. Once Argo was in place, a broad base of applications (see section "Core Argo" under the section "End User Engagement") including basic research, assessment of the state of the Earth's climate, tertiary and secondary education, and ocean modeling for reanalysis and operational prediction, drew strong community support. Effective partnerships developed between Argo teams and commercial suppliers, to exploit and improve float and sensor technologies. The IOC provided necessary protocols to facilitate the operation of Argo floats in national waters (Intergovernmental Oceanographic Commission

[IOC], 1999), while the AIC¹ supplied the mechanisms for tracking and reporting to coastal states (Pinardi et al., 2019).

Technology advances have continued throughout Argo's 20-year history. New generation profiling floats are smaller, lighter, and more energy efficient. A profoundly important transition from unidirectional to faster bidirectional communication (Iridium) improves vertical resolution and shortens surface times from 12 h to 20 min, greatly reducing bio-fouling, array divergence due to surface drift, grounding, and other hazards. Ice-avoidance measures in float controllers (Klatt et al., 2007) have extended the range of Argo through the seasonal ice zones (Wong and Riser, 2011). Improved CTD sensors, as well as procedures for delayed-mode quality control (Owens and Wong, 2009) have increased the accuracy and consistency of the Argo dataset. Float lifetimes have increased, to 4–5 years for most Argo National Programs, reducing the cost per profile while extending reseeded intervals. All of these improvements are propagated across the Argo national programs through communication of Best Practices (Pearlman et al., 2019).

Argo's systematic and regular observation of the global subsurface ocean has transformed ocean observing. Northern hemisphere, near-coastal, and seasonal sampling biases of earlier eras are removed. The global Argo array has been sustained and improved for more than a decade, providing data for over 3000 research publications and becoming a mainstay of global ocean data assimilation, modeling, and prediction applications. The notable convergence, in the Argo era, of diverse estimates of historical global ocean heat content changes (e.g., Johnson et al., 2016) has increased the confidence that can be placed on the reliability of national and international assessments of climate change. International partners in Argo merge their efforts to produce a seamless global array, providing standardized observations, and delivering near real-time and research quality data with public access. Argo has led the way among ocean observing networks with regard to international cooperation, operations planning, Data Availability, and metadata quality.

BGC-Argo

The Biogeochemical (BGC)-Argo program began with the deployment of optical (Bishop et al., 2002; Mitchell, 2003; Boss et al., 2008) and oxygen (Körtzinger et al., 2004; Riser and Johnson, 2008) sensors on profiling floats between 2000 and 2003. The success of these efforts was highlighted at the Autonomous Platforms and Sensors meeting (Rudnick and Perry, 2003), which was the founding meeting for this community. It was followed by the development of a global vision for biogeochemical data acquisition through the inclusion of oxygen sensors on Argo platforms (Gruber et al., 2007), and the launch the same year of a working group of the International Ocean-Color Coordinating Group, "Bio-optical sensors on Argo floats" (IOCCG, 2011). In the meantime, both the oxygen and optical communities were promoting their vision for developing a global network of profiling floats carrying oxygen and optical sensors as part of the OceanObs09 conference (Claustre et al., 2010;

¹<http://argo.jcommops.org/>

Gruber et al., 2010), following a meeting in Johnson et al. (2009) that addressed the development of a global observing system using both gliders and profiling floats.

In 2016, a meeting was held in Villefranche-sur-mer to develop an implementation plan for BGC-Argo. The subsequent report (Biogeochemical-Argo Planning Group, 2016) was the starting point of the BGC-Argo program. Observing system simulation experiments (OSSEs) performed for this meeting suggested that a 1000-float array would significantly constrain the processes that control global oxygen and carbon distributions, including air-sea fluxes and exports from the surface (Kamenkovich et al., 2017). Assuming a mean BGC float lifetime of 4 years, sustaining a 1000-float array requires 250 floats per year with an estimated annual cost near US\$25-M. Each of the floats would carry sensors for six core ocean variables measured with targeted accuracies²: chlorophyll fluorescence (Chla), particle backscatter, oxygen, nitrate, pH, and irradiance. The 1000-float array would provide observational data to transform ability to quantify: (i) air-sea carbon fluxes, (ii) ocean deoxygenation, oxygen minimum zones and related denitrification fluxes, (iii) ocean acidification, (iv) the biological carbon pump, and (v) phytoplankton communities. The observing system would improve management of living marine resources and carbon budget verification, both key societal goals. In 2017, a BGC-Argo Scientific Steering Committee was formed (under the Argo Steering Team), to guide the development of the network and the implementation of the program objectives, and to continue developing a vision for the future. In 2018, during the Executive Council of IOC, unanimous support from Member States was given to the proposal to incorporate the six biogeochemical measurements in the Argo array. Additionally the Executive Council approved a framework for the future addition of new parameters to Argo.

The first BGC-Argo deployments consisted of a few floats at a time. These have evolved to regional scale projects such as remOcean (North Atlantic sub-polar Gyre, 20 floats) and NAOS (Mediterranean Sea, 30 floats), and to basin-scale projects such as SOCCOM (Southern Ocean Carbon and Climate Observations and Modeling) with more than 100 floats deployed thus far, toward a target of 200. These pilots have showcased the potential of community-shared efforts to support better understanding of major biogeochemical processes at the global scale and to explore new research topics. The profiling float data sets have been vetted by research groups via publications approaching several 100 in total. BGC-Argo observations are open and free through the Argo data system both in NRT and DM.

These projects are transforming our understanding of variability in the ocean over time scales difficult to achieve with ship-based observations. A few of these achievements include characterization of ocean nitrate supply (Johnson et al., 2010; D'Ortenzio et al., 2014); observation of bloom dynamics beneath the surface (Boss and Behrenfeld, 2010; Mignot et al., 2018); novel carbon export mechanisms through a mixed-layer pump (Dall'Olmo and Mork, 2014; Dall'Olmo et al., 2016) or eddy subduction (Llort et al., 2018); oxygen

minimum zone processes (Whitmire et al., 2009; Prakash et al., 2012; Stanev et al., 2018); ocean net community production over complete annual cycles throughout the ocean (Riser and Johnson, 2008; Bushinsky and Emerson, 2015; Hennon et al., 2016; Plant et al., 2016); ocean ventilation (Körtzinger et al., 2004; Wolf et al., 2018); air-sea exchanges of O₂ (Bushinsky et al., 2017) and CO₂ (Williams et al., 2017; Bittig et al., 2018; Gray et al., 2018); and mesoscale/sub-mesoscale processes (Sukigara et al., 2011; Kouketsu et al., 2016). In a major advance, the data are now being assimilated into biogeochemical models to enable greater understanding and improved predictions (Verdy and Mazloff, 2017).

The development of BGC-Argo floats has been based on the standard Argo Pressure/Temperature/Salinity (P/T/S) platforms, integrating new sensors when their readiness level appeared compatible with long-term, operational use. Today, the community is operating three main BGC-Argo platforms (Figure 1): PROVOR, Navis, and APEX floats. While each of these platforms is capable of carrying the six core sensors outlined in the BGC-Argo implementation plan, due to present hardware limitations and the objectives of funded research programs, few have yet been deployed with all six. Deployments of floats carrying the six core variables are highly desirable as well as harmonizing of mission parameters with those of Core Argo.

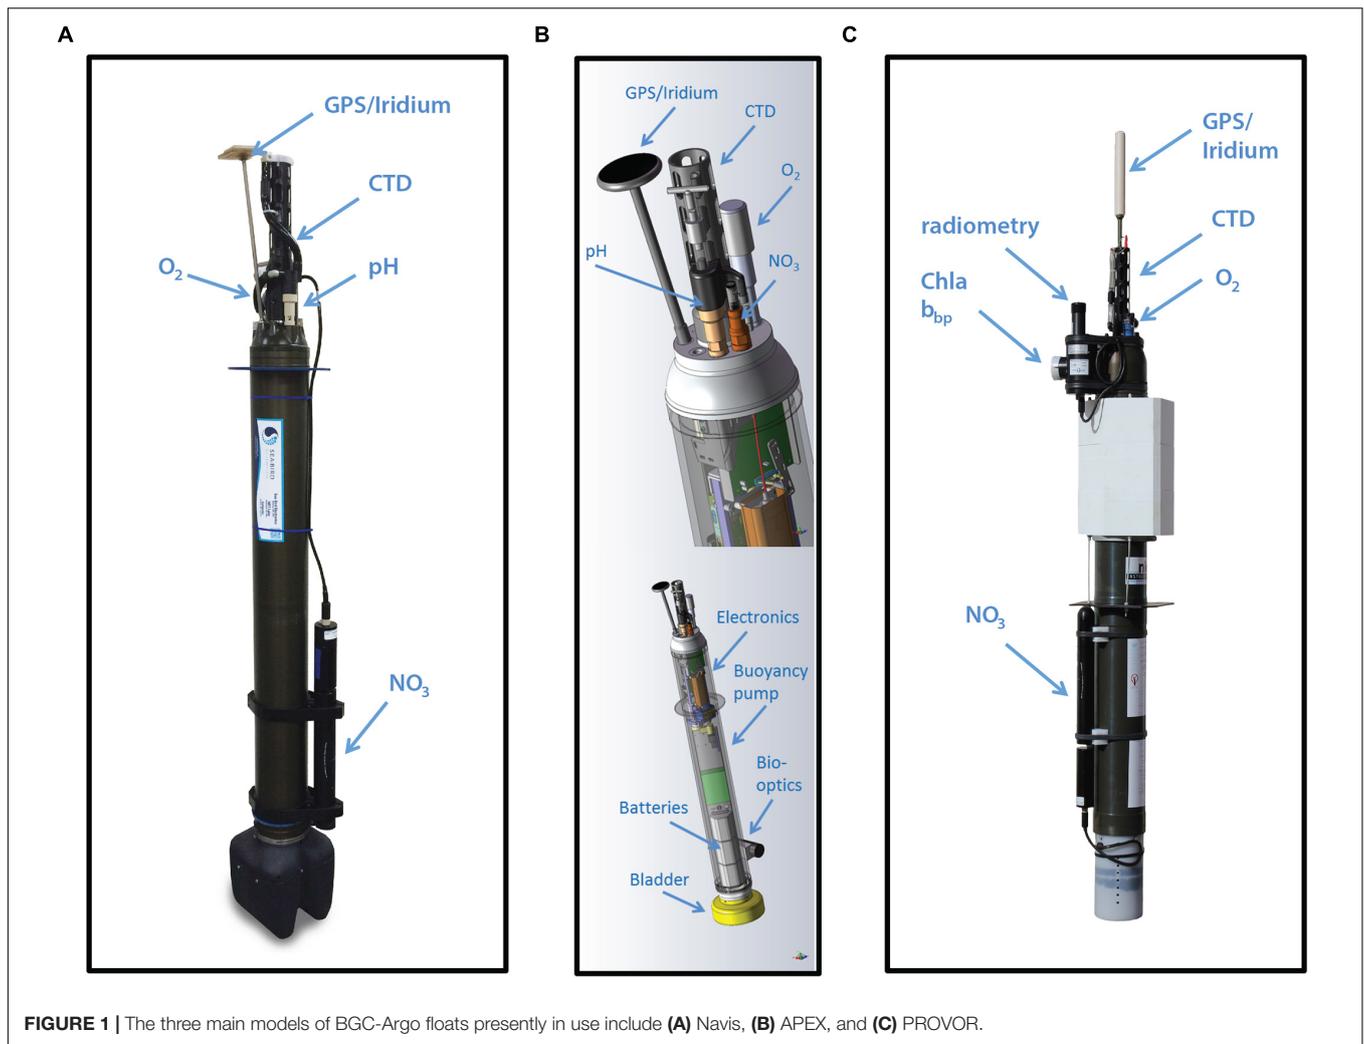

Deep Argo

Deep Argo is motivated by the substantial oceanographic variability found in the 50% of ocean volume that lies below the 2000-dbar profiling target for conventional Argo floats. Development of floats and CTDs capable of accurate measurements to 6000 dbar makes global full-depth Argo implementation feasible, including sampling of bottom-intensified ocean variability.

Antarctic Bottom Water, which fills much of the ocean below 2000 dbar (Johnson, 2008), has been warming and freshening during the past few decades, with these changes contributing to steric sea level rise (Purkey and Johnson, 2013). The rate of ocean heat-gain below 2000 dbar, of 0.065 (± 0.04) W m⁻² from 1991 to 2010 (Desbruyères et al., 2016) is about 10% of the 0.61 (± 0.09) W m⁻² from 2005 to 2015 in the upper 1800 dbar (Johnson et al., 2016). Deep ocean (>2000 dbar) heat content changes have been estimated over decadal intervals using a sparse network of repeat hydrographic sections that are sampled at quasi-decadal intervals (Talley et al., 2016), hence only decadal estimates are possible, and uncertainties due to the sparsity of observations are about 2/3 the size of the signal. In contrast, Core Argo data enables decadal estimation of ocean heat uptake shallower than 2000 dbar with uncertainties only about 1/7 the size of the signal. In addition, monthly global analyses of Core Argo data (Roemmich and Gilson, 2009³) have provided a basis for investigation of seasonal-to-interannual variability (e.g., Johnson and Birnbaum, 2017). Deep Argo will similarly reduce the uncertainties in decadal deep ocean heat uptake estimates, while providing data for a broad range of scientific investigations of deep variability (Johnson et al., 2015).

²<http://biogeochemical-argo.org/measured-variables-general-context.php>

³http://sio-argo.ucsd.edu/RG_Climatology.html

The fact that abyssal trends and diffusivities both seem to be insufficiently constrained in ocean state estimates is further evidence that deep Argo is needed (Wunsch and Heimbach, 2014; Forget et al., 2015).

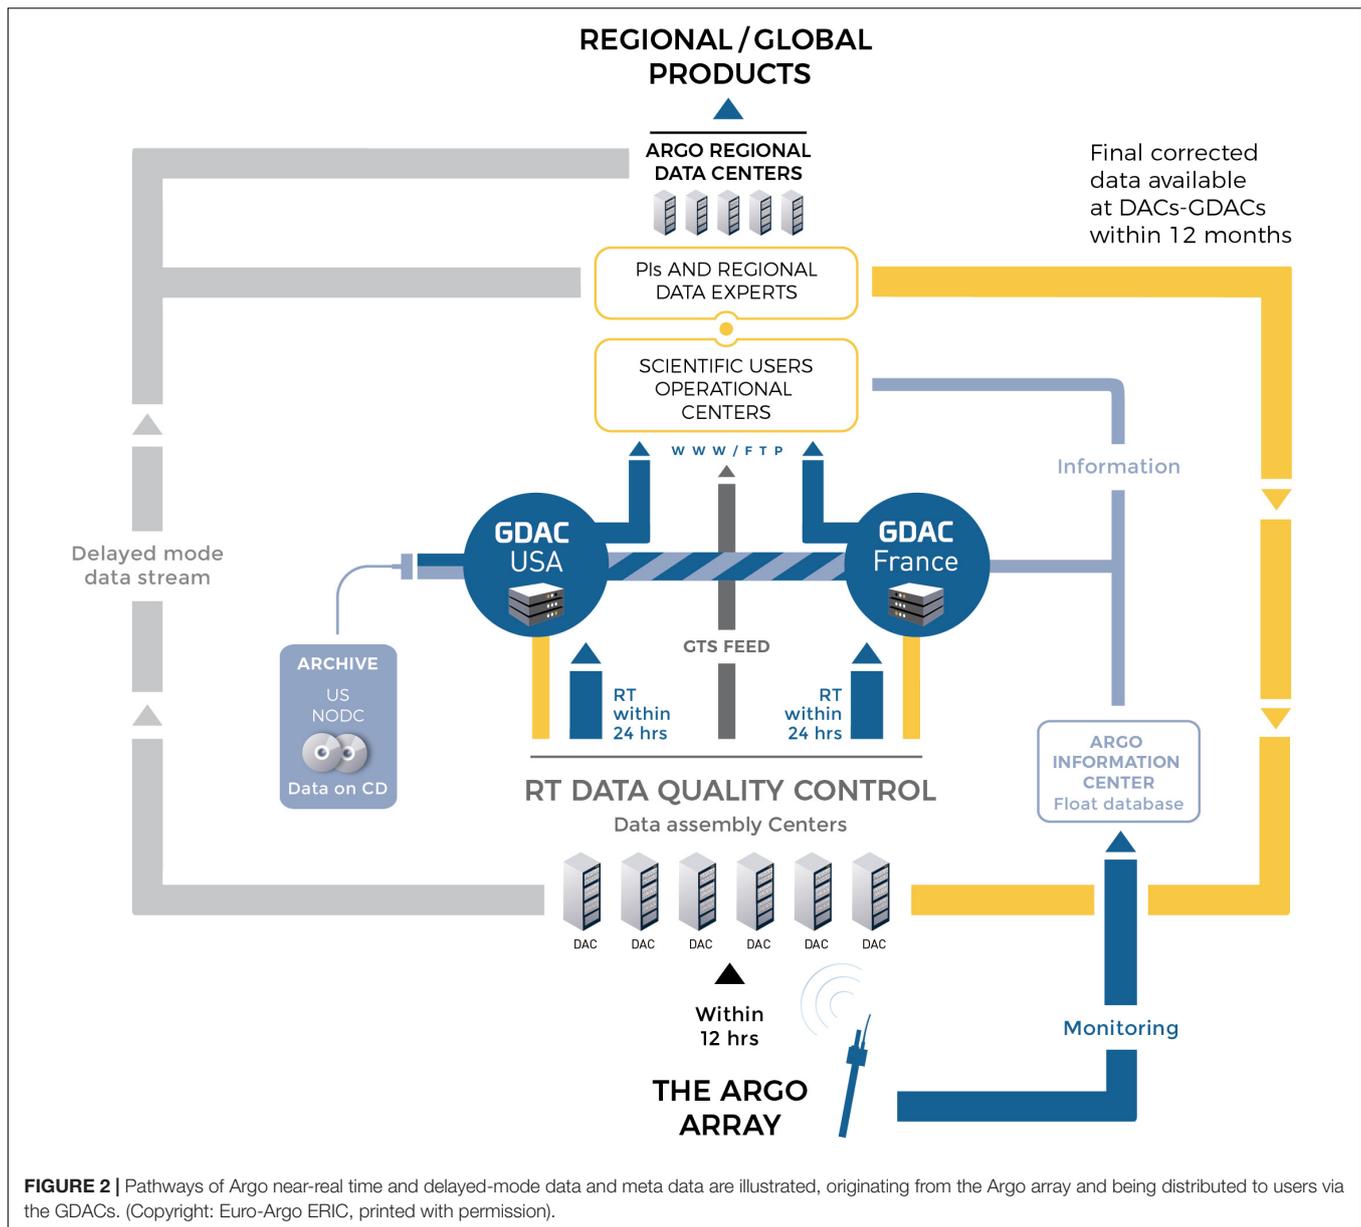

North Atlantic Deep Water is also changing, with the meridional overturning circulation decreasing measurably between 2004–2008 and 2008–2012 (Smeed et al., 2018). Deep ocean circulation variations have primarily been observed using transoceanic moored arrays, which are costly to maintain, and hence regionally limited (Lozier et al., 2017; Meinen et al., 2017; Smeed et al., 2018). Repeat hydrographic section data are also used for this purpose despite their sparse temporal sampling (Bryden et al., 2005; Kouketsu et al., 2011). Deep Argo would provide velocity and density information, complementing both the moored arrays and repeat hydrography, as well as facilitating decadal climate predictions and constraining full-depth ocean data assimilation (Robson et al., 2012; Yeager et al., 2012; Carrassi et al., 2016).

The value and technical feasibility of a Deep Argo Program were recognized at OceanObs'09 (Roemmich et al., 2010). Successful deployments of prototype deep floats and CTDs in

2012–2014 led to a Deep Argo Implementation Workshop in May 2015 (Zilberman and Maze, 2015), where a plan for Deep Argo's progression to a global $5^\circ \times 5^\circ$ array was endorsed. Regional pilot arrays have been established in the South Pacific, South Indian, and North Atlantic oceans, further demonstrating the feasibility of a global Deep Argo array.

Argo Data Management

The Argo data system was designed in 2001 at the 1st Argo Data Management meeting in Brest, France and its main components remain in place and function well (Figure 2). The national Data Assembly Centres (DACs) receive data via satellite transmission, decode it, and apply quality control according to a set of agreed NRT tests. Erroneous data are corrected if possible, flagged accordingly and then sent to two Global Data Assembly Centres (GDACs) and the GTS. The GDACs collect the data from the 11 DACs, synchronize their databases daily and serve the data on FTP sites. The AIC monitors the status of the Argo Program, including data distribution, and meta data that incorporate float location, model, transmission system, owner, etc. In addition, the AIC gathers feedback on data quality from

users and relays it to float owners and DACs. Argo's delayed-mode data system for P/T/S variables relies on Argo data experts examining the data and reflagging where necessary, using a standard method (Owens and Wong, 2009) to estimate salinity drift, in addition to applying salinity thermal lag adjustments and pressure adjustments.

To improve the quality of P/T/S variables between NRT and DM versions, a few tests have been developed to run on a regular basis (e.g., monthly, quarterly, etc.) on the GDAC data holdings. One of these is an objective analysis run monthly by Coriolis, where profiles that are inconsistent with neighbors are identified for further examination. Another is a quarterly comparison with satellite altimetry performed by CLS/France. When suspect profiles are identified, float owners and DACs are notified to make changes to data QC flags as needed.

The Argo Regional Centers (ARCs) perform a variety of tasks including coordinating float deployments, consistency checks on delayed mode quality control, finding additional reference data for delayed mode work, adopting floats for delayed mode quality control, and producing Argo data products.

While the complete data management chain (Figure 2) has been developed for the core mission (P/T/S, 0–2000 dbar), the extensions to Deep Argo and BGC Argo are under development to form an integrated Argo Data Management System.

ArgoMix

Here a new enhancement is suggested for possible future inclusion in Argo, consisting of direct shear and scalar microstructure (turbulence) measurements for both the upper and deep ocean. The rationale is provided by recent scientific

and technical developments. Microstructure measurements are not presently part of Argo but are presented as an example of how new experimental measurements on profiling floats can progress toward inclusion in the global array. This process, begins with limited deployment outside of Argo to demonstrate value and capabilities.

Turbulent mixing in the ocean is important because (1) it contributes to the transport and distributions of heat, freshwater, dissolved gasses, and pollutants, (2) it impacts biological processes by determining the flow field for the smallest plankton and setting large-scale gradients of nutrient availability, and (3) societally-valuable predictions from numerical models of quantities such as temperature and sea level depend sensitively on the geography of ocean mixing rates. Despite its importance, observations of ocean turbulence are extremely sparse, particularly in the deep ocean. Imprints of turbulent transport processes on the large scale ocean state, as readily observed by Core Argo, allow for inversion of diffusivity maps but direct mixing measurements are needed to further constrain inverse estimates (Forget et al., 2015).

Ocean turbulence is of leading order importance in determining the variability of many of the 11 physics-based GCOS “essential ocean variables” (EOVs). For example, turbulence determines the divergence of surface buoyancy fluxes across the surface mixed layer. On larger scales the flux of constituents (e.g., heat or salt) enhanced by turbulence are critical to understanding weather and climate. At present, physics-based EOVs include the surface and subsurface values of ocean currents (u, v), temperature (T) and salinity (S). At any subsurface location, these three EOVs vary in accordance to the Navier-Stokes equations, but thermodynamically they vary solely with the vertical (or diapycnal) divergences of turbulence-enhanced fluxes of momentum, heat, and salt. The physics-based EOVs also include the fluxes of momentum (wind stress) and heat at the sea surface. These fluxes provide surface inputs but do not quantify internal redistributions and so cannot define changes in u or T . However, fluxes of heat and momentum can now be reliably assessed using direct shear and scalar microstructure turbulence measurements (Pujiana et al., 2018) as witnessed by flux measurements that asymptote to and vary with independently-measured surface values (Figure 3).

Recent work suggests considerable temporal and spatial inhomogeneity in near-surface and deep-ocean mixing. Moored mixing time series in the upper few 100 m (Moum et al., 2009, 2013) have, for example, identified the importance of subsurface turbulence fluxes in setting the annual cycle of tropical sea surface temperature (SST), and shown variability on long time scales that include ENSO. Furthermore, mixing measurements in the deep ocean (Alford et al., 2011) show intense intermittency, indicating a need for sustained global measurements through the full water column.

The importance of small scale mixing to prediction of global scale circulation, including how this might be quantified, was a focus of the recent Climate Process Team on Ocean Mixing (MacKinnon et al., 2017). In particular, global distributions of mixing (Whalen et al., 2012, 2015; Waterhouse et al., 2014) based on indirect fine-scale parameterizations and internal wave

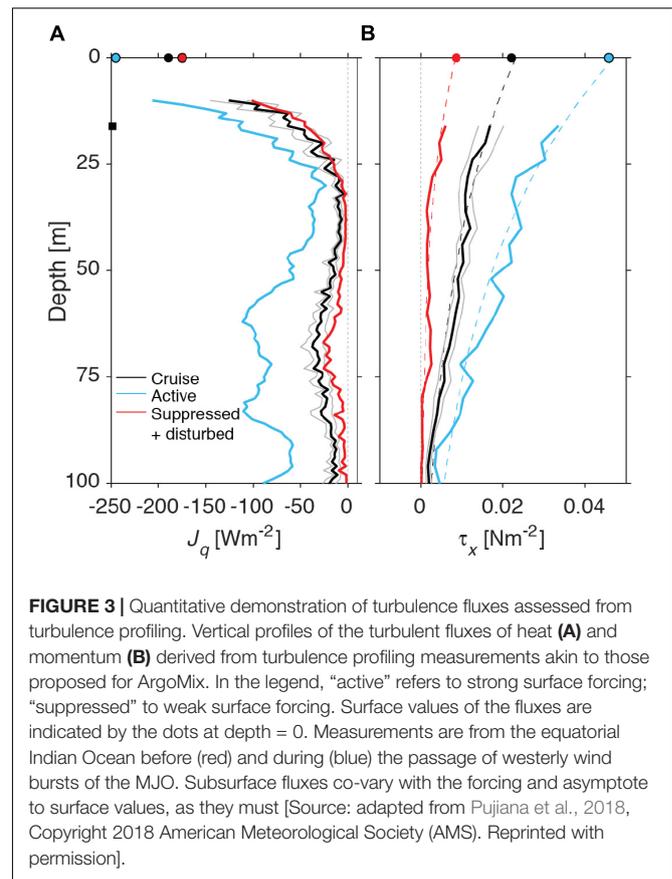

FIGURE 3 | Quantitative demonstration of turbulence fluxes assessed from turbulence profiling. Vertical profiles of the turbulent fluxes of heat (A) and momentum (B) derived from turbulence profiling measurements akin to those proposed for ArgoMix. In the legend, “active” refers to strong surface forcing; “suppressed” to weak surface forcing. Surface values of the fluxes are indicated by the dots at depth = 0. Measurements are from the equatorial Indian Ocean before (red) and during (blue) the passage of westerly wind bursts of the MJO. Subsurface fluxes co-vary with the forcing and asymptote to surface values, as they must [Source: adapted from Pujiana et al., 2018, Copyright 2018 American Meteorological Society (AMS). Reprinted with permission].

models (Gregg, 1989; Olbers and Eden, 2013; Polzin et al., 2014; Pollman et al., 2017) represent a new paradigm against which to test theory and models, and to target new process experiments. However, the underlying assumptions of these methods are uncertain and may be most suspect where the inferred turbulence is greatest. While the fine-scale parameterizations tend to agree with direct measurements to within a factor of two in the ocean interior, a significantly higher standard is required to understand turbulent flux *divergences* that govern evolution of EOVs. The assumptions in these methods are known to be violated near boundaries, with differences between parameterizations and direct measurements of up to a factor of 10 (Waterman et al., 2014). In addition to the diapycnal fluxes, direct microstructure measurements can also allow assessment of isopycnal stirring and its underpinning dynamics (Ferrari and Polzin, 2005; Naveira Garabato et al., 2015).

Direct measurements on both Argo and Deep Argo floats are now feasible, owing to recent advances in turbulence sensing technology that have reduced the cost, communications bandwidth, and power requirements. Recent technological advances in inexpensive and low-power circuitry, increased battery capacity and data storage density have led to an ability to make long-term continuous measurements of mixing from oceanographic moorings (Moum and Nash, 2009) and profiling instruments (Sherman and Davis, 1995; Nagai et al., 2015; Goto et al., 2016, 2018; Lucas et al., 2016; Shroyer et al., 2016).

These systems have been tested quantitatively via inter-platform comparisons (Perlin and Moum, 2012; Pujiana et al., 2018) and schemes to compress data for satellite transmission have been developed (Becherer and Moum, 2017). These are key technical ingredients for successful implementation of mixing measurements on the Argo fleet.

Roughly a dozen moored mixing measurements are now distributed around ocean basins, permitting important but highly limited geographic comparisons. While this effort has been an exciting development, these measurements cannot address problems associated with widespread geographical variations in mixing, deep thermocline and abyssal mixing, or variability away from the moorings. Existing monitoring efforts specifically do not address mixing variability at Argo resolution, as seen in sparse but highly variable deep microstructure observations (Figure 4; Waterhouse et al., 2014).

THE PRESENT STATUS, PROBLEMS, AND STRENGTHS

Core Argo

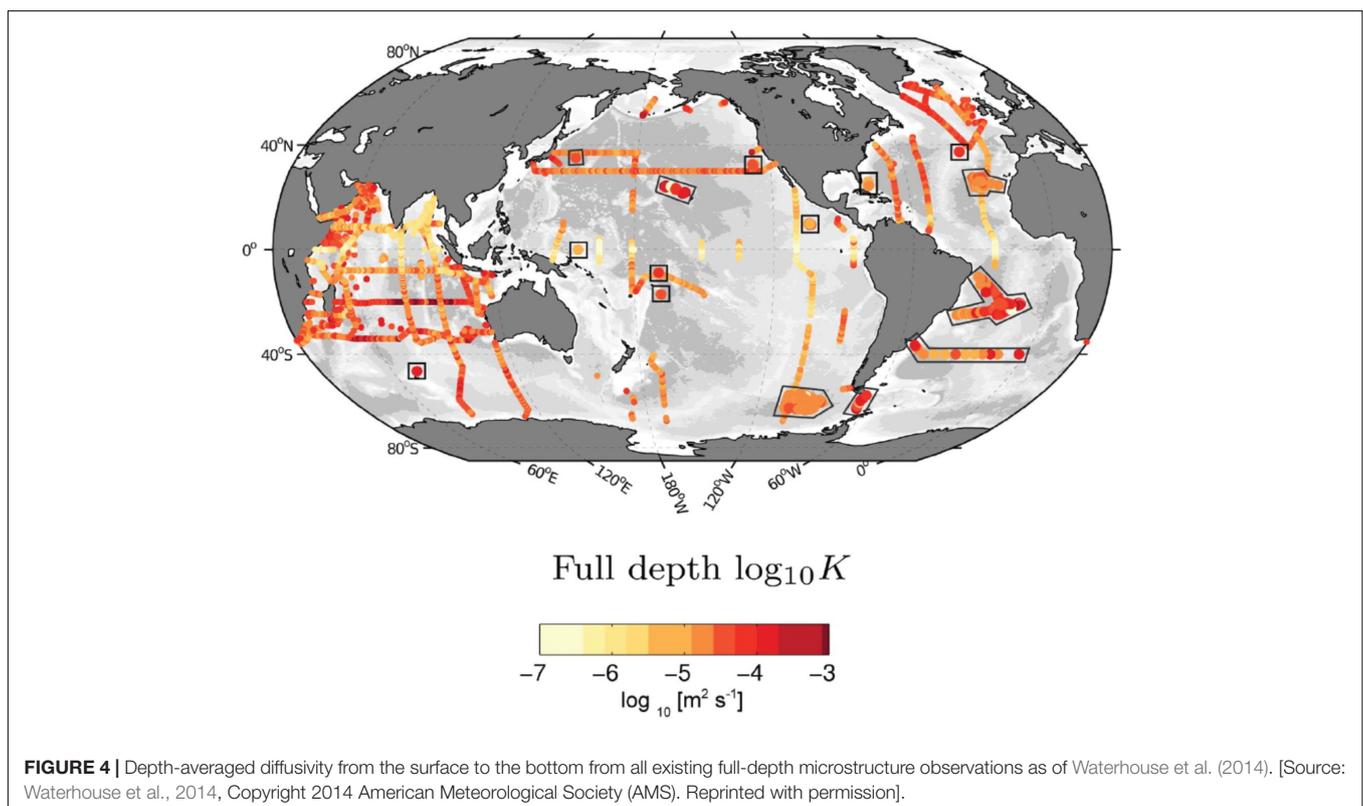

The number of floats reporting Core Argo parameters increased rapidly from 1999 until it reached 3000 during 2007, and has increased slowly over the last 10 years to its present number of 4000 (Figure 5). Recent increases reflect floats deployed in previously unsampled regions and regions of higher than standard sampling density. More than 90% of measurements made on Argo floats are available within Argo's 24 h target

(see section “Argo Data Management” under the section “The Present Status, Problems, and Strengths”), and all are freely distributed.

Core Argo has a mature leadership model, with Steering and Data Management Teams that meet annually in plenary, and with vigorous inter-session activity. These meetings are supplemented with workshops on technical aspects as required, such as hardware engineering, sensor development, and data quality control. Argo leadership has a strong corporate memory, which ensures the stability of the program. Argo regularly audits the performance of the array so that systematic problems can be identified before they seriously degrade the data.

Argo data acquisition is distributed across 25 national programs (Figure 5). The procedures for delivery of data in NRT and DM (see section “Argo Data Management” under the section “The Present Status, Problems, and Strengths”) are comprehensively described in public documents. This ensures a global dataset of consistent quality and uniform format ready for public use. Reliability of data does not depend on the originating national program or investigator.

Since 2013, Argo has undertaken a major revision of its data format in order to incorporate data from biogeochemical sensors and other auxiliary measurements. This includes improving the quality of meta data to enable more detailed array audits. This additional complexity (see section “Argo Data Management” under the section “The Present Status, Problems, and Strengths”), while essential, has placed a burden on the data system and has diverted effort from DMQC of the core physical parameters.

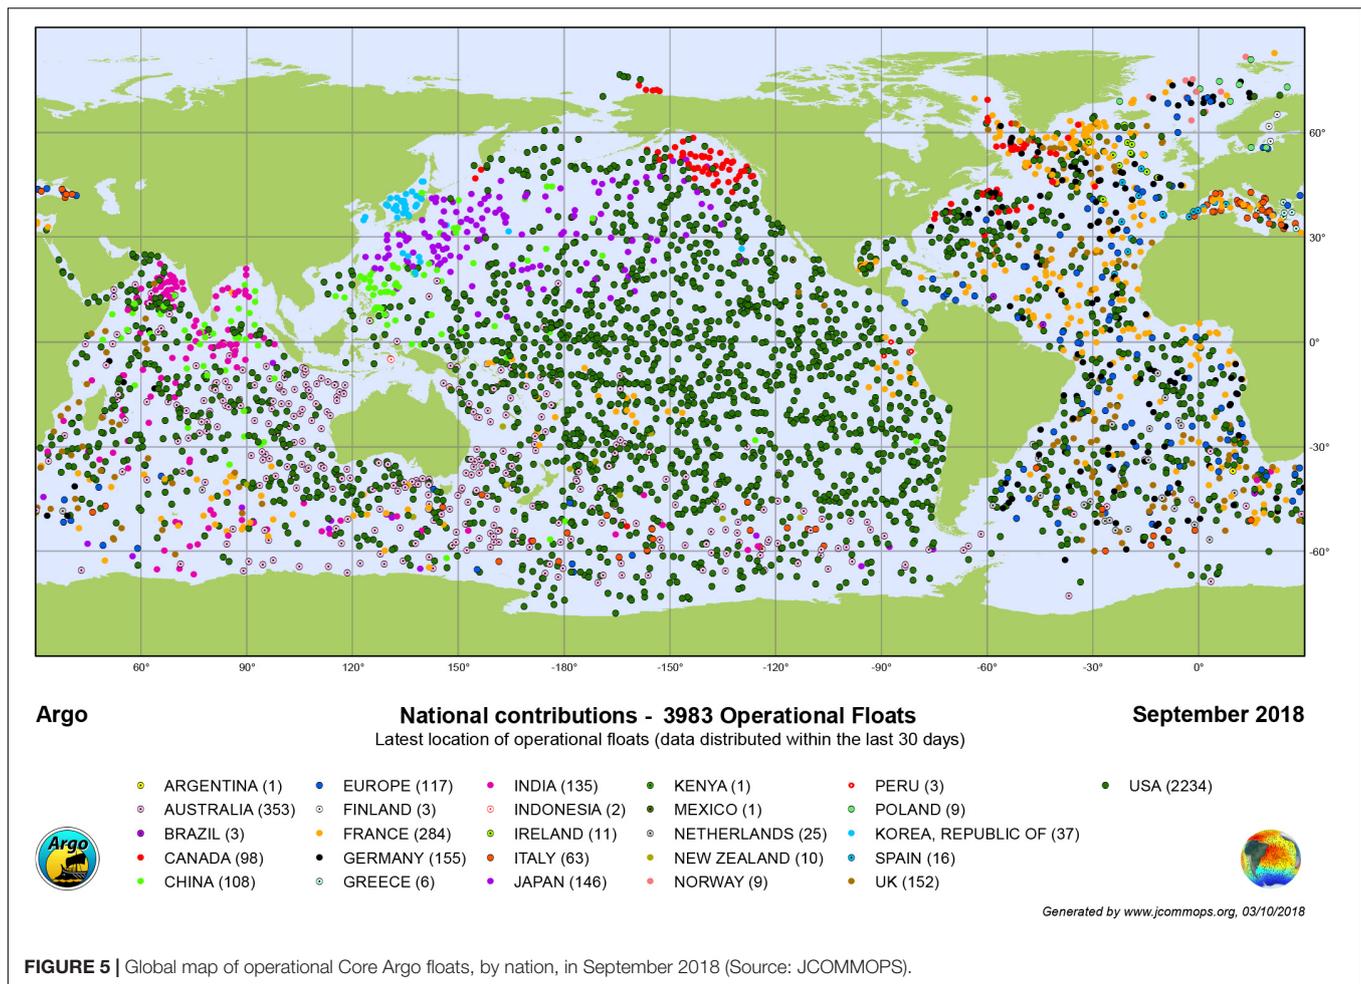

FIGURE 5 | Global map of operational Core Argo floats, by nation, in September 2018 (Source: JCOMMOPS).

The greatest challenge facing Core Argo is simply to sustain the global array, especially in remote southern hemisphere regions, in the face of limited budgets. In order to maximize the number of active floats for a given rate of deployment, vigorous attention is being given to improving float and sensor lifetimes and identifying deployment opportunities. A float technical workshop in 2017 identified differences of float longevity between groups using the same hardware. Differences were noted in ‘acceptance testing’ when floats are delivered by manufacturers and ‘final pre-deployment testing’ at port of departure. Post-delivery test protocols are being devised to minimize the number of floats and sensors that fail before battery energy is fully utilized.

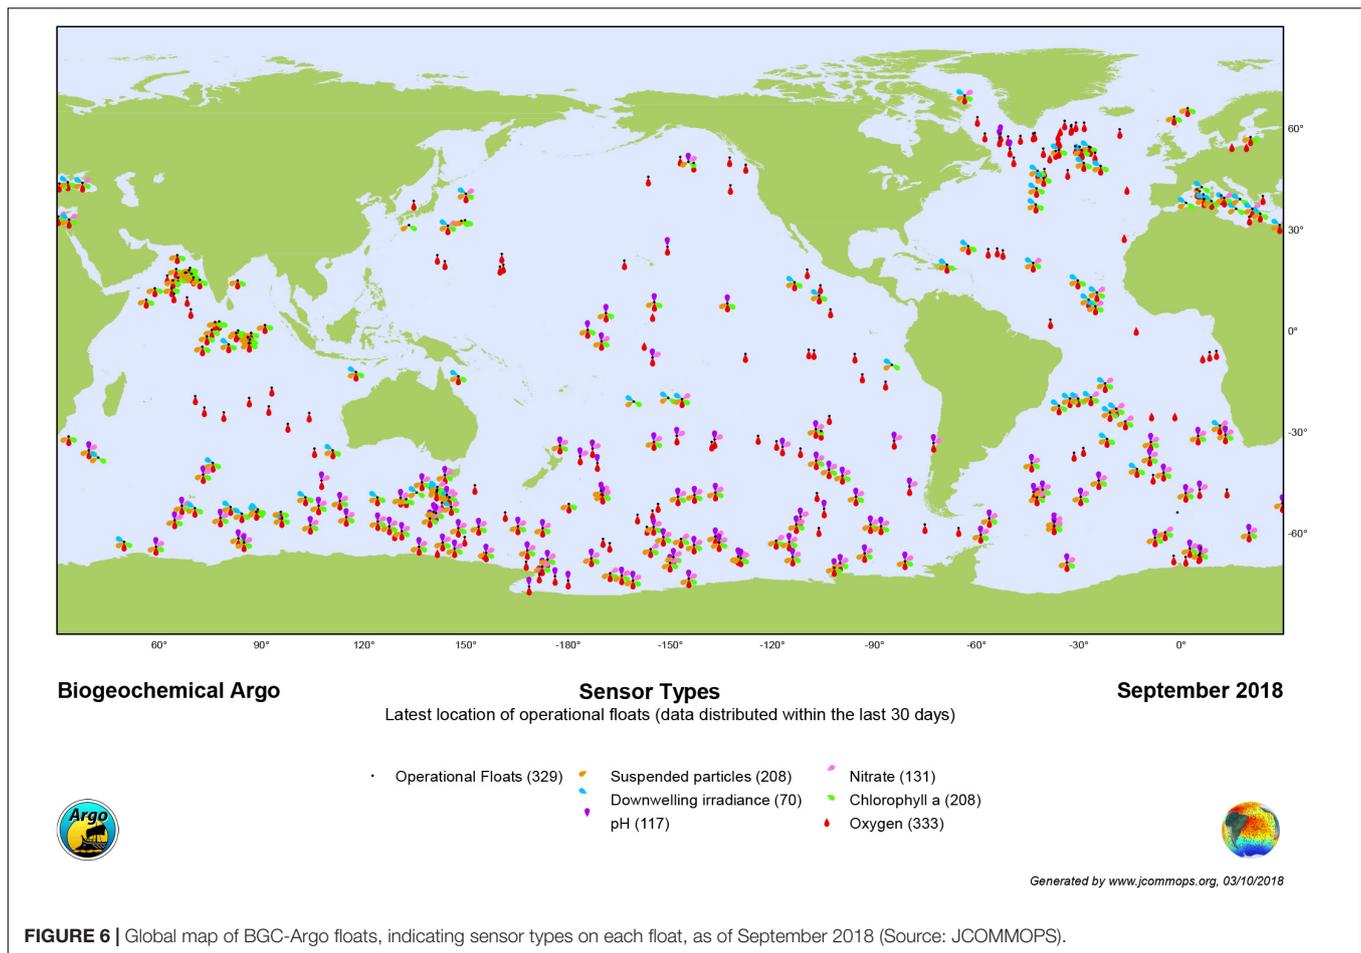

Technical issues presently under scrutiny include management of lithium batteries for efficient energy utilization, and stability of sensors, especially conductivity (and hence salinity) and pressure. Recent analysis has shown batches of floats in which the salinity reported by the float drifts toward higher than true values. The bias can exceed 0.03 in salinity. Salinity drift is estimated in DM by comparison with nearby measurements. The cause and mitigation of this new salinity drift is still under study. This issue highlights the need to exercise care in the use of NRT data, and the requirements for reference data

from GO-SHIP and other programs, to ensure the long-term consistency of the Argo dataset.

While there have been many different designs of the hull and buoyancy engines on which sensors are deployed, Core Argo has depended almost exclusively on the SBE41 and SBE41CP CTDs by SeaBird Electronics (SBE). This has led to good consistency of data, and implementation of uniform procedures for data handling across the national programs, but exposes the program to the risk of single points of failure. Twice during Argo there has been a major problem with the supply of pressure sensors to SBE for use in float CTDs, resulting in lost deployment opportunities and impacting Argo coverage. To reduce this risk, the Steering Team welcomes initiatives to establish alternative sensor payloads. The Steering Team has set up a rigorous process of trial and evaluation to ensure that the Argo dataset remains of consistent quality if and when alternative CTD sensors are introduced.

BGC Argo

The BGC-Argo network presently relies on research-based projects operated by individuals or institutions. Globally, these regional pilot programs operate as a collective resource of 335 floats carrying BGC sensors that can be accessed through the

Argo data system (Figure 6). With a goal of 1000 floats equipped with the six core BGC sensors, system status ranges from nearly 30% complete for oxygen to only 8% complete for pH and irradiance (Figure 6). About 10% of the floats in the BGC array carry 5 of the six core sensors, but few research programs have merged all six on one float. Moving from a 30% complete oxygen array to a 30% complete array with all six sensors will be a critical step in BGC-Argo development, as key synergies arise when all six core sensors are deployed on a single float.

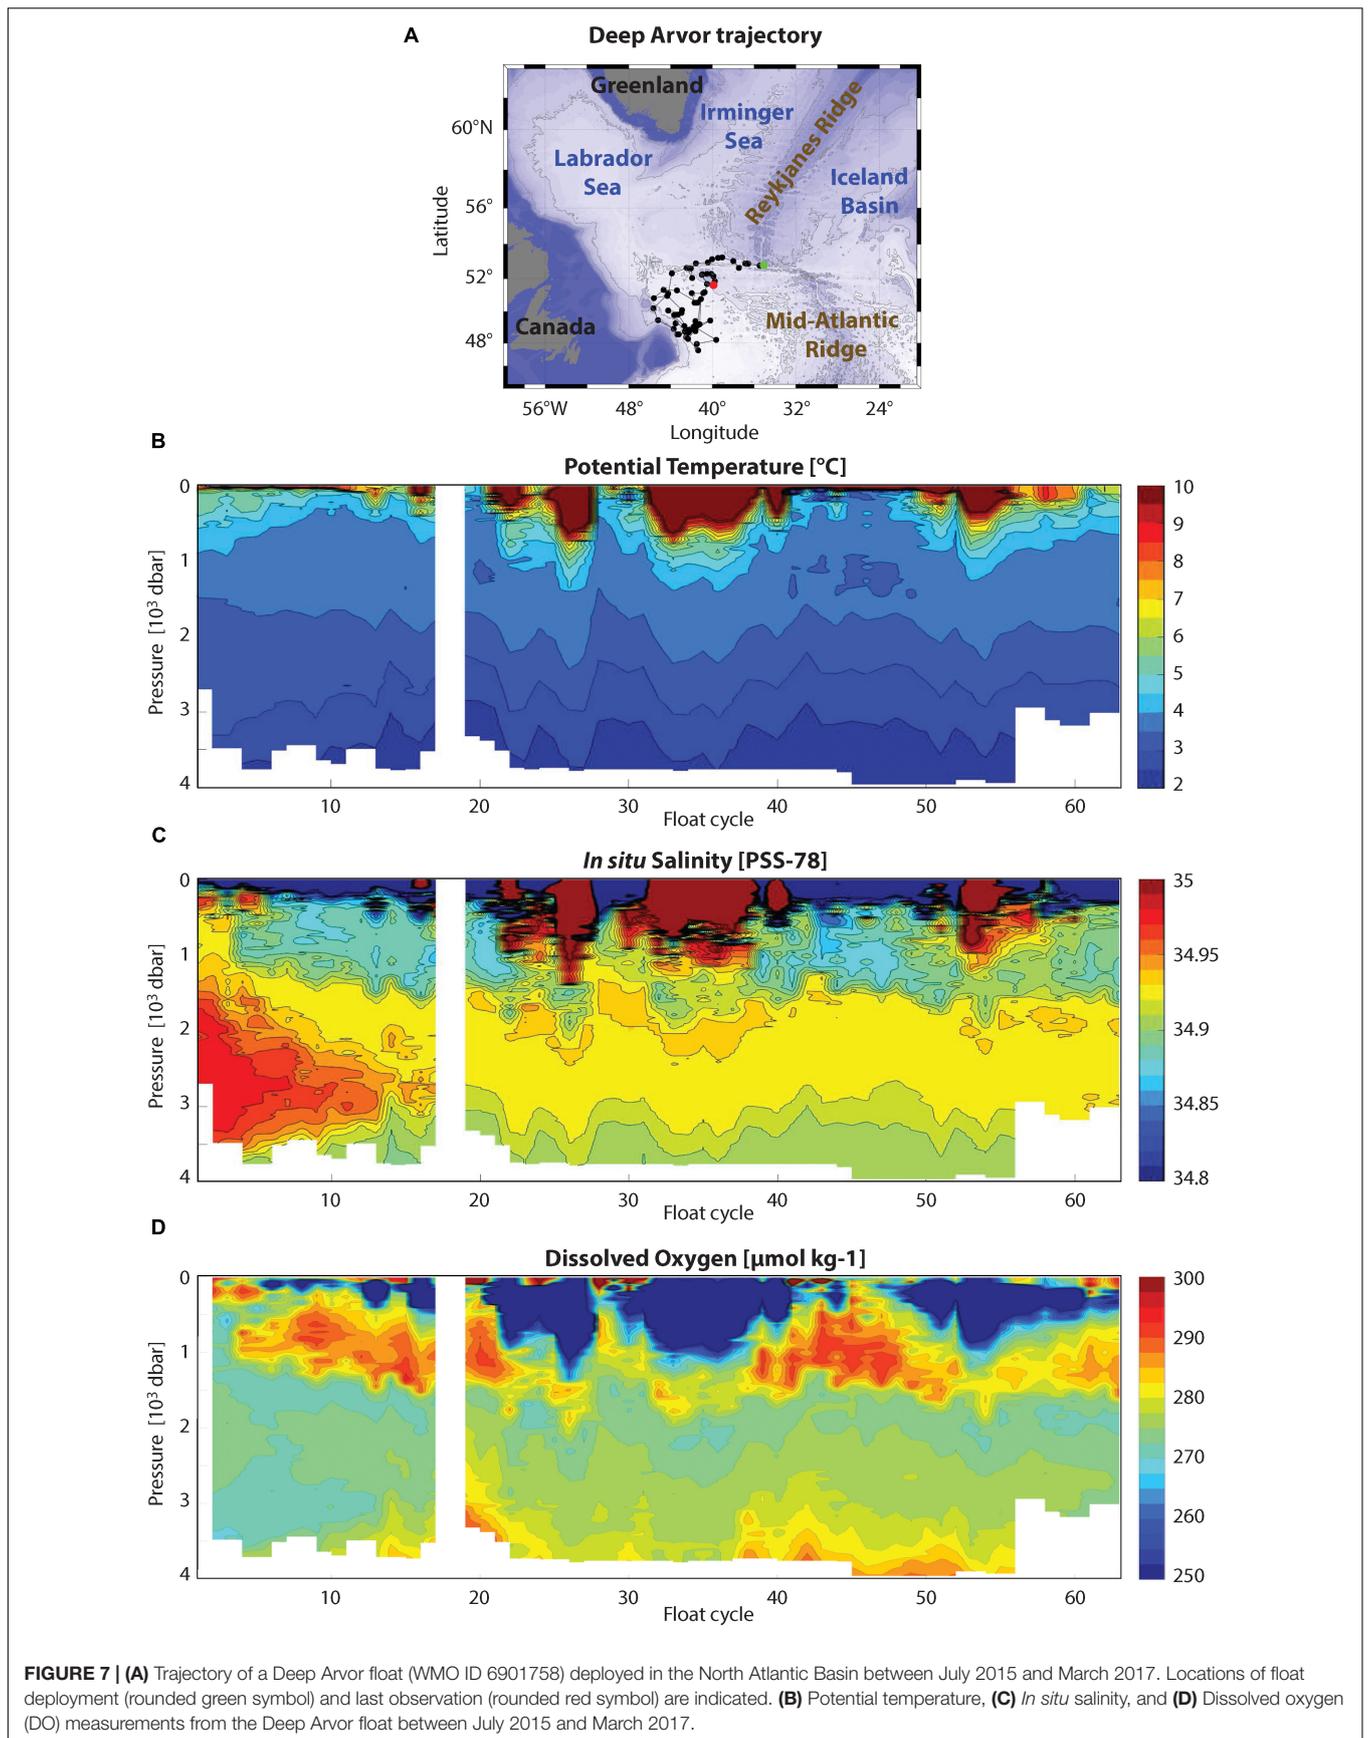

BGC-Argo is the first program with the capability to monitor biogeochemical processes globally, under seasonal sea-ice, throughout the year, and across all weather conditions. This allows BGC-Argo to access processes and timescales that cannot be observed from oceanographic cruises. It will revolutionize understanding of ocean biogeochemistry and marine resources, including fisheries, providing the foundation for informed ocean management. This strength results in particular from the cost-effectiveness of such robotic measurements, which lower the cost of a vertical profile by more than an order of magnitude compared to classical techniques of data acquisition. The consistency of the data collected and processed in this manner enable global assessments based on the entire data set. In some cases, analyses of these consistent datasets (Poteau et al., 2017) have identified sensor calibration issues at the manufacturer

level (Barnard and Koegle, 2018). The accessibility of BGC-Argo global datasets has allowed the measurements of Chla (Roesler et al., 2017) and optical backscatter (Poteau et al., 2017) to be reprocessed, producing an even more valuable product.

Deep Argo

Four models of Deep Argo floats have been developed and are currently in use. The Deep Arvor (Le Reste et al., 2016) and the Deep NINJA (Kobayashi, 2013) floats measure P/T/S, from the surface to 4000 dbar. The Deep SOLO and the Deep APEX record P/T/S to 6000 dbar (Zilberman, 2017). Two CTD models developed by Sea-Bird, the 6000 dbar SBE-61 CTD and the 4000 dbar SBE-41 CTD, were implemented on Deep Argo floats, and a 6000 dbar CTD from RBR is currently being tested. In addition, dissolved oxygen (DO) sensors have been mounted on most 4000 dbar floats (Figure 7). All Deep Argo floats have the ability to provide NRT P/T/S measurements during the float ascent to the surface. Deep Argo floats were designed originally to achieve 180 cycles to 6000 dbar; the migration to hybrid lithium batteries increases the Deep SOLO battery lifetime substantially above 200 cycles.

The trajectory uncertainty at parking depth, resulting from the vertical shear during the float ascent and descent, is higher for Deep Argo dives than for Core Argo. As for Core

Argo, the position uncertainty in Deep Argo float trajectories is highest in sea-ice covered areas, where estimated float positions are interpolated based on ice-free surface fixes that can be months apart.

Current challenges are to improve the accuracy and increase the long-term stability of the Deep Argo conductivity and pressure sensors. Target accuracies of Deep Argo P/T/S are ± 3 dbar, 0.001°C , and 0.002 PSS-78, similar to GO-SHIP standards (Hood et al., 2010). Comparisons of shipboard rosette-mounted SBE-61 CTDs with shipboard (SBE-911) CTD observations, show P/T/S uncertainties of ± 4.5 dbar, $\pm 0.001^\circ\text{C}$, and ± 0.005 PSS-78. Observations from SBE-61 CTDs mounted on Deep SOLO floats show a similar spread in salinity when compared with reference data (Figure 8). Efforts will continue to improve the performance of the Deep Argo CTD models to the accuracy levels envisioned by the Deep Argo community. Float recovery can be used to achieve CTD recalibration in regions with limited reference data.

Regional Deep Argo pilot arrays have been established in deep areas of the South Pacific, South Indian, and North Atlantic Ocean, with plans underway for deployments in the South Atlantic, to demonstrate the technology readiness and scientific potential of the Deep Argo Program. There were 69 Deep Argo floats active as of September 2018 (Figure 9).

Argo Data Management

The real time Argo data stream is used extensively by operational users who need the best quality data within 24 h of profile completion. To this end, Argo has transitioned from sending only TESAC⁴ ASCII messages to BUFR⁵ onto the GTS which

⁴Temperature, Salinity, and Current.

⁵Binary Universal Form for the Representation of meteorological data.

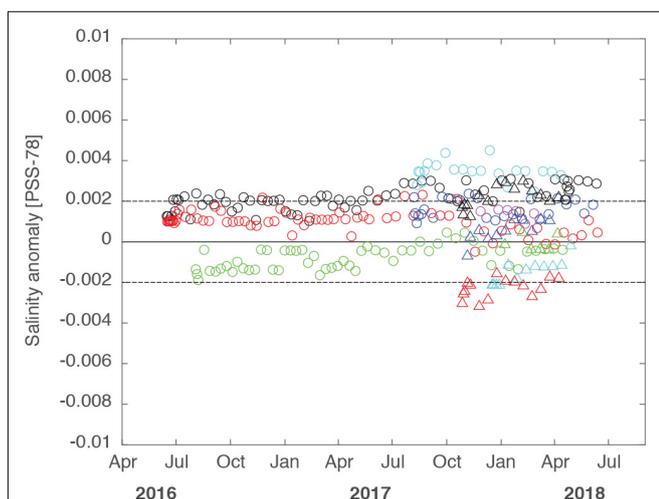

FIGURE 8 | Salinity difference between Deep SOLO SBE-61 CTDs and ship-based hydrographic data interpolated at Deep SOLO float location, projected on 0.74°C potential temperature surface. CTD measurements are for 11 Deep SOLO floats deployed in the Southwest Pacific Basin (WMO ID numbers 5902456, 5902457, 5902478, 5902528, 5902529, 5905161, 5905162, 5905163, 5905164, 5905234, 5905235).

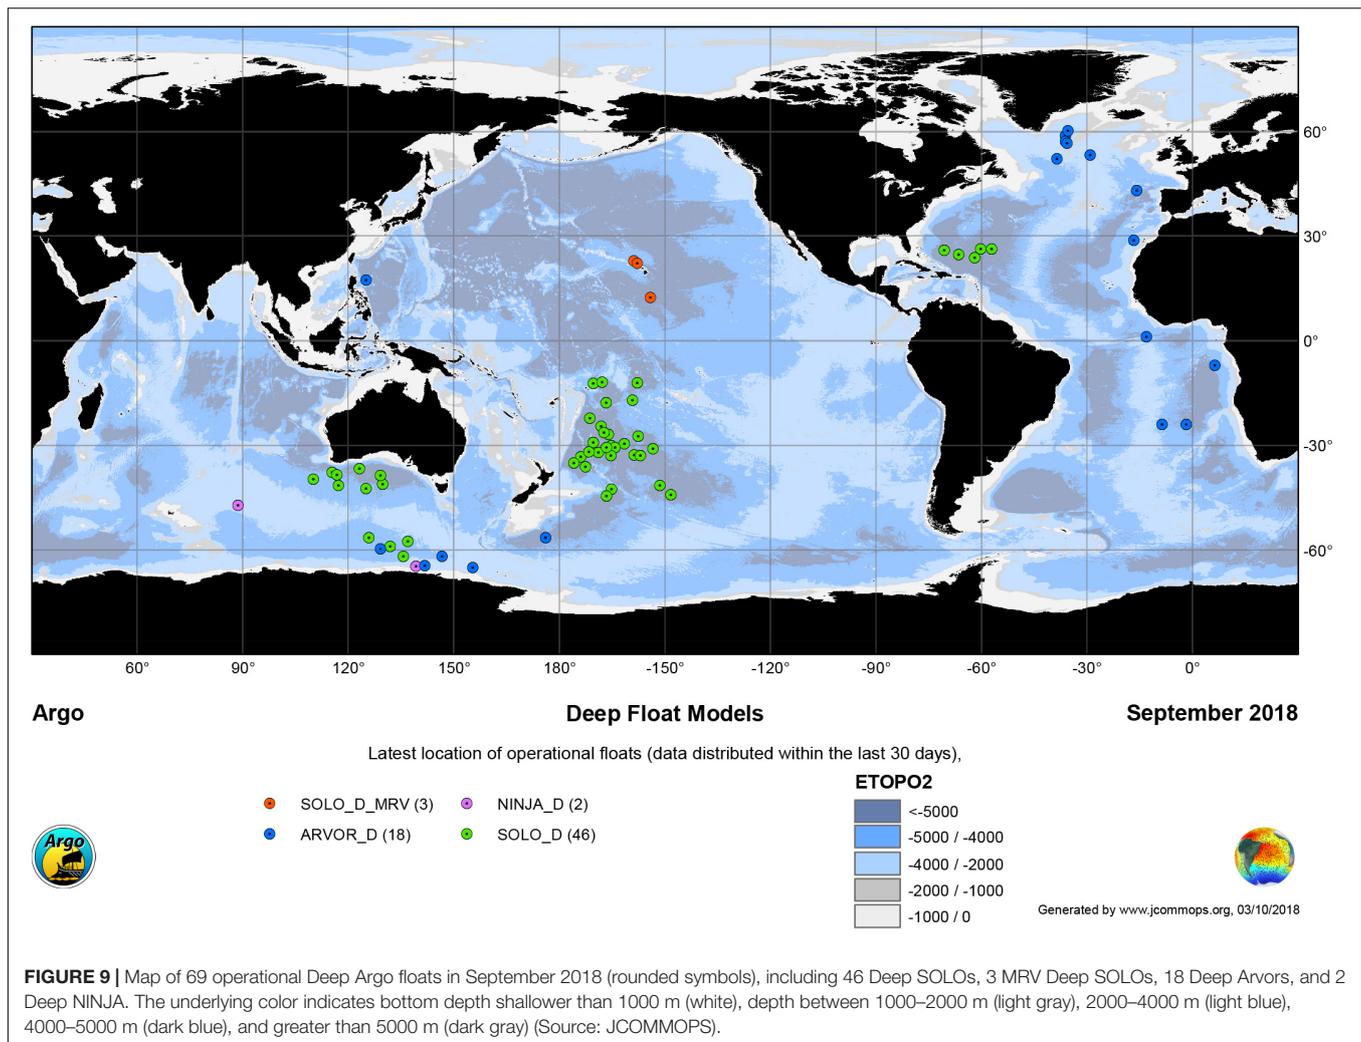

allows the inclusion of quality flags and additional profiles such as near-surface temperature and salinity as well as oxygen, and soon, other biogeochemical data. In 2017, Argo DACs delivered a monthly average of 12,328 TESAC messages, 93% of them within 24 h. The NRT quality control tests have remained the same for many years and with the majority of floats being deployed with two-way communications and returning high resolution data, it is timely to re-consider these tests. Specifically, Argo is exploring a test against gradient climatologies for better detection of anomalous profiles and better spike removal. In addition, over the past several years, RTQC tests for BGC parameters have been developed, some being more mature than others. All BGC RTQC tests are documented⁶ and the documentation is updated as tests mature and additional sensors are deployed.

The Argo data system underwent a major format change when all Argo file formats were transitioned to version 3 and higher. This format change was needed to manage mission changes due to two way communications via Iridium, to better accommodate non-core Argo profiles, to cope with different pressure sampling schemes for some parameters and to store more float metadata. It has been a multi-year process to convert legacy Argo files to the version 3 formats, but the majority of files have been updated. The additional meta data facilitates tracking the health of the array and identifying floats with potentially bad sensors. A large effort was put into homogenizing the meta data and technical files to simplify them and to make cross float model comparisons easier. The ability to store multiple profiles within one cycle has allowed the addition of BGC profiles and other non-Core Argo parameters. To minimize the impact of this change on Core Argo users, the Core Argo profile files kept their name and basic structure and do not contain any BGC parameters. There may be additional profiles in a Core Argo profile file, such as shallow near-surface CTD profiles. B-files were added to the Argo data stream containing the BGC parameters and all the intermediate variables measured and used to convert to the ocean state BGC parameters. Finally, to accommodate users whose research requires all parameters in one file, M-files are generated by the GDACs and contain both Core Argo and BGC profiles.

The transition into version 3 formats also allowed the development of GDAC File Checkers which check not only the format, but also the content of some variables. This has greatly increased the consistency and usability of Argo data. With all these changes, the GDACs today host over 2 million files comprising over 245 GB.

Argo DMQC of Core Argo variables occurs about 12 months after observation. The Owens and Wong (2009) method is the Argo standard, with local modifications depending on profile location. An ongoing challenge is ensuring that Argo DMQC is performed consistently across the program, with the best possible quality reference database for comparison. To this end, Argo is beginning to study the Argo DM dataset in a more robust manner. The North Atlantic ARC has analyzed a variety of floats from different DMQC operators in the North Atlantic to see if DMQC software is being applied properly and consistently (Cabanes et al., 2016). DMQC workshops continue to be held as

⁶<http://dx.doi.org/10.13155/40879>

needed to study the current status of DMQC data and to train new DMQC operators. To help with this, Argo is beginning to share source code more formally through Github, and with a Matlab version of the OW method that is publically available via <https://github.com/ArgoDMQC/matlabow/>.

The AIC has upgraded to an interactive dashboard interface that allows users to perform searches on different float samples, make plots, and display statistics of the float samples. This helps Argo PIs, users, and the public track Argo floats and monitor the health of the array on a real time basis.

Ensuring a timely and citable Argo dataset is a high priority. Over the past several years, the Argo GDACs have served the Argo data in a variety of ways. To facilitate research reproducibility, monthly snapshots of the GDACs are captured and are assigned digital object identifiers (DOIs)⁷. Through collaboration with the Research Data Alliance, Argo has moved ahead with issuing a DOI for its dataset with a monthly tag⁸

⁷<http://doi.org/10.17882/42182>

⁸<http://www.argodatamgt.org/Access-to-data/Argo-DOI-Digital-Object-Identifier>

that can be added to the end of the DOI string to indicate from which month Argo data was used in scientific papers. As work in this field progresses, if DOIs are further adapted to data sets that change over time, Argo will follow the recommended changes to adhere to the current DOI framework.

The Argo Data Management System has been acknowledged as a model for other observing systems and widely copied. Nevertheless, there are substantial challenges for sustaining this success. With additional Argo sensors comes increasing complexity, and the extra burden on human resources in the data management system is considerable to maintain consistent meta and technical data for all sensors and float types. Even the P/T/S elements of the Argo dataset increase in complexity as multiple vertical axes are accommodated, and new requirements for meta and technical data are implemented. Another strain on the human resources comes from producing high quality, consistent DM files in a timely manner for increasingly complex profile and trajectory files. Finally, integration of Argo and other elements of GOOS generates a need for improvement of interoperability across the GOOS data systems.

ArgoMix

The quantification of fluxes through turbulence measurements and models based on turbulence theory (Osborn and Cox, 1972; Osborn, 1980) has developed over the past several decades. Robust testing constrained by physics (Figure 3 and tracer release experiments; e.g., Ledwell et al., 1993) demonstrates a mature technology. Mixing measurements consist of temperature microstructure measured from thermistors and/or shear measured from piezoelectric airfoil probes, measuring thermal and kinetic energy dissipation rates, χ and ϵ , respectively. Both types of measurements have been documented on profiling floats (Sherman and Davis, 1995; Nagai et al., 2015; Goto et al., 2016, 2018; Lucas et al., 2016; Shroyer et al., 2016) and also conducted but not published by groups at APL/UW and Scripps. These successful demonstrations show the possibilities of a more complete integration.

Shear probes and thermistors deployed on Argo floats would need to survive long immersion times (>5 years) and 100s of pressure cycles. Sensors on microstructure gliders (St. Laurent, Personal Communication) have lasted several 100 profiles over several weeks; it is not known whether reported failures originated from cycling or immersion. While we are not aware of any fundamental issues with fully-potted sensors remaining sensitive and waterproof for 100s of cycles over 5 years, their endurance and stability under Argo conditions will need to be demonstrated.

Typical power consumption of modern turbulence packages is ~ 0.05 W, or about 1 kJ for a 2000 m profile (6 and 12% of the energy for APEX and SOLO profiles, respectively) and 3 kJ for a 6000-m profile (11% of the energy for a deep SOLO float). Using best practices for data compression and onboard processing (Becherer and Moum, 2017), only two variables (ϵ and χ) need be telemetered, at similar data rates to Argo's normal T and S.

PLANS FOR EVOLUTION, GROWTH, AND TECHNICAL ADVANCES

Core Argo

Several enhancements to Argo's original sampling design are being piloted, refined and recommended for implementation. Besides the major expansions into the deep ocean and biogeochemical parameters, the changes to the Core Argo array design involve either spatial expansion or regional increases in float density. The combined plan for spatial enhancements, along with Deep and BGC Argo, is termed the Argo2020 design, which will transform Argo into a truly global array with improved resolution in critical regions.

Seasonal Ice Zones

Due to a dearth of historical data (particularly in winter) and the fast rates of change in the polar oceans and cryosphere, there is strong demand to extend Argo into the seasonal ice zones (Lee et al., 2019; Newman et al., 2019). Pilots have demonstrated good float reliability in the sea-ice zone with a remaining challenge being accurately estimating location for under-ice profiles. Experience with ice-avoidance in the Arctic is less

mature than for the Antarctic, but pilots are underway. Access to remote ice-covered oceans for float deployment remains a logistical challenge that will require a dedicated effort.

Marginal Seas

Operating a float array in enclosed seas has been shown to be feasible, especially for Iridium-equipped floats, with successful arrays in the Mediterranean and Asian marginal seas. Many of these floats carry biogeochemical sensors (Figure 6). Only a modest number of floats are required to cover all marginal seas at double Argo density (Table 1). However, implementation requires active and strong logistical and political support from coastal states.

Tropical Enhancements

Tropical Oceans have a large influence on global climate variability and weather. The increasing challenges of maintaining large-scale tropical moored arrays (TMAs), combined with Argo's efficacy in measuring salinity and resolving narrow tropical thermoclines, have resulted in a recommendation to double the density of Argo sampling in the tropical Pacific. A similar increase is under consideration for the remaining basins (Foltz et al., 2019; Hermes et al., 2019; Smith et al., 2019).

Western Boundary Current Enhancements

With high levels of mesoscale variability, enhanced Argo sampling in WBC regions is needed to reduce noise in tracking the largescale temperature and salinity fields. A tentative design is to double the float density in regions of high eddy variability around western boundary currents.

The implementation of all of the above design changes would result in a 4600 float global array (Figure 10 and Table 1), roughly a 15% increase over present active float numbers, but also requiring a substantial redistribution of floats. Some of this might be achieved via efficiency, but full implementation will require additional resources and/or partners. Of the 4600 floats in the Argo2020 design, 1000 will be BGC-Argo (see section "BGC Argo" under the section "Plans for Evolution, Growth, and Technical Advances") and 1250 will be Deep Argo floats (see section "Deep Argo" under the section "Plans for Evolution, Growth, and Technical Advances").

Ongoing progress in extending float lifetimes (see section "Core Argo" under the section "The present status, problems, and strengths") will remain essential to Argo's future. Argo's ability to meet requirements for finer (~ 10 cm) near-surface resolution is being piloted and may be extended across the Argo array. Longer term developments might also include using surface currents and/or a glide mode to keep floats apart, driving up the array sampling efficiency.

BGC Argo

The immediate goal for BGC-Argo is to obtain national commitments to the long-term implementation of BGC-Argo (contribution to the array and its data system) so that the 1000-float array can begin full-scale deployment within the next 5 years. Successfully achieving long-term sustainability relies on clear long-term commitments from national agencies. Recently

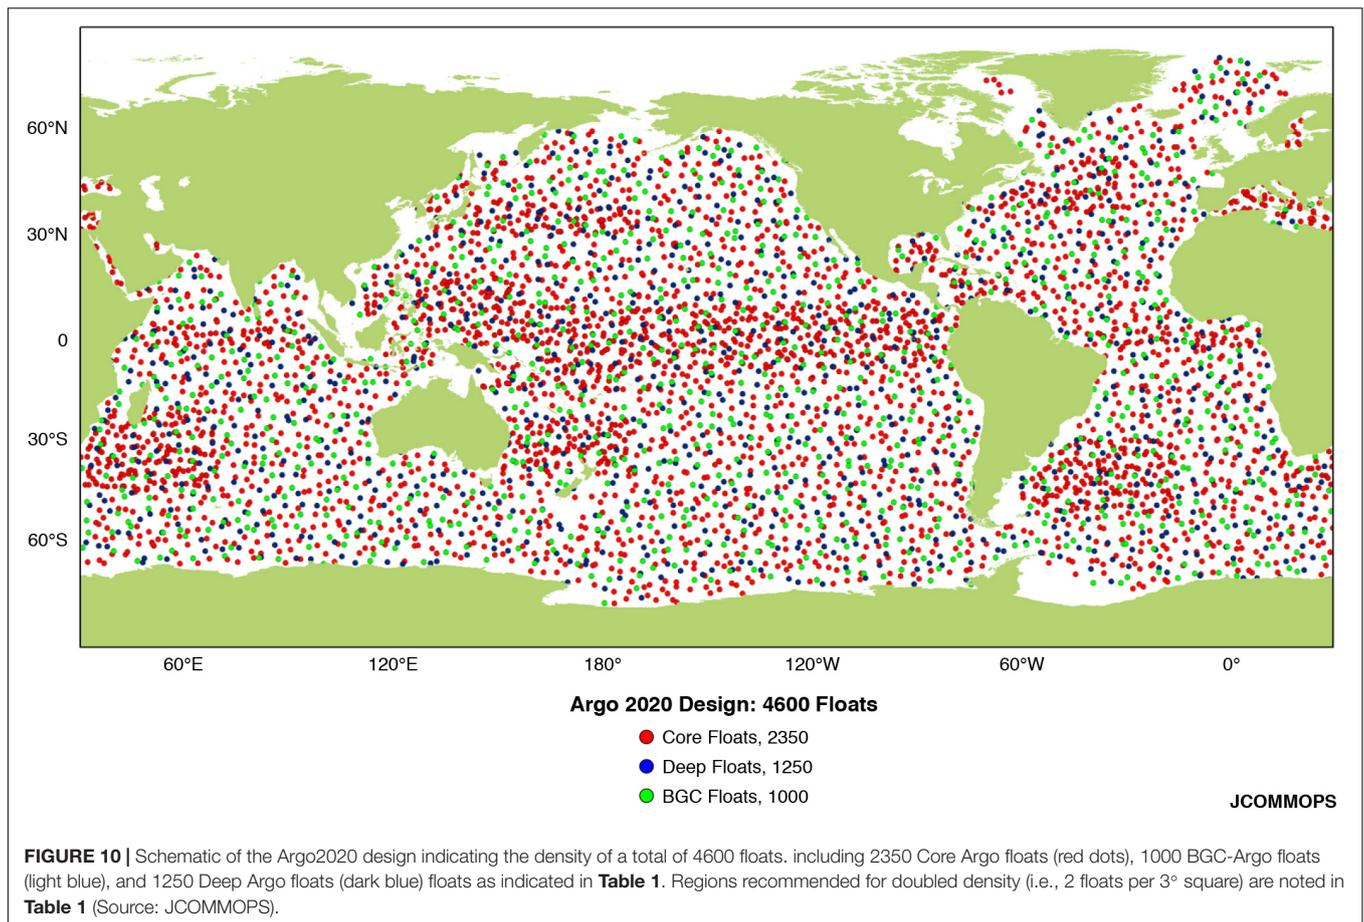

TABLE 1 | Summary of the Argo2020 design, including the required number of active floats and the present status of elements.

Design element 2x indicates doubled density (i.e., 2 floats per 3° square)	Active floats	Status
Global – Original	3000	Implemented
Global – Antarctic	290	Pilot completed; implementation not resourced
Global – Arctic	70	Pilot underway
Global – Marginal Seas (2x)	220	Implemented where regional GOOS alliances are active
Global – Total	3580	
Tropical Enhancement(2x)	560	W. Pacific implementation prioritized, but not resourced
Western Boundary Current Enhancement (2x)	460	Kuroshio pilot completed. Final design still in development.
Argo2020 Design	4600	

The needed number of deployments per year is equal to the number of active floats divided by the mean float lifetime, presently about 4.2 years. The number of floats is inclusive of Core Argo, Deep Argo, and BGC Argo floats, forming a single integrated Argo Program.

announced contributors to BGC-Argo include the government of Canada and the European Research Infrastructure consortium ERIC Euro-Argo (Euro-Argo-Eric, 2017).

Beside high level commitments at national or supranational levels, a key step toward increased accessibility for developing nations that wish to contribute to BGC-Argo is to increase cost-effectiveness (Biogeochemical-Argo Planning Group, 2016). The price of BGC Argo floats could be lowered by developing a competitive market for biogeochemical sensors once there is a clear vision of the market size, with a view to decreasing sensor costs. Additionally, where feasible, float retrievals, and subsequent refitting (for ~20% of their initial price) is a way to reduce the array cost.

Finally, long-term sustainability of BGC-Argo is dependent on data usage and satisfaction of the end-users, who are essential advocates for the BGC-Argo system. The continuous development of a large and diverse end-user community has to be a priority, in particular with the development of specific data products responding to user requirements. It will rely on the establishment of an evolving data management system that will combine (a) real-time data delivery for operational purposes, (b) delayed-mode quality-controlled data delivery for science purposes, and (c) new products supporting end-user requirements.

While the present BGC-Argo program target is to fulfill its objective of six core variables measured by 1000 operational floats, possible new extensions are being tested. These include passive acoustic listener (PAL) not only for wind and rain

(Riser et al., 2008; Yang et al., 2015) but also for anthropogenic noise and mammals, miniaturized imaging sensors for resolving particle and plankton (size range from 100 μm to few mm), and hyperspectral radiometry (phytoplankton functional types). There are promising efforts to develop additional new chemical sensors, such as alkalinity (Briggs et al., 2017) and to adapt existing chemical sensors such as pCO_2 (Fiedler et al., 2013).

Deep Argo

Plans for the next 10 years are to transition from the pilot phase to completed global implementation of the Deep Argo Program, including about 1250 Deep Argo floats at $5^\circ \times 5^\circ$ spacing (Johnson et al., 2015). Elements of the Deep Argo deployment strategy are as follows. Existing pilot arrays should be maintained to demonstrate the scientific value of Deep Argo, and to refine the design of the Deep Argo array as well as of its floats and data management system. The deployments of 4000 and 6000 dbar Deep Argo floats will be coordinated to achieve areal coverage of top-to-bottom P/T/S profiles. New pilot arrays will be implemented in regions believed to have substantial decadal changes, seasonal cycles, or other variability, and that are close to deep-water and bottom-water formation sites. The choices of globally-uniform or basin-specific parking depth, and of preferred cycle time are still under discussion. As occurred with Core Argo, the global implementation of an evenly distributed Deep Argo float array will follow from the expansion of the regional pilots.

Deep Argo's scientific objectives are to close the Earth's budgets of heat and freshwater, to assess the steric contribution to sea level rise, to improve our understanding of full-depth ocean circulation and water-mass transformation in the ocean interior, and to reduce uncertainties in coupled atmosphere-ocean models, reanalyses, and predictions. The deployment of new sensors for BGC or mixing parameters could enhance the value of Deep Argo, expand the scope of the Deep Argo dataset, and promote the integration of Deep Argo with other observing system elements. Power usage of additional sensors should be compatible with Deep Argo array refresh-times of 5 years or longer. Sensor accuracy should be sufficient to resolve interannual to decadal climate signals. Enhanced hydrographic sampling of the bottom boundary layer is recommended for studies of deep-ocean dynamics, including dense overflows, energy dissipation near topography, and geothermal heating (de Lavergne et al., 2016). Deep Arvor floats equipped with altimeter and bottom-looking ADCP, will be tested in the Weddell Sea as part of the Water Mass Transformation and Pathways in the Weddell Sea (WAPITI) project, to draw deep P/T/S and oxygen measurements closer to the topography, and to improve velocity estimates near the bottom. Deep SOLO floats already sample to within a few meters of the bottom, closer than GO-SHIP cruises, which stop at about 10 m off the bottom.

Argo Data Management

Argo encourages technological developments in floats and sensors, but the introduction of new floats and sensors places a burden on the Argo data stream. Therefore, the Argo Steering

Team (AST) and the ADMT have developed a framework for the definition of an Argo float, and have described a pathway for new sensors to become approved Argo sensors. Moving forward, there will be three categories of sensors: (1) accepted sensors that meet Argo's accuracy and performance standards, (2) sensors approved for pilot arrays by the AST and ADMT, and (3) experimental sensors on floats equipped with an approved Argo CTD where the experimental sensor data will be available in the Argo auxiliary data stream.

If pilot sensors are shown to meet Argo's accuracy and stability targets, the AST will accept these into the Argo data stream. This applies to Core Argo 2000 dbar CTDs, Deep Argo CTDs, and BGC-Argo sensors, and other prioritized parameters, and will involve coordination of the AST, ADMT, Deep Argo, BGC-Argo, and sensor manufacturers. The framework for incorporation into the Argo database explains what is required of float providers and articulates guidelines for the collection and distribution of all data collected by Argo floats. In summary, float providers must follow Argo governance rules for mandatory pre-deployment notification through the AIC and agree to timely data delivery of both NRT and DM data. In addition, float providers must have a plan for long term data ownership with a national Argo DAC. Floats that are to become part of the Core Argo Program should target the Core Argo profiling depth of 2000 dbar and the cycle time of 10 days.

Argo will also continue to develop more sophisticated code sharing among Argo DACs, PIs, and manufacturers to reduce the burden on DACs and PIs each time modifications are made to floats or sensors and to improve consistency across the Argo program. Code sharing may also help with turnover as scientists and DMQC operators within Argo retire and take some of their knowledge with them. Continuing to find interested and talented Argo data team members and train them appropriately in a timely manner will remain a challenge for the ADMT.

Quality control of Argo data involves a complex sequence of both automatic and manual tests to produce data of high scientific quality. With 400 profiles arriving daily, the burden on human resources dedicated to QC is large and Argo is considering whether machine learning can help ease the burden and improve the QC process.

Work still needs to be done on several BGC-Argo parameters to modify and develop DMQC procedures. In addition, the BGC Argo data community has developed BGC Argo products that collocate all parameters on the same pressure levels and that perform additional QC tests.

As Deep Argo continues to grow, there will be a need to extend the Core Argo DMQC processes to data deeper than 2000 dbar and to understand how the CTDs, both the SBE-41 and the specially designed for Deep Argo SBE-61, behave over multi-year lifetimes.

Besides profile data, Argo also provides trajectory data which can be used to calculate the velocity of the ocean at the drift depth of 1000 dbar. To improve the accuracy of these velocity calculations, newer floats send back more timing information to populate additional timing variables in the new version 3 file format for trajectory files. Argo is developing a DM process for trajectory files. This will include correcting the P/T/S

measurements made along the float's trajectory, and performing quality control on the float positions and on the timing variables.

ArgoMix

Some engineering challenges remain in designing and implementing the best (most reliable, lowest power, and least expensive) float-deployed microstructure system. The next step, already underway, is for turbulence and float groups to work together to develop design criteria and test procedures that will lead to experimental deployments of O(2-5) floats, carrying temperature and shear microstructure sensors and having Argo-like missions. Once success is demonstrated in experimental deployments, and data management is harmonized with Argo, a plan for regional pilot deployment of O(30-100) floats, to allow patterns of mixing to be mapped on regional scales, would be presented to the Argo Steering Team for consideration. In parallel, several next-generation sensors are being pursued such as pitot tubes, faster thermistors, and refractometers for resolution of salinity microstructure. In time, we expect the hardware to be simplified, and the endurance of the probes demonstrated, to the point that these measurements can be efficiently incorporated as an integral part of the global Argo Program.

END USER ENGAGEMENT

Core Argo

The Argo Program began with a strong “user pull” that informed decisions relating to the original Argo design (Argo Steering Team, 1998). Key beneficiaries of the Argo Program, along with the scientific community, include climate sensitive industries (e.g., agriculture, aquaculture, tourism, and fisheries), and industries with a significant maritime presence (e.g., oil and gas, shipping, and emergency response). In most cases, the Argo Community's end user engagement is maintained indirectly – either through the forecasting community, or through the scientific community.

The forecasting community (e.g., CLIVAR GSOP, GODAE OceanView) has impact through the provision of forecasts that are underpinned by GOOS – primarily through Argo and satellite observations. Such forecasts depend on the routine delivery of NRT Argo data. Public availability of NRT data has remained a core principle of the Argo community since its beginning. Forecasts are regularly exploited by the Blue Economy (Willis, 2015; Wenhai et al., 2019) to inform tactical and strategic decision-making. Adding value to seasonal forecasts to inform the agricultural industry has proved beneficial (e.g., Hochman et al., 2009). For example, inclusion of SST forecasts in crop models improves farmers' ability to manage stocks and crops more efficiently. Short-range forecasts are often used to support emergency response to oil spills (e.g., Deepwater Horizon; Mariano et al., 2011), marine pollution (Potemra, 2012; Maximenko et al., 2019), and search and rescue (e.g., search for MH370; Griffin et al., 2017). The impact of Argo observations on forecast systems is well-documented (Davidson et al., 2019), and the complementary nature of

information available from Argo observations and satellite observations (Ponte et al., 2019; Vinogradova et al., 2019), has been demonstrated many times (e.g., Oke and Schiller, 2007; Lea et al., 2014). An example of the impact of Argo data on FOAM – the 1/4°-resolution operational ocean forecast system run by the UKMet Office – is presented in **Figure 11**, showing the change of temperature at 110 m depth in the FOAM system after Argo data are withheld for just 1 month (Lea et al., 2014).

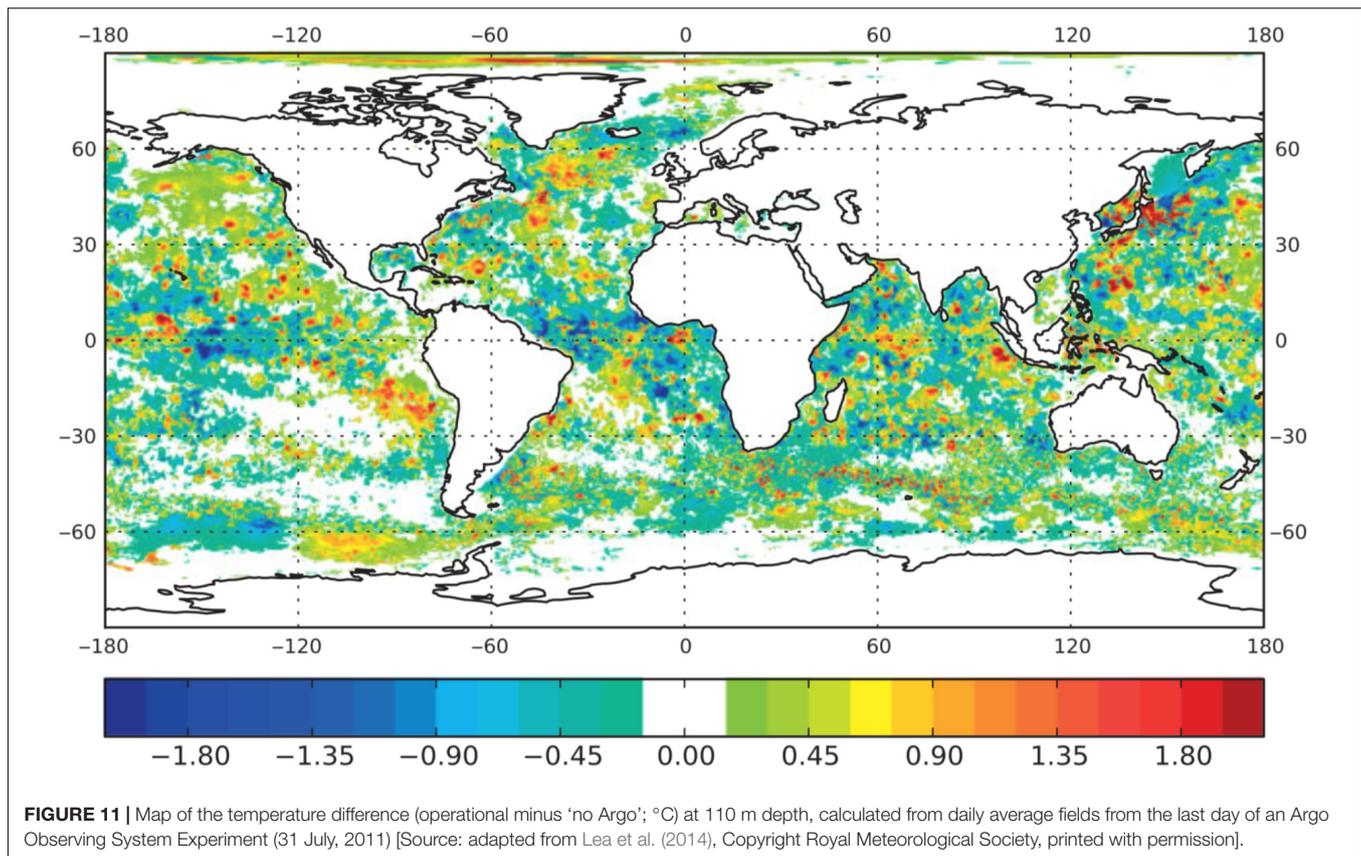

The delayed-mode Argo dataset underpins many efforts in global ocean reanalysis on climate-scales (e.g., de Boissésion et al., 2018) and eddy-scales (e.g., Oke et al., 2013), providing products that are the foundation for much scientific research. In return, the ocean reanalysis community, coordinated by the Global Ocean Data Assimilation Experiment (GODAE) OceanView Observing System Evaluation Task Team (Fujii et al., 2019) and the CLIVAR Global Synthesis and Observation Panel (GSOP), regularly articulate the ongoing need and continued benefit/impact the Core Argo program delivers to their stakeholders (e.g., Oke et al., 2009; Davidson et al., 2019; Fujii et al., 2019; Penny et al., 2019).

Impacts via the scientific community typically include the identification of potential opportunities and/or vulnerabilities that are “publicized” through popular media and/or the published scientific literature. Most of the relevant scientific studies are built on the publicly-available DM data – spanning the entire Argo mission (1999-present) – that have been subject to the highest standards of quality control (e.g., Wong et al., 2003; Kobayashi and Minato, 2005; Owens and Wong, 2009). The Argo dataset facilitates assessment of the variability and trends in ocean heat content (**Figure 12**, also see Wijffels et al., 2016), freshwater distribution, steric sea level rise, and intermediate depth ocean circulation. This fundamental monitoring program for the world climate facilitates understanding of climate variability and change with increased certainty and more precise attribution (e.g., Chen et al., 2017). Core Argo and BGC Argo also underpin the assessments of ecosystem health (Canonico et al., 2019) increasingly delivering metrics relevant to marine biodiversity and ocean acidification (e.g., Bender et al., 2016; Watanabe and Kawamiya, 2017; Cross et al., 2019).

A key Argo user community is Education, including K-12, undergraduate, and graduate levels. Gridded versions of the Argo dataset have been developed, as well as data viewers, to serve the needs of education, research, and government agency users having widely varying backgrounds and levels of technical expertise. Education applications of Argo have included teaching units tailored to curricula as well as “after school enrichment” web-based activities⁹. At the graduate level, about 300 Ph.D. theses have used Argo data. Despite substantial achievements in Education, there remains more to be done. All modern students should be aware of the Argo Program and able to explore the global ocean from their desktop.

It's important to the Argo Community that the Program remains relevant to the wider community and continues to deliver societal benefits. As new opportunities and vulnerabilities

⁹http://www.argo.ucsd.edu/Educational_use.html

arise, and as requirements for ocean observing are better understood, the Argo design will continue to be refined to better meet ongoing societal needs (e.g., Jayne et al., 2017).

BGC Argo

Already supporting a growing community of scientific end-users, BGC-Argo has enormous potential to contribute to societal engagement through a wider group of stakeholders. In particular, these include end-users of ocean observation and modeling products and services that utilize BGC-Argo data. The BGC-Argo science and implementation plan has notably identified two topics of societal relevance in the context of “climate variability and change” and “ocean ecosystem health.”

With regard to the climate variability and change, better constraints on ocean carbon fluxes will reduce the present residual in global carbon budget estimates (Le Quéré et al., 2018) and improve quantification of air-sea CO₂ fluxes (Gray et al., 2018). BGC-Argo floats measuring O₂, salinity (to enable estimation of alkalinity) and pH, have the potential to provide complete annual cycles of pCO₂ throughout the ocean (Williams et al., 2017). Direct measurement of pH and O₂ would contribute information on ocean acidification as well as deoxygenation.

Furthermore, the BGC-Argo network will provide an important underpinning for the observation of changes occurring at the base of the food web, for the attribution of changes in higher trophic levels to environmental stressors, and for the development of predictive capabilities for marine living

resources. The network would, for the first time, enable global monitoring of environmental conditions such as pH and O₂ concentrations, which directly affect the physiology and fitness of marine fauna. In addition, it would enable improved estimates of primary productivity, which supports the entire marine food web, through direct observation of nitrate concentrations and plankton biomass.

Realizing the potential of BGC-Argo for societal benefits will require provision of easily accessible products (Figure 13) through partnerships with the operational oceanographic community such as GODAE. Several national service providers are actively pursuing the development of biogeochemical forecasts and re-analyses but remain severely data limited. Currently the primary NRT data source for assimilation into numerical models is ocean color from satellites. BGC-Argo will fundamentally advance biogeochemical data assimilation by extending observations below the surface and significantly expanding the suite of observable parameters.

Deep Argo

Deep Argo will substantially reduce the uncertainty in the rate of deep ocean warming, helping to constrain future projections of ocean heat uptake and sea level rise. Sources of uncertainties in projections of the ocean heat uptake include changes in the deep-water and bottom-water mass formation rates, and in the strength of the deep meridional overturning circulation (Masuda et al., 2010; Marshall and Zanna, 2014). GODAE, and

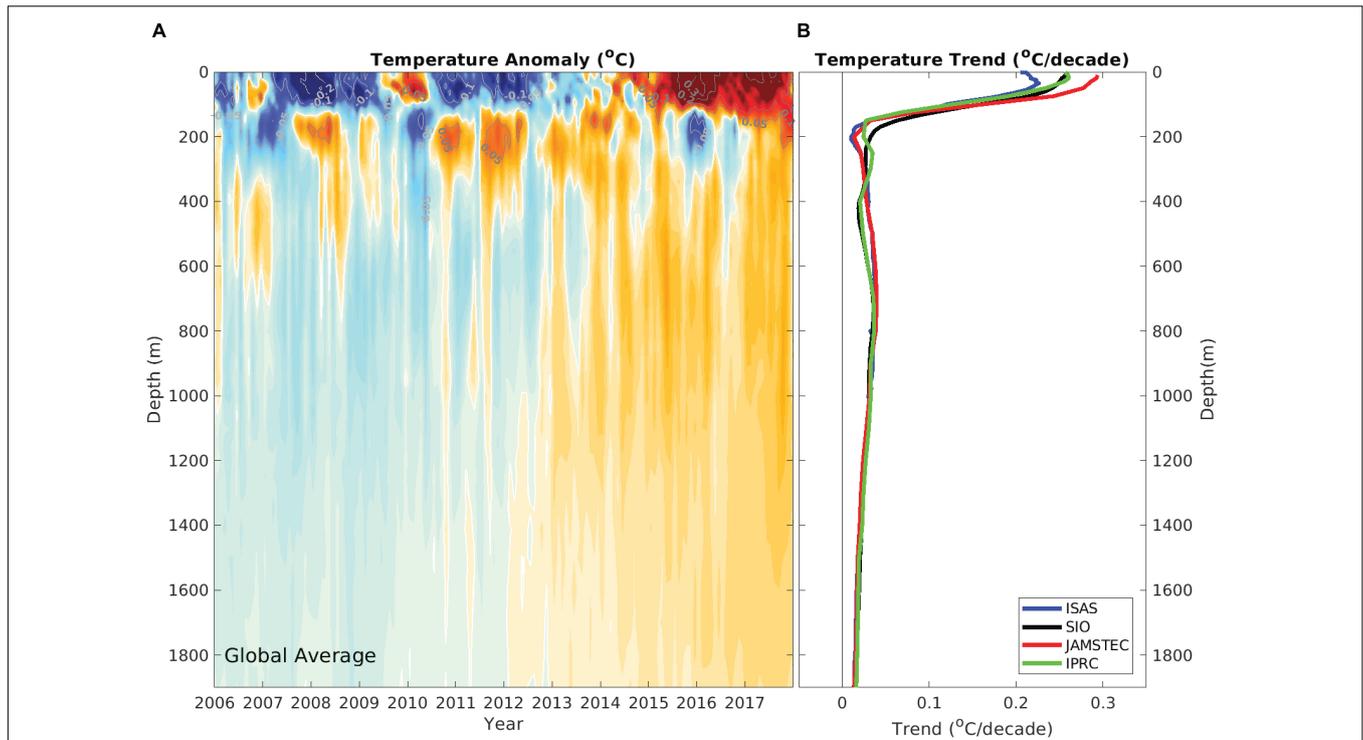

FIGURE 12 | (A) Global averaged temperature anomaly (°C – from SIO) and **(B)** trend (°C/decade, 2006–2018) versus depth, based on gridded Argo data. Gridded product sources are: ISAS (Gaillard et al., 2016), SIO (Roemmich and Gilson, 2009); IPRC- from the Asia-Pacific Data Research Center (http://apdrc.soest.hawaii.edu/projects/Argo/data/gridded/On_standard_levels/index-1.html); JAMSTEC (Hosoda et al., 2008).

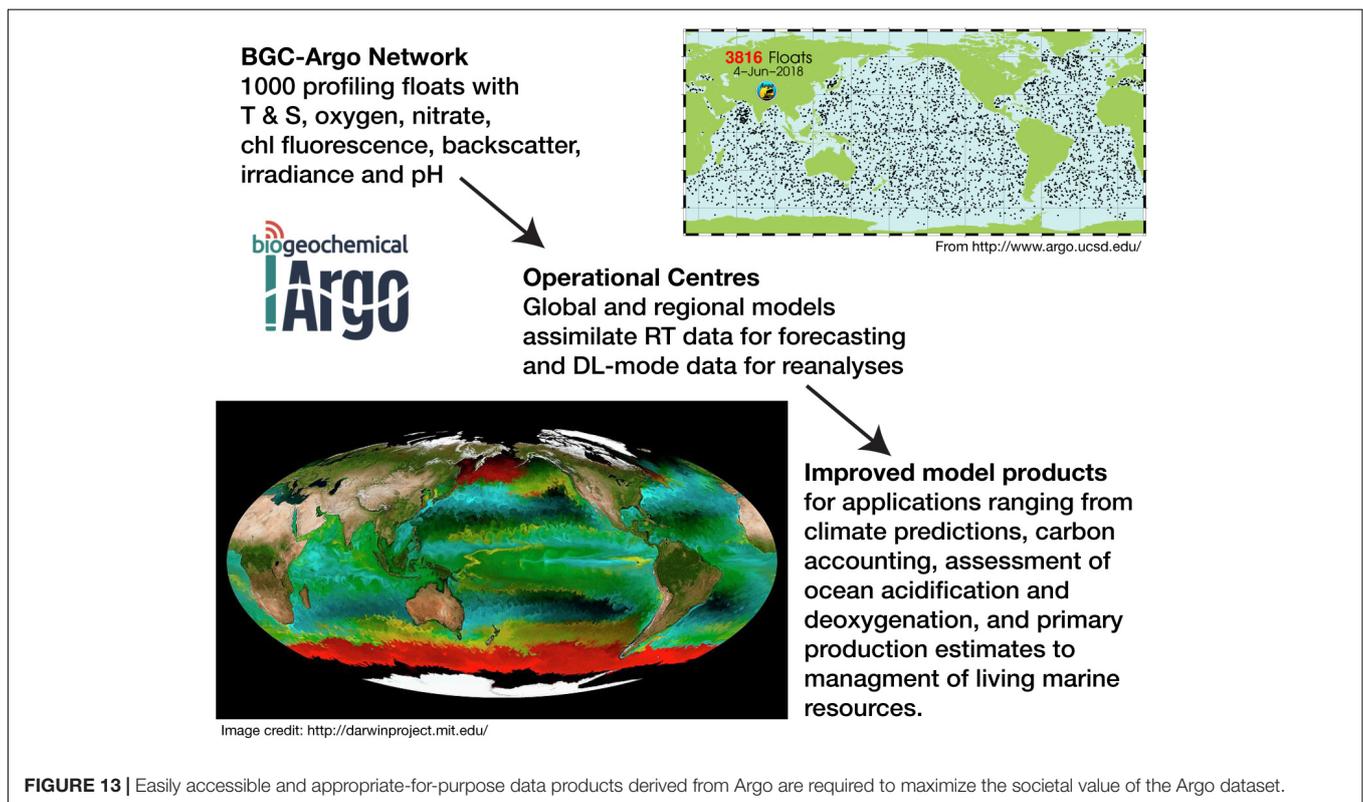

FIGURE 13 | Easily accessible and appropriate-for-purpose data products derived from Argo are required to maximize the societal value of the Argo dataset.

its follow-on extensions have identified the need for deep ocean observations in data assimilation systems, to improve long-term predictions of atmosphere and ocean conditions (Bell et al., 2015). Deep Argo will help fill this need. A series of OSSEs has been performed to assess the impact of Deep Argo observations for ocean analysis and forecasting within the AtlantOS project (Visbeck et al., 2015; Gasparin et al., 2018). Early results show that the assimilation of full-depth temperature and salinity profiles using sampling density similar to the anticipated Deep Argo design ($5^\circ \times 5^\circ \times 15$ -day), would reduce the root mean square errors of deep-ocean temperature and salinity by 20–40%.

Argo Data Management

Argo has developed an efficient data system that is used as a model for other operational observing systems, as it (1) serves both operational and research users, (2) works to standardize information in its files (scientific, meta, and technical data), (3) acts as a key player in data citation methodology in real time data systems (see section “Core Argo” under the section “End User Engagement”). These attributes illustrate the importance of identifying end user communities and developing data management systems that serve their needs. Argo did this from the outset, developing links with CLIVAR and GODAE beginning in 1998. Argo continues today to evolve the data management system to provide greater value to communities engaged in basic research, climate assessment, operational reanalysis and forecasting, and education.

ArgoMix

Numerical experimentation over the last decade has shown that key aspects of Earth’s climate depend on accurate representation of turbulent mixing in the ocean. In fact, the field has matured to a point where without better observational constraints on turbulent mixing it will be difficult to make further progress in understanding processes as diverse as abyssal circulation (Melet et al., 2016; MacKinnon et al., 2017), ice ages (Ferrari et al., 2016), tropical precipitation (Jochum et al., 2013), the sea-surface temperature cycle (Moum et al., 2013) or the extent of the oxygen minimum zones (Brandt et al., 2010). ArgoMix would provide the observational backbone needed to implement trustworthy parameterizations into climate models and achieve a deeper understanding of the Earth System.

INTEGRATION WITH OTHER OBSERVING SYSTEM ELEMENTS

Core Argo

From the outset, and explicitly with Argo’s naming, there has been an emphasis on the complementarity of the Argo float array and the Jason satellite altimeter missions (Argo Steering Team, 1998). Argo captures the subsurface temperature, salinity and thus density structure, with sufficient coverage and resolution to constrain the steric component of the altimetric signal, enabling interpretation of altimetric sea surface height variability. On the other hand, the satellite altimetry provides spatial/temporal

context, such as in terms of mesoscale variability, to each Argo profile. Even though the Argo/altimetry complementarity is remarkable, it is only one part of the synergy between Argo and many other *in situ* and satellite observing system elements (Roemmich and The Argo Steering Team, 2009; Freeland et al., 2010; Riser et al., 2016; Wuldera et al., 2016).

Argo, as a broad scale array with temperature and salinity measurements to 2000 m, has remarkable synergies with repeat hydrography (Sloyan et al., 2019) and high resolution XBT (HRX) transects (Goni et al., 2019). These transect-oriented data provide estimates of geostrophic velocity and transport, and hence heat and freshwater transport into enclosed regions or across basin-spanning transects. Combining estimated transports with Argo assessments of the storage of heat and fresh water in the enclosed regions provide a powerful tool for analyzing ocean heat and freshwater budgets along with air-sea flux products (Meyssignac et al., 2019). Argo also provides spatial/temporal context for HRX lines, which capture the mesoscale and hence the eddy flux for boundary current/basin scale heat flux measurements, and for the repeat hydrography program, whose decadal repeat cycle lacks the seasonal-to-interannual temporal resolution supplied by Argo. Also, high-quality repeat hydrography is also essential for quality control of Argo data.

While an accurate sea level record by satellite altimetry is key to monitoring and understanding sea level change, Argo serves as an essential integrant of the comprehensive observing system for sea level and its contributing components (Ponte et al., 2019). Argo provides an estimate of the steric component, resolving the temperature and salinity contributions and their depth distribution. Combining satellite altimetry and Argo, along with satellite gravimetry capturing ocean mass change, provide the capability to close local and global sea level budgets. The tide gauge network provided by GLOSS and coordinated global shipboard CTD observations provided by GO-SHIP are also essential parts of the observing system for sea level, by ensuring the accuracy of satellite altimetry and Argo data, respectively. Furthermore, variability in the globally integrated ocean heat content monitored by Argo provides constraints and validations of the satellite estimates of Earth’s top-of-the-atmosphere radiative energy imbalance (Johnson et al., 2016).

Sea surface temperature and sea surface salinity (SSS) are provided by satellite remote sensing globally, but requires *in situ* measurements for calibration purposes and interpretation (Vinogradova et al., 2019). Argo plays an essential role in these requirements along with other *in situ* observing elements such as a voluntary observing ship (VOS) network, surface drifters and moorings. Argo’s capability in this domain is being greatly improved by extension of profiles to include the near-surface layer.

Since Argo is the only global subsurface network, it occupies a special role in the integrated GOOS consisting of satellite and *in situ* networks. Argo’s interdependency and mutual value-adding relationships with other elements of the systems have been comprehensively discussed in the context of many regional observing systems such as the Tropical Pacific Observing System (TPOS 2020) (deYoung et al., 2019; Foltz et al., 2019;

Hermes et al., 2019; Lee et al., 2019; Newman et al., 2019; Palazov et al., 2019; Smith et al., 2019; Todd et al., 2019).

BGC Argo

The BGC-Argo network has significant synergy with other ocean observing programs. Its global, year-around presence will fill observational gaps for key biogeochemical variables. In the coming years it is essential to strengthen the relations and interactions with other components of the ocean observation system.

Argo

The interaction with the Core Argo Program and its extensions (deep, marginal seas, polar seas) is a natural interaction. BGC-Argo floats also provide Core Argo measurements that are seamlessly integrated into the Argo data system. This interaction allows a more cost-effective and efficient usage of a multidisciplinary array. Additional synergies related to science have already been described (e.g., physical – biogeochemical coupling, radiometry, and heating rate of the upper ocean).

OceanGliders

As the target of Argo is the open ocean it is highly complementary to glider observations conducted over the shelf-open ocean interface. BGC-Argo and OceanGliders share biogeochemical sensors used with similar mode of operations.

OceanSites

Fixed point observatories integrate a strong biogeochemical component. Synergies between BGC Argo and Eulerian observatories will be beneficial from both scientific and technical perspectives.

Ocean Color Remote Sensing

Chla and particle backscatter are quantities that are inferred from remote sensing of ocean color. BGC-Argo floats provide the vertical dimension to the global and synoptic measurements of the satellites, with a high degree of consistency (Haëntjens et al., 2017). The integration of both observation systems has to target the development of merged 3D/4D products (already prototyped, e.g., Sauzède et al., 2016). Additionally building on float arrays dedicated to satellite calibration (IOCCG, 2011; Gerbi et al., 2016; Leymarie et al., 2018), the progressive densification of an *in situ* database, with the addition of radiometry, is a way to validate remote sensing products and eventually to refine algorithm retrieval, including at regional scales. BGC-Argo can be used to validate space-based products (e.g., Haëntjens et al., 2017), fill in gaps in cloudy regions, during polar night, and under ice.

GO-SHIP/GLODAP

GO-SHIP is an essential partner to BGC-Argo. Its cruises take calibrated observations of most of the biogeochemical variables measured by floats, providing an important source of reference data. The GO-SHIP data set and the merged internally consistent product produced by the GLODAP project (Olsen et al., 2016) are essential for construction of the reference data set used to detect errors and make adjustments in BGC sensors

(Johnson et al., 2017) in a similar manner to that used by Core Argo to detect salinity drift (Owens and Wong, 2009). Floats with chemical sensors (O₂, pH, NO₃) can then extend these accurate, but infrequent, GO-SHIP cruises in the time domain to seasonal and inter-annual scales over the entire ocean.

SOCONET and SOCAT

Floats with carbon system parameters, such as pH, would extend the surface pCO₂ observations collected by the SOCONET ship of opportunity and mooring network and served from the SOCAT database. SOCAT (Bakker et al., 2016) produces a collated dataset with annual updates of *in situ* surface pCO₂ measurements. However, the observations are infrequent, at high latitude, and biased to summer months. Merged products of ship, mooring-based and float-based estimates have the potential to improve our understanding of seasonal and interannual variability of ocean acidification and air-sea CO₂ fluxes.

Deep Argo

At present, the deep ocean is primarily monitored by temporally-limited repeat hydrographic sections provided by GO-SHIP, and fixed-point time-series at the OceanSITES moorings (e.g., TAO/TRITON, PIRATA, and RAMA arrays; Send et al., 2010). Deep Argo will complement existing deep-ocean observations by increasing the top-to-bottom P/T/S sampling in the ocean interior. As in Core Argo, Deep Argo's success will build upon collaboration and integration across elements of the GOOS. Comparison with highly accurate P/T/S and oxygen measurements from GO-SHIP is the basis for Deep Argo DMQC, to monitor CTD and oxygen sensor drift, and to provide scientific background for data analysis. The implementation of the Deep Argo array relies on partnerships with ship-based hydrography programs including GO-SHIP, the HRX network, Core Argo, and OceanSITES. Deep Argo sea-going operations will provide deployment opportunities for other observing system elements (e.g., the Global Drifter Program).

Deep Argo, will improve the integration of satellite remote sensing observations, including sea level, net top-of-the atmosphere energy flux, and ocean mass and land ice variability, with *in situ* ocean data. Changes below 2000 dbar account for about 8% of the steric sea level rise, and 10% of the ocean heat uptake since the 1990s (Purkey and Johnson, 2010; Desbruyères et al., 2016). Combining estimates of the deep-ocean thermal expansion derived from Deep Argo, with ocean mass observations from the Gravity Recovery and Climate Experiment (GRACE; Tapley et al., 2004), and sea surface height data from satellite altimetry, will advance current understanding of the partitioning of steric and mass contribution to sea level rise (Purkey et al., 2014). In addition, systematic observations of top-to-bottom ocean temperature from Deep Argo will improve the monitoring of year-to-year fluctuations in the net accumulation of anthropogenic heat in the Earth system. Increased deep ocean P/T/S sampling will provide *in situ* validation for variability in the Earth's energy imbalance estimated from the satellite-based Clouds and the Earth's radiant Energy System (CERES; Johnson et al., 2016).

Argo Data Management

Argo is already used by operational users and scientists together with other platform data and therefore enhancing the interoperability of Argo data with other data systems by implementing the FAIR¹⁰ principles is an important next step for Argo. Improving the FAIR-ness of the Argo data system may imply updates in data and metadata format as standards evolve or the addition of services to supplement existing services. As stated earlier, serving high quality data is a top priority for Argo and comparison with other observing systems will help each system with improving data quality and services (see section “Core Argo” under the section “Integration with Other Observing System Elements”).

ArgoMix

ArgoMix would greatly expand the number of direct observations of ocean turbulence, enabling improvement of fine-scale parameterizations made from existing P/T/S measurements (Gregg, 1989; Polzin et al., 1995; Whalen et al., 2012, 2015). Turbulence measurements from ArgoMix can validate and improve the underlying assumptions applied to convert P/T/S measurements from Core Argo, Chi-pods, and ship based hydrography data to fine-scale parameterizations of turbulence. Additionally, ArgoMix would bridge the gap between geographically isolated moorings and process studies and the global scale of ocean mixing. Global spatial coverage will provide the necessary context to link moorings and process studies, which may be located in special regions of enhanced mixing, to the large scales of water mass properties and circulation, and their variability.

CONCLUSION

Argo’s continuous, real-time, global coverage of P/T/S in the upper 2000 m of the ocean has revolutionized our ability to monitor, understand, and forecast ocean variability. Starting in the late 1990s, the oceanographic community recognized the need and opportunity for a major enhancement of subsurface measurements to complement recent advances in remote sensing and to better monitor the global oceans for climate variability and change. The community designed and implemented Argo as an autonomous profiling float array capable of sampling the interior global ocean in a temporally and spatially continuous way that revolutionized the existing GOOS (Argo Steering Team, 1998). Argo has been a tremendous success in terms of engineering advancements, data management, and data dissemination, accomplishing its initial goal of monitoring global change and its consequences, improving ocean forecasts, and providing data underpinning many scientific advances. By combining the successful groundwork of Core Argo with recent float and sensor technology developments, there is now the opportunity to expand Argo as a next-generation observational array with enhanced societal value. The expanded Argo array envisioned here is capable of documenting the regional and global heat

and freshwater budgets, biogeochemistry, and circulation of the top-to-bottom and pole-to-pole ocean.

This report calls for the expansion of Argo by (1) supplementing Core Argo to cover marginal seas and seasonal ice zones, (2) increasing Core Argo float density in the tropics and western boundary current regions, (3) deploying a global BGC-Argo float array capable of measuring chlorophyll fluorescence, particle backscatter, oxygen, nitrate, pH, and irradiance, (4) deploying a global Deep Argo array to monitor ocean variability down to 6000 m, (5) validating and deploying new sensors, for example those capable of measuring ocean turbulence, (6) maintaining and advancing data management to keep up with growing data inflow and new requirements, and (7) continuing to engage with the end-user community to best maximize accessibility and utility of Argo data for the scientific, Blue Economy, and educational communities alike. The expanded design of the Argo Program, termed Argo2020, includes all of the elements described above while continuing as a single unified ocean observing system sharing platforms, logistics, data management, scientific objectives, and international governance, and with powerful synergies across its components and with other satellite and *in situ* observing systems.

The expanded Argo array will increase end user engagement through enabling basic research, climate assessment, education, and industry, the latter by means of improved long and short term ocean reanalysis and forecasting. Argo will better monitor climate variability and ecosystem health to allow for improved parameterization in models, and thus improved climate forecasting enabling better societal adaptation. In addition, real time assimilation of ocean heat, freshwater, and biogeochemistry will improve short-term forecasts vital for climate sensitive industries such as agriculture, aquaculture, fisheries, oil and gas. Finally, full-depth monitoring of ocean heat content will allow for synthesis with satellite observations for better closure of the global sea level rise and energy budgets. The Argo2020 design (Figure 10 and Table 1) describes the next-generation Argo Program that includes enhancements to Core Argo as well as BGC-Argo and Deep Argo elements, all fully integrated in their spatial distributions and through the comprehensive Argo Data Management System.

In the face of increasing anthropogenic forcing and accelerating global and regional trends in sea level, heat content, ocean acidification and deoxygenation, there is urgent need to continuously monitor the physical and biogeochemical variability of the global ocean with sufficient spatial and temporal resolution. The Argo *in situ* profiling array is a crucial piece of GOOS, and essential for meeting this challenge. Here, we have outlined a practical and scientifically compelling plan to expand Argo into a global full-depth physical and biogeochemical observational array.

AUTHOR CONTRIBUTIONS

Lead authors, designated by the symbol “+” and listed first in the list of authors, had primary responsibility for writing entire sections of the manuscript as follows: Abstract – SPU and DR;

¹⁰FAIR: Findable Accessible Interoperable Re-Usable.

Introduction – WBO and DR; Core Argo subsections – DR, BK, SWi, PO, and TS; BGC Argo subsections – KJ, HC, and EB; Deep Argo subsections – NZ; Argo Data Management subsections – MS and SPo; ArgoMix subsections – MA and JM; Conclusion – SPu and DR; DR compiled the manuscript and edited it for consistency. Co-authors (DB, MBa, MBe, HB, EB, PC, FCa, TC, FCh, DC, FD, GD, DD, KF, IF, RE, GF, HF, TF, MG, BG, RH, TH, SH, SJ, MJ, GCJ, KK, NK, AK, TM, TN, JN, AG, AO, RP, SP, SR, CSchmechtig, CSchmid, ES, AS, PS, LT, TTa, VT, ST, JTo, AT, TTr, JTu, PV, WW, HW, RW, AW, SWa, AWa, CW, AWo, JX, P-YT, Y-DL, GM, KM, and IY) wrote the passages, as coordinated and assembled by the lead authors, and edited the manuscript for completeness, clarity, and accuracy.

FUNDING

DR, MS, and NZ were supported by the US Argo Program through the NOAA Grant NA15OAR4320071 (CIMEC). WO, SJ, and SWi were supported by the US Argo Program through the NOAA Grant NA14OAR4320158 (CINAR). EuroArgo scientists were supported by the two grants: (1) AtlantOS funding by the European Union's Horizon 2020 Research and Innovation Programme under the Grant Agreement No. 633211 and (2) Monitoring the Oceans and Climate Change with Argo (MOCCA) Co-funded by the European Maritime and Fisheries Fund (EMFF) Project No. SI2.709624. This manuscript represents a contribution to the following research projects for HC, CaS, and FD: remOcean (funded by the European Research Council, grant 246777), NAOS (funded by the Agence Nationale de la Recherche in the frame of the French "Equipement d'avenir" program, grant ANR J11R107-F), AtlantOS (funded by the European Union's Horizon 2020 Research and Innovation Programme, grant 2014-633211), and the BGC-Argo project funded by the CNES. DB was funded by the EU RINGO project (730944 H2020-INFRADEV-2016-1). RF was supported by the AGS-1835576. GCJ was supported by the Global Ocean Monitoring and Observing Program, National Oceanic and

Atmospheric Administration (NOAA), U.S., and the Department of Commerce and NOAA Research. LT was funded under the SOCCOM Grant No. NSF PLR-1425989. VT's contribution was supported by the French National Research Agency (ANR) through the EQUIPEX NAOS (Novel Argo Observing System) under the reference ANR-10-EQPX-40 and by the European H2020 Research and Innovation Programme through the AtlantOS project under the reference 633211. WW was supported by the Argo Poland program through the Ministry of Sciences and Higher Education Grant No. DIR/WK/2016/12. AmW was funded by the NSF-OCE1434722. K-RK is funded by the National Institute of Meteorological Sciences' Research and Development Program "Development of Marine Meteorology Monitoring and Next-generation Ocean Forecasting System" under the grant KMA2018-00421. CSchmid is funded by NOAA/AOML and the US Argo Program through NOAA/OOMD. MBa is funded by NOAA/AOML.

ACKNOWLEDGMENTS

Argo data were collected and made freely available by the International Argo Project and the national programs that contribute to it (<http://www.argo.ucsd.edu>, <http://argo.jcommops.org>, <http://doi.org/10.17882/42182>). The authors gratefully acknowledge support from their respective Argo National Programs and/or national agencies. This is the PMEL Contribution Number 4863. The Surface Ocean CO₂ Atlas (SOCAT) is an international effort by numerous researchers and funding agencies to deliver a uniformly quality-controlled surface ocean CO₂ database. BGC Argo data were collected and made freely available by the Southern Ocean Carbon and Climate Observations and Modeling (SOCCOM) Project funded by the National Science Foundation, Division of Polar Programs (NSF PLR -1425989), supplemented by both the NOAA and NASA. The authors would also like to thank the US Ocean Carbon and Biogeochemistry (US-OCB) for their support to BGC Argo in the United States.

The need for improved access to ocean observations for Pacific Island countries (PICs) and territories has been increasingly recognized over the last decade, particularly in the face of a changing climate. Although more remote sensing and *in situ* data are available than ever before, however, oceanographic, and marine forecasting expertise in the region is limited. To support capacity building in these areas, the Climate and Oceans Support Program in the Pacific (COSPPac) has engaged with partners in the National Meteorological Services (NMS) and other relevant agencies in 14 Pacific Island nations, to identify priorities and to develop tools and training to address these needs. A key tool is the online Pacific Ocean Portal. With a focus on the Pacific Islands region, this website provides ocean data relevant to a range of sectors and applications such as tourism, fishing, shipping, coastal inundation, and environmental management. Via a user-friendly interface, the portal serves up data from a variety of sources including near real-time observations, historical information and forecast data. Training modules have been designed for portal users and delivery has gone hand-in-hand with in-country stakeholder engagement workshops, allowing sector users to make requests for ocean information products. Eight workshops have been delivered from November 2015 to June 2018, training a total of 97 NMS staff and 116 ocean sector stakeholders including port authorities, disaster management, tourism, fisheries, community leaders, and many more. As a result, five Pacific Island NMSs (Tonga, Tuvalu, Kiribati, Samoa, and Vanuatu) are now producing monthly Ocean Outlooks, guided by the needs of in-country stakeholders. Outlooks are tailored for each country and can include forecasts such as sea surface temperature, coral bleaching, and sea level, as well as information about current chlorophyll conditions, wind, and wave climate.

Keywords: Pacific Islands, capacity building, SIDS, portal, ocean outlook

INTRODUCTION

Pacific Island countries (PICs) are custodians of 20% of global Exclusive Economic Zones (EEZs), where ocean space exceeds land area by an average factor of 300 to 1. Pacific Island countries often referred to as small island developing states (SIDS), can be more accurately described as large ocean developing states due to the size of their EEZs, which are rich in biodiversity and natural resources (Appeltans et al., 2016). The majority of economic activities in these countries- from tourism to fishing- rely upon the ocean, justifying the Pacific Island Forum's focus on the development of a sustainable Blue Pacific Economy (Pacific Islands Forum Pacific Islands Forum Secretariat, 2017).

The need to support SIDS in implementing the United Nations Sustainable Development Goal 14 was highlighted in the call for action from the 2017 Oceans Conference in New York. Ocean information has also been identified as a requirement for successful implementation of the United Nations-led initiative Global Framework for Climate Services (GFCS) in SIDS that are particularly vulnerable to climate variability and climate change (WMO, 2014).

The diffuse geography of PICs presents many challenges in disseminating ocean information to isolated communities. Datasets covering entire EEZs can be very large and this is especially true for data that extend below the ocean surface. Transmission of large datasets puts significant strain on internet bandwidth in locations that already have limited or unreliable capacity (Iwamoto et al., 2017). Datasets are becoming more sophisticated with improvements in spatial and temporal resolution, exacerbating transmission issues. Depending on the technical ability of the user, analysis of raw data may be too difficult and time consuming for practical application. Although many ocean data sources include visual representations, these may not always be ideally suited for the given application or target audience. Most ocean datasets only include a global or ocean basin view, which is not practical for small island nations.

Pacific Island National Meteorological Services (NMSs) are primarily responsible for weather observations, climate services, and seasonal climate outlooks. Many NMSs have expressed their aspiration to better engage the marine sector within their respective countries. For this to occur, NMSs require access to relevant ocean data that is frequently updated, low bandwidth, tailored for priority applications within their EEZs, and accompanied by a training program. It is essential that guidance is provided to NMSs and relevant stakeholders on how to access and interpret ocean data, which can then inform relevant decision-making (Bax et al., 2018).

The Climate and Oceans Support Program in the Pacific (COSPPac) was an AU\$36 million program funded by the Department of Foreign Affairs & Trade (DFAT formerly AusAID) over 6 years (July 2012 to June 2018). It was recently extended for an additional 4 years and AU\$23 million until June 2022. The COSPPac program carries on the legacy from previous phases of support for NMSs in sea-level monitoring and climate prediction with the inclusion of capacity development and communication, information technology services, and ocean services (Commonwealth of Australia, 2012). The program

objective is to enhance the capacity across NMSs and key stakeholders in 14 Pacific Island nations in climate and ocean variability and its applications. The countries participating in this program include the Cook Islands, Federated States of Micronesia, Fiji, Kiribati, Marshall Islands, Nauru, Niue, Palau, Papua New Guinea, Samoa, Solomon Islands, Tonga, Tuvalu and Vanuatu (illustrated in **Supplementary Figure 1**).

This paper offers a case study perspective on the development and roll-out of the COSPPac Pacific Ocean Portal (<http://oceanportal.spc.int>), a web-based delivery system for ocean data in support of Pacific NMSs and in-country stakeholders. It also discusses lessons learnt, outcomes, and benefits to portal users, and explores future opportunities.

OCEAN INFORMATION REQUIREMENTS FOR THE PACIFIC

For the majority of Pacific Island countries, the ocean is the most significant natural asset available to support sustainable economic development. Pacific regional leaders have promoted numerous initiatives to secure the conservation and sustainable use of the ocean and its resources. These include, but are not limited to, the Western and Central Pacific Fisheries Convention of 2004, the Framework for Resilient Development in the Pacific (2017–2030), and the Framework for a Pacific Oceanscape of 2010. Building upon the “Blue Pacific” concept endorsed by Pacific Island Leaders in 2017, the 49th Pacific Islands Forum Meeting in 2018 highlighted oceans, fisheries, and climate change and disaster resilience among the priority issues confronting the region (Pacific Islands Forum Secretariat, 2018).

At the Pacific Meteorological Council in Nuku'alofa, Tonga in 2015, the region highlighted the critical need for improved ocean and marine services and established the Pacific Islands Marine and Ocean Services (PIMOS) Expert Panel, tasked to advise NMSs on how best to meet these needs. Subsequently, the mid-term review of the Pacific Islands Meteorological Strategy in 2017 resulted in the revision of Pacific Key Outcome (PKO) 2 to include: *Improved marine weather and establishment of ocean services* (Secretariat of the Pacific Regional Environment Programme, 2017).

Underscoring the regional effort are actions at national levels seeking a better understanding of ocean processes to support management and conservation. Despite growing political support in the Pacific, the ocean science capacity of Pacific governments is limited and oceanographic expertise is available almost exclusively at the regional level. Improved ocean science and analysis capacity is required, not only for informed and sustainable resource management, but also for robust early warning systems, sea-level rise monitoring, adaptation planning, climate-smart development, and growing the blue economy.

Feedback from representatives of 14 PICs captured at a consultation in April 2011 identified 65 references to ocean information products and services. There was significant focus on disaster mitigation, especially inundation events experienced from high tides, sea-level rise, high waves, and storm surge. Sea-level historical climatology, predictions, and long-term

projections were of interest. Fisheries were identified as an important aspect of Pacific livelihoods requiring decision-making tools. Sea surface temperature relating to coral bleaching and the impact on local fisheries was also a key concern. Consequently, delivery of a set of PIC ocean products and services was planned under COSPPac (Commonwealth of Australia, 2012) to fulfill the outcome “Pacific Island NMSs and other relevant in-country agencies understand and use climate, ocean, and sea level products for the benefit of island communities and governments.”

Based on requests and needs identified, it was determined that a Pacific Ocean services web portal would be useful for NMSs to deliver more comprehensive climate and ocean data services. Most of the data available in the portal can be accessed via other individual websites online, but the Pacific Ocean Portal seeks to make them available in a single location, organized by application, and visually consistent in their presentation, to facilitate interpretation.

A similar approach was successfully undertaken to synthesize climate change time series data into the *Pacific Climate Change Data Portal* under the Pacific Climate Change Science Program (McGree et al., 2014). In terms of a visual map-based portal, the most similar product for the Pacific is the *PacIOOS Voyager* tool (Iwamoto et al., 2017, Potemra et al., 2017). The *Voyager* website was developed for US-affiliated PICs and later extended to all PICs. It is comprehensive, including detailed historical, near-real time, and forecast data, resulting in a high bandwidth requirement. Feedback from Pacific users stated that it was difficult to ascertain the application of the different datasets when they were grouped by data sources or data type. User feedback and specialist reviews of these tools directly informed the development of the COSPPac Pacific Ocean Portal.

PACIFIC OCEAN PORTAL DESIGN AND DATA

The Pacific Ocean Portal is an interactive website for visualizing and accessing historical, real-time and predictive ocean data categorized by marine applications on an integrated and user-friendly platform. The intended primary users of the portal are scientists within NMSs and other government agencies, marine industry and conservation stakeholders, and the general public. It is a tool that aims to both obtain and communicate ocean information. A range of visual formats are employed to support different downstream applications (i.e., maps, time-series, statistical charts, profiles as illustrated in **Supplementary Figure 2**). Data sources include satellite observations, *in situ* observations, and numerical models (reanalysis and forecast).

From the outset, the portal aimed to provide regional-to-country level information (Commonwealth of Australia, 2012). The intention was to make the portal as intuitive as possible through use of a point-and-click interface to access data, graphs, and tables. Early on in the project, an IT capacity mapping of 14 PIC NMSs was undertaken. Following the discovery that PIC internet speeds were all in the order of kilobytes

per second, significant effort was made to ensure the portal minimized bandwidth use. The design needed support of all major browser platforms.

The architecture for the portal was informed by business requirements for the COSPPac project, user cases, and feedback from PIC and Australian climatologists. COSPPac prioritized the sustainability of products beyond the life of the project. With this in mind, only open-source components were selected so they could be used in the PICs without licensing fees. The tools and libraries selected are the most suitable for the purpose and also widely supported by developers and organizations around the world. Using familiar products ensures that it is easy to find experts capable of extending the tools and enables re-use of the components in future products. As will be discussed in section References, this design attribute has already proven valuable.

High-resolution datasets were chosen as the preferred option where possible to better resolve small islands, although there were limitations across many gridded datasets. The datasets and sources initially selected for integration into the portal are listed in **Table 1**, along with the potential applications of this data for PICs.

The portal's landing page, shown in **Figure 1**, is designed to direct specialist and non-specialist users alike toward the datasets or information that will be most relevant for their needs, based primarily on its application. All of the spatial datasets within the portal are accessible via an interactive mapping environment that permits exploration through zooming, scrolling, and data point extraction, allowing the user to create tailored imagery for communication purposes, and to screen capture data outputs for any location.

EDUCATION, TRAINING, AND AWARENESS BUILDING

As recommended, COSPPac sought to facilitate the uptake the Pacific Ocean Portal to PIC users (Commonwealth of Australia, 2012; Thompson et al., 2012). Sustainable capacity building is a frequent challenge in development initiatives, particularly those that introduce a new tool or technology. To address this challenge, an integrated approach was employed spanning portal design, tailored training, and training material development, collaboration with Pacific regional organizations and in-country partners, ongoing consultation, high-level endorsement, and ultimately, integration into existing regional products, services, courses and initiatives.

A series of “help” documents were created for each dataset that describes the dataset, background science behind the data, how to navigate the portal to obtain the information, suggested applications for the dataset in the Pacific, and technical details regarding the data sources, including references.

The portal was the key teaching tool introduced in a series of *Ocean & Tides Workshops* delivered across the Pacific between 2015 and 2018. Sub-regional and national workshops were conducted in the Solomon Islands (November 2015), Fiji (September 2016), Cook Islands (November 2016), Marshall

Islands (March 2017), Tuvalu (October 2017), Tonga (November 2017), Niue (March 2018), and Samoa (May 2018) with NMS and other ocean-related agencies and organizations in each country. A total of 97 NMS staff across 14 countries were trained, plus an additional 116 stakeholders. Of the 213 total Pacific Islanders trained, 41 of them were women (19%).

The workshops aimed to provide background ocean science behind the portal, teach workshop participants how to navigate the portal, provide examples of marine applications, and support NMSs in initiating dialogue with in-country users of ocean data. Workshops were hosted by and developed in consultation with the local NMS, according to their needs. Typically, the program would include a few days of technical training for NMS staff, followed by a stakeholder training and consultation allowing sector users to make requests for

ocean information products. Where practical, case studies, demonstrations, field trips, and presentations by local experts were incorporated to cater to different learning styles and reinforce the local relevance of science tools and training. At regional workshops, participants were encouraged to develop science posters using outputs from the portal and national workshops focused around the development of national ocean services and, where relevant, products using the portal as illustrated in **Figure 1**.

Nine training modules with explicit learning outcomes were designed to familiarize users with ocean science concepts, the portal, and other ocean data products. Each module includes a step-by-step guide, followed by a series of exercises to help self-directed learners explore. The modules were progressively tailored to ensure relevance to each country prior to the

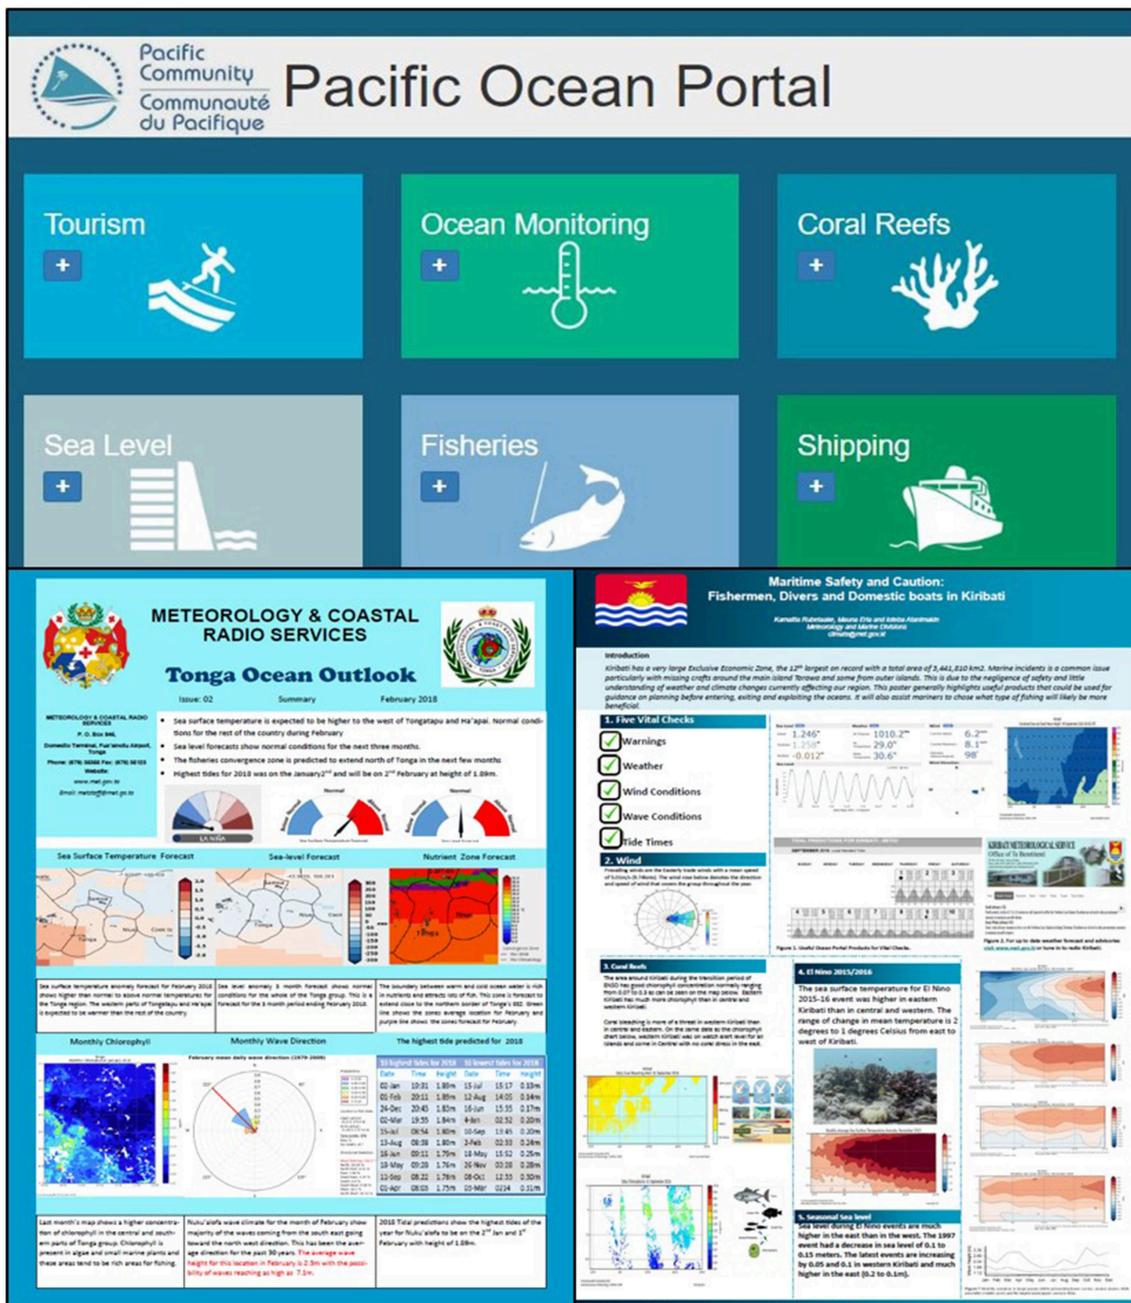

FIGURE 1 | (Top) landing page of the Pacific Ocean Portal <http://oceanportal.spc.int> **(Bottom left)** Monthly Ocean Outlook produced by Tonga Meteorological Service (Tonga Meteorological Service (TMS), 2018) and **(Bottom right)** an Ocean Science for Maritime Safety and Caution poster produced by Kiribati stakeholders at the Fiji Sub-regional Workshop in 2016 (Eria et al., 2016).

workshop, and later updated based upon participant and facilitator feedback.

The Pacific Ocean Portal was officially launched by the President of the Republic of Fiji, Jioji Konrote on World Oceans Day, 8th June 2018, in Suva, Fiji, as the opening event at the World Oceans Day Symposium. In the Pacific region, securing a visible and formal endorsement of such a tool is a unique opportunity to boost awareness and use among key stakeholders.

The 1-day event directly reached more than 200 participants, invited guests and visitors, and many more people through television, radio, and newspaper features and interviews. In addition, an introductory Know Your Ocean YouTube video demonstrating applications of the portal was produced for this event to reinforce the user-friendly nature of the portal, encourage sharing on social media, and promote ocean awareness and monitoring.

OUTCOMES, BENEFITS, AND FUTURE OPPORTUNITIES

Since the soft-launch of the first portal version in 2015 until the official launch in June 2018, there have been a number of successful outcomes and significant benefits of this new tool to the Pacific Islands region. Notably, the portal has been integrated into routine early warning products and services of Pacific NMSs, regional organizations, and regional training courses, including the University of the South Pacific (USP)'s post-graduate Physical Oceanography course.

The open-source design of the portal has proven a prudent strategy, as hosting and management was successfully handed-over from the Bureau of Meteorology (BoM) to the Pacific Community (SPC) based in Suva, Fiji in June 2018. This handover was intended to ensure the sustainability of the portal and to reinforce the regional ownership and relevance of the products. SPC is the Pacific Islands' regional technical organization, with an established Ocean & Maritime Programme providing the region's hub of oceanographic expertise, and has led delivery of in-country portal training since 2016. The portal is also poised to contribute to the proposed Pacific Community Center for Ocean Science (PCCOS), an integrated facility to improve accessibility of ocean knowledge and facilitate interdisciplinary partnerships (Pacific Community, 2018a). As the regional coordinator for the UN Decade of Ocean Science for Sustainable Development 2021–2030, SPC is thus well-placed to ensure the continued investment in portal development and support for training.

Even with its low bandwidth design, the portal was observed to have difficulty loading larger maps and graphs in countries with lower bandwidth internet access. Since the portal was first designed, however, internet access across the region has improved significantly. Further upgrades are planned and therefore an associated improvement in portal performance is anticipated into the future. As a bandwidth comparison, accessing the portal web page, and producing the most recent SST anomaly required 1.9MB, compared to *PacIOOS Voyager*, which required 3.3MB. Since the transition, SPC has continued to add value to the portal and is currently integrating a new data management interface, updating wave climate reports, and adding new resources to the site. Regular maintenance is required as data sources are constantly changing and being upgraded. As new applied research and Pacific data become available, SPC can expand the portal to include these features if there is a clearly identified application and benefit for the additional data.

Since 2015, the website has received over 14,000 users worldwide with 3,500 separate users accessing the portal across Melanesia, Polynesia, and Micronesia. SPC counted over 2,500 hits in September 2018, and 285 users, 62% of whom were returning users. The largest peaks in traffic occurred during cyclonic events in the Pacific, demonstrating that users have a strong interest in ocean information in the fields of risk management and disaster mitigation. There was a noticeable uptick in users in countries following COSPPac in-country workshops. Follow-up surveys conducted 6 months after workshops held in Niue and Samoa indicate that at least 25% of

workshop participants gained new skills, passed new skills onto another colleague, and have implemented changes to their work as a result of the training.

Following in-country workshops and NMS staff attachment trainings at BoM and SPC, six Pacific Island NMS (Tonga, Tuvalu, Kiribati, Samoa, Fiji, and Vanuatu) are now producing monthly ocean outlooks, as in **Figure 1**. Ocean outlooks are tailored to individual country user needs and include forecasts such as SST, convergence zone location, coral bleaching alerts, and sea level, as well as information about current chlorophyll conditions, wind and wave climate. In Tonga, Tuvalu, Fiji, Vanuatu and Samoa, the outlooks were co-designed by users to include priority sector-specific information. With close collaboration between PICs and support from SPC, these outlooks offer other NMSs an example of what can be achieved using the portal. In another example, in March 2019, the Fiji Met Service used the portal to respond to requests from local media on marine heatwaves in the region, providing SST anomaly and bleaching risk maps, a textual interpretation of the data, and background science that was sourced from the included “help files” within the portal.

Targeted in-country training and stakeholder engagement on ocean data applications under COSPPac has helped to cement NMSs as focal agencies for ocean forecasting services while also providing tools and skills to other ocean-data users such as fisheries, shipping and maritime, environment, and disaster management. Ocean stakeholders have also reported beneficial outcomes. Following the Niue workshop in March 2018, the owner of Niue Tours and Commodore of the Niue Yacht Club reported, “After the workshop, we immediately started using the tide chart for our tour operations. I am also collating all the relevant information from the ocean portal to be included in the Niue Yacht Club's website for the coming season” (Pacific Community, 2018b).

SPC conducted a COSPPac Ocean Information Products user-survey in September 2018. This is an inter-annual practice to assess the relevance of products, and to plan improvements and future products. Of 94 participants (out of 400 surveyed) from 15 different Pacific countries and territories, 65% indicated that it was a highly valuable tool for them or their work. Users reported that Ocean Monitoring (74.5%) and Sea Level (71.3%) were most useful datasets and functions of the portal. As knowledge brokers for climate and ocean science, NMSs were the most frequent users, integrating the portal into their daily operations, monitoring severe weather conditions, and producing monthly outlooks. In addition, other users reported using the portal as a reference for search and rescue operations, scheduling of recreational activities, fishing, and fieldwork, and even using outputs or information from helpfiles to create new information products or country reports. Survey results are reported in **Supplementary Table 1**.

Looking toward the future, SPC aims to continue to develop the portal in response to regional needs and requests. In coordination with the PMC, PIMOS Panel and WMO, SPC plans to develop an accredited online oceanographic competency module for NMSs that incorporates the portal and training materials. In addition, continued collaboration with regional

educational institutions is proposed to explore the development of online courses and other options to formalize portal training and increase accessibility.

While satellite technology is revolutionizing ocean observations, the resolution of many large ocean datasets is still insufficient to resolve the small island states in the Pacific. Downscaled, local models are essential for understanding the impacts of increasing SSTs in atoll lagoons, sea-level rise, and wave transformation on small island coastlines, for example.

It is hoped that an increase in PIC oceanographic capacity will contribute to increased investment in ocean observations infrastructure and increased engagement with the global ocean observing community. The Pacific may be the world's largest ocean, but it is also the most data-sparse and PICs are significantly under-represented in global discussions on ocean observations (Secretariat of the Pacific Regional Environment Programme, 2017). The region also needs to engage in international discussions on improved data sharing standards so that systems can be upgraded easily and information shared.

The UN Decade of Ocean Science presents a timely opportunity to catalyze action on ocean monitoring, and the Pacific Islands region is poised to be a key player, as the stakes are high for Large Ocean States. Protecting ocean resources, ensuring economic security, understanding vulnerability to climate change and variability all rely on robust ocean monitoring systems. However, the importance of human capacity to interpret and act upon information available from these systems is equally vital. Facilitating the transformation of data to information, information to knowledge, and knowledge to policy and action is a critical challenge for ocean observations. This requires not only scientific expertise and technological advances, but an integrated

approach informed by science communication, social science, user-centered design, and policy best-practice.

In conclusion, the Pacific Ocean Portal is an example of consultative design and, accompanied by outcome-driven training, it is already contributing significantly toward the development of ocean and marine services in the Pacific Islands. Embedded within SPC's Ocean and Maritime Programme and with the ongoing Australian Aid support through 2022, it is anticipated that the portal will continue to develop and play a key role in building the marine meteorological competency of Pacific NMSs to meet the needs of the Pacific marine community into the future.

AUTHOR CONTRIBUTIONS

MP: primary drafting, editing of the paper, circulated for feedback among other authors, Ocean Literacy & Capacity Building Leader at SPC- led delivery of workshops. GS: drafted first three sections, shaped the content, edited, provided some references, led development of BoM Ocean Portal, curriculum development and helpfile drafting. ZB: edited, proof-read, and provided details on ocean portal data sets in **Table 1**, currently overseeing and maintaining Ocean Portal. EM: edited and suggested future-forward content, supported development of the Portal.

The WMO-IOC Joint Technical Commission for Oceanography and Marine Meteorology (JCOMM) has devised a coordination mechanism for the fit-for-purpose delivery of an end-to-end system, from ocean observations to met-ocean operational services. This paper offers a complete overview of the activities carried out by JCOMM and the status of the achievements up to 2018. The JCOMM stakeholders consist of the research and operational institutions of WMO members and the IOC member states, which mandated JCOMM to devise an international strategy to move toward the achievement of the United Nations Sustainable Development Goals. The three areas of activity are the Observation Program Area (OPA), the Data Management Program Area (DMPA) and the Services and Forecasting Services Program Area (SFSPA), and several expert teams have been established to contribute to the international coordination efforts. OPA is organized into observing networks connected by different observing technologies, DMPA organizes the overall near-real time and delayed mode data assembly, and the delivery methodology and architecture, and the SFSPA coordinates the met-ocean services

resulting from the observations and data management. Future developments should enhance coordination in these three program areas by considering the inclusion of new and emergent observing technologies, the interoperability of met-ocean data assembly centers and the establishment of efficient research to operations protocols, in addition to better fit-for-purpose customized services in both the public and private sectors.

Keywords: marine meteorology and oceanography, global ocean observing networks, data management, ocean services, capacity development

INTRODUCTION

The World Meteorological Organization (WMO) and the Intergovernmental Oceanographic Commission of UNESCO (IOC) started the WMO-IOC Joint Technical Commission for Oceanography and Marine Meteorology (JCOMM) in 1999. JCOMM was mandated to enhance coordination between the meteorological and oceanographic communities to support the delivery of ocean forecasts and services, and the efficient design of global climate research programs, such as the Tropical Ocean Global Atmosphere (TOGA) program (McPhaden et al., 2010) and the Global Ocean Observing System (GOOS) (IOC Assembly Resolution XXVI-8, 2011; Task Team for the Integrated Framework for Sustained Ocean Observing, 2012).

The ocean economy is predicted to double by 2030 in terms of value-added products and employment (OECD, 2016) and population expansion and urbanization in coastal regions will increase people's vulnerability to climate change (McGranahan et al., 2007). To address this, JCOMM devised a coordination system that will help to standardize access to met-ocean data and services for the National Meteorological and Hydrological Services (NMHS) and for national oceanographic infrastructures. The system consists of the IOC International Oceanographic Data and Information Exchange (IODE), National Oceanographic Data Centers (NODCs) and the operational ocean forecasting services. JCOMM works at the interface between the WMO members, IOC member states and the research community (Figure 1), coordinating standardized research and operation transition, as required by environmental data services (Serafin et al., 2002; National Research Council, 2003; Shao et al., 2016). WMO members and IOC member states set the requirements of JCOMM activities, and the international community implements the solutions. JCOMM also facilitates the provision of observations to support other WMO and IOC applications, such as numerical weather prediction, climate monitoring, and other ocean services not solely governed via JCOMM.

In Internet terms, an end-to-end system is a network designed to connect nodes with maximum efficiency and quality. The application of such a principle to users and producers of meteorological and oceanographic information is a complex value chain structure, which is shown in Figure 2. JCOMM considers all the building blocks of the value-added chain, from the collection and distribution of observations in near-real time and delayed mode, the production of generic data products by modeling and data assembly centers, to the further customization

of such products so they can be utilized by the final end-users to provide societal benefit. It should be noted that the value-adding chain shown in Figure 2 is not totally governed by JCOMM. The non-ocean and climate related components are governed by other international coordination entities that JCOMM must interface with.

The marine meteorology and ocean services generated by the meteorological and oceanographic (operational) centers and by research institutions provide information for a large number of users including governments, emergency responders, industry, navies and the public. JCOMM supports the National Meteorological and Hydrological Services (NHMS), the National Oceanographic Data Centers (NODC) and operational oceanographic services and strives to reach the UN's sustainable development goals (SDGs, Kates et al., 2005). The JCOMM beneficiaries are a complex network of research institutions, meteorological and oceanographic centers, navies, and industry that need international standards for exchanging observations and producing forecasts, to meet the challenges of climate change, coastal resilience, safe maritime transport and a productive and healthy ocean.

In this study we first provide an overview of the approach taken by the JCOMM in its coordination efforts (section The JCOMM Approach). We then examine the four pillars of JCOMM activities: the standardized collection of ocean

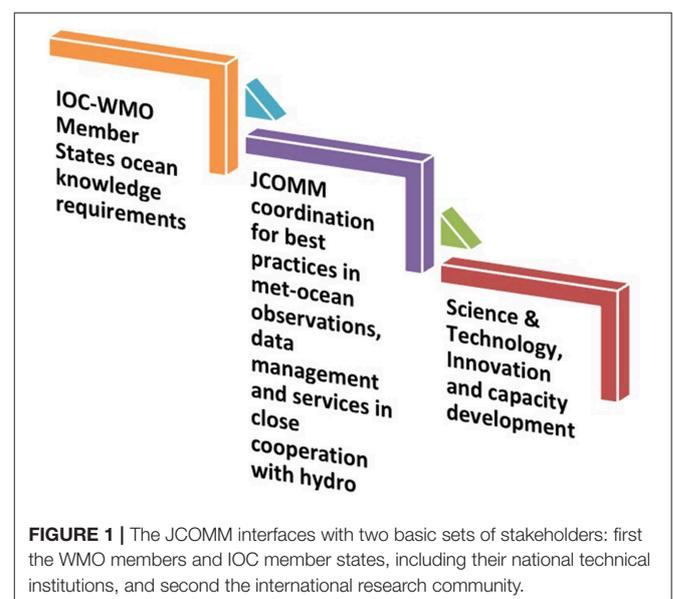

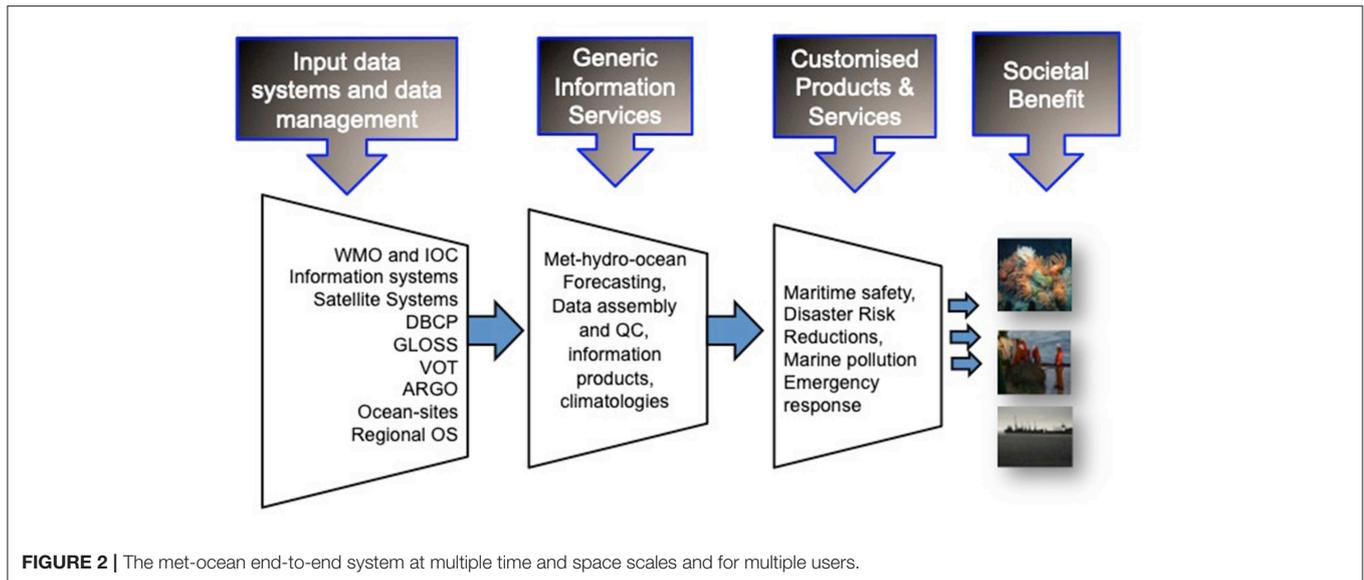

FIGURE 1 | The JCOMM interfaces with two basic sets of stakeholders: first the WMO members and IOC member states, including their national technical institutions, and second the international research community.

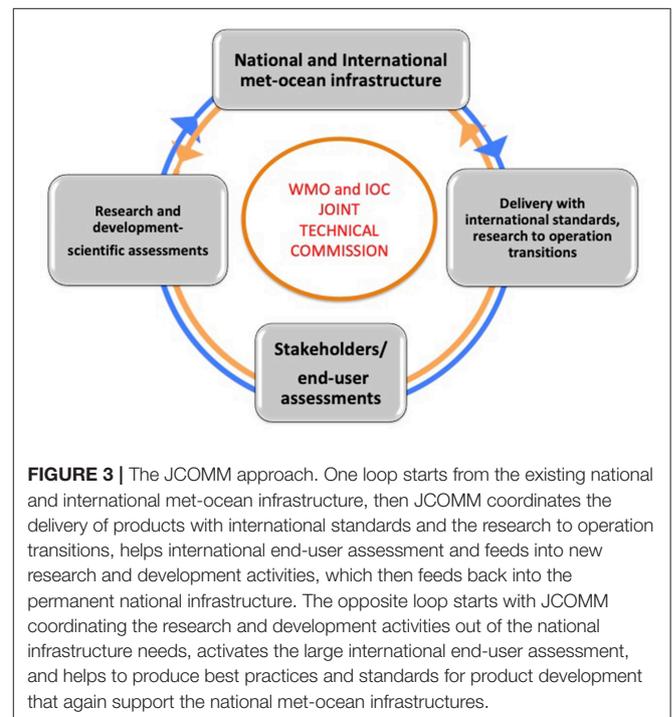

observations (section Operational Observing Networks and Systems), the networking of data management and data assembly centers (section Data Management Systems, From Near-Real Time to Delayed Mode), the ocean services (section From Monitoring to Services) and capacity building (section Capacity Development). A discussion and conclusions are provided in sections Discussion and Future Foci.

THE JCOMM APPROACH

In most nations of the world, NMHS, NODCs and oceanographic institutions are responsible for the delivery of meteorological and ocean marine products and services. They must consider the whole data information chain, from observations, to data assembly and predictions, to customized products for specific users (Figure 2). This delivery is the aim of the JCOMM international coordination activity, and to achieve it with the maximum interoperability, standardization, and sustainability.

The approach followed by JCOMM in building the international coordination for the met-ocean end-to-end system is summarized in Figure 3. The four building blocks are:

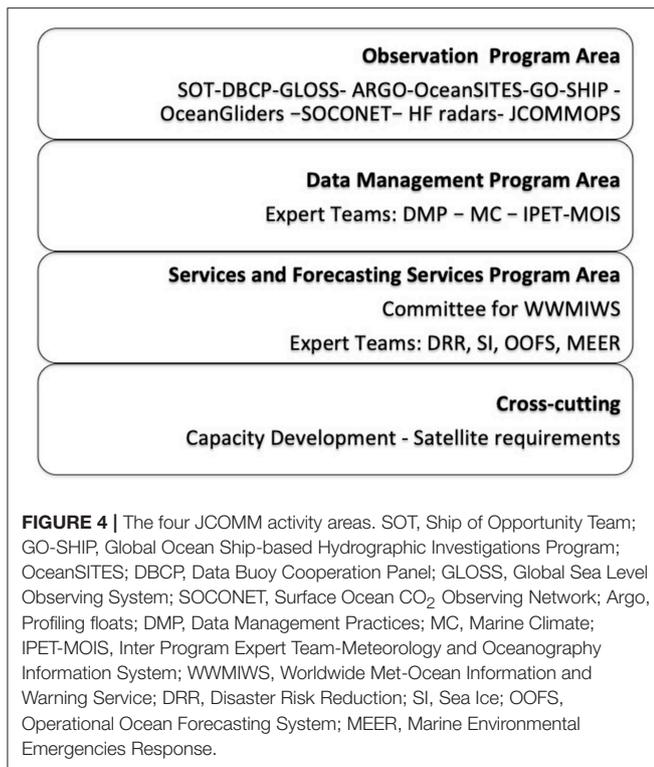

- (1) The Member States met-ocean research and operational infrastructure, which is the basis of the WMO and IOC coordination responsibilities;
- (2) The delivery of met-ocean products and services related to the WMO and IOC strategic goals, which require standardization and the transition from research to operations;
- (3) Stakeholder and end-user assessments organized by JCOMM along with specific user consultation activities to evaluate the fitness for purpose of the service delivery;
- (4) The scientific assessment of the status of the networks, which in principle should establish the fitness for use of the observations in the data product and service delivery,

thus prompting new research and innovation activities to fill the gaps.

Since its inception 20 years ago, JCOMM has developed a coordinating structure for the delivery of met-ocean products and services. Over the past 5 years a scientific and stakeholder assessment of the existing coordinating structure has been conducted and will continue in the future.

To achieve its goals, JCOMM has been organized into four focal activity areas of technical expertise, as described in the next section.

The JCOMM Activity Areas

In JCOMM, the end-to-end system (Figure 2) is sub-divided into three program areas and a cross-cutting activity, as shown in Figure 4. These are:

- (1) The Observations Program Area (OPA), in which the Observations Coordination Group (OCG) is charged with reviewing, advising on, and coordinating the effective operation of the ocean and marine observing systems and related activities. This group also has the mandate to assess new and emerging technologies and enable their transition into operational networks.
- (2) The Data Management Program Area (DMPA), in which the Data Management Coordination Group (DMCG) has the primary objective of reviewing, implementing and maintaining a fully integrated end-to-end data management system across the entire marine meteorology and oceanographic community. Recent work in this area includes metadata management and the implementation of the Marine Climate Data System (MCDS), which can be considered an interface between the WMO Information System (WIS, <http://www.wmo.int/pages/prog/www/WIS/>) and the future IOC Ocean Data and Information System (ODIS, <https://www.iode.org/odis>).
- (3) The Services and Forecasting System Program Area (SFSPA), in which the Services Coordination Group (SCG) has the mandate to overview and coordinate state-of-the-art globally distributed and inter-connected marine services, including

sea ice and emergency responses, natural- and human-induced coastal hazards, and maritime safety.

- (4) The cross-cutting area consists of two activities: Capacity Development (CD), whereby JCOMM has progressively implemented a training framework that considers the complete marine weather and oceanographic end-to-end system; and Satellite requirement activities, which focus on setting the requirements of WMO and IOC for the timely collection of remotely sensed met-ocean environmental data.

JCOMM activities have recently been evaluated, and selected conclusions are outlined in the next subsection.

User-Based Surveys

In April-May 2016 the IOC organized the first stakeholder survey on JCOMM performance. The survey was sent to the NMHS, NODCs and oceanographic institutions listed in the IOC and WMO JCOMM contacts and 90 responses were returned. The survey addressed the following areas: experience/familiarity with JCOMM (five major objectives/activities); impact/influence of JCOMM on Met-Ocean Institutions; importance/priority of JCOMM activities; management/coordination and capacity building of JCOMM; benefits of JCOMM; needs and new activities/approaches of JCOMM.

The results showed that 85% of respondents were involved in JCOMM activities for at least the past 5 years, but 40% were not aware of the breadth of topics in the program and the range of objectives. JCOMM was perceived to have a positive impact on NHMS and Oceanographic Institution activities by 35% of respondents. Almost half of the answers confirmed that JCOMM was effective in coordinating the development of an integrated met-ocean system. However, the scores were low in terms of the training offered JCOMM for sharing met-ocean products and services, and it was suggested that JCOMM's role in the global development of tools/training for the local use of met-ocean products and services should be enhanced.

Recommended developments in JCOMM activities included the need for effective stakeholder consultation and less top-down governance, with enhanced inclusive and broader participation by countries and organizations. It was recommended that it should continue with its current activities, while improving its communication strategy and developing new partnerships with the private sector, and other programs.

The second survey was carried out by WMO to assess the perceptions of mariners on whether the Maritime Safety Information (MSI) services provided in the Global Maritime Distress and Safety (GMDSS) network met the user requirements. Overall, the survey demonstrated the importance of delivering wind, wave, sea ice, and visibility information to ships, but it also highlighted inadequate packaging of information, gaps in areas covered by observations, and the need for more wave information, such as swell, in addition to significant wave height and direction.

The outcomes of these initial surveys indicated that JCOMM was recognized as useful by the WMO and IOC stakeholders, but that much more work was needed to further raise awareness and update existing products and services.

Working Practices

The primary governance structure of JCOMM is the management committee (MAN), which makes the strategic decisions regarding the programs and expert teams, evaluates the progress of the activities, and interacts with external groups. The JCOMM MAN consists of the two co-presidents, the IOC and WMO secretariats, the coordinators of the activity areas, and representatives from IODE, GOOS, and the GOOS Regional Alliances. External experts are invited as required, depending on the topic under discussion.

The expert teams (Figure 4) are the technical implementing bodies of the JCOMM strategy, and they can also directly feed back to the JCOMM management on problems and developments. This pyramidal structure, and thus the absence of a common “project-oriented” implementation strategy, was identified as a weakness of the system. In addition, the technical nature of the groups at all levels, from the JCOMM MAN to the expert teams, added to the complexity of making priorities and strategies for these joint activities, beyond their first decades. As discussed in the conclusions, a new structure is now envisaged for the future of JCOMM.

A more detailed analysis of the strengths and weaknesses of the JCOMM effort in general is presented in the discussion section, after we describe the work of the three program areas.

OPERATIONAL OBSERVING NETWORKS AND SYSTEMS

Observations Program Area

The JCOMM Observations Program Area (OPA) is appointed with reviewing and coordinating the effective operation of ocean and marine observing systems and related activities. Its focus is on developing synergies across the *in situ* observing networks, leading to a sustained global ocean observing system that meets research requirements and those of weather, ocean, and climate services, and maximizes opportunities for engaging with new technology and observing networks as they mature.

The Observations Coordination Group (OCG) leads the OPA. It is comprised of representatives of the major global networks involved in observational oceanography and marine meteorology. The OPA has defined the following attributes of a JCOMM ocean observing network, which are consistent with the Framework for Ocean Observing (Task Team for the Integrated Framework for Sustained Ocean Observing, 2012):

- **Global in scale:** Broader than regional, and if feasible, the intention to be global.
- **Sustained observation:** Sustained over multiple years, beyond the time-span of single research or experimental projects, by undertaking routine, systematic and essential observations.
- **Community of practice:** Has an identified community governance structure that provides a means of developing a multi-year strategy, implementation plans and targets, and standards and best practices.
- **Delivers data that are free, open, and available in a timely manner:** Has a defined data management infrastructure that delivers interoperable and inter-comparable data in real-time

and/or with minimal delay after becoming available, through an internationally recognized data center/s and/or standard services, including the WMO Global Telecommunications System (GTS, real-time data), the MCDS (delayed-mode data) and web based services (real-time and delayed-mode data), and operates with a view of encompassing findable, accessible, interoperable and reusable (FAIR) principles (Wilkinson et al., 2016), with at least a minimum (as defined by JCOMMOPS) level of metadata.

- **Observes one or more essential ocean variables or essential climate variables:** Contributes to meeting requirements through observing one or more of the Global Ocean Observing System (GOOS) Essential Ocean Variables (EOVs) or Global Climate Observing System (GCOS) Essential Climate Variables (ECVs).
- **Maintains network mission and targets:** A role in the GOOS is defined and progress toward targets can be tracked and progress assessed.
- **Develops, updates and follows standards and best practices:** To ensure consistent delivery of observational data and encompassing measurement technique, deployment and sampling, reference materials and standards, calibration and validation, data retrieval and formatting, primary quality control and secondary quality control, as appropriate. Ideally these are documented, consistent with other OPA networks, and their use is encouraged.

The OCG works with the following global networks that have met these attributes (Figure 4): ship-based observations (managed by the Ship Observations Team-SOT), moored and drifting buoy observations (managed by the Data Buoy Cooperation Panel-DBCOP), tide gauge observations (the Global Sea Level Observing System-GLOSS), Argo float observations (managed by the Argo Steering Team-Argo) and ocean reference stations (OceanSITES). Additional “emerging” networks are developing these attributes and are actively engaging in OPA activities and meetings: OceanGliders, HF Radar, SOCONET (Surface Ocean CO₂ Observing Network), and Animal Marine Monitoring.

The OCG ensures all coordinated networks deliver data of known quality through appropriate data systems. Stakeholders include the research community, a range of weather, ocean, and marine service providers (many of whom are represented in JCOMM’s parent organizations, the WMO and the IOC), and others who rely on ocean information.

Ocean Observing System Requirements

To communicate and advocate for the development of the ocean observing system, requirements are developed through a number of forums to ensure that the full range of stakeholders and implementers of ocean observations are engaged.

The JCOMM OPA works primarily with the GCOS-GOOS-WCRP Ocean Observation Physics and Climate panel (OOPC) on setting the requirements for observations for climate applications. The OPA does not itself set requirements but contributes toward a requirement-setting iterative process, which considers the costs and feasibility of observations vs. their value or impact. To enable the consistent communication

of requirements for observations, Essential Ocean Variable (EOV) specification sheets have been developed by the GOOS panels (OOPC, Biogeochemistry, and Biology and Ecosystem) to specify the requirements for the observation of a variable, its applications, the processes/phenomena that need to be captured, and how the observations of variables come together to meet these requirements. This was initiated by the OOPC for climate and operational services requirements and will enable the eventual evaluation of the observing system by each variable.

The OPA also engages with the WMO Rolling Review of Requirements (RRR) process, which compiles the requirements for the various WMO application areas by variable in terms of five criteria: horizontal resolution, vertical resolution, observing cycle, timeliness, and uncertainty. The WMO Observing Systems Capabilities Analysis and Review tool (OSCAR/Requirements) provides a record of observational user requirements formulated by WMO and various co-sponsored programs, such as GCOS, GOOS, and WCRP. The requirements are regularly reviewed by groups of experts nominated by these programs, although a systematic approach is still lacking.

Coordination, Development, and Integration of Observing Systems

The OPA assesses ocean observing enterprises and approaches and engages emerging and transitional observational networks that meet the aforementioned attributes of a JCOMM network as they mature and become ready for sustained operations. Developing guidance and monitoring the transitions of such capabilities into the sustained observing system will also become an important set of processes and products. The OPA also supports assessments/studies that consider the mix of platforms/technologies to best meet JCOMM requirements (e.g., SOCONET, Sabine et al., 2010). Changes in sensors and platforms, improved satellite capabilities and coverage, and shifts in the use of platforms (particularly from research ships, due to the high cost with respect to autonomous vehicles) are evolving due to technological advances and economies. This will require the OPA to coordinate strategic changes to the observing systems and manage transitions over time.

The OPA will also work to address new frontiers (e.g., Arctic, the deep ocean) that are presently poorly observed and bring about system improvements through regionally focused observing pilots (e.g., TPOS-2020; Cravatte et al., 2016). The OPA will also work with other JCOMM program areas to address the increased demand for information products and new services, such as for climate trends (Figure 5). It will work with service providers to encourage observing/service pilot activities to address ongoing and new needs.

Observing System Reporting, Metrics, and JCOMMOPS

The OPA is working with OOPC, GOOS, and the JCOMM networks to develop network specification sheets to document the role of components of the observing system, highlight interdependencies, missions, and to set targets for implementation. JCOMM networks are developing Key

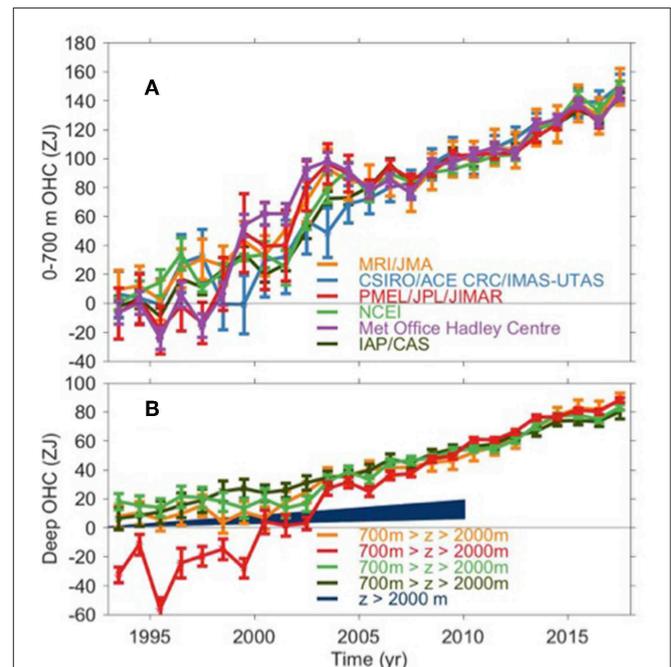

FIGURE 5 | (A) Annual average global integrals of *in situ* estimates of upper (0–700 m) Ocean Heat Content Anomaly (OHCA) (ZJ; 1 ZJ = 1,021 J) for 1993–2017 with standard errors of the mean from six different analyses. See Johnson et al. (2014) for details on uncertainties, methods, and datasets. For comparison, all estimates have been individually offset (vertically on the plot), first to their individual 2005–17 means (the best sampled time period), and then to their collective 1993 mean. **(B)** Annual average global integrals of *in situ* estimates of intermediate (700–2,000 m) OHCA for 1993–2017 with standard errors of the mean, and a long-term trend with one standard error uncertainty shown from 1992 to 2010 for deep and abyssal ($z > 2,000$ m) OHCA following Purkey and Johnson (2010) but updated using all repeat hydrographic section data available from <https://cchdo.ucsd.edu/> as of Jan 2018 (Johnson, 2018).

Performance Indicators (KPIs), in line with their mission targets to more easily track progress, such as identifying challenges/risks and reporting the state of the global ocean observing system to a broader set of stakeholders. System metrics beyond KPIs have demonstrated value in managing the observing system (e.g., coordinating deployment opportunities, identifying geographical observing gaps, and data flow). Additional metrics, to be aligned for future use by stakeholders (e.g., researchers, forecasters, and others), are also under consideration and development.

The JCOMM *in situ* Observations Program Support Center (JCOMMOPS—www.jcommops.org) was established in 2001 and it provides a focal point of technical coordination across the ocean observing networks, encourages timely reporting and the conveyance of data and metadata, and develops appropriate tools for monitoring the status and reporting of the observing system. JCOMMOPS functions are critical for the integrative development, operations, tracking, and monitoring of the global system.

In the recent years, JCOMMOPS has developed a new generation of Information System with an integrated metadata management and web applications. It has developed KPI to

track network status and anticipated gaps. It gained enhanced responsibilities with JCOMM fifth session (e.g., allocation of unique identifiers for all met ocean platforms, production of WIGOS compliant metadata through WMO). In 2018 JCOMMOPS was reviewed through an independent team to identify strengths and challenges of the structure, and prepare its future through the development of a strategy plan.

A major JCOMMOPS deliverable, the JCOMM Ocean Observing System Report Card, takes full advantage of the development of new metrics. The first issue, distributed in 2017, was to inform major stakeholders and sponsors about the observing system. The 2018 version included more information on the status and projections of satellite systems, and an initial assessment of the health of the *in situ* observing networks. Future versions will provide an annual snapshot of system health, highlight developments and areas of concern, and could be expanded to include reports on regional networks and pilot projects (Figure 6).

Observing System Standards and Best Practices

Ocean Observation best practices are procedures and/or processes that have been shown by experience to produce reliable, efficient, accurate, and replicable results, and that are established or proposed as a reference technique or process suitable for widespread adoption. The OPA goal is to provide a standards and best practices framework to ensure the standardization of data collection protocols and the traceability of ocean data, so that the quality of the observing systems and resulting data are maintained at the highest possible levels.

Many JCOMM platforms are based on community practices, and have evolved to develop best practices. Although they may be widely accepted, they have not all undergone a documented review process. Data collection activities are often oriented around a range of instruments, hence measurements of the same variable are often made from different instruments with varying characteristics. Those, such as climatologists who use this data for products that involve all measurements find that many different programs must be consulted. One focus of the OPA Standards and Best Practices is to work toward consistency across the best practices around EOVs.

The OPA vision and strategy for observing system standards and best practices includes the following goals and activities:

- Identify, coordinate, and promote the development and use of standards and best practices across all areas of ocean observing and marine meteorological platforms of JCOMM, and all partner networks and activities;
- Develop a strategy to update these important resources;
- Create a publication or endorsement method through WMO regulatory and guidance materials (such as manuals and guides of GOS, CIMO, and WIGOS), IOC guides, and/or JCOMM technical reports, and peer-reviewed journal publications to communicate those best practices not currently disseminated;
- Support the development of best practices for new observing technologies, drawing from experienced networks;

- Make recommendations to JCOMM OPA for future actions to address these needs; and
- Work toward consistency across best practices for EOVs.

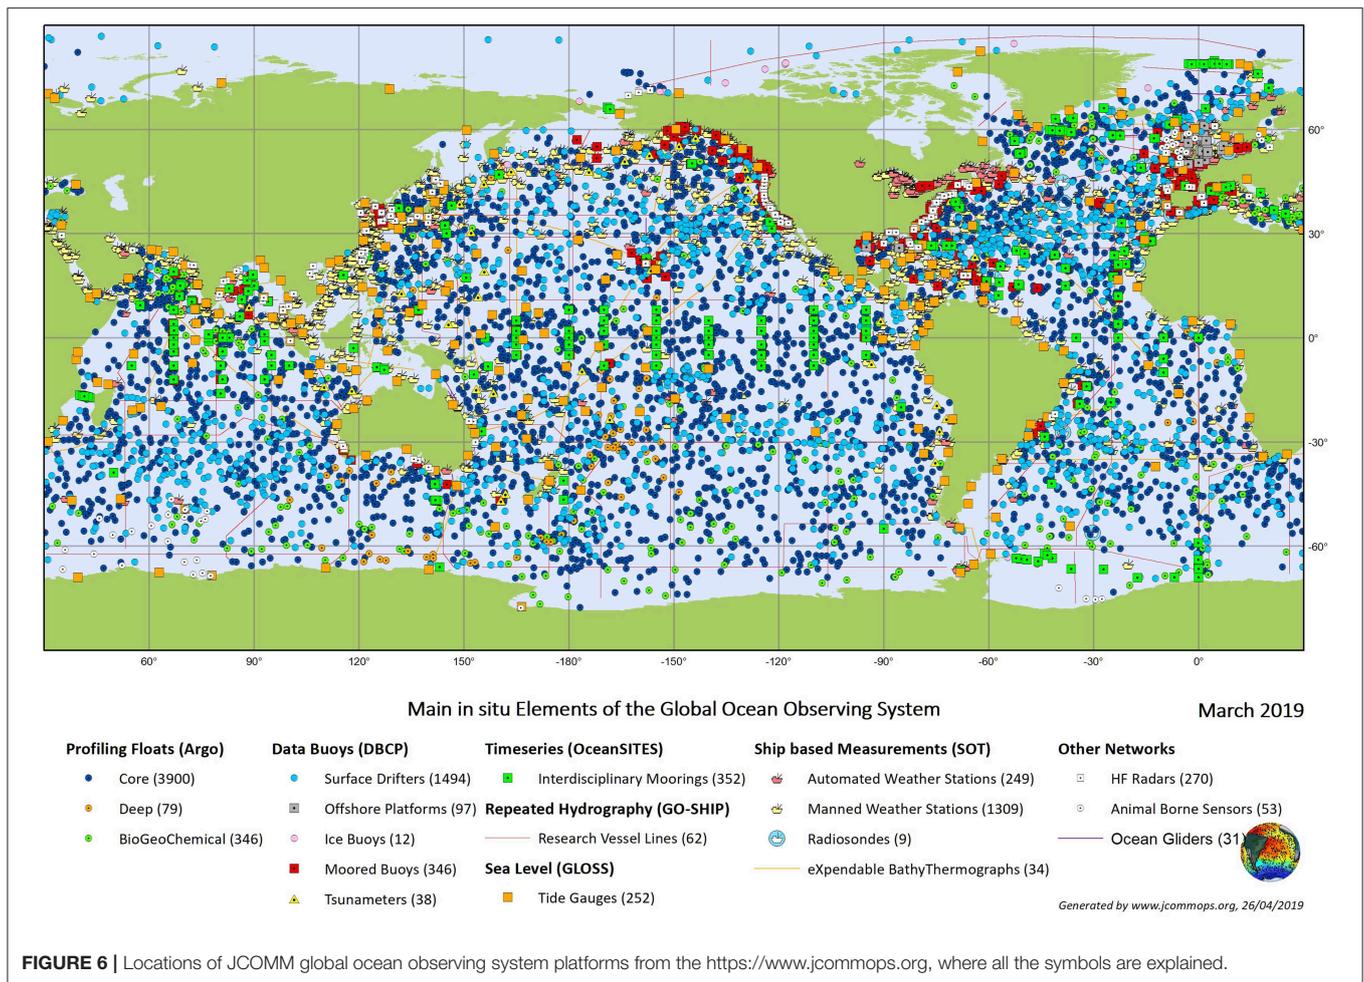

The OPA standards and best practices vision is already being addressed, with two initial foci: (1) a JCOMM network focus; and (2) the integration of JCOMM standards and best practices within a larger set of systems (e.g., IODE Ocean Best Practices, Pearlman et al., 2019) and improved organization of, and access to, this information (Hermes et al., 2018).

Near-Real Time Ocean Data Acquisition and Distribution

Importance of Real-Time Observations

Much of the ocean information collected as part of the ocean observing system has a very high value in near real-time. These data, and their near real-time dissemination, are critical for ocean and weather prediction, disaster response and climate monitoring, detection, and mitigation, i.e., for the end-to-end met-ocean system. In resource-limited environments, such as ocean research, it is essential to continually evaluate and implement workflows, which improve the efficiency and effectiveness of overall investments. One way to increase the impact of observations is to ensure that when possible, data have been at least minimally quality controlled and also are distributed in a timely fashion as possible.

Unfortunately, for many years ocean and marine meteorological data has faced barriers to near-real time distribution beyond the WMO system. The GTS (http://www.wmo.int/pages/prog/www/TEM/GTS/index_en.html) has been the distribution mechanism of choice for global time-critical weather information, which also allows for near real-time distribution. WMO (2017c) defines the GTS as: “The coordinated global system of telecommunication facilities and arrangements for the rapid collection, exchange and distribution of observations and processed information within the framework of the World Weather Watch.” The GTS has been an effective method of distributing both land-based and marine weather observations to all NMHS. However, the research community has faced difficulties in trying to mirror the weather world by utilizing the GTS for real-time data distribution. Limited connectivity to GTS endpoints, the use of standard WMO data formats (such as the Binary Uniform Form (BUFR) for the representation of meteorological data), and research-project technical maturity levels have limited the amount of global ocean data that is available in near-real time. Furthermore, for many years it has not been in the culture of research to make oceanographic data widely available in near real-time. Networks, such as Argo and drifting and moored buoys under DBCP have overcome this barrier because they incorporate real-time data transmission systems in their observing platforms. However, there remains a wealth of ocean data that is not being distributed in real-time, as only a small number of national met services have established links with their national oceanographic institutes to facilitate the delivery of their data to the GTS. For example, there are many tide gauges that are not reporting their data to the GTS.

In an attempt to bridge this gap, the JCOMM OCG undertook a pilot project designed to make it easier for research institutions to distribute and access data using the GTS. The ocean data community has begun to embrace widely used standards and conventions, such as the climate and forecast (CF) metadata conventions (<http://cfconventions.org/>), NetCDF binary file format (<https://www.unidata.ucar.edu/software/netcdf/>), and distributed data service protocols, such as the Data Access Protocol (DAP) (<https://cdn.earthdata.nasa.gov/conduit/upload/512/ESE-RFC-004v1.1.pdf>). By leveraging these services and conventions, it should be possible to create a simplified workflow that would provide data producers with an easier path for distributing their data to the real-time community.

The pilot project, aptly named “Open Access to GTS” (Figure 7), identified and utilized a dozen platforms whose data would not otherwise have been placed onto the GTS. These included well-known platforms, such as ocean moorings and sailing vessels, and new platforms, such as Sailandrone (<https://www.sailandrone.com/>). In all cases we were able to leverage a simple workflow incorporating the widely used science data formats of ASCII and NetCDF, and the ERDDAP data platform (Simons, 2017). The use of ERDDAP allowed a National Data

center in the US, the National Data Buoy Center (NDBC), to harvest the data collected from the various platforms. Once harvested through machine-to-machine services, the data was encoded by NDBC into BUFR, using the appropriate template, and distributed globally via the GTS. Among the many benefits of this workflow was the important advantage that the scientists and data providers were not required to understand the BUFR format, and only needed to make their data available through the ERDDAP distributed data service.

By leveraging such modern data services and conventions, it was also possible to provide access to this data beyond the distribution arc of the GTS. Although data submission to the GTS by the wider oceanographic community is strictly regulated, accessing GTS data for them is challenging. In the JCOMM OCG pilot the same data platform, ERDDAP, was used to provide access to the wider observations that are distributed on the GTS. This allows any user, regardless of their technical background, to access near-real time data from any of the 4,000+ platforms currently reporting in the global oceans. This data is available for all without the burden of decoding BUFR, and users are able to use the data through any software client they are familiar with. There is no need to download, reformat, or chase down BUFR

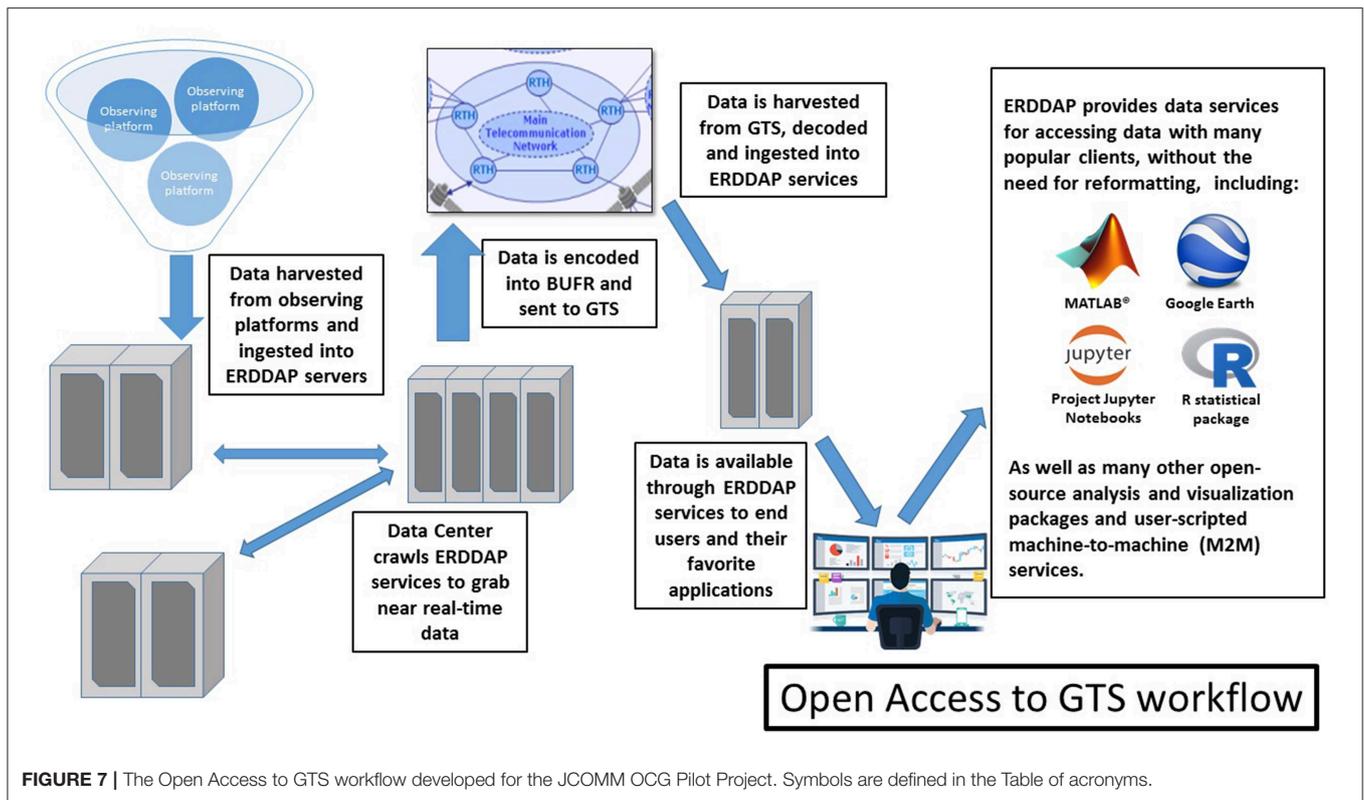

FIGURE 7 | The Open Access to GTS workflow developed for the JCOMM OCG Pilot Project. Symbols are defined in the Table of acronyms.

code tables. In addition, as the data is available through ERDDAP web services, it is much easier for traditional data systems to retrieve the data and ingest it into their products.

As the GTS distribution mechanism was established to support operational forecasting there are of course strict guidelines regarding what can be sent via the GTS and how. Although the JCOMM OCG pilot project was a demonstrable success, it is imperative to define a strategy for the wider implementation of this project. The JCOMM OCG has undertaken the task of developing an Open Access GTS strategy to ensure issues, such as data duplication and the national sensitivity of data are addressed. However, reducing the burden of requirements for GTS data distribution can clearly be accomplished using current technology and standards to provide an easier path for near real-time data distribution. The challenge is not a technical one but cultural, which must be addressed in the future to improve data availability.

This need to embrace modern data formats and distributed services is also reflected in the evolution of the WIS, as it develops to meet the current and future demands of data interoperability.

Evolution of the WMO Information System

As noted above, the WMO GTS has been successful in meeting its primary objective of the cost-effective dissemination of meteorological information in near-real time (<https://wiswiki.wmo.int/tiki-index.php?page=ManualGTS>). As the GTS was conceived, developed and implemented in a period where teletype communication was the norm some of the protocols,

standards, and capabilities of the system evolved to meet the needs of the modern era. However, the full advantages of modern IT technologies have not always been allowed for in this evolution. While the GTS is well-managed, reliable and effective, it is also limited in capability and complexity and has restricted access.

To address the shortcomings of the GTS and to expand the data services offered by the WMO, the WIS offers three services areas (<http://www.wmo.int/pages/prog/www/WIS/overview.html>):

1. A routine collection and dissemination service for time-critical and operation-critical data and products.
2. A data discovery, access, and retrieval service.
3. A timely delivery service for data and products.

While the first service area will incorporate the GTS, the third expands the GTS offering through the utilization of public networks, such as the Internet. It is this service area that has the potential to provide greater access to WMO data services.

The WIS does present a unique opportunity to increase the dissemination of marine observations and modeling data toward operational forecast use. The key to meeting this goal is to ensure the certification of oceanographic data centers as data providers to the WIS. The WIS should also adapt data transmission message standards to accommodate new platforms used in the oceanographic community.

The WIS has the potential to provide greater access to near real-time data without the procedural overhead now imposed by

the GTS. The second service area listed above should address this need, and the WIS and its task teams must ensure the provision of adequate mechanisms for accessing these modern data services. The development of WIS 2.0 (the upgrade of WIS by 2030) will contribute to new and modern data access and dissemination services beyond GTS using cloud technologies.

Improved Workflows for End-to-End Systems

The early steps of a workflow (telecommunication, quality assurance, and communication) are usually the responsibility of the owner of the platform/instrument. JCOMM and other relevant bodies and initiatives, such as the OBP project, strive to standardize these steps and to facilitate efficient pathways from instrument/platform to databases. The workflow for ocean data is at its most intense during this period: many applications are run in real-time and demand rapid processing steps from the point of measurement to the point of use (assimilation, analysis, and monitoring).

The workflow must accommodate high-volume data streams, but often with repeated and similar characteristics (e.g., satellites), and at relatively low volume with more individual characteristics (e.g., surface data buoys). The users require a workflow that is efficient and timely, irrespective of the source, and standardized for ease of use.

Multiple concurrent usage, often in high-impact systems (e.g., weather prediction, safety, risk management, hazards), means the data value is at its peak. In contrast, the arrival of some data is delayed and is only used off-line, while yet other data may be subject to constraints (e.g., proprietary use) and may never move beyond a single user into the general data system. This is wasteful and inefficient.

The workflow for ocean data is open-ended. Reprocessing for reanalysis is now commonplace, to take advantage of knowledge that was not available in real-time, and/or to exploit improved techniques. Such reprocessing may occur multiple times. The added value of reprocessing can be compromised if the associated data processes do not provide clear details about how the data were re-processed, or how it is improved (or different) from earlier versions, and if they are not accompanied by adequate metadata/information to allow users to distinguish between differing versions.

A data system that contains different levels of data, from engineering units through to quality-controlled observations, presents significant challenges both to the workflow and to users: which is best for their application? How easy is it to decide and access the data? Does the user need to consider different formats and standards? The architecture of the system, its workflow, and its efficiency are all important factors.

Complexity does impact efficiency and, perhaps just as importantly, uptake on the provider side and utility on the user side. In reality there are multiple manifestations of such workflows, all aimed at similar outcomes but with slightly different assumptions and implementations, and often with different spatial-temporal windows and variables. As with ocean and climate models, such diversity can be a good thing, but it also comes with risks in terms of the efficiency and integrity of the database as a whole.

In summary, the explosion in observing technology over the last decade has exposed weaknesses in current global data management practices. The ever-increasing number of sensors and the volume of data they are producing demonstrates a need for improved data acquisition and distribution systems to meet the current and future needs of users, which equally applies to near-real time, delayed mode, and reprocessed data. However, technological advances and the embracing of standards and conventions by science communities provide opportunities to successfully meet these challenges.

DATA MANAGEMENT SYSTEMS, FROM NEAR-REAL TIME TO DELAYED MODE

The Met-Ocean Data Management System

The JCOMM data management system is jointly organized by IOC's IODE (International Oceanographic Data and Information Exchange) program and the JCOMM Data Management Coordination Group (DMCG), and the existing marine meteorology data management programs in WMO are considered. The DMCG's mission is to maintain a data management plan that identifies, assesses, and specifies priorities of activities relevant to both near-real time and delayed mode marine meteorological and oceanographic data management. Expert teams and pilot projects review, assess, and coordinate appropriate new approaches, standards and best practices, methods, and tools.

Since 1961, IODE has coordinated a network of national oceanographic data centers (NODCs), and since 2013 associated data units (ADUs) and global data assembly centers (GDACs). These centers form the structural elements of IODE and JCOMM for data management, which provide access and stewardship for the national resources of oceanographic data. This requires the gathering, quality control, processing, summarizing, dissemination, exchange, and preservation of data generated by national and international agencies. National institutions (such as navies, universities, fishery agencies, government research bodies, and industry) and programs and projects collect oceanographic data. This wealth of data can be complementary to that collected and archived by the coordinated global and regional programs of JCOMM OPA described in the previous section. NODCs and ADUs often manage more data types than those of interest to JCOMM.

IODE structural elements are organized into networks and projects (ODIN) at regional and thematic levels. Examples of such network and projects are the pan-European Infrastructure for Ocean and Marine Data Management (SeaDataNet, <https://www.seadatanet.org/>), the Ocean Data and Information Network for Africa (ODIN-Africa, <http://www.odinafrica.org/>), and the IODE Ocean Data Portal (ODP, <http://www.oceandataportal.org/>), which provide access to more than 100 IODE data centers worldwide.

Recently the IOC decided to undertake the development of its Ocean Data and Information System (ODIS), which will initially offer an inventory of existing online data and information sources (ODISCat: <http://catalogue.odis.org>). The system will

considerably increase the discoverability of data and information, but more importantly, also of products and services, particularly those relevant to SDGs. The structural IODE units make available physical, chemical, and biological (including biogeographic) data and information that are the basis of at least SDG goals 13 and 14: NODCs are traditionally archiving facilities for climate trend assessment from *in situ* observations and ADU/GDACs collect and make available biogeochemical data that are fundamental to the sustainable use of marine resources. ODIS will make all these data assembling facilities more visible and discoverable.

Another very important action that is being promoted by IODE, GOOS, and JCOMM data management is the Ocean Best Practices System (OBP, <http://www.oceanbestpractices.org>) that aims to provide the ocean research, observing, and application communities with a mechanism to discover, review, agree upon, adopt, and support the widest possible dissemination of ocean best practices (see the paper by Pearlman et al., 2019, this issue). This is the most important activity for the JCOMM end-to-end system, because the capacity development of data access and dissemination for IOC member states and WMO members will be based on it.

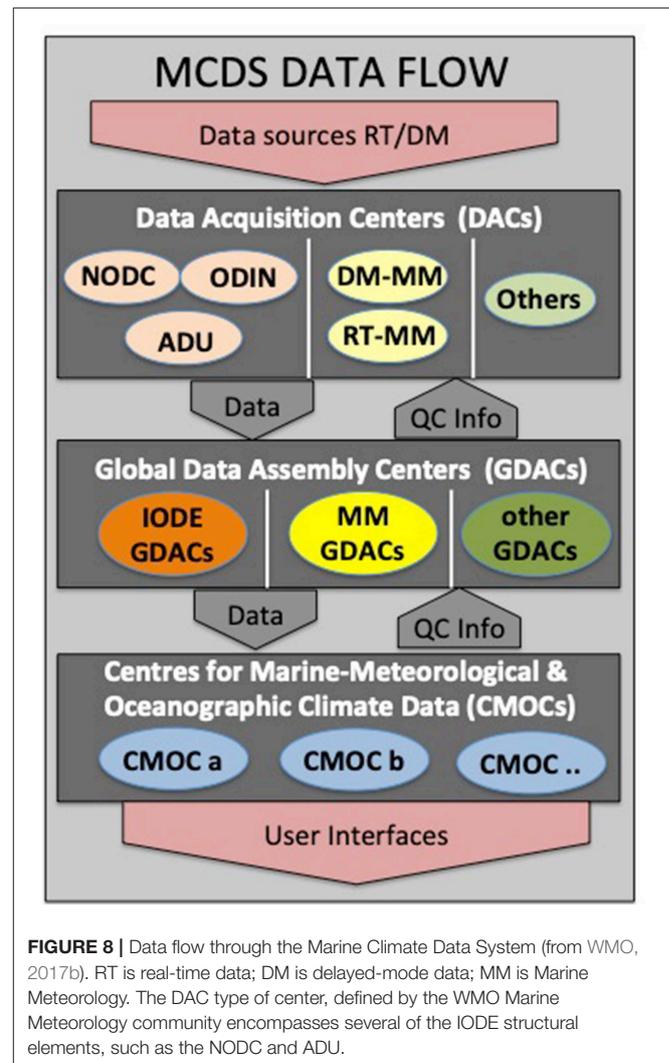

While the real time data flow has been described in section Near-Real Time Ocean Data Acquisition and Distribution, here we describe the delayed mode data flow developed by JCOMM, so-called Marine Climate Data System. Both data flows, the near real time and the MCDS, are essential in the structure of ODIS. Near real time data should be converted into high quality climate data sets by enhanced quality control and they should contribute to the IODE structural elements as well as the MCDS. Furthermore, the near-real time data management system, as described in section Near-Real Time Ocean Data Acquisition and Distribution, should be the main link between DMPA and OPA network activities.

The Marine Climate Data System

Purpose and Structure of MCDS

Delayed mode and quality-controlled ocean data are the cornerstone of earth climate monitoring, as they are the basis for the estimation of deep ocean trends. The air-sea and ice-sea-atmosphere interface is a critical subcomponent of the earth's climate and it requires the assembly of observations at the marine surface that are collected by very different sensors. The MCDS has been developed to produce highly quality controlled marine meteorological and oceanographic data sets that can fulfill the IOC and WMO requirements for climate long-term series observations.

The purpose of the Marine Climate Data System (MCDS, <http://www.iode.org/mcdis>) is essentially to enable the provision, on a free and unrestricted basis, of consistent, coherent, discoverable, and documented marine meteorological and oceanographic climate data sets of known quality to address the needs of WMO and IOC applications. Such applications include long-term climate monitoring (Global Climate Observing System—GCOS; <https://public.wmo.int/en/programmes/global-climate-observing-system>), seasonal to inter-annual climate forecasts, and climate services. A critical function of the MCDS is to compile added-value and variable-based products,

including essential ocean variables (EOVs; Task Team for the Integrated Framework for Sustained Ocean Observing, 2012) and relevant essential climate variables (ECVs; Bojinski et al., 2014). Other functions include the provision of added value bias-corrected data-sets.

This system is expected to improve the timescales for met-ocean climate data availability and facilitate the exchange of historical met-ocean climate data sets between countries, thereby increasing the amount of ocean observations eventually made available to the relevant end user applications. Furthermore, integrated data and metadata will be available that contains comprehensive dataset information, such as historic details on current and past data codes and formats.

The MCDS data flow is based on a three-tier structure (Figure 8) of Data Acquisition Centers (DAC), Global Data Assembly Centers (GDAC) and Centers for Marine-Meteorological and Oceanographic Climate data (CMOC) that standardize data flows from operators to end users. The general structure coordinates data flow through different levels

of the MCDS providing a traceable and robust flow of data of known quality:

- DAC is the basic level of the MCDS and receives data directly from the measurement source, applies basic quality/duplicate checks, and forwards the data to an associated GDAC. The definition of this type of center encompasses several of the IODE structural elements, including the NODC and ADU;
- GDACs combine the streams of associated DACs to produce a global aggregation for a specific observation system, apply further quality/duplicate checks, and provide the data to an associated CMOC;
- CMOCs collect data from GDACs, aggregate all the relevant data types for a specific set of environmental variables, and produce integrated datasets and products for end users.

Each center in the MCDS data flow is responsible for the completeness and consistency of the data they acquire and to provide it to other centers within the MCDS or to end users. This provides an efficient mechanism for routinely collecting, processing, and delivering high quality data with known quality control procedures and documented processing details of ocean data to various users. The terms of reference for the MCDS Centers is provided in the Manual WMO (2017a) and the Guide WMO (2017b) on Marine Meteorological Services. The harmonization of standards and nomenclature between MCDS and IODE structural elements has not yet been fully achieved, and is the goal for future collaborative work between IOC and WMO. Furthermore, the integration of the IODE networks in MCDS is still to be clarified.

Present Status of the MCDS

The aim of the MCDS is to implement the described structure for about ten ocean data areas and respective CMOCs. The two areas of surface drifters and ocean profile data are in the process of being implemented. A third, surface and marine meteorology data, is planned and will be built on existing legacy structures.

CMOC-China (<http://www.cmoc-china.cn>), operated by the National Marine Data and Information Service (NMDIS), was the first CMOC to be provisionally accepted into the MCDS in 2012, and then formally in 2015. While CMOC-China has wide-ranging activities, its contribution to the MCDS will focus on surface velocity products, essentially based on integrating data and metadata from Lagrangian drifters and constructing relevant data products. While the drifting buoy GDACs (see below) communicate well amongst themselves, coherent and well planned tools for disseminating and utilizing the surface velocity data will be of benefit, which will enhance the utility of the data for climate and environmental studies using the buoy trajectory information, and recorded environmental variables. CMOC China will also be involved in other activities, such as ocean observing platform metadata integration, and data rescue focusing on the Asia Pacific region.

Two GDACs for drifting buoys have been established, led by “Fisheries and Oceans Canada” and Coriolis (a French organization including Météo-France and Ifremer). Both GDACs also perform the function of DACs. The main data source consists of data circulated on the Global Telecommunication System

(GTS) of WMO. Both GDACs routinely compare GTS bulletin headings and the data volume received and are able to make data available to requesters (Canada: through an offline form request system, France: through the Copernicus Marine Environment Monitoring Service). A public FTP server distributing data and metadata using one NetCDF file per buoy is under construction.

The World Ocean Database (WOD; https://www.nodc.noaa.gov/OC5/WOD/pr_wod.html, Boyer et al., 2013, also available through <http://wod.iode.org>) was endorsed as a CMOC for ocean profile data in 2017. The WOD is a database operated from the U.S. National Centers for Environmental Information (NCEI) and is also a project of the IOC International Oceanographic Data and Information Exchange (IODE). The WOD aggregates historic and recent subsurface ocean profile EOVs. The WOD role as CMOC is to provide all available ocean profile data in a uniform way to the public through both machine-to-machine discovery and individual discovery and download. As a CMOC, the WOD can flexibly prepare metadata and discovery options, which feed into the WIS and ODIS systems for dissemination with other types of ocean and marine meteorological data.

Several ocean profile GDACs will in the future provide the infrastructure for collecting the most up-to-date and highest quality and resolution ocean profile data, integrate the near real-time data streams with historical (delayed-mode) data, and deliver the integrated data sets to relevant CMOCs for further products developments. Near real-time ocean profile data are those made available within 48 h, often at less than full resolution and without full quality control/calibration. Delayed-mode data are those made available after 48 h, and often much after, usually with full quality control and calibration. Another key role for the ocean profile GDACs is to coordinate activities among all participating relevant DACs, to standardize quality control procedures (IOC, 1993). Ocean profile GDACs include, but are not limited to, Argo (http://www.argo.ucsd.edu/Argo_Project_Office.html; Jayne et al., 2017), CLIVAR and Carbon Hydrographic Data Office (CCHDO; <https://cchdo.ucsd.edu/>), and the Global Temperature and Salinity Profile Program (GTSP; <https://www.nodc.noaa.gov/GTSP/>) for ocean temperature and salinity profiles.

Building the MCDS

The governance for defining the designation procedure, function, and evaluation process for MCDS centers (i.e., DACs, GDACs, and CMOCs) is recommended by JCOMM and adopted by both the WMO and IOC governing bodies. The host of a candidate MCDS center is required to produce a statement of compliance with requirements and commitments, and to list and demonstrate the capabilities of the proposed center, state the scope of the data and/or products managed, and formally commit to hosting the center in line with its specific terms of reference. A committee comprised of at least three members then evaluates the statement of compliance and a unanimous decision is required for approval.

The detailed designation and evaluation process for the DACs and GDACs is provided in WMO (2017a), while WMO (2017b) provides this for the CMOCs.

Based on its terms of reference, and particularly the standards and procedures regarding the overall collection, management, exchanging, and archiving of high-quality marine meteorological and oceanographic data, information and products, JCOMM in collaboration with the IODE will further monitor the implementation status of MCDS through evaluating the efficiency of the network, including the operation of DACs, GDACs, and CMOCs. The CMOCs must provide the high level functions of the MCDS and make products available to end users, so it is essential that the flow of marine meteorological and other appropriate oceanographic data is ensured through the diversity of data sources, whether real-time or delayed mode, to the CMOCs. This data flow is ensured through oversight and regulation with the MCDS, provided by JCOMM and IODE. In addition, JCOMM will work to establish new centers to cover a wider spectrum of oceanographic and marine meteorological observing platform types. Currently, the JCOMM Expert Team on Marine Climatology (ETMC) and the JCOMM-IODE Expert Team on Data Management Practices (ETDMP) is responsible for the oversight, regulation, and additions to the MCDS. Active coordination between these teams and between the teams and the elements of the MCDS is essential for the maintenance and growth of the MCDS. More accessible documentation and outreach from the expert teams will also encourage the awareness of and participation in the MCDS.

One of the initial goals of the MCDS was to modernize and expand the existing Marine Climatological Summaries Scheme (MCSS) established in 1964 by WMO. Marine climatology then only consisted of data collected by the Ship Observation Team, which includes the traditional Voluntary Observing Ships (VOS) and Ships Of Opportunity Program (SOOP). The initial system was built around several VOS DACs responsible for collecting VOS data in delayed mode from recruited vessels, and for forwarding those data to two GDACs that applied minimum quality control standards and conducted duplicate removal. The GDACs apply additional reformatting where needed, along with additional metadata. The two VOS GDACs operate in parallel and provide mirroring services to avoid loss due to technological failures. The critical updates of the MCSS to the MCDS maintain data flow through the system and insert the global functionality of the CMOC. Currently there is no CMOC that can function as a repository for the VOS data, but the International Comprehensive Ocean-Atmosphere Data Set (ICOADS) is considering fulfilling a CMOC role and will collect the VOS data from the VOS GDACs together with other marine meteorological data sources.

FROM MONITORING TO SERVICES

The JCOMM value adding chain (**Figure 2**) requires international coordination for operational weather and oceanographic forecasting and the development of targeted applications, notably for maritime transport and fisheries, and for the coastal communities.

Improvements in numerical weather prediction through better data assimilation, improved algorithms, and increased

spatial resolution, have been facilitated by advancements in supercomputing techniques and capacity (Bauer et al., 2015). Operational oceanographic services have also been developed, such as the Copernicus Marine Environment Monitoring Service (CMEMS) (Le Traon et al., 2019, this issue), producing high-resolution, short-term, and accurate forecasts of up to 10 days for global and regional wave and currents, temperature, sea level, and salinity, together with long term reconstructions of the ocean state over several decades. The broader operational use of ensembles and the transition to fully combined ocean, air, and cryosphere models will further improve numerical weather and ocean guidance. Hydrological forecasting is lagging behind, but this is soon to be addressed by new activities at WMO and IOC. As we develop and operationalize a total earth systems prediction capability in the coming decade we will bridge the gap between atmosphere and ocean weather and climate predictions, enabling us to predict across weather, sub-seasonal, seasonal, annual, and decadal time scales. To achieve these goals, JCOMM has collaborated with research networks, such as the Global Ocean Data Assimilation Experiment (GODAE, <https://www.godae-oceanview.org/science/ocean-forecasting-systems/>) and the WMO Global Data-Processing and Forecasting System (GDPFS, <http://www.wmo.int/pages/prog/www/DPS/gdps.html>).

To harmonize and strengthen the global network of weather and operational oceanographic services support for the maritime and coastal environments in terms of coastal populations and fisheries, the JCOMM Services and Forecasting Systems Program Area (hereafter referred to as JCOMM Services) provides standards and protocols to national authorities regarding the delivery of marine weather and ocean services, which protect lives and property at sea and in the sensitive coastal environment. While JCOMM services support a wide range of met-ocean activities, the primary focus is on promoting safe shipping, reducing the risk from disasters along the coasts, responding to marine emergencies, and providing the international coordination necessary for these services to be successful.

The Maritime Safety Services

Although the investments made in observations and forecasts described above have substantially improved predictability, ships still transit into hazardous conditions. Incidents of ships encountering extreme weather at sea in recent years highlight the challenges of exchanging information among ships, national marine forecasting centers, and commercial weather providers, which have adverse effects on the decision-making of mariners. The situation is further exacerbated by a maritime weather infrastructure that remains heavily reliant on decades-old technology for dissemination, such as radiofax, text, and brief voice broadcasts.

To ensure forecasts and hazardous weather warnings are provided to ships at sea, JCOMM has established a Worldwide Met-Ocean Information and Warning Service (WWMIWS) Committee. Aligned with the International Hydrographic Organization (IHO) Worldwide Navigation Warning Service (WWNWS) Sub-Committee, WWMIWS ensures that standards and procedures are developed for the preparation and issuance

of marine weather support that are compatible with systems that disseminate navigation warnings to ships, and that these protocols are equitably implemented around the world. The basis for these services dates back to the initial international Convention on the Safety of Life at Sea (SOLAS), held in 1914 following the sinking of the RMS Titanic in 1912 by an iceberg in the waters of the North Atlantic Ocean. Subsequently adopted as the UN Convention on the SOLAS, the convention has been revised four times, most recently in 1974, with the International Maritime Organization (IMO) responsible for regulating under the technical guidance of the WMO, through JCOMM, and IHO.

IMO manages this maritime safety information through the Global Maritime Distress and Safety System (GMDSS). As shown in **Figure 9**, the world's oceans are divided into 21 zones called METAREAs. JCOMM WWMIWS guides the provision of services through METAREA coordinators, who are responsible for monitoring and reviewing the provision of meteorological maritime safety information within the GMDSS and also for other vessels not covered by the SOLAS Convention.

Sea ice is particularly dangerous to vessels. To address this specific navigational hazard, JCOMM's Expert Team on Sea Ice (ETSI) coordinates with and advises coastal states on products and services required by user communities in sea ice areas, to support navigation, coastal and offshore activities, and monitoring of the sea ice cover for both the northern and southern hemispheres. Such services are becoming more relevant as the polar seas warm and become less ice-bound during the summer months, resulting in an increase in shipping and other maritime activities in these regions. Recognizing this, the IMO adopted the International Code for Ships Operating in Polar Waters, and the "Polar Code" (MEPC, 2015) entered into force in 2017. ETSI will have the important role of providing guidance for national ice services to ensure the sea ice information they provide meets Polar Code requirements.

The Disaster Risk Reduction Services

Inundation in the coastal zone resulting from tsunamis, storm surge, increased river flow, and other weather-related causes kills thousands annually and hundreds of thousands more are displaced from their homes and communities. Although regional warning systems are increasingly available, these phenomena continue to wreak havoc due to the lack of preparedness and effective mitigation strategies. This led to the inclusion of a specific target in the Sendai Framework to "substantially increase the availability of and access to multi-hazard early warning systems and disaster risk information and assessments to people by 2030."

Innovative solutions are required to minimize the impacts of these events, and since 2009 WMO and JCOMM have partnered to develop tools that can be used to improve prediction and lessen the effects of these disasters. The Coastal Inundation Forecasting Demonstration Project (CIFDP) is a cooperative effort by the WMO's Commission for Hydrology and JCOMM to pilot an initial capability in Bangladesh, Fiji, the island of Hispaniola encompassing both the Dominican Republic and Haiti, and Indonesia, with a focus on the development and implementation

of multi-hazard early warning systems leading to long-term disaster risk reduction services in these coastal states (Swail et al., 2010). The project integrated observations of sea level, ocean waves, and meteorological variables including wind, pressure, and rainfall with hydrological information, such as river level and flow. This observational information was combined with the forecast modeling techniques used for waves, storm surge, tide, sea surface height anomaly and river flooding by organizations, such as the WMO's Regional Specialized Meteorological Center (RSMC) for Tropical Cyclones in Miami, USA, and the RSMC Tokyo's Typhoon Centre, along with national meteorological agencies where available, such as in Indonesia.

Based on the technical description of CIFDP, as given in **Figure 10**, the national forecast agencies can provide essential guidance on potential inundation hazards to national disaster management agencies according to their established protocols. The outcomes of these demonstration projects are being evaluated to help create an optimal path for the full operational implementation of a program to extend these multi-hazard forecast systems to other nations that are subject to disasters resulting from coastal inundation events.

To help provide coastal states with the technical expertise and tools needed to mitigate the impacts of these deadly coastal weather events, JCOMM Services established an Expert Team on Disaster Risk Reduction (ETDRR) in 2017. This ETDRR will be comprised of experts from both developed and developing coastal states, and is aimed at improving the links between observations and emergency management officials in states vulnerable to such disasters. In addition, to actively supporting the CIFDP, the expert team will help promote and develop regional coastal hazard warning solutions for all vulnerable nations, including capacity building activities. ETDRR will also promote trans-disciplinary connections between scientists, engineers, planners, and policy makers, to deliver the tools needed for effective coastal resilience.

Marine Environmental Emergency Services

Operational services that deliver marine pollution forecasts and hazard/risk mapping for marine environmental emergencies and disaster risk reduction will be co-ordinated. The initial framework involved the setting up of a network of response centers within the 21 WMO metareas (**Figure 9**) within the GMDSS, and is called the Marine Pollution Emergency Response Support System (MPERSS). This NMHS network liaises with oceanographic centers to provide environmental emergencies response information. These centers should provide basic meteorological and oceanographic forecasts and advection-diffusion and transformation models capable of simulating and forecasting the movement and weathering of pollutants at the sea surface. The MPERSS system is being revised by the Expert Team on Marine Environmental Emergencies Response (ETMEER), which will facilitate the implementation and operation of GDPFS specialized centers for marine emergency management, and establish and maintain standards for information products, thus supporting members and member states in their responses to marine environmental emergencies.

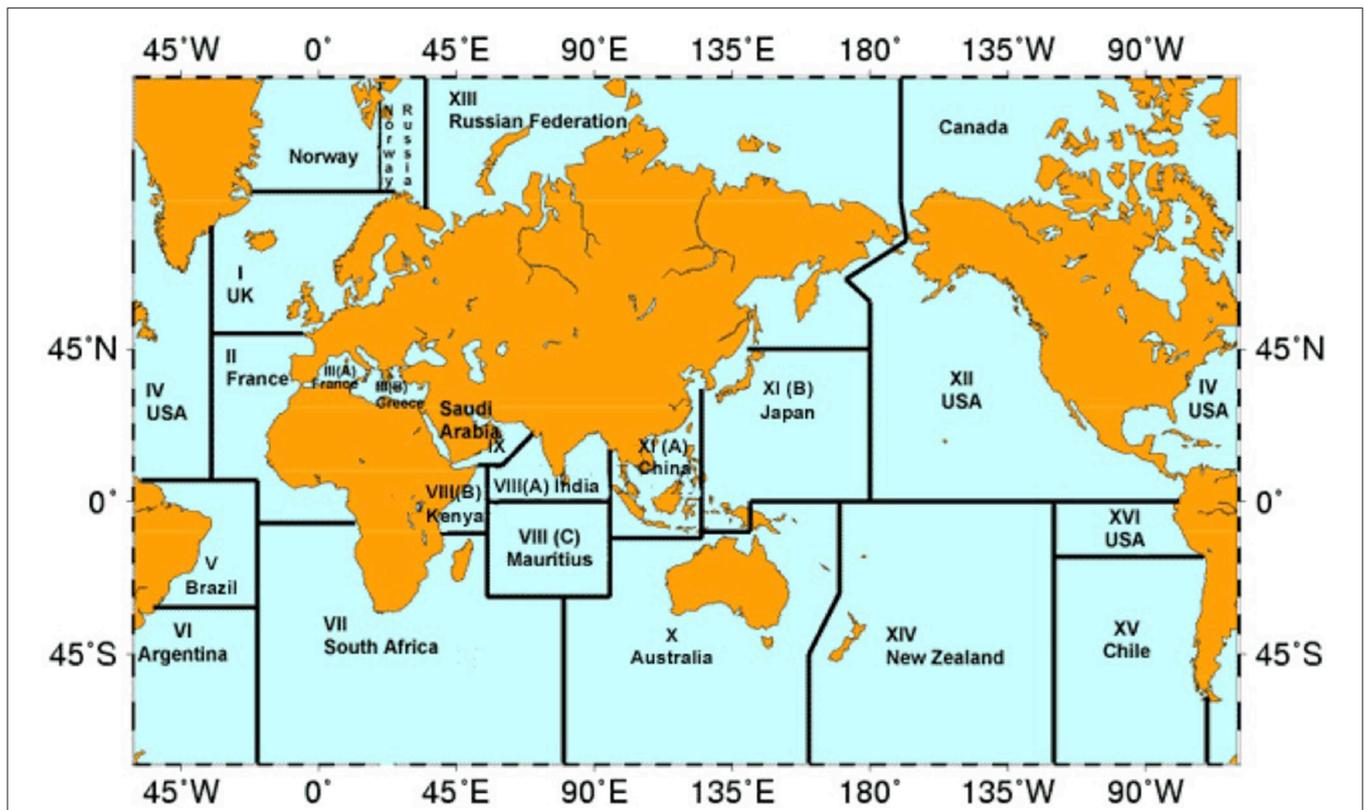

FIGURE 9 | The 21 WMO METAREAS, established for the provision of marine products and services on the high seas, <http://weather.gmdss.org/metareas.html>.

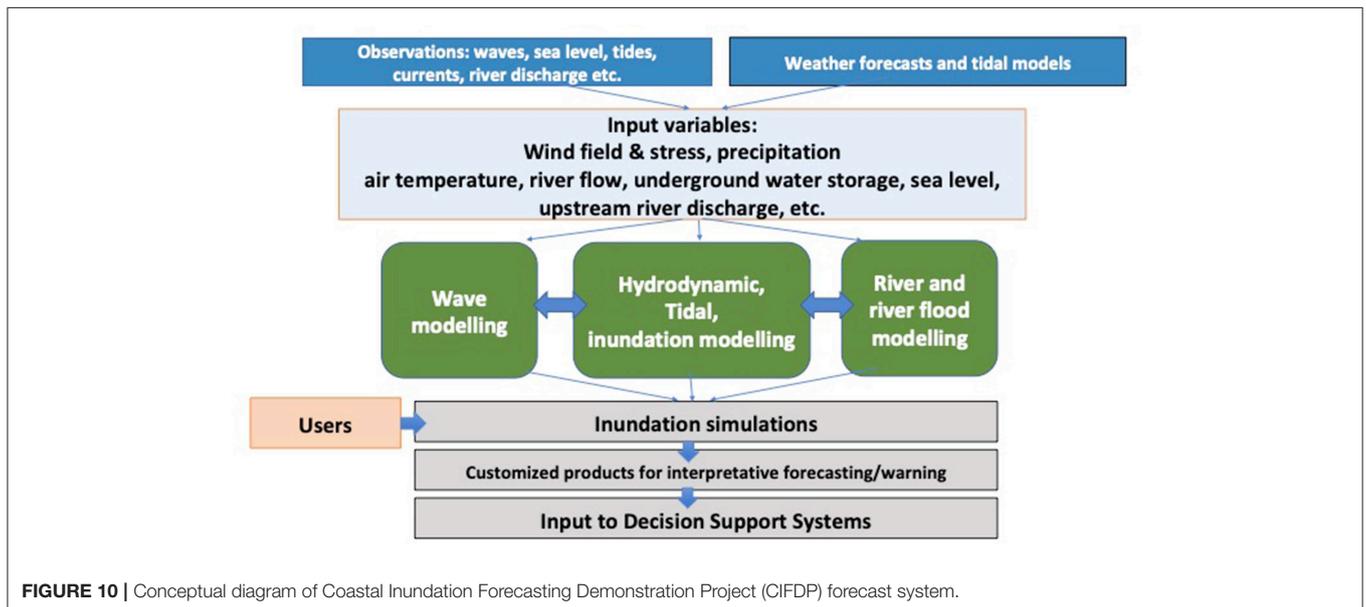

FIGURE 10 | Conceptual diagram of Coastal Inundation Forecasting Demonstration Project (CIFDP) forecast system.

This global system must liaise with the International Convention for the Prevention of Pollution from Ships (MARPOL), which is the main international convention addressing the prevention of pollution of the marine

environment by ships from operational or accidental causes. It should also connect with regional conventions that develop contingency plans for marine pollution emergencies in the Mediterranean (REMPEC), the Baltic (HELCOM), and the

North Sea (OSPAR). The International Maritime Organization (IMO) and International Atomic Energy Agency (IAEA) are already involved in JCOMM activities and provide guidance for ship pollution and radioactive accidents.

The complexity of such a network cannot be underestimated. Environmental emergencies range from radioactive material discharges, such as the Chernobyl nuclear power plant accident in 1986 (Margvelashvili et al., 1997; Staneva et al., 1999; Evangelidou et al., 2016), the Fukushima Daiichi nuclear power plant accident in 2011 (Dietze and Kriest, 2012; Estournel et al., 2012; Miyazawa et al., 2012; Tsumune et al., 2012; Draxler et al., 2015; Periañez et al., 2015), and the ruthenium-106 release in 2017 (IRSN, 2017), to oil spills from operational release and/or ship or platform accidents (Price et al., 2003; Abascal et al., 2010; Olita et al., 2012; Fernandes et al., 2016; Liubartseva et al., 2016a; Sepp-Neves et al., 2016; Zodiatis et al., 2018), accidents related to objects/debris/people drift (Kawamura et al., 2014; Jansen et al., 2016; Trinanes et al., 2016; Maximenko et al., 2018), other hazardous and noxious substances (Neuparth et al., 2011; Legrand et al., 2016), harmful algal blooms (He et al., 2008; Li et al., 2009; Glibert et al., 2010; Hense, 2010; McGillicuddy, 2010; Anderson et al., 2012), and plastic pollution (Maximenko et al., 2012; Mansui et al., 2015; Van Sebille et al., 2015; Liubartseva et al., 2016b, 2018; Fossi et al., 2017; Politikos et al., 2017; Zambianchi et al., 2017). All of these accidents/events require specific information and competency, particularly if a global support system for mitigation and response has to be organized. Nothing is yet available for underwater pollution sources and hazard/risk mapping information, although severe accidents can result from underwater explosions and so risk/hazard mapping is extremely important for the few 10 min after the accident, to understand the potential environmental conditions that can affect pollutant dispersion.

Ocean Forecasting From the Global to the Regional Scales

Over the past 20 years oceanographic operational services have emerged and developed (Pinaridi et al., 2017), and together with the sea state provide 10 days forecasts of the deep ocean state and long-term reanalyses. Ocean forecasting has been developed (Pinaridi and Woods, 2002; Chassignet and Verron, 2006) under the scientific coordination and guidance of the Global Data Assimilation Experiment (Bell et al., 2009; Dombrowsky et al., 2009), which has now evolved into GODAE OceanPredict. This promotes the development and improvement of operational ocean analysis and forecasting systems worldwide and involves 15 different ocean forecasting systems from various countries and institutions. The most important aspects of this work relate to scientific advances in ocean modeling and data assimilation. The particular challenges for the future will be in terms of high-resolution physical modeling, downscaling, biogeochemical and ecosystem modeling, ocean/wave/atmosphere coupling, data assimilation and coupled data assimilation, error estimates, long-term reanalyses, and the use of new observations.

In 2012 JCOMM established an expert team to monitor and maintain an overview of the worldwide Operational Ocean

Forecasting Systems portfolio, including ocean physics and marine biogeochemistry, and to promote the adoption of international standards for ocean forecasting activities. Users of this new ocean forecasting are those within the socio-economic sectors of maritime transport and safety, coastal and marine environment management and protection, marine resources and weather, and climate and seasonal forecasting. Tonani et al. (2015) offers an exhaustive overview of the global and regional operational forecasting systems across the world.

To achieve forecast accuracy, ocean operational systems must from the outset consider mesoscale resolution, from global to regional scales. For coastal forecasting, higher-resolution models are nested into global forecasts both as limited area models and as stand-alone systems that are initialized only once. Coastal models and forecasting introduce new challenges. The issue of big data management, in terms of the exchange of large amounts of data for initial and lateral boundary condition updates, a high-resolution bathymetry-topography mapping to allow for coastal inundation, and the data assimilation of local observations into the nested models (De Mey et al., 2017). These problems will be partially tackled by JCOMM coordination to establish best practices in the NMHS and responsible oceanographic institutions, but they will remain a research, development, and innovation challenge.

CAPACITY DEVELOPMENT

JCOMM Capacity Development (CD) activities are carried out in each program area (Figure 2) using the existing IOC Capacity Development and WMO Education and Training structures, to leverage the CD expertise and experience in both organizations (i.e., WMO Global Campus and Regional Training Centres (RTC), the IOC-IODE Ocean Teacher Global Academy (OTGA) and its OTGA Regional Training Centres, IOC/WESTPAC Regional Training and Research Centres, etc.). JCOMM CD activities are also undertaken on the basis of the Partnership for New GEOSS Applications (PANGAEA—<https://www.jcomm.info/pangea-concept>) using voluntary contributions from WMO members and IOC Member States. In the following we provide an overview of the main principles for CD activities in IOC and WMO.

The IOC Capacity Development Strategy (2015) Mission Statement states that “The IOC will undertake relevant actions to assist Member States with developing and sustaining the necessary capacity to undertake activities necessary to achieve the IOC vision at the national level as well as at the international cooperation level.” It further suggests that the IOC Criteria and Guidelines on the Transfer of Marine Technology should be taken into account along with IOC’s custodianship role for SDG 14 (ICSU, 2017), particularly under targets 14.3 and 14.a. The first target, 14.3, is related to the minimization of ocean acidification including ocean scientific cooperation and the second, 14.a, is concerned with the increase of scientific knowledge and the development of research capacities in order to improve ocean health.

Thus, member states have recognized the need to address the ocean scientific knowledge gaps in national infrastructures, NODCs, and operational ocean forecasting centers. In this context, IOC governing bodies have endorsed the proposal for an International (UN) Decade of Ocean Science for Sustainable Development to be established for the period 2021–2030, which will significantly contribute to CD across the end-to-end met-ocean system. From 2015 to 2021, the IOC CD strategy proposes a framework of outputs and activities, which are summarized in **Table 1A**.

The WMO CD mission is to foster stronger NMHS that can meet the need for further information on weather, climate, and water, for the safety and well-being of people throughout the world. CD should be conducted, particularly for developing countries, the least developed countries (LDCs), and small island development states (SIDSs), through advocacy, education and training, outreach, partnerships and resource mobilization, demonstration and pilot projects, service delivery, and research. The WMO Capacity Development Strategy identifies six strategic objectives and corresponding Strategic Approaches, which are summarized in **Table 1B** (https://www.wmo.int/pages/prog/dra/documents/WMO_Capacity_Development_Strategy.doc).

The IOC and WMO CD strategies have several similar outputs and/or objectives, including increased education, research, human resources, visibility, awareness, strengthening of global, regional and sub-regional mechanisms, and sustained resource mobilization for CD. Their differences are that the IOC CD strategy includes increased access to physical oceanographic infrastructures while the WMO CD strategy begins by explicitly defining the required capacities and deficiencies, emphasizing ownership and optimizing knowledge management.

DISCUSSION

Over the past 20 years JCOMM has worked to ensure coordination in the delivery of an integrated, global meteorological and ocean monitoring and forecasting system, for the benefit of WMO members and IOC member states. This coordination has been fruitful, and the efficient use of available resources has led to advancements in the overall management capacity of this complex system, from observations to generic services and customized products.

The demand for improved integration, coordination, and standards across global ocean observing and forecasting systems is increasing. The effective monitoring of the earth's climate requires a system that is continuously updated by new technologies, well-coordinated within the research community, and fully near-real time and operational. The four JCOMM activity areas only partially meet the expectations resulting from these new challenges. The JCOMM MAN has carried out a Strength and Weaknesses, Opportunities and Threats (SWOT) analysis (**Table 2**) to attempt to devise a better fit-for-purpose collaboration between IOC and WMO, in view of the changes that will involve JCOMM in 2020.

In general, the weaknesses outlined in **Table 2** are due to the technical nature of the three program areas, which have not

included any periodic review of stakeholder needs. A bottom-up approach has been taken in the program area activities, which has been adequate over their 20 years joint activity development period, but they now must be revisited.

In particular, there is a weakness in the connections between the observational program area and the ocean infrastructure of IODE and MCDS. Many real-time OPA networks have defined both their real-time and delayed mode data management strategies separately from the IODE structural elements described in section Data Management Systems, From Near-Real Time to Delayed Mode. Furthermore, there has been little cross-fertilization between the IODE system and the MCDS itself. The technical institutions represented by the WMO members and the IOC members states require international best practices across communities, so they can take advantage of past experiences in building a fit-for-purpose met-ocean data exchange system. JCOMM DMPA began to define a strategy for the met-ocean archiving system but failed because information about the working practices of IODE networks was not fully considered.

In an attempt to bridge the gap, IODE is developing an ODIS system that will initially be in the form of a “Catalogue of Sources” (<http://catalogue.odis.org>), aimed at being an online searchable catalogue of existing ocean-related web-based data and information sources/systems of as well as products and services. It will also provide information on products and visualize the landscape (entities and their connections) of ocean data and information sources. This may lead to a design for combining real-time and delayed mode data flows and the ongoing storage of the data. However, this process is far from being accomplished and will require future activities to focus on the strategic objectives. The future ODIS will be an e-environment in which users can discover data, information, and associated products or services provided by member states, projects, and other partners associated with IOC and WMO. The system will aim to align itself with accepted community data management principles, such as the FAIR principles (Wilkinson et al., 2016) and, where appropriate, interoperate with existing data exchange solutions. ODIS will also allow additional metrics to be defined that record the data flow and if the data are securely archived within the IODE network and links with the satellite data centers.

To achieve this objective, JCOMM began defining standards for networking between IODE, OPA networks, and WIS (https://www.jcomm.info/index.php?option=com_oe&task=viewDocumentRecord&docID=20327). The Inter-Program Expert Team on Integrated Marine Meteorological and Oceanographic Services (IPET-MOIS) will continue this work (**Figure 11**). This group will define a formal procedure to interconnect all the relevant WIS to the IODE centers and eventually ODIS, using best practices with standards-based data and metadata exchange. With real-time data as its initial focus, IPET-MOIS will identify marine observing assets that have real-time value and facilitate the inclusion of these data on the GTS and WIS.

Another major weakness of the system is the lack of strong links between the three pillars of the met-ocean value chain

TABLE 1 | (A) IOC CD Strategy; (B) WMO CD Strategy.

(A) IOC (2015–2021)	
Outputs	Activities
1. Human resources developed	1.1 Academic (higher) education 1.2 Continuous professional development 1.3 Sharing of knowledge and expertise/community building 1.4 Gender balance
2. Access to physical infrastructure established or improved	2.1 Facilitating access to infrastructure (facilities, instruments, vessels)
3. Global, regional and sub-regional mechanisms strengthened	3.1 Further strengthening and supporting secretariats of regional commissions 3.2 Enhance effective communication between regional sub-commission secretariats and global programs as well as other communities of practice (incl. other organizations)
4. Development of ocean research policies in support of sustainable development objectives promoted	4.1 Sharing of information on ocean research priorities 4.2 Developing national marine science management procedures and national policies
5. Visibility and awareness increased	5.1 Public Information 5.2 Ocean Literacy
6. Sustained (long-term) resource mobilization reinforced	6.1 In-kind opportunities 6.2 Financial support by Member States to IOC activities
(B) WMO	
Objectives	Strategic approaches
1. Define required capacities and identify deficiencies	1.A: Emphasize compliance with WMO technical requirements to address priorities 1.B: Assist countries in identifying deficiencies of the NMHSs 1.C: Encourage development of services to address specific user needs 1.D: Establish modalities for partner and stakeholder engagement
2. Increase visibility and national ownership	2.A: Emphasize socio-economic benefits of services provided by NMHSs to decision makers 2.B: Assist NMHSs to incorporate requirements into national policy, legislative frameworks and national development plans 2.C: Enhance outreach to end users and decision makers 2.D: Develop leadership and management capacities 2.E: Reinforce national support to meet societal needs for weather, climate and hydrology services
3. Optimize knowledge management	3.A: Enhance mechanisms for collecting and sharing of up-to-date information relating to NMHSs development 3.B: Share best practices and success stories relating to the development of NMHSs 3.C: Enhance communities of practice dealing with the development of NMHSs
4. Reinforce resource mobilization and project management	4.A: Enhance coordination and actively explore new funding opportunities and develop proposals through dialogue with stakeholders and development partners 4.B: Enhance capacity to develop, implement, monitor and evaluate projects 4.C: Encourage innovative voluntary and bilateral cooperation
5. Strengthen global, regional and sub-regional mechanisms	0.1.1 5.A: Strengthen the work of global and regional centers 5.B: Strengthen global, regional and sub-regional mechanisms to provide support for weather, climate and hydrological services
6. Increase education and research opportunities	0.1.2 6.A: Improve access to and provision of fellowships 6.B: Strengthen applications of research findings

(Figure 2). Neither the OPA networks nor the IODE/MCDS infrastructure get requirements from the forecasting and/or downstream services. As outlined in the user survey, it is clear that maritime safety services do not as yet benefit from the existing new observation data streams and the advanced met-ocean forecasts.

The activities carried out by JCOMM have begun to create strong and important links between the meteorological and the oceanographic communities, but the level of connections required surpasses the governance put together by JCOMM.

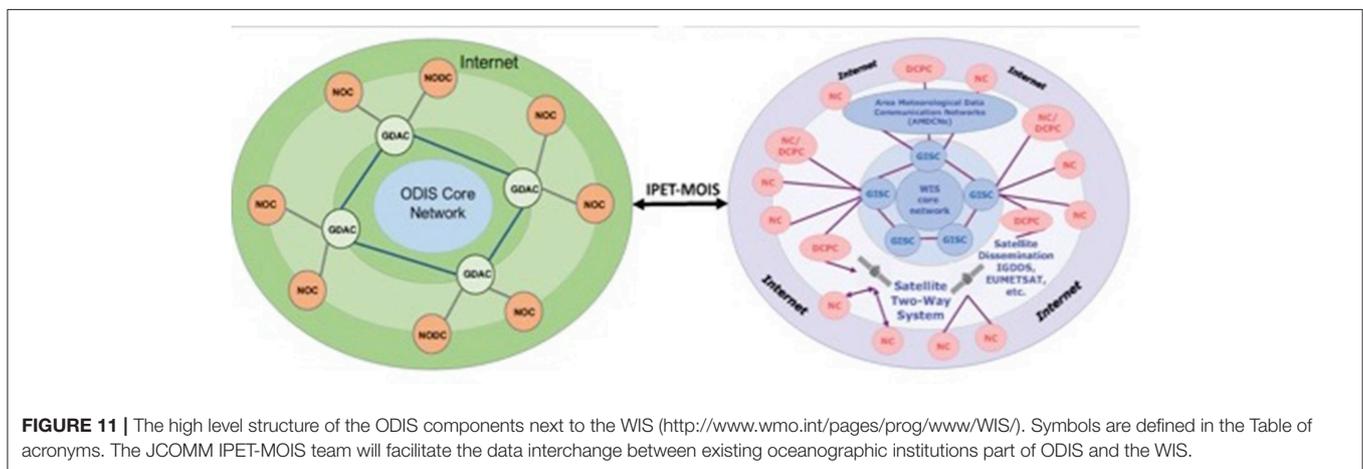

FUTURE FOCI

The areas identified as weaknesses and opportunities in **Table 2** are considered the starting points for the focus of the new Joint IOC and WMO collaborative activities, which will begin in 2020.

The WMO reform advice was to abolish JCOMM and establish a new joint collaborative board between WMO and IOC that will take on all the activities of the present JCOMM but within a new governance structure and with new working practices.

TABLE 2 | SWOT analysis for the Joint activities between WMO and IOC.

Strengths	Weaknesses
Effective coordination between Meteorology and Oceanography (90% impact) Global ocean observing system monitoring tool implemented and fully operational Increased number of Observing Networks connected to JCOMM Near-real time data flow from oceanography to meteorology and vice versa increased Ocean Best Practices (OBP) System elevated to higher importance in all PA	Weak stakeholder analysis when setting the specific requirements for the Joint WMO and IOC activities Weak across-program area activities Capacity Development activities still weak in interfacing IOC and WMO specialized groups Weak external and internal communication plan Weak inter-program activities within WMO and IOC Weak satellite— <i>in situ</i> observing connections
Opportunities	Threats
Strengthen connection between the PAs and GOOS and WMO reformed internal structures Strengthen connections to Decade of the Ocean initiatives Better research/innovation to operations coordination at all levels Strengthen JCOMMOPS/openGTS activities for new networks Put in place stronger connections with GRAs with RAs for “end-user” understanding Strengthen OBP and CD activities	Many JCOMM processes still being in the phase of definition Threat is to stop advancements for many years (services still in the phase of definition) Design of met-ocean data assembly centers and interfaces with WIS halted Loss of end-to-end system overview Loss of impact at the level of NMHS and/or IODE national infrastructures

The new Joint Collaborative Board should develop and provide strategic advice, directly derived from the overall strategic plans of IOC and WMO, to achieve joint objectives with the mandate to propose decisions directly to IOC and WMO governing bodies.

It will also provide a forum for WMO and IOC bodies and external partners, to negotiate and fast-track projects and joint work plans, which include objectives that cut across meteorology and oceanography and WMO and IOC regional structures to enhance implementation and capacity development, and the value chain connecting observations, data management, forecasting systems, services, and research.

In this future structure, the expert teams will become involved in active IOC programs, such as GOOS, IODE, the IOC Tsunami Program, and the new two restructured commissions of the WMO (to be approved in June 2019). One of the major tasks of the new Joint Board will be to ensure the sustainability of

the JCOMMOPS service, its connections with the IODE centers, and the full development of a fit-for-purpose data management system for the global met-ocean data and information system. The following goals form the backbone of the JCOMMOPS roadmap over the next 5–10 years:

- (i) Reach its metadata “gold” standard for all networks itemized in its initial Terms of Reference (Argo, OceanSITES, DBCP, SOT, GO-SHIP, GLOSS) and develop standard metadata services.
- (ii) Expand its support and monitoring capacity; to new OCG networks (such as OceanGliders) and develop a regional pilot on e.g., Mediterranean Sea.
- (iii) Enabling a responsive and truly global monitoring system. Over the long term, JCOMMOPS could expand its monitoring capacity to most of GOOS/WIGOS regions, and give visibility and monitoring capability to a cluster of coastal observing systems, with the cooperation of national focal points.

The Joint Collaborative Board will oversee the work of the expert teams from an overall strategic point of view, and will organize the necessary exchanges with other programs, including GODAE OceanPredict, WCRP, GeoBluePlanet, etc. IMO and IHO should be invited to engage in the Joint Board, and particularly in the activities of maritime safety and bathymetric mapping, with an eye to the synergistic opportunities.

A major focus of the new Joint Board will be to organize projects that will advance the sharing of data and training on met-ocean products and information, including the new ocean forecasts, analyses and reanalyses, and the early warning systems, navigation safety services, and emergency response decision support systems.

In conclusion, we should again consider the success of the first 20 years of collaborative work between the IOC of UNESCO and WMO. Those in the fields of oceanography and meteorology have, at various levels and at the country level in particular, started to develop common plans and share expertise. These common activities are essential to gain knowledge and develop applications to fulfill the sustainable development goals.

The role ships play in atmospheric, oceanic, and biogeochemical observations is described with a focus on measurements made near the ocean surface. Ships include merchant and research vessels; cruise liners and ferries; fishing vessels; coast guard, military, and other government-operated ships; yachts; and a growing fleet of automated surface vessels. The present capabilities of ships to measure essential climate/ocean variables and the requirements from a broad community to address operational, commercial, and scientific needs are described. The authors provide a vision to expand observations needed from ships to understand and forecast the exchanges across the ocean-atmosphere interface. The vision addresses (1) recruiting vessels to improve both spatial and temporal sampling, (2) conducting multivariate sampling on ships, (3) raising technology readiness levels of automated shipboard sensors and ship-to-shore data communications, (4) advancing quality evaluation of observations, and (5) developing a unified data management approach for observations and metadata that meet the needs of a diverse user community. Recommendations are made focusing on integrating private and autonomous vessels into the observing system, investing in sensor and communications technology development, developing an integrated data management structure that includes all types of ships, and moving toward a quality evaluation process that will result in a subset of ships being defined as mobile reference ships that will support climate studies. We envision a future where commercial, research,

and privately owned vessels are making multivariate observations using a combination of automated and human-observed measurements. All data and metadata will be documented, tracked, evaluated, distributed, and archived to benefit users of marine data. This vision looks at ships as a holistic network, not a set of disparate commercial, research, and/or third-party activities working in isolation, to bring these communities together for the mutual benefit of all.

Keywords: ships, observations, meteorology, physical oceanography, biogeochemistry, data management, climatology

INTRODUCTION

Since the days when sailing vessels were the primary vehicle for commerce and exploration on the high seas, ships have observed the marine environment (Woodruff et al., 2005). With the exception of a few research voyages (e.g., HMS Beagle, Keynes, 2012; HMS Challenger, Corfield, 2003), these early observations of sea water temperature, winds, and atmospheric pressure were made to support day-to-day operations (e.g., Richardson, 1980). Today, all types of ships make routine weather and ocean observations that are shared internationally to support weather forecasting, safety at sea, and commercial ventures (e.g., energy, fisheries, and transportation), while dedicated oceanographic research vessels make a wide range of atmospheric, oceanographic, chemical, biological, and other observations to support research into the complex interactions between the marine atmosphere, hydrosphere, cryosphere, and biosphere. Research vessels provide an extremely versatile sampling platform from which highly sophisticated instrumentation can be deployed by national research facilities, navies, coast guards, universities, or private institutions. Many are designed to operate in remote and inhospitable waters, providing data from regions outside commercial shipping lanes; however, sampling from research vessels often suffers from a lack of regularity and repeat sampling at given locations and can be subject to large seasonal biases, with high latitude regions rarely visited during the winter months. In contrast, commercial ships tend to traverse the ocean along traditional and, with decreased Arctic ice cover in recent years, evolving shipping lanes, thus repeating observations in spatially limited regions of the ocean. Over long timescales (decades to centuries), meteorological and oceanographic observations made from pre-industrial sailing vessels, research vessels, and commercial ships and more recently autonomous surface vessels underpin our understanding of marine climate variability and change.

The focus herein is on the role ships presently play in atmospheric and oceanic observations and outlines a vision for the coming decade. The vision builds upon the recommendations from the OceanObs'09 meeting (Smith et al., 2010). Of the 14 recommendations made in Smith et al. (2010), successes include improving linkages between the physical, biological, and carbon communities [e.g., through the Joint Technical Commission for Oceanography and Marine Meteorology (JCOMM, see **Appendix**) Observation Coordination Group]; working toward standardized metadata [e.g., converging on World Meteorological Organization (WMO) Integrated Global

Observing System (WIGOS) metadata standards and developing unique identifiers for observing platforms]; identifying new ships to provide observations (e.g., recruiting racing yachts from the Volvo Ocean Race and research vessels to underway data programs); and outlining new approaches to recruit ships through non-traditional methods [e.g., JCOMM approval in 2018 of a new third-party class to recruit ships outside of the traditional national meteorological and hydrographic services (NMHS)]. There has also been success in developing automated precipitation systems for ships (e.g., Klepp, 2015) and including air-flow modeling in new ship design (e.g., specifically for the research vessels *Sikuliaq*, *Sally Ride*, and *Neil Armstrong* in the United States). One recent success in the area of addressing diplomatic obstacles was the workshop on enhancing ocean observations and research, and the free exchange of data, to foster services for the safety of life and property hosted by WMO in February 2019. The workshop recognized the importance of Observing System Simulation Experiments (OSSEs) and sensitivity analyses to be used to investigate the importance of data collected within nation's exclusive economic zones. Despite the successes since OceanObs'09, a number of the recommendations saw little progress in the past decade. There is still a need to advance instrument technology for autonomous sampling, particularly for cloud cover, cloud type, and sea state. Adequate resources have not been available to coordinate research vessel cruise data, to develop consolidated marine datasets, standardize data quality evaluation across multiple ship measurement programs, or conduct systematic comparisons of different sensor systems typically deployed on ships. The proposed vision includes some of the topics not addressed over the past decade.

Throughout this review, the term “ship” includes, but is not limited to, merchant and research vessels; cruise liners and ferries; fishing vessels; coast guard, military, and other government-operated ships; yachts and other private crafts; and a growing fleet of autonomous surface vessels. The primary focus will be on ships with a crew; however, autonomous surface vessels (e.g., Caccia et al., 2005; German et al., 2012) and large fixed or mobile platforms (e.g., drilling platforms and light towers) can provide similar observational capabilities. While recognizing the great importance of ships for deploying atmosphere- and ocean-observing technology (e.g., balloon soundings, McBean et al., 1986; expendable bathythermographs, Goni et al., 2019; Argo floats, Roemmich et al., 2009; drifters, Pazan and Niiler, 2004; moorings, McPhaden et al., 1998; Send et al., 2010; and gliders, Rudnick et al., 2004), the focus here is on measurements

TABLE 1 | Parameters observed by ships near the ocean surface.

Parameter	Observation method	Comments	Ship type	First year systematically observed
Essential climate/Ocean variables				
Air Temperature	A, M		C, R, P, G, Y	1784
Water Vapor	A, M	A variety of humidity parameters are reported.	C, R, P, G	1873
Atmospheric Pressure	A, M	Either pressure at measurement height or adjusted to mean sea level can be reported.	C, R, P, G, Y	1785
Wind Direction and Speed	A, M, V	Visual estimates of winds derived from sea state (Beaufort wind scale). Also manually recorded by crew reading analog or digital display from anemometer.	C, R, P, G, Y	1750
Radiation	A		C, R, G	1970
Precipitation	A		C, R, P, G	1970
Cloud Properties	M		C, R, P, G	1852
Sea Water Temperature	A, M	Including water measurements at the ocean surface and at depths within the scope of this paper	C, R, P, G, Y	1816
Salinity	A, M	Including salinity measurements at the ocean surface and at depths within the scope of this paper	C, R, P, G, Y	1873
Inorganic Carbon	A, M	Including pCO ₂ measured in the atmosphere and ocean.	C, R, P, G, Y	1958
Dissolved Organic Carbon	A		R, G	1990
Nutrients	A		R, G	1921
Nitrous Oxide	A		R	2000
Oxygen	A		R	1900
Ocean Color	A		R	1954
Transient Tracers (e.g., CFC11)	M		R	1982
Aerosols	M	Semi-manual approach	R	1995
Sea State	A, M, V	Visual estimates by crew, automated measurements via wave radars and the Ship Bourne Wave Recorder	C, R, G	1876
Surface and Subsurface Currents	A	Measured directly by acoustic Doppler current profilers, indirectly via ship drift calculations (using navigation data)	C, R, G, Y	1920 (surface), 1985 (subsurface)
Additional shipboard measurements				
Visibility	M		C, G	1854
Sea Ice	A, M	Automated measurements by ice radars	C, R, P, G	1955
Chlorophyll Concentration	A	Supports ocean color and biomass EOVs	R, G	1954
Alkalinity/pH	A		R, G	1972

Essential climate variables are noted for the atmosphere (ECV; Global Climate Observing System [GCOS], 2016) and ocean (EOV; Global Ocean Observing System [GOOS], 2018). Typical observation methods include A, automated sensor; M, manual instrument reading; and V, visual observation. The authors provide, based on their own knowledge, the type of ships with the capability to make observations and the approximate year when systematic observations began on ships for each parameter. Ship types include C, commercial (cargo, fishing, etc.); R, research vessels; P, passenger (e.g., cruise liners and ferries); G, government (e.g., coast guard and military); Y, yachts and other private crafts; and A, autonomous surface vessels.

by automated instrumentation and both visual estimates and instrumental readings taken by observers on board ships. Ships provide a platform for simultaneous measurements of the physical and biogeochemical properties within the atmosphere and ocean through the use of fully automated instruments, manual observations, or a combination of the two. The suite of observations (Table 1) that can be made from ships includes essential climate variables (ECVs; Bojinski et al., 2014; Global Climate Observing System [GCOS], 2016) and essential ocean variables (EOVs; Global Ocean Observing System [GOOS], 2018), along with other parameters that address a wide range of applications. The instrumentation installed on ships (along with human observers) supports making measurements over a wide range of heights in the atmosphere and depths in the ocean. While we recognize that ship-based instruments can make atmospheric and ocean profiles (e.g., balloon sondes,

rosette casts, and expendable bathythermographs) and include remote sensing systems (e.g., radar, sonar, and acoustic Doppler current profiler), the discussion herein focuses on measurements made near the ocean surface and typically within the physical dimensions of the ship. This limitation is motivated by community requirements (see Community Requirements) to observe those parameters near the ocean surface that are essential to (1) understand the processes that govern the energy, nutrient, and chemical exchanges at the ocean–atmosphere interface; (2) support operational weather, ocean, and climate forecasting; (3) provide observations to validate and evaluate space-based observations of the ocean’s surface and numerical model analyses; (4) quantify biases in ship observations and derived products used in climate research and assessments; (5) examine and understand the variations in the near-surface marine climate system on

timescales from hours to centuries; and (6) support ocean ecosystem management.

The decadal vision expands the multivariate observations needed from ships to understand and forecast the exchanges across the ocean–atmosphere interface. The vision addresses (1) recruiting additional vessels to improve both spatial and temporal sampling, (2) conducting multivariate sampling on ships, (3) raising technology readiness levels of automated shipboard sensors and ship-to-shore data communications, (4) advancing quality evaluation of observations, and (5) developing a unified data management approach for shipboard observations and metadata that meet the needs of a diverse user community. Leveraging existing programs and developing innovative methods will be a cost-effective approach to support the measurement of multiple physical and biogeochemical observations on individual ships, thereby maximizing ship contributions to GOOS. The authors envision a ship-based observational network that integrates across operational and research communities to deliver needed information.

COMMUNITY REQUIREMENTS

Overview

Marine data are used directly and indirectly by a broad community to address operational, commercial, and scientific needs. User requirements differ between the real-time versus delayed-mode (climate) communities resulting in various sampling and collection strategies, data transmission technologies, metadata and documentation, and data quality evaluation. A primary challenge is effectively managing resources provided by commercial, governmental, and private entities to meet these varied requirements. Most observations made to support operational marine forecasting are funded and managed by NMHS, while many other observations are supported by time-limited national or private sector research funding. A continuing challenge is how to sustain observations that are initiated within the research community, but where users see a need for long-term observations and data management. Equally challenging is ensuring that observations primarily funded and made available by the operational community, but used downstream for climate analyses and research, (a) are of sufficient quality and quantity, (b) are appropriately described by metadata, and (c) have suitable provision for sustained data management.

Forecasting, Navigation, and Safety

For centuries observations from ships have provided safety-related meteorological services for ships at sea and have been used for climatological purposes (e.g., Maury, 1854; Mallory, 1855; International Maritime Organization [IMO], 2018). The Safety of Life at Sea Convention (International Maritime Organization [IMO], 2002), Regulation 5, "Meteorological Forecasts and Warnings," specifies provisions whereby contracting governments are encouraged to arrange for a selection of ships to be equipped with tested marine meteorological instruments and to take, record, and transmit meteorological observations

at the main standard times for surface synoptic observations. Contracting governments are also instructed to encourage other ships to make, record, and transmit observations in a modified form, particularly in areas with sparse data. In addition, ship observations have set an early open-access example: WMO (1995) Resolution 40 Annex 1 lists marine data among "data and products to be exchanged without charge and with no conditions on use." Presently, the Voluntary Observing Ships' (VOS) Scheme (Kent et al., 2010), a panel of the Ship Observations Team of the JCOMM of WMO and the Intergovernmental Oceanographic Commission (IOC), provides the governance by which ships are recruited by NMHSs for making and transmitting meteorological observations. For near-real-time applications, the data are delivered to users *via* the WMO Global Telecommunication System (GTS). VOS meteorological reports are a unique and invaluable contribution to operational meteorology and marine meteorological services (Fletcher, 2008).

Requirements for near-surface ship observations to support numerical weather prediction and operational forecasting include, but are not limited to, atmospheric pressure, wind speed and direction, air temperature, relative humidity, and sea surface temperature (SST), as well as wave height, direction, and period (Anderson, 2018). A major ongoing problem is the scarcity of *in situ* data from vast areas of the world's oceans. While the near global coverage from satellite-based remote sensing helps overcome this, data from ships remain essential. Ship-based observations provide parameters that satellites cannot observe (e.g., atmospheric pressure), data from regions with gaps in satellite coverage (**Figure 1**), and validation data that are relevant to forecast operations. Beyond their use in numerical weather prediction, data from ships are also used operationally in the preparation of forecasts and warnings, including those for the Global Maritime Distress and Safety System, and to support the routing of ships to avoid adverse weather and efficiently transport cargo (International Maritime Organization [IMO], 2018).

An example of ship observations assisting in the issuance of a warning for the high seas of the North Atlantic occurred July 29, 2015, when a ship observation on the near-west side of an extratropical cyclone reported hurricane-force sustained winds of 65 knots (**Figure 2**). The low-pressure center in the 6-h forecast of the National Centers for Environmental Prediction Environmental Modeling Center's Global Forecasting System model (**Figure 3**) was located too far west and was too weak. Using the ship observation, a forecaster at the National Weather Service's Ocean Prediction Center upgraded high seas forecasts to include a hurricane-force wind warning for the cyclone. While the skill of global numerical weather prediction models is increasing (Bauer et al., 2015), human guidance still adds value to daily forecasts, watches, and warnings. This is especially true for high-impact events, specifically in the 12–48 h of the forecast period (e.g., Stern and Davidson, 2015).

Ship-based observations transmitted *via* the GTS are also essential to the growing field of operational oceanography, which provides a basis for our knowledge of the marine environment on timescales sufficient to support Blue Growth applications. Operational short-term ocean prediction systems (e.g., Bell et al., 2015) require both surface and subsurface observations of

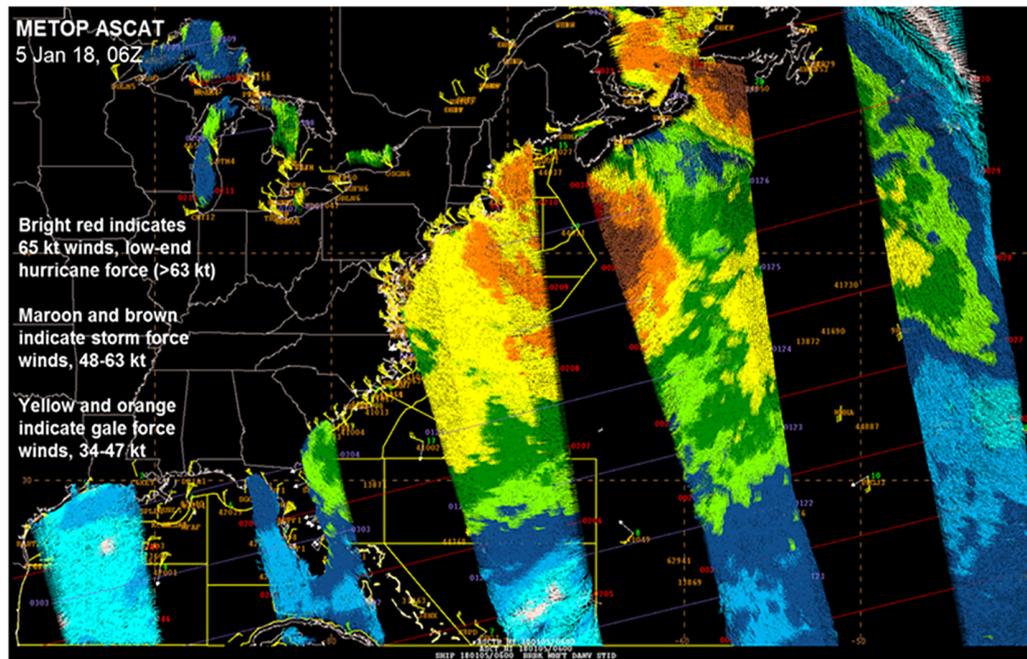

FIGURE 1 | EUMETSAT MetOp Advanced Scatterometer data (colored swaths), with available ship observations (using standard synoptic station notation), from 0600 UTC on 5 January 2018. Courtesy of National Oceanic and Atmospheric Administration, National Weather Service, Ocean Prediction Center.

sea water temperature, salinity, and ocean currents. Ships can provide these observations (Table 1), although SST is the most commonly measured parameter on ships, for direct assimilation or to support satellite product development (see Development and Evaluation of Models and Products) prior to assimilation of satellite products into the model.

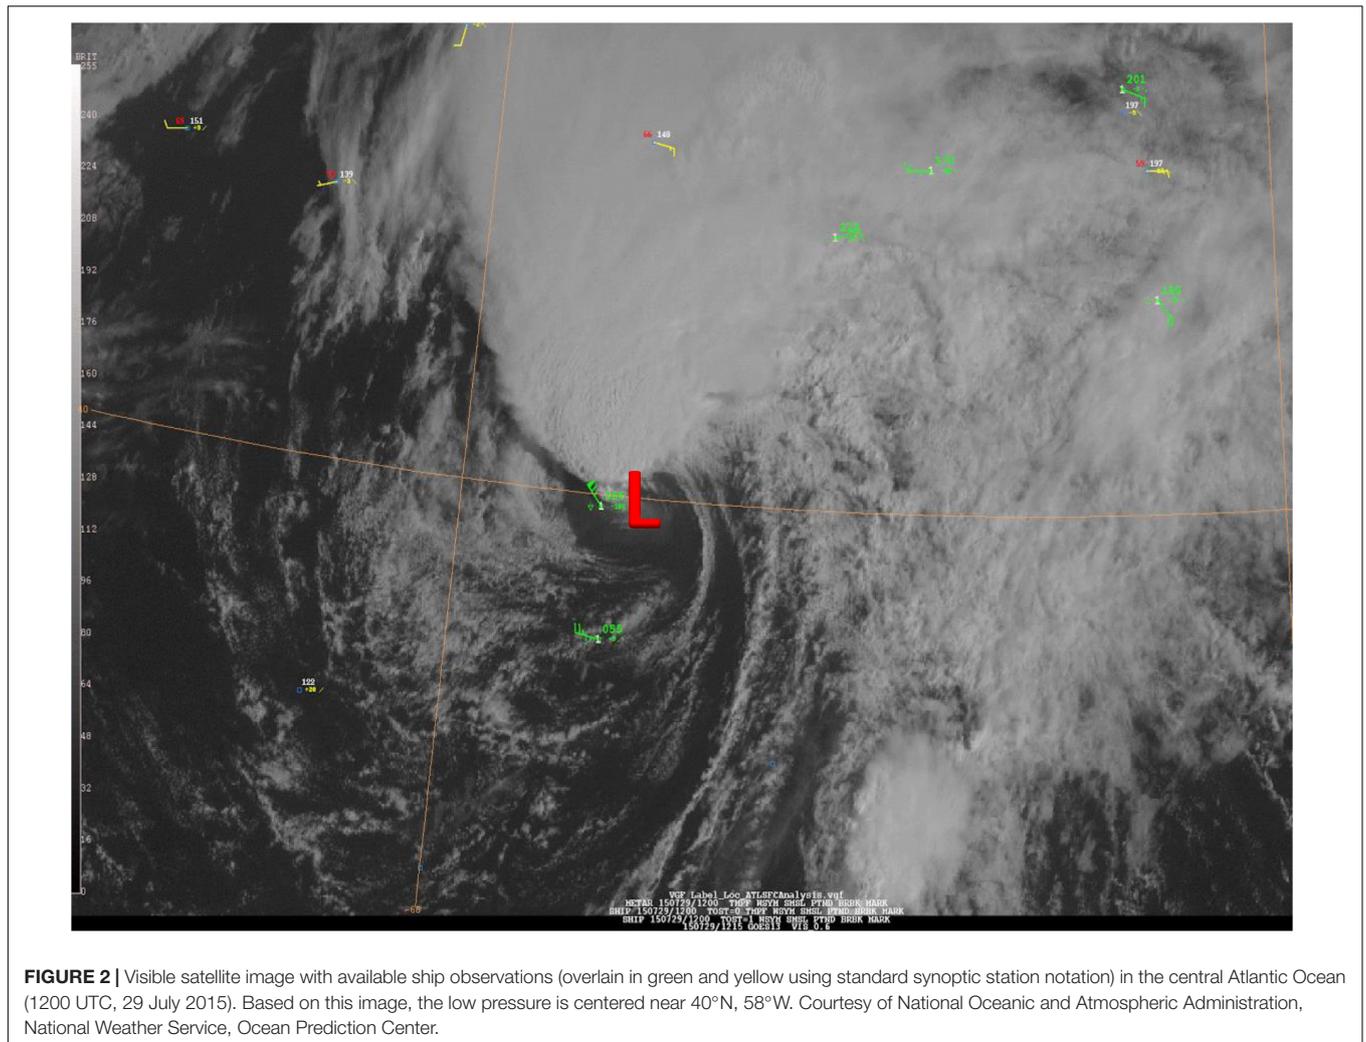

Climate Monitoring, Assessments, and Services

Observations from ships are an essential component of the Global Climate Observing System (GCOS) and complement observations from other marine networks (e.g., Argo, drifting buoys, and moorings). The key challenge is that the surface marine climate record is mainly constructed from observations originally collected for other reasons, typically from weather logs that are part of normal ship activities or to support numerical weather prediction. Even among those observations collected for climate applications, the motivation was to establish normal conditions rather than to quantify variability and long-term change. Requirements for the construction of long-term surface marine records are detailed in Kent et al. (2019). Ship observations of ECVs and EOVs (Table 1) are far more valuable for the construction of climate records when they are a multivariate record described by extensive platform and observational metadata, including information related to quality assurance and quality control, uncertainty estimation, and bias adjustment. Routine weather reports from the VOS Scheme contribute to GCOS “comprehensive” global networks (Global Climate Observing System [GCOS], 2016), providing frequent sampling over much of the ocean to capture variability. Research

vessel observations are often used in a similar way. Although research vessels are fewer in number, hence covering less of the ocean on any given day, they typically collect observations at higher temporal frequency (sampling rates of 1 min or higher) with sensors that are designed for research-quality observations; thus, they have the potential to be used for evaluation, quantification of uncertainty, and as “baseline” or “reference” observation stations.

Climate services provide climate information to assist decision-making. The sources of information used range from observational data, through model forecasts and hindcasts, to climate projections and socioeconomic data, with timescales ranging from a few days to decades and centuries. Marine climate services include applications in both coastal and open ocean environments, ranging from design criteria for vessels, offshore structures, and coastal defenses to seasonal prediction and forecasting seasonal energy production and demand. Examples of developing climate services can be found through the European Union Copernicus Climate Change Service and the Sectoral Information System (e.g., for global shipping, a demonstration project can be found at <https://climate.copernicus.eu/global-shipping-project>).

The variables required to develop climate services include, *inter alia*, the following: air and sea temperature and humidity (e.g., for human safety/comfort operating at sea and seasonal prediction); wind, waves, and pressure (e.g., to establish design criteria and wind/wave loading of structures, coastal inundation, and ship routing); and oceanographic parameters (for seasonal prediction, evaluating ecosystem health, and studying biogeochemical cycles). Historically, ship observations have been the primary source of many of these variables

(**Table 1**) and underpin many of the climate datasets used (e.g., Kent et al., 2019).

More recently, ship observations are used indirectly through assimilation into model forecasts, hindcasts, reanalyses, and resulting databases (e.g., Pilar et al., 2008; Geyer and Rockel, 2013; von Schuckmann et al., 2018) to support climate studies. Models provide a self-consistent and spatiotemporally complete representation of the atmosphere and oceans beyond what can be sampled directly. Ship observations, alongside other ocean, land-based, and satellite observations, are now regularly assimilated into global and regional climate analyses that depict the four-dimensional evolution of our environment. Atmospheric reanalyses (e.g., Gelaro et al., 2017), ocean reanalyses (e.g., Storto et al., 2016), coupled reanalyses (e.g., Saha et al., 2010), and ocean/sea-ice state estimates assimilate observations from various sources into domain models (ocean, land, atmosphere, and ice) used for a range of climate applications. New approaches combining components *via* coupling are emerging (Laloyaux et al., 2018), while traditional approaches continue to mature. Multivariate climate reanalysis products form the

backbone of climate services, describing the past and present states of the climate.

The first use of ship data to describe the steady ocean circulation using different hydrographic datasets and inverse box applications was introduced in the 1970s (Wunsch, 1978). Since then, a great variety of integrated ship data products have been developed, demonstrating the essential role of ship data in producing ocean state estimates, including, but not limited to, circulation, ocean energetics, air–sea exchange, property fluxes, dynamical balances, and ventilation and mixing. For many applications, such gridded information forms the tip of the iceberg of Earth’s environmental digital history, alongside geological and biological datasets (Keim, 2011).

Development of datasets to support climate studies began in 1963 when the international exchange of delayed-mode marine climatological data was put in place through establishment of the WMO Marine Climatological Summaries Scheme. The JCOMM Expert Team on Marine Climatology updated the summaries scheme to facilitate timely exchange, access, and long-term preservation of marine climate data (Pinardi et al., 2019). This new Marine Climate Data System (MCDS), endorsed in

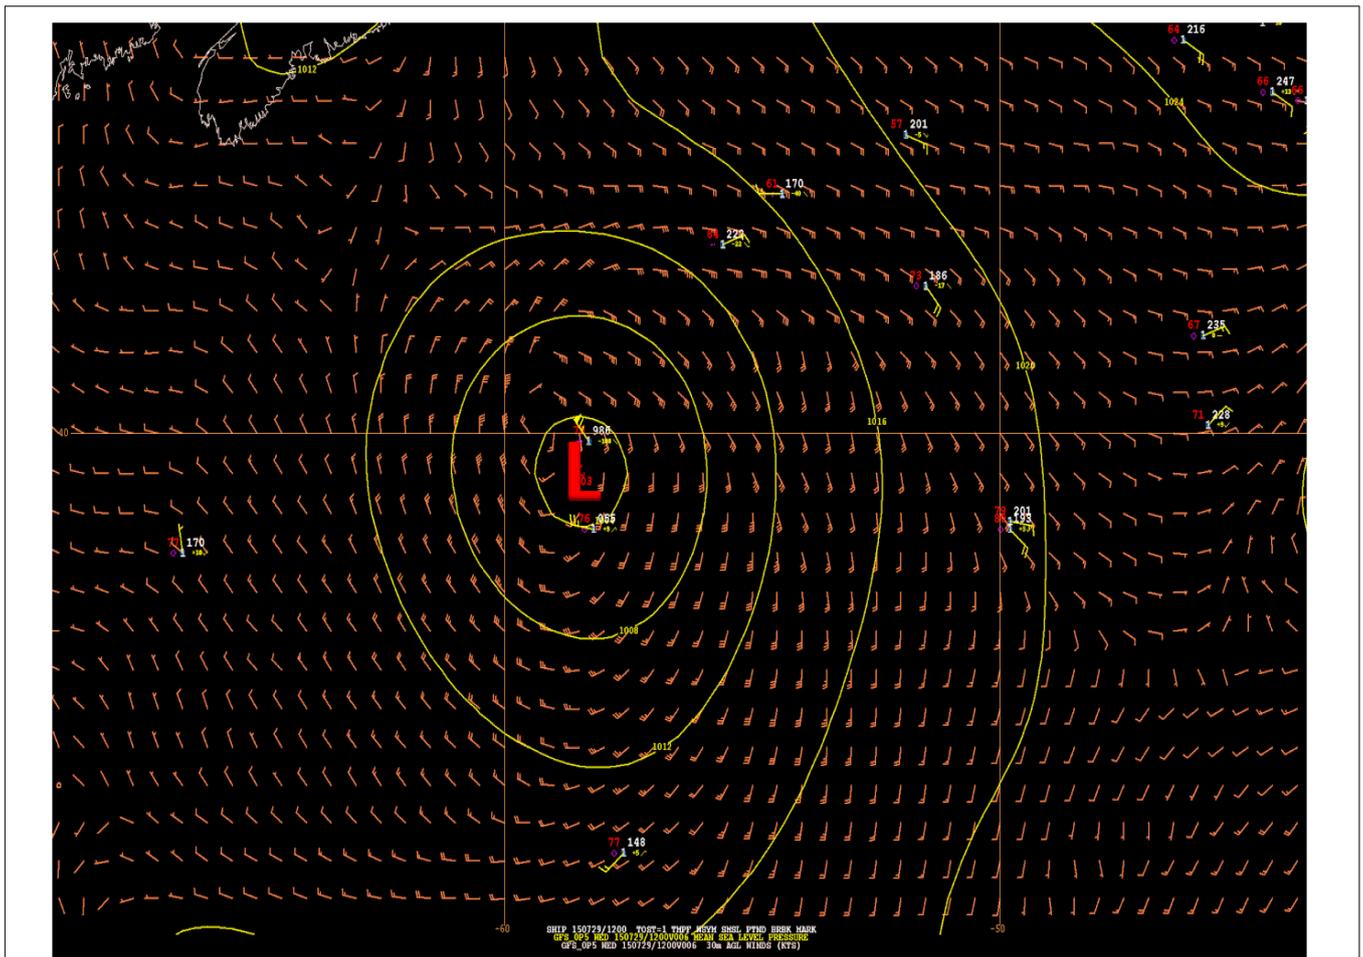

FIGURE 3 | GFS model 29 July 2015 0600 UTC 6-h forecast, valid 1200 UTC 29 July 2015, with available ship observations using standard synoptic station notation. Isobars are drawn with yellow lines, and the model wind field is indicated by wind barbs in orange. The low pressure center is located near 39°N, 58.5°W. Courtesy of National Oceanic and Atmospheric Administration, National Weather Service, Ocean Prediction Center.

2012 by JCOMM, provides a JCOMM-wide unified approach to data management and higher-quality climate observations. The MCDS is now in the implementation phase and encompasses a data flow structure with defined roles and tasks to be applied to all data types across JCOMM. In 2016, JCOMM confirmed the establishment of the first MCDS Center for Marine Meteorological and Oceanographic Climate Data. Since then, additional centers have been established and the MCDS will be operational by 2020.

Ship data, as in the International Comprehensive Ocean-Atmosphere Data Set (ICOADS; Freeman et al., 2017), are among the most important contributions to reanalyses (Buizza et al., 2018) and for climate studies. The surface marine observational record is almost entirely based on ship observations prior to the 1980s (Freeman et al., 2017) with records for some parameters dating back to approximately 1750 (Table 1). Efforts to extend and enhance the climate data record *via* data rescue (Brönnimann et al., 2018) are often motivated by the need to improve reanalyses (e.g., Allan et al., 2011). With the top few meters of the ocean containing as much heat as the atmosphere,

global SST observations from ships are essential to develop longer reanalyses such as the 20th Century Reanalysis (Compo et al., 2011) or the ERA20C (Poli et al., 2016), which aim to estimate past climate and weather. These reanalyses also assimilate ship surface pressure observations (Figure 4) for a realistic timing of the synoptic events.

Development and Evaluation of Models and Products

Production of models or data products, for either climate research or operational needs, requires careful assessment of the underlying numerical system or data processing algorithms, evaluation of the model skill and realism, and definition of its application domain (i.e., scales and processes that are resolved by the model or analysis). Ship observations are routinely used in model development studies to demonstrate the system's stability, identify deficiencies in model physics, and derive new numerical schemes and parameterizations to enhance the system's overall performance. The majority of model evaluation studies (e.g.,

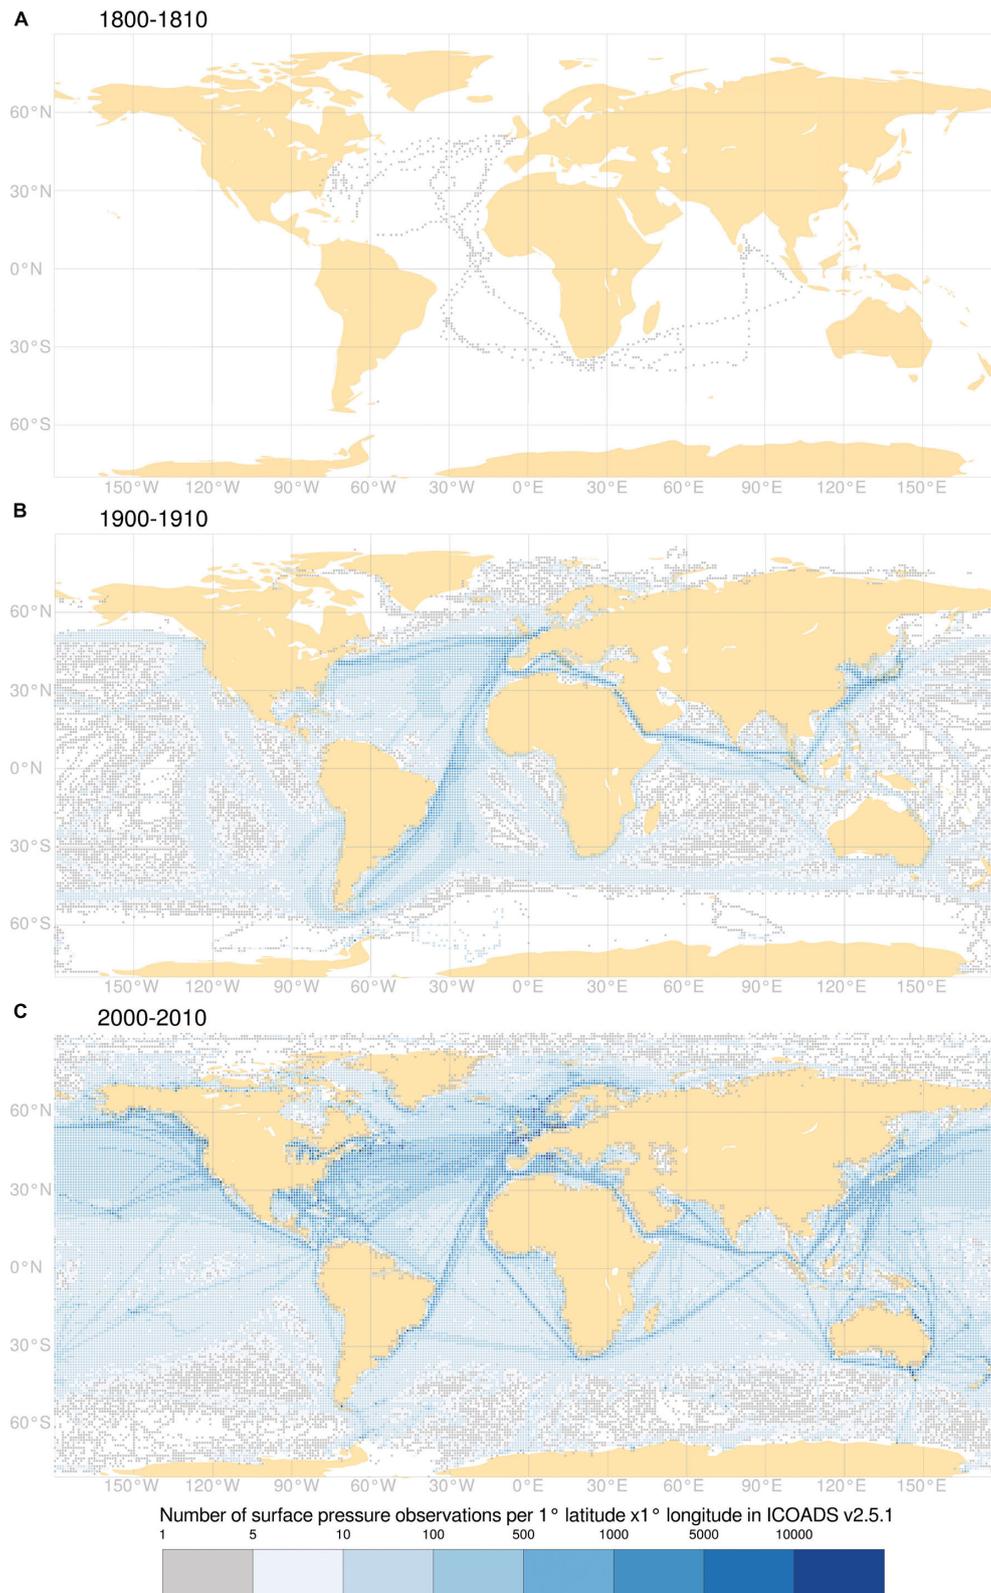

FIGURE 4 | Data counts per $1^\circ \times 1^\circ$ latitude, longitude of surface pressure observations by ships in ICOADS (version 2.5.1: Woodruff et al., 2011), used by the National Oceanic and Atmospheric Administration and European Centre for Medium-Range Weather Forecasts 20th century reanalyses, for three selected time periods: **(A)** 1800–1810, **(B)** 1900–1910, and **(C)** 2000–2010.

Smith et al., 2001, 2016a; Delcroix et al., 2011; Perlwitz et al., 2015; Jones et al., 2016) are completed using historical (delayed-mode) shipboard observations; however, real-time ship observations can be used to validate operational models and near-term forecasts. Another requirement for evaluation studies is for the shipboard observations to be independent of the observations assimilated into the model. For this reason, it is necessary to provide model feedback metadata (ship identifier, vessel type, data quality, etc.) that allow users to select observations that are not assimilated (frequently, these observations are from research vessels and other research platforms that are not routinely transmitted over the GTS). To evaluate fluxes and other derived fields within numerical models, it is essential to have multivariate observations (e.g., winds, SST, air temperature, pressure, and humidity) that are taken simultaneously (or as near as possible to the same time and location). This is one great advantage of ships as an observing platform—they are capable of carrying numerous instrument systems and making simultaneous observations.

Ships also provide observations of SST, waves, sea ice, salinity, chlorophyll concentration, humidity, air temperature, and winds (Table 1), each of which has corresponding remote sensing systems deployed on Earth-orbiting satellites or aircraft. Remote sensing communities rely on surface observations to develop and validate retrieval algorithms used to derive geophysical parameters from the measurements made by remote sensing systems. For example, satellites can measure a backscatter from the ocean surface that is then used to derive wind direction and speed (Naderi et al., 1991) or radiance, which is used to derive air temperature and humidity. Ship-based observations are used to develop and refine these retrieval algorithms (e.g., Benallal et al., 2016; Jackson and Wick, 2016). Satellite-based estimates of chlorophyll concentrations rely on *in situ* measurements of surface water optical properties to refine and calibrate retrieval algorithms (McClain, 2009; Brewin et al., 2016). In addition, *in situ* ship measurements are used to validate and evaluate products developed from one or more remote sensing systems (e.g., Bourassa et al., 2003; Liman et al., 2018). The remote sensing community is seeking observations taken at high temporal sampling rates (1 min or less) to support precise collocations with satellite measurements and from a wide range of ocean environments (e.g., tropics to polar regions and light winds to storm conditions) to help constrain the retrieval algorithms and ensure the measurements are accurate across all oceanic and atmospheric conditions. Ships can also measure the multiple, simultaneous parameters needed to adjust observations measured at various sensor heights to a common reference height or depth. The high horizontal resolution of ship measurements also resolves sub-footprint processes, helping to interpret and validate the satellite measurements (e.g., Kolodziejczyk et al., 2015b; Boutin et al., 2018).

Monitoring and Process Studies

Ship-based observations are used for a wide range of activities to monitor the marine environment and to conduct research into the fundamental processes that govern the interactions between the ocean and atmosphere. Observations of air/sea

temperature, wind speed, relative humidity, radiation, and the concentration of dissolved gasses are critical in quantifying atmosphere–ocean fluxes of heat, freshwater, momentum, and gasses. Knowledge of these fluxes over the global ocean is important in understanding ocean dynamics, biogeochemical cycling, and the global water cycle. For example, SST, wind velocity, air temperature, and relative humidity are key factors in determining the magnitude and direction of the air–sea fluxes of momentum and latent/sensible heat (e.g., Smith et al., 2016b). Similarly, water temperature, wind speed, and the air–sea difference in the partial pressure of carbon dioxide ($\Delta p\text{CO}_2$; which is a component of the inorganic carbon ECV) are important factors in determining the air–sea flux of carbon dioxide (CO_2 ; Watson et al., 2009). Ocean acidification is recognized as a major threat to the marine environment and methods for measuring ocean pH directly or indirectly *via* automated systems are just becoming available for use on ships (e.g., Shanguan et al., 2019). The water cycle drives tropical atmospheric circulation and is therefore a key component of climate and weather. Ship-based observations of salinity and temperature provide *in situ* data to monitor the water cycle response to increasing global mean temperature (e.g., Terray et al., 2012). On smaller scales, diurnal heating or freshwater input (from precipitation, rivers, or melting ice) can cause a stable density stratification with vertical gradients in temperature and/or salinity over the upper few meters of the ocean (e.g., Tomczak, 1995; Kawai and Wada, 2007). This stratification can affect the air–sea fluxes of heat and moisture, and a better understanding of its formation, evolution, spatiotemporal statistics, and effect on air–sea interaction and satellite remote sensing measurements is needed. The presence of near-surface temperature and salinity gradients (e.g., Reverdin et al., 2013; Anderson and Riser, 2014; Boutin et al., 2018) complicates the comparison between near-surface *in situ* and skin-layer satellite measurements, which are made at different depths. One way to address this issue is to make simultaneous measurements at multiple depths to characterize the near-surface vertical gradients and hence the *in situ*–satellite comparisons.

Atmospheric composition and processes over the oceans in general are poorly known. The flow of chemicals from land to ocean and changes in atmospheric composition (e.g., levels of pollution) have been greatly increased by human activity and have the potential to perturb ocean ecosystems. Working Group 38 of the United Nations' Joint Group of Experts on the Scientific Aspects of Marine Environmental Protection¹ and others reveal that atmospheric deposition represents the major route by which nutrients, such as iron and nitrogen, and contaminants, such as cadmium, lead, and copper, reach the open ocean (Duce et al., 1991; Jickells et al., 2017). These substances are removed relatively quickly from the atmosphere, than are less reactive components (e.g., CO_2), creating strong concentration gradients over the oceans. Accurate estimates of these atmospheric inputs, *via* deposition samples, are vital to improve estimates of atmospheric inputs into the ocean (e.g., Baker et al., 2010; Powell et al., 2015) and for prediction of their ecological impacts.

¹<http://www.gesamp.org/work/groups/38>

In several cases, especially for the trace metals, knowledge of the chemical form of the substance that is deposited is needed, since insoluble forms are typically unavailable to biota. Direct observation of atmospheric deposition chemical composition is therefore essential. Multi-year averaged observation- and model-based estimates of the inputs of these nutrients and contaminants are in good agreement at the ocean basin scale but are more difficult to evaluate at the higher resolutions relevant to ecosystem impacts (Baker et al., 2010, 2013). Improved model flux estimates require improved data on the atmospheric concentrations of these components to test and validate models. A step change in observations of nutrients and contaminants over and into the ocean, ideally using commercial ships, is required if we are to provide reliable estimates of atmospheric deposition at appropriate scales to quantify the impact of these atmospheric fluxes.

Building knowledge of atmospheric composition over the oceans requires a significantly greater number of direct observations. Several Global Atmosphere Watch (GAW) stations (e.g., Mauna Loa, Mace Head, Cape Verde, Cape Grim)² are able to sample air that arrives from the open ocean, but these observatories are located on land and routinely measure terrestrial signals. Presently, the vast majority of sampling for aerosol composition over the ocean is done from research vessels, with a focus on the Southern Ocean. This allows researchers to develop a better understanding of the composition and chemistry of the marine atmosphere, which is important for climate science because understanding "pristine, pre-industrial-like" environments is needed to reduce climate model uncertainty (Carslaw et al., 2013).

Supporting monitoring of the marine environment and process studies requires measuring or estimating the range of both surface ocean and atmospheric variables simultaneously. Only limited observational platforms are currently able to obtain these measurements, namely, ships (e.g., Berry and Kent, 2011) and surface moorings (e.g., Ogle et al., 2018). Ships also provide a platform to support sensors that require human intervention and monitoring. Additionally, routine underway observations from well-maintained and well-sited sensors on ships can provide information to quantify variability and co-variability of ECVs and EOVs. Improved quantification of short-term variability, including diurnal variations, would enable a more informed comparison of observations separated in space or time or that resolve different spatial or temporal scales.

PRESENT CAPABILITIES AND CHALLENGES

Observations

Weather, sea state, and surface ocean observations have been collected and disseminated on a systematic basis for over 200 years (Table 1). Observations from ships are now relayed to shore in real time, providing important information on meteorological conditions at sea, along with a long-term record

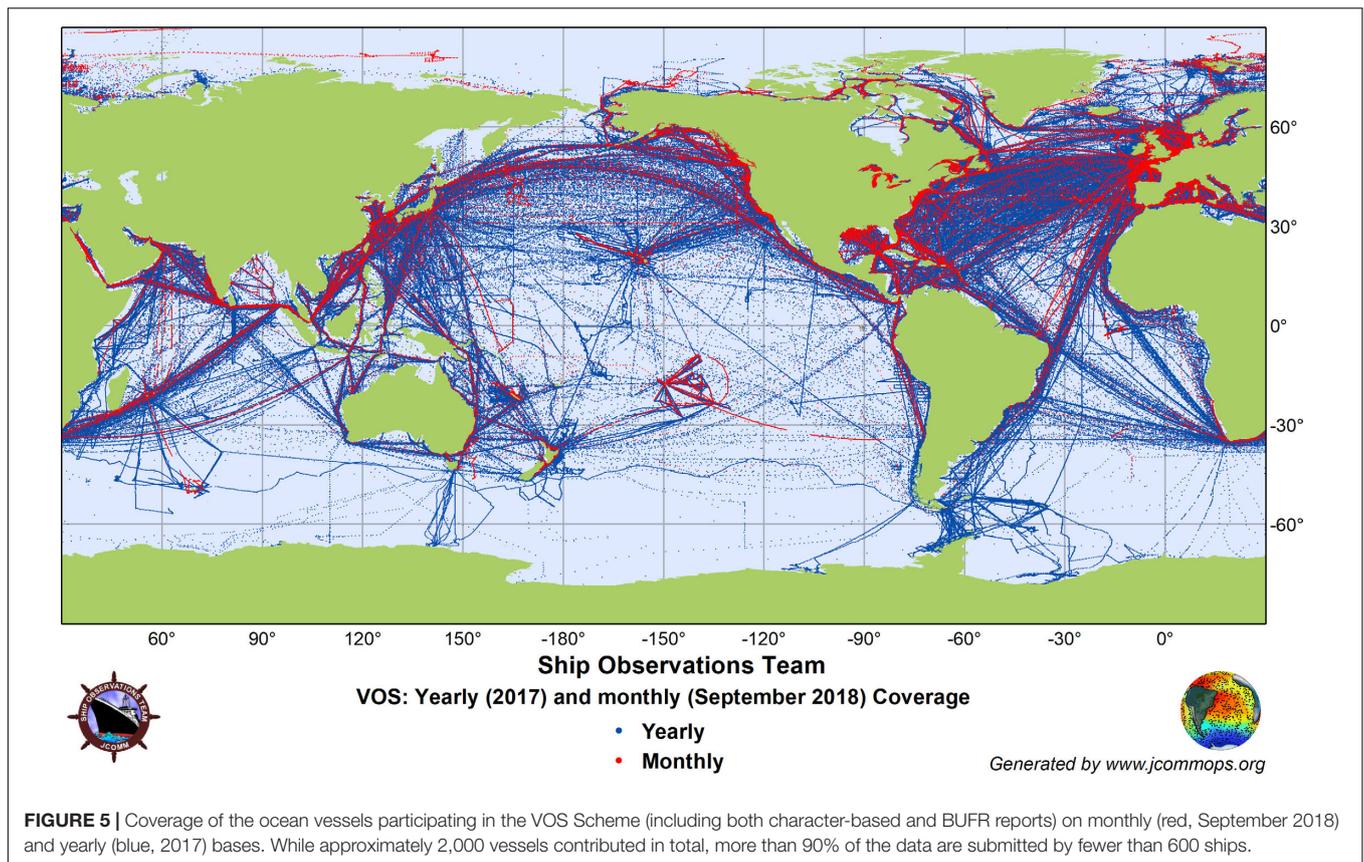

of observations important for climate applications. Traditionally, observations were made using human-read instrumentation supplemented by visual observations made by officers serving on ships operating worldwide. In recent decades, there has been a substantial shift toward shipboard automatic weather stations and a decline in the visual observations.

The VOS Scheme is the primary source of real-time meteorological observations from ships (Figure 5) and the main source of several ECVs, including air temperature and humidity. Unfortunately, the number of VOSs has declined over the last 30 years. This decline can be attributed to a number of factors, including, but not limited to, (1) successive changes in ships' ownership and widespread use of flag of convenience; (2) reduction in the number of crew members aboard vessels; (3) concerns of vessel owners and operators, for perceived or actual economic as well as legal reasons, not to provide any meteorological information that could reveal a vessel's geographical position; (4) ship companies claiming not to be able to take up meteorological tasks due to budgetary constraints; (5) perception that increased satellite and available buoy observations are sufficient and ship observations are not used; and (6) financial strain on NMHSs to recruit and retain vessels in national VOS fleets (JCOMM, 2002; Kent et al., 2010). But while the number of ships has declined, new technologies, such as automatic weather stations and electronic logbooks, have led to an increased number of reports per ship from a smaller VOS fleet, as well as some increase in the quality of observations (Ingleby, 2010). However, fewer ships (typically only 300–400 may be reporting at any given synoptic hour) mean less coverage of the oceans (e.g., Berry and Kent, 2017). The numerical weather prediction need for atmospheric pressure data has led to installation of pressure-only automatic weather stations, and this increase in pressure observations has been offset by a reduction in measurements of other ECVs (e.g., air temperature, humidity, clouds, weather, waves, sea ice, and sea state) required by the marine climate community.

Increasing satellite communications bandwidth continues to reduce the latency and to increase the volume of real-time VOS data transmissions. The recent introduction of table-driven codes (the Binary Universal Form for the Representation of meteorological data or BUFR) to replace traditional alphanumeric codes (i.e., FM-13 SHIP Code) will help to increase the availability of high-resolution data and more detailed metadata in the coming years. However, the transition to BUFR is ongoing, and challenges remain for real-time data systems relating to varying ship-to-shore data exchange formats, the shore-side conversion to BUFR, and ensuring that all required data and metadata make it from real-time observations into the long-term climate archives (Kent et al., 2019).

Meteorological observations on research vessels include both the standard weather observations made to support the VOS Scheme and also dedicated air-sea interaction experiments that directly measure turbulent exchanges (i.e., momentum, heat, water, gasses, and aerosols; Weller et al., 2008), radiative fluxes (typically in wavelength bands required to measure the upwelling/downwelling thermal infrared flux, solar radiation, and photosynthetically active radiation), precipitation

²<https://gawsis.meteoswiss.ch/GAW SIS/index.html#>

(e.g., Galloway et al., 1983; Klepp, 2015), and atmospheric composition measurements (Baker et al., 2010, 2013). The longest observation-based estimates of surface heat and momentum fluxes are based on ICOADS (da Silva et al., 1994; Berry and Kent, 2011) and currently begin in the middle to late 20th century. Research vessels also measure variables necessary to interpret flux observations and develop parameterizations such as mean conditions (wind speed and direction, air and sea temperatures, humidity, pressure, pCO₂, and salinity) and sea-state parameters (such as wave heights, periods, lengths, directions, spectra, and whitecap fraction). Although capability to make comprehensive flux measurements on other types of ships, moored buoys, or autonomous surface vessels is developing rapidly (Cronin et al., 2019; Swart et al., 2019), research vessels will be the primary platform used to evaluate data from these emerging technologies.

Research vessel observations are geolocated *via* the high-precision navigational systems typically deployed to support research vessel science operations. Research vessels often carry both standard weather instruments of the type supplied to vessels by NMHS to contribute to the VOS Scheme and sophisticated automatic weather stations, which are frequently custom designed and built by individual research vessel operators. Although research vessels may transmit a subset of their observations in real-time *via* the GTS, most observations are recorded and used in delayed mode, typically as part of an end of cruise dataset. There are no international standards for meteorological parameters to be sampled by research

vessels, but since 2005, the U.S.-funded Shipboard Automated Meteorological and Oceanographic System (SAMOS) initiative (Smith et al., 2018) has provided guidance to the research vessel community. SAMOS has developed standard data formats for research vessel ship-to-shore data exchange, distribution, and archival along with training materials for marine technicians on research vessels with regard to sensor selection, siting and exposure, data processing, and quality evaluation.

Most research vessels, selected commercial vessels (e.g., Alory et al., 2015; Gaillard et al., 2015), and more recently racing yachts (e.g., Kramp et al., 2010)³ are equipped with flow-through sea water systems that measure sea temperature and salinity [using a thermosalinograph (TSG)], fluorescence, transmissivity, and other biogeochemical properties (e.g., oxygen, alkalinity, chlorophyll, and carbon). Flow-through water sampling systems on ships typically take water from a single port in the hull at a depth of a few meters. There is large uncertainty on this depth on commercial ships, as it can vary by several meters depending on the ship's load; moreover, the incoming water can be strongly mixed by the ship's wake. While these observations are invaluable for gaining information on the temporal variability in the ocean surface, they cannot provide information on vertical gradients of water properties or concentrations. To study vertical gradients in temperature, salinity, gas concentrations, and other properties,

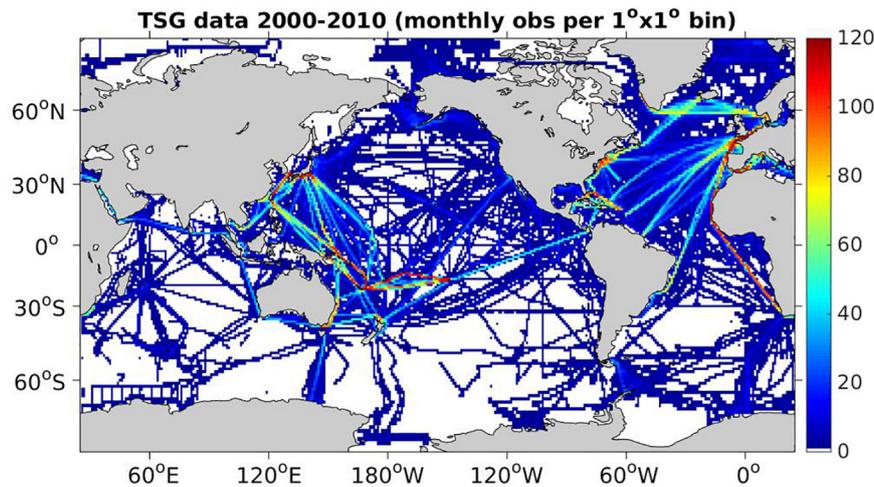

FIGURE 6 | Density map of global real-time and delayed-mode thermosalinograph observations covering 2000–2010 from multiple data sources, including the following: French Sea Surface Salinity Observation Service; GOSUD; SAMOS; National Oceanic and Atmospheric Administration Atlantic Oceanographic and Meteorological Laboratory, Pacific Marine Environmental Laboratory, and National Centers for Environmental Information; Japan Agency for Marine-Earth Science and Technology; Japan National Institute for Environmental Studies; VOS Nippon; Commonwealth Scientific and Industrial Research Organisation; Australian Antarctic Division; and the Alfred Wegener Institute for Polar and Marine Research.

the Applied Physics Laboratory at the University of Washington installed through-hull ports for sensors and water sampling at depths of 2 and 3 m (below mean water level) aboard three global-class research vessels (*R/V Thomas G. Thompson*, *R/V Roger Revelle*, and *Ronald G. Brown*; Jessup and Branch, 2008; Asher et al., 2014). When instrumented with salinity sensors (Asher et al., 2014), the data from the instruments in these ports combined with the ship's own TSG sampling at a depth of 5 m provide profiles of temperature and salinity in the upper ocean. These data have proven valuable in studying diurnal warm layers and rain-formed salinity gradients and could be readily extended to include underway measurement of vertical gradients in alkalinity, partial pressure of carbon dioxide, and biological properties of interest. Additionally, flow water systems can be used to pump water through filters to measure concentrations and conduct analyses of particulate, plankton, or microplastics.

The global network of ship-based TSG measurements (Figure 6) has enormously increased our ability to study variations in ocean salinity. Ongoing projects managing flow-through water data include SAMOS, the U.S. Rolling Deck to Repository⁴, Global Ocean Surface Underway Data (GOSUD; Kolodziejczyk et al., 2015b), Ferryboxes (Petersen, 2014)⁵, and the Surface Ocean Carbon Observing NETWORK (Wanninkhof, 2019). Although profiles of surface temperature and salinity are available at single points through Argo (Roemmich et al., 2009; Riser et al., 2016), conductivity–temperature–depth (CTD) casts (e.g., Talley et al., 2016), and moorings (McPhaden et al., 1998; Bourlès et al., 2008), only TSGs on ships, drifters, and autonomous surface vessels provide the capability to measure high-horizontal salinity variations in frontal and

sub-mesoscale structures (e.g., Kolodziejczyk et al., 2015a). Repeat transects of ships instrumented with TSGs provide long-term salinity time series at relatively low cost (e.g., Alory et al., 2015). Additionally research vessels provide TSG (along with carbon) measurements in ocean regions outside of well-traveled commercial shipping lanes.

Regardless of the vessel, making continuous SSS measurements poses significant challenges. TSGs on research vessels can be serviced regularly, while those on commercial ships or autonomous surface vessels can only be inspected and serviced during harbor calls. Salinity measurements tend to drift due to sensor fouling in turbid waters or abruptly shift after calls in dirty harbors. Therefore, measurements often need to be calibrated with independent SSS data, from water samples collected onboard and later analyzed, from CTD casts done on the same ship, or from collocated Argo profiles. External temperature sensors cannot always be installed at the water intake, and the temperature measured by the TSG, often located in a hot engine room, is then biased warm. Systems without a flow meter can also have undetected data degradation when flow is insufficient.

The recent advancement of fairly small (~2–7 m in length) and robust autonomous surface vessels have also provided opportunities for air–sea flux measurements. Miniaturized sensors, improved battery capacity, and energy harvesting techniques (currently limited to using wind, waves, and sunlight) have allowed these robotic platforms to support mainstream ocean observing approaches. Examples include Wave Gliders and SAILdrones, but there is an ever-growing number of platforms emerging (e.g., Sailbuoy, Autonaut, Navocean's Nav2, and C-Enduro). Autonomous surface vessels are proven to work well in a variety of regions ranging from the tropics to the ice-free polar oceans and in extreme conditions such as enduring multi-month

⁴<https://www.rvdata.us/>

⁵www.ferrybox.org

missions in the Southern Ocean (e.g., Monteiro et al., 2015; Schmidt et al., 2017; Thomson and Girton, 2017) or transecting through hurricanes (Lenain and Melville, 2014).

Several projects have shown over the last decade that sailing expedition vessels and ocean racing yachts can not only deploy autonomous instruments (drifters and floats) in sea areas with very limited or no other shipping (e.g., Arctic and Antarctic waters) but also directly gather ocean–atmosphere data with innovative underway instrumentation (Choquer, 2014). Such projects are often well covered by the media and thus help in reaching out to a broader public. The emerging data are of sufficient quality for many operational or research applications (Kramp et al., 2010), for example, the validation of SMOS remotely sensed salinity (Salat et al., 2013). The IOC has signed several cooperation agreements, including for the joint organization of the second international ocean research conference⁶. The sailors are highly motivated and sometimes submit data gathered with their own instruments and at their own satellite cost (Kramp and Rusciano, 2016). Several round-the-world races (Volvo Ocean Race, Barcelona World Race, and Vendée Globe) now comprise corresponding science projects and will thus create valuable time series from particularly the Southern Ocean.

Presently, RVs also provide the primary platform capable of measuring a wide range of chemical and biogeochemical properties and processes within the atmosphere and ocean, including atmospheric deposition of nutrients and contaminants (e.g., Powell et al., 2015) and characterization of atmospheric aerosols in the marine troposphere (Quinn and Bates, 2005). Examples include the collection of wet deposition samples onboard research vessels and the deployment of two dedicated atmospheric sampling laboratories on the research vessel *Investigator*⁷, which measure major tropospheric long-lived greenhouse gasses along with carbon monoxide, ozone, radon, and a broad range of aerosol microphysical and chemical properties. The *Investigator* routinely transits the Southern Ocean, providing atmospheric and oceanic data in a region with minimal anthropogenic influence; however, reliance on research vessels and a limited number of coastal and island stations provides only limited measurements from a small fraction of the oceans. Aerosol sampling (e.g., Martino et al., 2014), sampling for climatologically important trace gasses (Nara et al., 2011, 2014; Yokouchi et al., 2012), and potentially deposition sampling from ships of opportunity is also possible but requires fairly high levels of support from the ship's crew and operators. Automation may simplify this sampling in the future, and further sampler development (e.g., automated switching of sampling cassettes in the case of aerosol collection) is required to decrease the impact of sampling on shipboard operations.

Although the focus of this paper is primarily on physical and chemical observations, a number of biologically relevant measurements can be made by ships. In addition to sensors in flow water systems that measure pH, transmittance, fluorescence,

chlorophyll, oxygen, and inorganic carbon, we note that the Continuous Plankton Recorder (CPR) has been deployed regularly from a select group of commercial ships since the 1930s⁸, with the initial aim of improving knowledge of zooplankton stocks for fisheries management purposes. The CPR has also delivered an immensely valuable long-term record of ocean biological variability and how marine species respond to climate change (e.g., Beaugrand and Kirby, 2018). However, the nature of the CPR operation is necessarily based on small numbers of ships with subsequent painstaking laboratory analyses of the collected samples and, hence, is rather different to the approach of using a wide range of research, commercial, and private ships discussed herein.

Metadata

Almost as important as the measurements themselves are the associated metadata that provide supporting information about host vessels, instrumentation, and the data. A sophisticated metadata catalog allows for detailed and standardized quality monitoring of individual vessels and instruments, as well as the health of the network of VOS, research vessels, and complementary private and autonomous vessels. WIGOS has developed metadata requirements (WMO, 2017) that are designed to make the observations (e.g., **Table 1**) useful to downstream users. Mapping community-developed metadata schemas (e.g., VOS, SAMOS, and GOSUD) to identify overlaps and gaps with respect to these requirements is an ongoing challenge.

Information on the ship's characteristics and meteorological instrument type and siting is also important for climate studies. Different observing methods have different error characteristics, with systematic errors leading to biases in derived climate products if not corrected. When the observing methods change over time, the mean biases also change, leading to artificial signals being introduced into the climate record. For example, the height at which air temperature observations have been made have changed by several tens of meters since the late 1800s. If unaccounted for, this would result in the recent climate warming being underestimated by 0.25°C over the past 100 years and by 0.1°C over the past 30 years (Kent et al., 2013). Conversely, if not accounted for, the change from SST measurements made using buckets to engine room intakes would result in an overestimation of the change over the last 100 years (Kent et al., 2017). To account for these changes, metadata are required, such as the height or depth of observation and the measurement method.

Metadata for ships participating in the VOS Scheme are recorded in the WMO Publication No. 47 (Pub 47; Kent et al., 2007). This framework was initially developed by the WMO but is presently managed by a task team of the JCOMM Ship Observation Team. In an effort to modernize and sustain the VOS metadata record and transition from Pub 47 to the WIGOS standard, a new VOS metadata database is being implemented and managed by the JCOMM Observations Programme Support Centre (JCOMMOPS). While Pub47 is an extensive metadata schema, there are only five mandatory metadata fields required to register a ship within the VOS Scheme: recruiting country,

⁶<http://iocunesco-oneplanetoneocean.fnob.org/>

⁷<https://www.csiro.au/en/research/facilities/marine-national-facility/research-case-studies>

⁸<https://www.cprsurvey.org/>

callsign, VOS recruitment date, vessel type, and general observing practice. The present challenge is to map all the prior Pub47 metadata fields into the new WIGOS schema and define new metadata fields to support a broader user community while also working with VOS operators to collect and provide a larger number of mandatory metadata fields.

Another metadata challenge arose from an increased sensitivity of vessel owners and operators to the location and identification of their vessels (IDs) being available in near real time. There have been a number of different schemes [callsign masking, use of generic callsigns (e.g., SHIP), callsign encryption, etc.] implemented to accommodate the vessel operators and maintain their contribution to the VOS Scheme. However, these all come with limitations, for both the operational and climate communities. The loss of IDs makes quality control and blacklisting of low-quality data difficult for the operational users. The loss of callsigns makes associating the observations with vessel metadata (e.g., Pub 47) impossible, resulting in lower-quality climate monitoring products. Some attempts have been made to overcome this by expanding the range of metadata in the VOS real-time formats to include those required to fully understand and use the observations, but reporting of the additional metadata has been limited to date.

Parallel to these developments, advancements in Automated Information Systems (AIS) technology largely negate attempts to "hide" ships from unwanted interest. In light of this, JCOMMOPS is implementing a new approach for ship metadata that separates the "ship" metadata from the "observing station" metadata so that no detectable reference to the ship is included with the observation. A master list of all participating ships will be retained by JCOMMOPS to re-associate the ship with the instruments for authorized users. At present, not all countries operating VOS contribute their metadata to the international database. With the global decline in the number of manually observing VOS and the increasing number of automated systems, a fully representative metadata database containing records for all international VOS would improve the capabilities of operational monitoring and therefore maximize data availability for climate and research purposes.

Discovery metadata are required to enable users to find and retrieve the observations. This includes information such as the spatial and temporal coverage of the observations, information on the reported parameters, licensing and usage rights, and how to access and download the data. Historically, this information has been provided through project web pages, but there is an increasing requirement for the metadata to be machine readable and interoperable, driven by, *inter alia*, the following: the volume and distributed nature of the observations; ease of use and the increasing standardization of data delivery; and the development of web services. This is usually achieved through the publication of discovery metadata records for observation collections based on international standards (e.g., the ISO 19115 standard). Once published through online data catalogs, such as those provided by the IODE Ocean Data Portal⁹ and the ERDDAP software¹⁰,

the observation collections are easily locatable and retrievable through a single or limited number of locations. In addition to providing access to observational collections, systems are being developed to provide bespoke access to individual observations (e.g., through the Copernicus Climate Data Store¹¹, systems based on the OGC Web Feature Service interface).

Quality Assurance and Control

Well-documented data quality evaluation and adjustment procedures (e.g., post-deployment calibration) are essential to develop a wide range of products. Quality assurance is more of an end-to-end process where attention is given to all stages of data collection, transmission, processing, and distribution, while quality control focuses more on evaluating the observations relative to some standard of physical reality or plausibility. Quality control is typically done following the data collection and may or may not rely on or be an integral part of the quality assurance for an observing system. Additionally, the level of and approach to quality control depend on the particular purpose and use of the evaluated data. Most real-time quality control focuses on assigning flags to suspect data without removing these values. In contrast, quality control for data assimilation typically rejects suspect data or even blacklists entire data records, based on lack of agreement with the data assimilation assumptions. Finally, quality evaluation to create research data products, including the use of visual quality control, can result in a combination of value rejection and value flagging.

Real-time quality control is frequently done by NMHS and other centers to meet operational mission requirements and tends to be limited to basic quality tests (e.g., range checks, consistency, and validity of position data). The SAMOS initiative provides an example of a fully automated real-time quality control with the data processing being completed within a minute of data being received (Smith et al., 2018). Real-time quality control associated with the data assimilation process for numerical weather prediction or other operational modeling (e.g., Cummings, 2011) is basically a "buddy check" whereby the individual observations typically are compared to the first guess model fields and accepted or rejected according to tolerances set for the assimilation process.

Alternatively, a number of projects and centers [e.g., GOSUD; Kolodziejczyk et al., 2015b, SAMOS; Smith et al., 2018, Surface Ocean CO₂ Atlas (SOCAT); Pfeil et al., 2013, Global Ocean Data Analysis Project (GLODAP); Olsen et al., 2016, MCDS, World Ocean Database¹²] focus on developing research products using delayed-mode quality evaluation, each using techniques that are specialized to their area of scientific expertise. For example, data from flow-through systems, for which fouling can induce sensor drift, typically undergo preliminary automatic quality tests but often require manual evaluation from science area experts to ensure the highest data quality. For time series adjustment, pre-calibration/post-calibration data can be used along with comparison with discrete samples or collocated data. The best practice for research product development is to employ

⁹<http://www.oceandataportal.org/>

¹⁰<https://coastwatch.pfeg.noaa.gov/erddap/>

¹¹<https://cds.climate.copernicus.eu/>

¹²https://www.nodc.noaa.gov/OC5/WOD/pr_wod.html

a quality control system that only applies flags to data values and does not remove the values—decisions to accept or reject data failing quality control tests are left up to the data user. Furthermore, the best practice includes checking the consistency of the quality control and adjustment from different groups that produce delayed-mode ship data. Indeed, post-calibration or co-located measurements are not systematically available; thus, quality control and correction decisions need to be checked and discussed to provide the highest data quality for climate.

In performing observations, the traceability to the common standards also plays an important role. Such traceability especially for the measurement of the same qualities ensures that the biases are minimized and the data from different platforms can be used together (e.g., in the data assimilation systems). In the case of the physical measurements, the traceability is usually established to the international system of units through the initial calibration of equipment versus standards supported by the National Metrology Institutes. In the cases of the chemical or biological measurements, the primary standards and the measurement traceability are established by the relevant networks.

If data are accompanied by estimates of their uncertainty, this is extremely beneficial for users, allowing a simple assessment of whether the data quality meets the requirements for their application. In practice, the assignment of uncertainty estimates is challenging, and this is typically done by expert users rather than by data providers. In some cases, biases in the observations can be identified and quantified, adjustments applied, and the uncertainty in that adjustment estimated (Kent et al., 2019). The quality of the adjustment for bias and the estimation of uncertainty in observations are dependent on the availability of observational metadata (providing information on instruments, observing protocols, etc.), on information on data management practices (e.g., data precision and any conversions or calibrations applied), and, in some cases, on knowledge of the ambient environmental conditions (Kent et al., 2019).

An alternative to the provision of uncertainty estimates is an end-to-end quality assessment, which is much more challenging than quality control completed following data collection as described above. The GAW atmospheric composition monitoring program is one example of a quality assessment approach that ensures all its observing sites are comparable. This is essential to produce globally consistent datasets. GAW mandates the use of a primary standard for most parameters to define a measurement scale. The scale is maintained by a single institution and propagated to all other members of the program in a traceable manner. Clear data quality objectives have been articulated, and these are supported by measurement guidelines developed by the community of researchers. Detailed logbooks and metadata are required to be maintained, along with a commitment to submit data to the World Data Centers in a timely manner. Audits and inter-comparison programs are routine. Participating institutions are encouraged to deliver measurements with uncertainty within agreed limits.

The atmospheric laboratories on the research vessel *Investigator* have opted to adhere to the quality assessment guidelines of the GAW program, making it the first mobile

GAW station. Personnel for the research vessel *Investigator* have committed to the GAW quality assessment principles for a suite of ship-borne measurements. This includes regular maintenance of all instrumentation, routine calibration and quality control, annual delivery of data to the relevant World Data Centers (with a view to [near] real-time delivery in future), and provision of appropriate filter methods to remove local pollution (e.g., ship exhaust).

Vision for the Next Decade

An efficient shipboard observational network needs to include ships from commercial, private, and research fleets with sufficient operational flexibility to take advantage of continued advances in technology and communications. Many industries (e.g., cruise lines, ferries, fisheries, energy, and transportation) operate thousands of ships that could contribute to cost-effectively collecting data (Holthus, 2018). A comprehensive structure and process is needed to connect these industries with the scientific data collection community to expand the spatial and temporal extent of observations. Vessel owners and operators are often interested in the health of the oceans and seek opportunities to make measurements to support marine operational and research activities (e.g., Watson et al., 2009; Nara et al., 2011). These communities need a mechanism to register their instrumentation and provide observations to the community with both real-time or delayed-mode options. For research vessels, the challenges are less in making the observations but more focused on the coordination of observations between nations, standardizing observational methods and quality assessment/control, and ensuring consistent data management.

Over the next decade, the international community needs to focus on a unified program of marine observations from crewed ships and autonomous surface vessels. Challenges to be addressed include (1) recruiting additional vessels to improve both spatial and temporal sampling of the parameters outlined in **Table 1**, (2) conducting multivariate sampling on ships, (3) raising the technology readiness level of automated sensors for autonomous shipboard observation and ship-to-shore data communications, (4) advancing quality evaluation of observations, (5) and developing a unified data management approach for shipboard observations and metadata that meet the needs of a diverse user community. Given the diversity of operational and research applications (see Community Requirements), there is no ideal sampling scheme for near-surface marine observations from ships, but the need for additional sampling over the global oceans to increase measurements of parameters listed in **Table 1** is recognized. More vessels are needed to increase sampling in remote oceans (e.g., polar seas, South Atlantic, and the Pacific), to increase the frequency of observations (more per day) even along well-traveled shipping lanes, and to measure multiple parameters simultaneously on a single ship.

Vessel Recruitment

The decline in ships contributing to the VOS Scheme and the impact this has on both operational forecasts/warnings and climate studies are described above. Recruiting additional ships to contribute to the VOS Schema and make other atmospheric

and oceanic observations requires communication with the ocean industries that operate ships across the global ocean. The first recommendation to recruit additional vessels is for users of shipboard observations to create a list of the instruments they wish to see deployed on ships that will meet their needs to measure the parameters in **Table 1**. Once developed, this list can be used to approach owners/operators to determine what level of instrumentation they are willing to host on their ships. It is anticipated that partnerships will be needed between NMHS, World Ocean Council (WOC), the research community, and individual vessel owner/operators to deploy a combination of instrumentation on each vessel (see Coordinating Vessel Recruitment). Better coordination between the observational programs is essential for unified requests (i.e., not from multiple individual researchers or operational groups) to be made to the vessel owner/operators to ensure that requests do not adversely impact the core mission of the vessels. The WOC is one option to address these coordination needs.

Despite the diverse observing capabilities of research vessels, they are an underutilized component of the observing network. A concerted effort is needed to coordinate marine observations from research vessels. Firstly, we recommend all research vessels to be recruited into the VOS Scheme, have their metadata documented by JCOMMOPS, and be provided with tools to submit data *via* the GTS. Ensuring research vessel data acquisition systems are compatible with existing (e.g., TurboWin) or new VOS reporting software will increase research vessel capabilities to provide real-time observations. The authors further recommend engaging the research vessel operator community in a dialogue to (a) determine which research vessels routinely operate in high-priority ocean regions, (b) support installation of multiple sensor packages on research vessels in these regions, and (c) maximize data collection by ensuring that all sensor packages on each research vessel are operating on every voyage. The Arctic Research Icebreakers Consortium¹³ program provides an example of how countries are working to coordinate research vessels for data collection, and interaction with the commercial fleets *via* the WOC.

Additional ships are needed to collect observations to estimate air–sea fluxes by installing sensors and undertaking further automated approaches to collect the full suite of observations required. This is particularly true in regions where we currently have few observations and large uncertainties (e.g., the Southern Ocean, Swart et al., 2019; Western Boundary Currents, Bentamy et al., 2017) and yet where there is growing ship activity *via* research, tourist, or other ships. We recommend enhancing current capability for direct flux measurements from research vessels and ensuring that high temporal resolution underway observations from all research vessels and a subset of commercial ships are routinely collected and managed in a SAMOS-type data system, including real-time transmission if needs are identified. These enhancements will help identify biases and improve data quality. Direct flux measurements will always be sparse, so meeting required accuracy targets for regional and global fluxes (Cronin et al., 2019) requires expanding our knowledge of

near-surface atmospheric and oceanic states and improvements to parameterizations of air–sea exchange. Ship and potentially autonomous surface vessel observations can provide direct measurements of fluxes and the observations required to calculate fluxes *via* bulk methods to enable improvements to flux parameterizations and uncertainty characterization.

Since NMHS and the research community do not have adequate resources to deploy instrumentation on all the ships they may be able to recruit, it is essential for the marine community to develop a method for vessel operators to provide weather, ocean, and other measurements using instrumentation purchased and deployed by the owner/operator. Such "third party" data collection can be facilitated through a crowd-sourced data collection approach, which have been widely successful in other communities. Examples include the Community Collaborative Rain, Hail and Snow Network¹⁴, and Weather Underground's Personal Weather Station Network¹⁵. Several user communities (e.g., satellite product developers and numerical modelers) acknowledge the value of observations from third-party platforms, provided that the platform metadata are sufficient to allow these users to conduct quality evaluation necessary for their application. In some cases, this may result in rejection of these records based on comparison with model first guess fields or neighboring ship, mooring, or other observations with a known quality. The authors recommend establishing a pilot project, possibly in partnership with JCOMM, to develop a web portal to support third-party data collection. Such a portal would support registration of the vessel, collecting minimum vessel and instrumental metadata, and submission of their observations. Promotion of third-party ship observations may be achieved *via* international organizations (e.g., WOC and JCOMM), ship owners' associations, maritime exchanges, marine training institutes, mariners' or shipmasters' associations, and outreach to yacht and pleasure craft owners.

Multivariate Shipboard Observations

As platforms with ample space and power, along with the presence of human resources, ships are ideally suited for multivariate observations. Achieving the goals outlined by the broad community of shipboard data users requires collaboration between existing international research and operational activities to build a program to measure multiple parameters across a network of ships. Many users need co-located observations to address their operational and scientific goals. For example, the heights at which observations of the marine air temperature, humidity, and wind speed are made vary, which means that applications such as satellite calibration and evaluation require adjusting data to a common reference height. This requires co-located measurements of these parameters be combined with accurate metadata on observing heights. Furthermore, many users calculate fluxes of heat, moisture, momentum, carbon, and other quantities using shipboard observations (e.g., Smith et al., 2016b). Accurate flux estimation requires co-located measurements of winds, air and sea temperature,

¹³<https://www.arice.eu/>

¹⁴<https://www.cocorahs.org/>

¹⁵<https://www.wunderground.com/weatherstation/overview.asp>

humidity, pressure, salinity, and other quantities (e.g., pCO₂ and chemical properties). Temperature and salinity must always be measured on platforms where alkalinity and pCO₂ are measured, as this allows improved empirical relationships for calculating the latter from the former that are more widely available (e.g., Lee et al., 2006; Bonou et al., 2016). To maximize efficiency by which observations are made, the authors recommend that multiple sensor systems be deployed on individual ships and every effort should be made to ensure all systems are operating and transmitting data on every voyage. As described in the “Quality Assurance and Control” section, the estimation of data uncertainty is often improved by the availability of co-located observations providing information on the ambient conditions.

Technological Advancement

Over the next decade, there is a need for additional investment to advance the technological readiness level of instrumentation and sensors, increase the capabilities of ship-to-shore communications, and enhance the design of new vessels to support marine observations.

Although autonomous sensors are becoming more common on all types of vessels, many technologies need improvement to expand autonomous marine measurements, as ships offer a cost-effective way to vastly increase data collection. Examples include automated atmospheric aerosol samplers (Sholkovitz and Sedwick, 2006) that could provide routine estimates of biogeochemical fluxes; sensors to measure cloud parameters, precipitation, and visibility; and automated sensors for carbon cycle parameters of high enough quality to be comparable with manual analytical instrumentation. Some land-based sensors for these measurements exist but are typically too costly and not sufficiently robust to be routinely deployed on ships. The authors recommend additional investment into autonomous sensors for shipboard use. We also recommend using research vessels as well-established labs for testing new sensors prior to their wider deployment on commercial and private ships. Any such effort will require partnerships with sensor manufacturers to leverage their design and engineering experience and also to allow scientists to inform the design to ensure that all essential data and metadata are correctly encoded into sensor data records. As a community, we should be moving away from the days when data and metadata (e.g., calibration factors and units) are provided separately from the data values—they should be provided simultaneously by “smart sensors” in any electronic data records using community-developed methodology (e.g., SensorML¹⁶; Aloisio et al., 2006).

In addition to new sensor development, existing technologies should be further exploited. For example, the AIS may be used to increase the availability of observations globally. AIS is a maritime navigation safety communications system standardized by the International Telecommunication Union and adopted by the IMO that provides vessel information (i.e., identity, type, position, course, speed, navigational status, and other safety-related information) automatically to appropriately equipped shore stations, other ships, and aircraft. Its primary use is as a navigation tool for collision avoidance; however, a promising

methodology has been recently developed to estimate surface currents from AIS navigation data (Guichoux et al., 2016), potentially in real time, as an updated version of historical ship drift data (e.g., Richardson and Walsh, 1986). Services like AIS can also be used to transmit Application Specific Messages¹⁷. The Environmental Application Specific Messages can be incorporated into AIS messages and has great potential to transmit meteorological and oceanographic information from automated sensors. For example, pressure is variable from which other parameters could be derived to assist in improved weather forecasts and warnings over the high seas. From pressure, conceivably one could generate better model wind information that, in turn, could generate better model wave information. The potential of AIS technologies to increase ship observations can be estimated by viewing the hundreds of millions of ship locations from 2012 displayed at <https://www.shipmap.org/>.

As data volumes from autonomous sensor technology grow, continued development of ship-to-shore communications technology is needed. The obvious first step is to continue to increase the bandwidth of satellite broadband technology; however, collaboration with telecommunications companies is needed to develop reasonable cost models for these transmissions, including two-way communication. Much like space agencies communicate with satellites, shore-side personnel should be able to monitor shipboard sensor performance at sea, to provide updates to software/firmware, and to alter the sampling characteristic of the sensors as needed. To achieve further mutual benefit, the communities active in shipboard and autonomous surface vessel observations need to jointly develop and advance two-way communications.

Needs for marine observing should be built into new vessel design (Rossby, 2011), as this would simplify the installation of scientific instrumentation and ensure more consistent data quality when sensors are moved from vessel to vessel. For commercial ships, the focus should be on providing a dedicated water intake and location to install flow-through systems, together with cable and tubing routes (e.g., to the bridge level for satellite communication instrumentation and atmospheric gas sensors). On research vessels, designs should also include well-stabilized forward masts to support meteorological and air-sea flux sensors. Several examples of these designs have been implemented on recently constructed research vessels (e.g., *Sikuliaq* and *RRS Sir David Attenborough*). Whenever possible, all vessels should also undergo both atmospheric and oceanic flow modeling during the design phase, and these results should be made available to the user community. Finally, when vessel designs cannot be changed, the alternative is developing new sensor technology that can easily be fitted onto any vessel (e.g., magnetic sensor packages for deployment on ship hulls).

Evaluating Data Quality

All observations need to undergo timely, standardized quality control procedures established by the wider community of data managers to identify gross errors (e.g., check data within defined ranges, time and location, and climatological test).

¹⁶<https://www.opengeospatial.org/standards/sensorml>

¹⁷<http://www.iala-aism.org/asm/weather-observation-report-ship/>

Near-real-time quality control should take advantage of collocated measurements from other marine networks (e.g., ships versus Argo) and be optimized by retrospective comparison with more refined delayed-mode processing (e.g., Alory et al., 2015). Coordination is needed between the different components of the marine observational community (e.g., meteorological, oceanic, and biogeochemical observations) working toward standard approaches to evaluate the data.

Ideally quality control activities are conducted by scientific experts using community-developed, accepted, and shared tools. Programs like SAMOS, GOSUD, ICOADS, SOCAT, GLODAP, Copernicus, and others have developed quality control software and tools specific to a type of ship (commercial versus research vessel) and various parameters. Many of these systems are highly customized, making them difficult to disseminate to the wider observational community, but these tools should be harmonized and open-source code made available. The authors recommend organizing an international working group to focus on developing and distributing quality control tools. Such an effort may be coordinated by the MCDS or JCOMM or *via* workshops to include the diverse research communities that conduct much of the not presently "operational" marine observing from ships.

A further challenge is to identify some shipboard observations to serve as "reference" stations similar to what is being done in the land-surface community (e.g., Thorne et al., 2018). Most likely, these would be research vessels, but they should adhere to the highest standard for quality assessment/control. Presently, no standards for shipboard reference stations exist, but lessons can be learned from GAW program or the definition of core voyages in GLODAP (Olsen et al., 2016). We recommend identifying a set of vessel operators willing to work toward developing and supporting a standard to be known as a mobile reference station. Ideally, these vessels would host as many data systems as possible, meeting the multivariate observing goal outlined in the "Multi-Variate Shipboard Observations" section.

Data Management

Operational data need to be made available as soon as possible after transmission from the ship to shore. For synoptic meteorological data, procedures are well established to push observations onto the GTS; however, for a number of oceanographic and biogeochemical parameters, especially those made on research vessels, the procedures for real-time data dissemination are not as clearly defined. Over the next decade, there is a need for the meteorological, oceanographic, and biogeochemical observing communities to come together to establish protocols for real-time transmission of at least a subset of the parameters in **Table 1**. Further efforts will be needed to manage full-temporal resolution observations that are collected from vessels post voyage (in delayed mode).

It is important to recognize that data collected for operational purposes also serve a wide range of climate applications. For example, the National Centers for Environmental Information currently combines two GTS data streams to create monthly updates of ICOADS (Freeman et al., 2017). Creating such interim products supports climate assessment and monitoring.

Identifying duplicate and near-duplicate reports can be difficult, especially if ship identifiers have been masked. Data derived from the GTS are periodically combined with data from delayed-mode data systems in major ICOADS updates, again with challenges for identifying duplicate reports received from different data management systems.

For the climate record, it is sometimes the case that only a real-time observation exists, and there is no corresponding delayed-mode source. We recommend preserving all metadata included with BUFR or earlier fixed character-based messages. With the current transition to BUFR, more metadata can be made available alongside the observed data, which should eventually remove the need for the VOS delayed-mode data system. While metadata fields available in BUFR are much more expansive than those in past formats, encoding of metadata into the BUFR records may not be complete, depending on the network owner responsible for providing this information; so a central metadata repository, such as that provided by JCOMMOPS, is still required to maintain historical vessel/platform metadata and lineage.

GTS collections at different NMHS may vary in their contents (JCOMM, 2010), and in some cases, data are circulating on the GTS with a low level of metadata (a situation that will significantly improve when the BUFR format is fully adopted). To facilitate capturing the full range of observations on the GTS, the authors recommend establishing a real-time GTS data assembly center within the JCOMM MCDS to harvest and manage all ship observations circulating on the GTS. This center could accept data received from the GTS by multiple NMHS, conduct duplicate evaluation, and provide these observations to downstream users and product developers. The result would be a consolidated source for real-time GTS data with agreed quality control that could be aggregated to climate datasets such as ICOADS or the World Ocean Database, providing full provenance from instruments to archives/products as intended by the MCDS (Pinaridi et al., 2019). Aggregating the data in the MCDS would provide a more complete collection and assure permanent preservation in international archives and repositories, guaranteeing their existence for future applications.

Beyond the real-time data transmitted *via* the GTS, there presently is no global repository dedicated to all data types (**Table 1**) collected onboard vessels. Most research vessel observations are neither available in near real time for operational applications nor processed in delayed mode to be submitted to global climate archives. There are examples of good stewardship of EOVs and ECVs, including the Rolling Deck to Repository, SAMOS, GOSUD, SOCAT, GLODAP, PANGAEA Data Publisher¹⁸, and the Australian Ocean Data Network, which provide quality assurance and dissemination and securely archive observations from research vessels (e.g., Gaillard et al., 2015). Much of the data are archived by different national data centers, and only some of these data are included in global marine climate databases (e.g., ICOADS and World Ocean Database). There are counter-examples where national research vessel operators do not always continuously log or manage data from underway systems. The authors recommend establishing

¹⁸www.Pangaea.de

a distributed set of data assembly centers, possibly affiliated with the MCDS, to catalog, manage, and deliver underway data from research vessels in a manner that support efficient data exchange across different computer platforms. The first step is to develop a unified catalog of vessels collecting data in **Table 1**, including metadata on what parameters are being sampled, at what frequency, and who is responsible for managing the individual sensor systems on research vessels. Any global research vessel observation catalog will need to leverage ongoing vessel metadata efforts at JCOMMOPS and from individual operational and research projects. This could be achieved in the next few years by organizing cross network workshops to engage the diverse shipboard observing community with the goal being to unlock existing data collected by research vessels and to expand observing capabilities by coordinating deployment of existing and new autonomous technology.

COMMUNITY ENGAGEMENT

Coordination between the operational and research observational communities needs to be strengthened at national and international levels, drawing on expertise in making the observations, collecting and tracking comprehensive metadata, and ensuring the observations are distributed and available in a manner that is transparent to the user. Data user communities need to be involved to assess their requirements for observations (e.g., identifying regions to improve sampling and focusing on specific physical parameters). Coordination is needed in the recruitment of ships to make observations, in developing technology for autonomous use on ships, and in collecting, tracking, and archiving of both the observations and the metadata that are critical for real-time (e.g., forecasting and warnings, and safety of life at sea) and delayed-mode (e.g., reanalyses, process studies, satellite algorithm development and product evaluation, and model evaluation) applications of the observations.

Coordinating Vessel Recruitment

For vessel recruitment, additional coordination is needed between international governing bodies and panels that are central to specific ship communities. For example, additional interaction is needed between international research vessel operators, the passenger cruise industry (e.g., Cruise Lines International Association, International Association of Antarctic Tour Operators), and the panels of JCOMM to coordinate recruitment across these large fleets. The WOC Smart Ocean-Smart Industries program provides a potential platform/portal to facilitate communication between the scientific ocean observing community and marine industries. The program goal is to increase the number of companies from a range of ocean industries involved in the sustained collection and reporting of standardized data for input to operational and scientific programs that improve the safety and sustainability of commercial activities at sea and contribute to understanding the ocean. The WOC brings together representatives from (a) shipping, oil/gas, ferries, offshore wind, and fisheries

industries; (b) marine technology, instrumentation, and IT/communications companies; (c) international and national oceanographic/meteorological organizations; and (d) existing voluntary observation programs.

One major issue in using commercial vessels as observing platforms is that ships are frequently on short-term charters due to changing markets in a globalized world, while climate monitoring requires repetitive long-term observations. The resulting instability of repeat ship lines makes climate monitoring difficult and costly since a ship recruited for one line can switch to another line, sometimes on the other side of the world, on very short notice when the contract ends, and the in-port window can be very short for retrieving instrument for installation on another ship. Advancing vessel design to support observations may help to reduce this problem (see Technological Advancement), but more direct coordination with shipping companies will be required.

Not all marine observations are made from or coordinated by vessels officially recruited by an NMHS. Where commercial operators have a requirement for meteorological data for their operations, these data can be purchased or shared with NMHSs as a supplement to official operated networks. An example of third-party data includes automatic weather stations situated on offshore rigs, platforms, and floating production units. The oil and gas industries have a requirement for high-quality meteorological data (particularly wind) to carry out safe helicopter operations. Additional engagement with these third-party operators is essential to ensure valuable data are shared and made available, ideally free of cost, to the wider marine community.

Within the VOS Scheme, a dedicated "ZZ" category exists for recruited VOS ships that have no particular affiliation with a national VOS fleet. There are currently over 300 such ships registered within the VOS metadata database. This allows for the *ad hoc* recruitment of certain vessels where, for example, their voyage route looks to be beneficial (e.g., within a data sparse area), the voyage is only for a dedicated period of time, or there is limited resource to manage the data as part of a national fleet. Other benefits can be obtained by building relationships with private operators (e.g., yachts and racing teams) of vessels equipped with atmospheric or oceanic sensors, which may not be of the highest quality, but are occupying routes/regions not typically occupied by vessels recruited to VOS or research vessels (e.g., Southern Ocean). The advantage of doing so is that data supply is increased and the wider community is engaged with the making of ocean observations. As long as the platform metadata describe the source of the data sufficiently, data users can assess the usefulness for their operational or research goals. The recommendation to develop tools to collect third-party data using ships outside the traditional commercial and research vessel operators (see Vessel Recruitment) will engage new operators in the collection of the parameters in **Table 1**.

Leveraging Technological Advances

The authors recommend establishing routine communication between ship- and autonomous surface vessel-based science communities to develop and disseminate techniques between

their domains, as an optimum ocean observational network is multi-platform. We expect autonomous surface vessels to play an ever-growing role in ocean observations for a variety of disciplines as new sensors become integrated (e.g., air–sea fluxes, ocean biogeochemistry, and fisheries; Swart et al., 2016; Centurioni et al., 2019). The role of the autonomous surface vessels to enhance and broaden existing and future ship-based observing needs to be defined. There is significant benefit to connect these communities, since the introduction of autonomous surface vessels creates the potential to scale up traditionally ship-limited observations and reduce the space-time data gaps inherent with ship-based surveys (Greene et al., 2014; Swart et al., 2016), such as envisioning a quasi-permanent science platform presence and year-round monitoring in both local and remote ocean regions. Meanwhile, ships will continue to be a primary contributor to the marine observational network and will be required for calibration, validation, and technological testing of sensors deployed on autonomous surface vessels, as well as to launch/recover autonomous surface vessels.

As noted above, AIS is a promising option to transmit observations for AIS-equipped ships. Although AIS was not designed for satellite reception and it has very limited bandwidth, there has been substantial success in receiving AIS transmission from satellites, increasing its potential for collecting weather observations. Recently, the VHF Data Exchange System (VDES) is being developed with higher bandwidth and designed to include two-way satellite communication capabilities. VDES will augment AIS and holds promise to be well suited for collection of weather observations from ships. AIS and VDES are inexpensive, essentially free beyond equipment cost, and likely to be aboard many, including smaller, vessels. The authors recommend the establishment of pilot projects, to include industry, governments, and providers of hardware and software, which will transmit meteorological and oceanographic information *via* AIS messages. This is in keeping with the U.S. National Transportation Safety Board's recommendation to the National Oceanic and Atmospheric Administration in their report on the *El Faro* sinking¹⁹ (United States Coast Guard [USCG], 2017).

Data Users

Within the marine climate research community, international workshops promote best practices: the JCOMM Workshop on Advances in Marine Climatology and the International Workshop on Advances in the Use of Historical Marine Climate Data. These workshops focus on data management aspects of marine climatology, the development and production of multidecadal to centennial climate products, and sharing improvements in bias adjustment and uncertainty estimation methodologies. Both series include dataset developers and users, but it would be beneficial and is recommended to expand the scope to include operational users of marine data, allowing connections to be made between the need to make observations to support immediate operational needs and also to foster understanding that reusing these data is essential to meet longer-term climate objectives.

¹⁹<https://www.nts.gov/investigations/AccidentReports/Reports/MAR1701.pdf>

Models, from simple to fully coupled atmosphere–ocean biogeochemical global circulation models, benefit from observations for assimilation and evaluation. A more coordinated, multivariate approach to the collection of marine data from ships, along with easing accessibility to and better documentation of these data, will increase the use of observations by the modeling community. For example, the annually published global carbon budget (Le Quéré et al., 2018) now routinely combines data from observations and models, which reduces uncertainties and increases the confidence level in contemporary analyses as well as future model predictions. Such efforts foster not only communicating result to non-specialists but also enabling information flow to policy makers, either direct or *via* other organizations (e.g., the Intergovernmental Panel on Climate Change). It is essential in the next decade that shipboard observation of biogeochemical parameters become routine, in addition to traditional meteorological and physical oceanographic measurements, and the authors recommend further investment in the personnel and technology required to advance shipboard biogeochemical observation.

The role of shipboard observations in retrieval algorithm development and the calibration/validation of remotely sensed marine parameters will continue throughout the next decade. Indefinitely, the role of these observations in transportation and safety will be very important. More advanced satellite and aircraft remote sensing system will be developed, each requiring *in situ* observations to evaluate sensors and systems. Continued collaboration between the shipboard and remote sensing communities, and even among these communities, NMHSs, and the private sector (e.g., AIS and instrumentation developers and manufacturers), is important, whether at joint workshops, meetings of opportunity, or, ideally, joint observing projects. The authors recommend that agencies supporting satellite and remote sensing systems development provide complimentary funding to enhance shipboard observations. In many cases, the cost will be minimal compared with the cost of deploying new remote sensing systems.

SUMMARY AND RECOMMENDATIONS

All types of ships have the capability to provide essential atmospheric, oceanic, and biogeochemical observations. We envision a future where commercial, research, and privately owned vessels are making multivariate observations using a combination of automated and human-observed measurements. All data and metadata will be documented, tracked, evaluated, distributed, and archived to benefit users of marine data. This vision looks at ships as a holistic network, not a set of disparate VOS, research, commercial, and/or third-party activities working in isolation. The idea is to bring these communities together for the mutual benefit of all.

Toward that end, the authors make the following summary recommendations to be discussed at OceanObs'19²⁰ and to be acted on over the coming decade. The authors note that the

²⁰<http://www.oceanobs19.net/>

level of capital investment, both financial and human, varies between these recommendations. Those marked with bold text are deemed by the authors to be feasible with lower investments that may be supported through the funding infrastructure of individual nations (or small collaboratives). The other recommendations, though necessary to advance the coordination of shipboard observing and data management, will require higher levels of international cooperation and capital investment.

- **Expand recruitment of new ships to make observations of the parameters outlined in Table 1 to**
 - include recruitment *via* traditional means, ensuring that all research vessels are contributing to operational and research data collection efforts, and seeking new collaborations with commercial and private ship owners/operators,
 - increase and improve communications between the WOC, JCOMM, the research community, and relevant panels/communities in identifying additional ships to make observations, and
 - **engage the user community to develop a list of sensors to be widely deployed on ships and to define high-priority regions of the ocean to target for increased sampling.**
- The research vessel community should
 - **provide metadata regarding their observational capabilities to international metadata catalogs,**
 - expand capabilities to conduct direct flux measurements,
 - host new technology to provide a testbed prior to installation on commercial or private ships,
 - **support installation of multiple sensor packages on research vessels, and**
 - ensure that all sensor packages on each research vessel operate on every voyage (to maximize data collection).
- Agencies should invest in technology development by, but not limited to
 - **establish pilot projects; to include industry, governments, and equipment and software providers; and to develop methods to transmit meteorological and oceanographic information *via* AIS messages,**
 - work with sensor manufacturers to develop cost-effective, self-describing sensors that could deliver their metadata in a normalized format,

- **develop automated atmospheric composition sampling systems that could be installed on ships of opportunity, and**
- **develop a web portal and other recruitment tools to support third-party data collection.**
- Improve data access and interoperability by
 - agreeing internationally to a fully open policy for the exchange of and access to data and metadata from ships and
 - establishing distributed, but interoperable, regional/global data centers (affiliated with the MCDS), to catalog, evaluate, and distribute shipboard underway data, including VOS and research vessels, collected in real time and delayed mode. One center should focus on receiving, processing, and evaluating GTS data from multiple NMHS.
- **Move ship observing networks toward standard quality control and assessment methodology by organizing an international working group to focus on developing and distributing tools and best practices.**

AUTHOR CONTRIBUTIONS

All authors contributed to writing sections of the manuscript, and each read and approved the submitted version. DF, PP, MK, and GA developed and contributed the figures.

FUNDING

Preparation of this article by SRS and associated page charges are provided by a cooperative agreement (NA16OAR4320199) from the Climate Program Office, Ocean Observing and Monitoring Division of the National Oceanographic and Atmospheric Administration (FundRef#100007298) *via* a subaward (191001.363513.01D) from the Northern Gulf of Mexico Cooperative Institute administered by the Mississippi State University. EK and DB were supported by the UK NERC under the CLASS program (NE/R015953/1). SS was supported by a Wallenberg Academy Fellowship (WAF 2015.0186). US was supported by the UK NERC projects ABC Fluxes project (NE/M005070/1), the SONATA (NE/P021417/1), and the EU Horizon 2020 projects RINGO (#730944), and the AtlantOS (#633211).

Ocean reanalyses combine ocean models, atmospheric forcing fluxes, and observations using data assimilation to give a four-dimensional description of the ocean. Metrics assessing their reliability have improved over time, allowing reanalyses to become an important tool in climate services that provide a more complete picture of the changing ocean to end users. Besides climate monitoring and research, ocean reanalyses are used to initialize sub-seasonal to multi-annual predictions, to support observational network monitoring, and to evaluate climate model simulations. These applications demand robust uncertainty estimates and fit-for-purpose assessments, achievable through sustained advances in data assimilation and coordinated inter-comparison activities. Ocean reanalyses face specific challenges: (i) dealing with intermittent or discontinued observing networks, (ii) reproducing inter-annual variability and trends of integrated diagnostics for climate monitoring, (iii) accounting for drift and bias due, e.g., to air-sea flux or ocean mixing errors, and (iv) optimizing initialization and improving performances during periods and in regions with sparse data. Other challenges such as multi-scale data assimilation to reconcile mesoscale and large-scale variability and flow-dependent error characterization for rapidly evolving processes, are amplified in long-term reanalyses. The demand to extend reanalyses backward in time requires tackling all these challenges, especially in the emerging context of earth system reanalyses and coupled data assimilation. This mini-review aims at documenting recent advances from the ocean reanalysis community, discussing unsolved challenges that require sustained activities for maximizing the utility of ocean observations, supporting data rescue and advancing specific research and development requirements for reanalyses.

Keywords: data assimilation, uncertainty, inter-comparisons, observational requirements, historical reanalyses

INTRODUCTION: THE USEFULNESS OF REANALYSES

Ocean and sea-ice reanalyses (ORAs, or ocean syntheses) are reconstructions of the ocean and sea-ice states using an ocean model integration constrained by atmospheric surface forcing, and ocean observations via a data assimilation method (e.g., Storto and Masina, 2016). Over the last decade, performance of ocean reanalyses has improved thanks to (a) increased model resolution (e.g., Zuo et al., 2018); (b) improved physics (e.g., Breivik et al., 2015); (c) better forcing from new atmospheric reanalyses (e.g., Dee et al., 2011); (d) more and improved quality-controlled observation data sets (e.g., Legeais et al., 2018); and (e) advances in data assimilation methods (e.g., Sakov et al., 2012; Storto et al., 2018b). This is exemplified by several works showing the increase of verification skill scores between successive versions of reanalyses (e.g., Lellouche et al., 2013, 2018; Storto et al., 2016; Zuo et al., 2017). Balmaseda et al. (2015) gave a detailed overview of the recent development of ocean reanalyses, with focus on the uncertainty level of climate signals. Ocean reanalyses have thus become an established tool for a variety of climate services and science-driven studies.

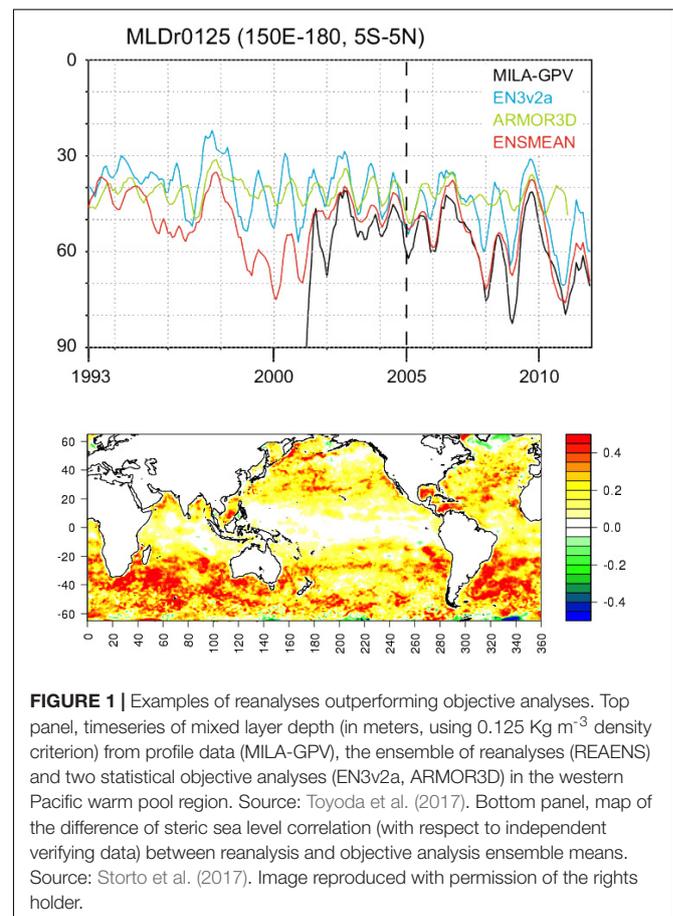

For instance, on-line tools examining multiple ocean reanalyses (e.g., the CREATE¹ initiative, Potter et al., 2018) enable immediate evaluation of model simulations such as the Coupled Model Inter-comparison Project (CMIP5). Visualization tools for near real-time reanalyses permit the monitoring of climate-key diagnostics, such as heat and salinity budgets in the Tropics (Xue et al., 2017)².

Reanalyses are superior to objective analyses since, by construction, they provide increased and multi-variate dynamical consistency (e.g., Forget, 2010; Forget et al., 2015a; Evans et al., 2017; Fukumori et al., 2018) as compared to objective analyses (i.e., statistical processing of observations without model constraints, e.g., Johnson G.C. et al., 2018). One major advantage of reanalyses is their potential usefulness as a tool for studying important climate diagnostics that are only partly or indirectly observed. Examples include deep ocean variability (Balmaseda et al., 2013b), ocean transports (Duan et al., 2016), Atlantic Meridional Overturning Circulation (AMOC, e.g., Jackson et al., 2018), sea-ice thickness and drift (Massonnet et al., 2013), deep convection, and many more.

Dynamical ocean reanalysis have shown better capabilities than their statistical counterparts to assess observables where short timescale variability, or a changing or irregular observing network have large influences. Toyoda et al. (2017) showed that an ensemble of ocean reanalysis could outperform monthly mean statistical gridded products when validating monthly means of (shallow, especially summer time) mixed layer depths derived directly from original profile data, likely due to the reanalysis ability to more accurately simulate the short temporal timescale fluctuations the profiles measured (Figure 1, top panel). Similarly, Storto et al. (2017) showed the enhanced capabilities of

ocean reanalyses over gridded statistical products to capture the inter-annual variability of extra-tropical steric sea level changes, particularly in the southern ocean, where a sparse observational network combined with small temporal and spatial scale eddy activity would have a heavy influence (Figure 1, bottom panel).

Appropriateness of using reanalyses for ocean transport investigations is particularly relevant to understand large to regional scale climate changes (Zuo et al., 2011; Vidar et al., 2016). Transports are mostly unobserved, unavailable from objective analyses and poorly reproduced by free-model running simulations. Reanalyses have been shown to reproduce the AMOC variability seen in the RAPID data at 26°N (Jackson et al., 2016, 2018; Masina et al., 2017), although these data are not assimilated. Reanalyses extending back prior to the deployment of the RAPID array may indicate longer term variability, although the changing observational coverage from distinct periods may affect results. Heat and volume transports through the Indonesian Throughflow, which are not continuously observed and are relevant to ENSO monitoring, are another excellent example where ocean reanalyses successfully reproduce anomalous events (Mayer et al., 2018). Monitoring multi-annual heat, mass and freshwater transports at key Arctic ocean gateways by means of reanalyses has also successfully emerged in several recent studies (Bricaud et al., 2018; Garric et al., 2018; Uotila et al., 2018).

² Real-Time Ocean Reanalysis Inter-comparison Project (RT ORA-IP), available at: https://www.cpc.ncep.noaa.gov/products/GODAS/multiora93_body.html

Reanalyses are also consistent integrators of the ocean dynamics, and there exist several studies that indicate the superiority of reanalyses with respect to model simulations and observation-only products, e.g., improving Mean Kinetic Energy at depth (1000 m) at low- and mid-latitudes (Storto et al., 2016); improving the near-surface Eddy Kinetic Energy (Masina et al., 2017), improving the statistics of the eddy population (Cipollone et al., 2017), and improving the dynamics of poorly observed regions (Koenig et al., 2017a).

Reanalyses that enforce strict budget closures such as ECCO (Estimating the Circulation and Climate of the Ocean) can be very informative for balance studies even though sometimes they may also underfit data (Forget and Ponte, 2015; Forget et al., 2015a). Reanalyses also avoid spurious high-frequency variability in global energy budgets, which is typically found in objective analyses (Trenberth et al., 2016).

In the cryosphere, sea-ice volume from the PIOMAS reanalysis fits well with independent validating data (Schweiger et al., 2011) although the PIOMAS data assimilation only ingests sea-ice concentration and sea surface temperature data. Melia et al. (2015) used the PIOMAS reanalysis to bias-correct climate model scenario predictions using both mean and interannual variability from the reanalysis, demonstrating a new use for such products.

One long-term application of ocean reanalyses has been for the initialization of ocean and sea ice components of seasonal (e.g., at Met Office, ECMWF, NCAR, GFDL, CMCC, Meteo-France, etc.; e.g., Johnson S.J. et al., 2018), and more recently decadal, retrospective forecasts (e.g., Bellucci et al., 2011). The importance of the role of the ocean (e.g., Alessandri et al., 2010; Doblas-Reyes et al., 2013) and sea ice (e.g., Guemas et al., 2016) in initialization is indeed widely accepted. Despite the growing community interest, ocean reanalyses, and the ocean component of coupled reforecasts, are underutilized, largely due to the existing terrestrial emphasis of most of the derived products of these systems. Efforts are being made, for instance by the Copernicus Climate Change Service (C3S³) and Copernicus Marine Environment Monitoring Service (CMEMS⁴), to release the ocean reanalysis component in a more timely manner, and to incorporate their information into climate monitoring reports (i.e., the Ocean State Report, von Schuckmann et al., 2018a,b, or the State of the Climate, Hartfield et al., 2018). A particular benefit of having the reanalysis of these systems readily available, is that this now leads to the ability to access error growth in the forecast components, leading to much better assessment of model forecast error and ultimately to bias correction and model improvement (e.g., Mulholland et al., 2016).

Global reanalyses also provide lateral boundary conditions for regional high-resolution simulations/reanalyses, which are found to significantly improve the local circulation compared to the use of, e.g., climatology (Barth et al., 2008). Additionally, reanalyses are extensively used to monitor the impact of past and present observing networks, thus helping the optimal maintenance and

the future design of the global ocean observation system (e.g., Fujii et al., 2019; Gasparin et al., 2019).

A relatively new application of reanalyses is the investigation of climate variability over centennial timescales by extending back throughout the 20th century and even further. Such historical ocean reanalyses (Giese et al., 2016; de Boissésion et al., 2017; Yang et al., 2017) can particularly provide initial conditions for more extensive decadal predictions. However, caution must be used with “20th century” ocean reanalyses because of the spurious variability resulting from the inhomogeneous observations, especially for ocean transport diagnostics (Yang et al., 2017). Historical ocean reanalyses rely on historical atmospheric reanalyses also extending back to the 19th century (e.g., 20CR, Compo et al., 2011), making the emerging field of historical coupled reanalyses (Laloyaux et al., 2018) doubly attractive to make use of the sparse observations.

ASSESSING THE UNCERTAINTY OF OCEAN REANALYSES

The quality of ocean reanalysis relies upon the accuracy of ocean models, forcing products, and observational data accuracy, namely both data and model errors contribute to the reanalysis uncertainty, as in any other data assimilation context. Model and forcing errors are reduced through assimilation of satellite and *in situ* data, and the availability of accurate observations, with reliable uncertainty estimates associated, is therefore crucial.

Unfortunately, the first satellite missions sensing the ocean surface (sea surface temperature and sea-ice concentration) are available only after 1979; high-precision altimetry missions sampling the sea surface height only began in 1992; *in situ* surface observations only increased when the Global Drifter Program became efficient, after the 1990s, and subsurface profile data from the Argo program achieved near-global coverage only around 2007 (Roemmich et al., 2019). This implies that ocean reanalyses are increasingly less reliable going further back in time. So, it is crucial to carefully assess their performance, particularly in light of the problems noted in the section “Introduction.”

Estimating ocean reanalysis skill and uncertainty can be performed in several ways. First, validating the reanalyses against independent (non-assimilated) datasets, typically available from special campaigns at regional scale (e.g., Koenig et al., 2017b, for the Arctic Ocean), delayed time reprocessed data (e.g., drifter-derived currents or cross-calibrated tide-gauge measurements) or by using multi-source data to evaluate complex frontal dynamics (Artana et al., 2018) and adopting popular skill score metrics (bias, root mean square error, etc.).

Second, probabilistic reanalyses based on ensemble data assimilation possibly maintained through perturbed forcing and physics, provide probability distribution functions of the ocean state. These also require that the dispersion of the limited-size ensemble also requires validation based on objective methods (Desroziers et al., 2005; Candille et al., 2015; Yan et al., 2015; Rodwell et al., 2016; Storto et al., 2018a).

Third, inter-comparison activities that assess reanalyses through evaluation of inter-system consistency provide valuable

³See product catalog at: <https://climate.copernicus.eu/>; <https://cds.climate.copernicus.eu>

⁴See product catalog at: <http://marine.copernicus.eu/>

information. The spread of different reanalyses inform on the relative accuracy of the reanalyses for different ocean parameters. This approach has been performed by the CLIVAR/GSOP and GODAE communities, in particular during the recent ORA-IP project (Balmaseda et al., 2015; and the Climate Dynamics Special Issue⁵), followed by regional reanalysis inter-comparison assessments (e.g., the POLAR ORA-IP, Uotila et al., 2018).

An example is provided in **Figure 2**, which compiles findings from the ORA-IP project, showing the ensemble mean and spread of the reanalyses and reporting the Signal-to-Noise Ratio (SNR, see the figure caption for details) for several inter-compared parameters. The figure highlights how the net surface heat flux, the halosteric (hence salinity content) sea level, the thermosteric sea level below 700 m (hence heat content), and the sea-ice volume are much less constrained than sea surface temperature, 0–700 m thermosteric sea level and sea-ice concentration as indicated by the SNR values. CMEMS also provides multi-reanalysis assessments (e.g., Storto et al., 2018a) and a reanalysis ensemble mean product to end users, following a first attempt by Masina et al. (2017).

Inter-comparison exercises also provide detailed information on the deficiency of the current ocean observing network. For instance, Mignac et al. (2018) showed that the AMOC in the South Atlantic among several ocean reanalyses strongly disagree with each other, due to the discrepancies in the flow strength in the upper and deep western boundary currents. However, the interior gyre circulations showed much greater consistency between products. This shows the effectiveness of data assimilation in the basin interior but also highlights the difficulty of constraining the western boundary currents with the present observations of Argo and altimetry, and illustrates the requirement for a sustained coastal observing system (De Mey-Frémaux et al., 2019).

CHALLENGES

A number of specific challenges concern ocean reanalyses that are not necessarily shared with operational systems (Masina and Storto, 2017; Moore et al., 2019), because one of the fundamental goals of reanalyses is the reproduction of low-frequency (e.g., inter-annual) variability and trends. This is conceptually linked with the fact that most reanalyses implement sequential data assimilation tools that correct the state of the ocean at high frequencies (typically daily), thus introducing an intrinsic jump of spatial and temporal scales (Tardif et al., 2015).

Additionally, discontinuous observing networks often lead to inhomogeneous reanalysis time-series. The sampling of *in situ* profiles is always intrinsically irregular in space and time, but this is particularly so during periods of expansion of observing networks such as XBTs (1970s) and Argo floats (2000s). This is still true today with the inhomogeneous vertical sampling that can lead to large and unrealistic drift in unobserved layers below 2000 m depth (Lellouche et al., 2018).

⁵Climate Dynamics Special Issue on “Ocean estimation from an ensemble of global ocean reanalysis,” Volume 49, Issue 3, August 2017, available at: <https://link.springer.com/journal/382/49/3/page/1>

At the surface new observation types are set to provide more complete global coverage, for instance Surface Water and Ocean Topography (SWOT) altimetry will provide sea level measurements reaching the sub-mesoscale, extended HF-radar systems can provide high-resolution surface current observations in the coastal areas, and a strengthened constellation of ocean-sensing satellites (e.g., from the Copernicus program) should increase dramatically in the next decades. Reanalyses will need to adapt their capabilities (i.e., resolution, data assimilation schemes) to the new observation sampling and types in order to still provide consistent climatic metrics.

Accounting for drift and bias due, e.g., to air-sea flux errors, inadequate model resolution and parameterizations is another non-trivial problem (Zuo et al., 2017). Model bias correction through observation-based (Balmaseda et al., 2007b; Storto et al., 2016), analysis increments-based (Dee, 2005; Canter et al., 2016), ensemble (Zuo et al., 2018), or adaptive (Lea et al., 2008) bias estimates, assimilation of additional climatological observations (Lellouche et al., 2018), on-line correction of atmospheric forcing and mixing terms (Stammer et al., 2004; Forget and Ponte, 2015; Forget et al., 2015a), assimilating anomalies instead of full-field observations (Weber et al., 2015; Counillon et al., 2016), are all bias mitigation methods which have been used in the last decade.

In data-sparse periods, the initialization of ocean reanalyses remains challenging, due to our intrinsic lack of knowledge about the ocean state at earlier times, and is acute in ocean reanalyses before the 1980s (see, e.g., de Boissésou et al., 2017). Inclusion of stochastic initialization (Zuo et al., 2018), point-wise linear regression from objective analyses (Lellouche et al., 2018), or adjoint methods resolving the entire reanalysis period at once (Wunsch and Heimbach, 2007; Forget et al., 2015a) are all possible solution methods that generally require additional computational costs. Other problems such as spurious vertical velocity fields caused by dynamical imbalance after data assimilation, are particularly detrimental to downstream applications such as biogeochemical reanalyses, where these imbalances propagate onto unrealistic distributions of nutrients (Forget et al., 2015b; Park et al., 2018), revealing consistency problems otherwise neglected.

In the context of high-resolution ocean reanalyses that approach eddying scales, additional challenging topics, derived by the increase of ocean model resolution, include among others (i) the coupling with tides and waves; (ii) dealing with mesoscale eddies and sharp gradients in properties; (iii) two-way nested analysis schemes (e.g., Barth et al., 2007); (iv) discontinuities at choke points or in key coastal areas; (v) downscaling of atmospheric forcing, and (vi) accuracy of bathymetry. All these aspects call for a close collaboration between the ocean modeling and the reanalysis communities. Furthermore the increasing demand for temporal and spatial resolution by end-users, for instance for ocean downscaling applications, translate into a big data challenge for high-resolution reanalyses, making the dissemination of full-resolution datasets prohibitively expensive with the current data infrastructure paradigms.

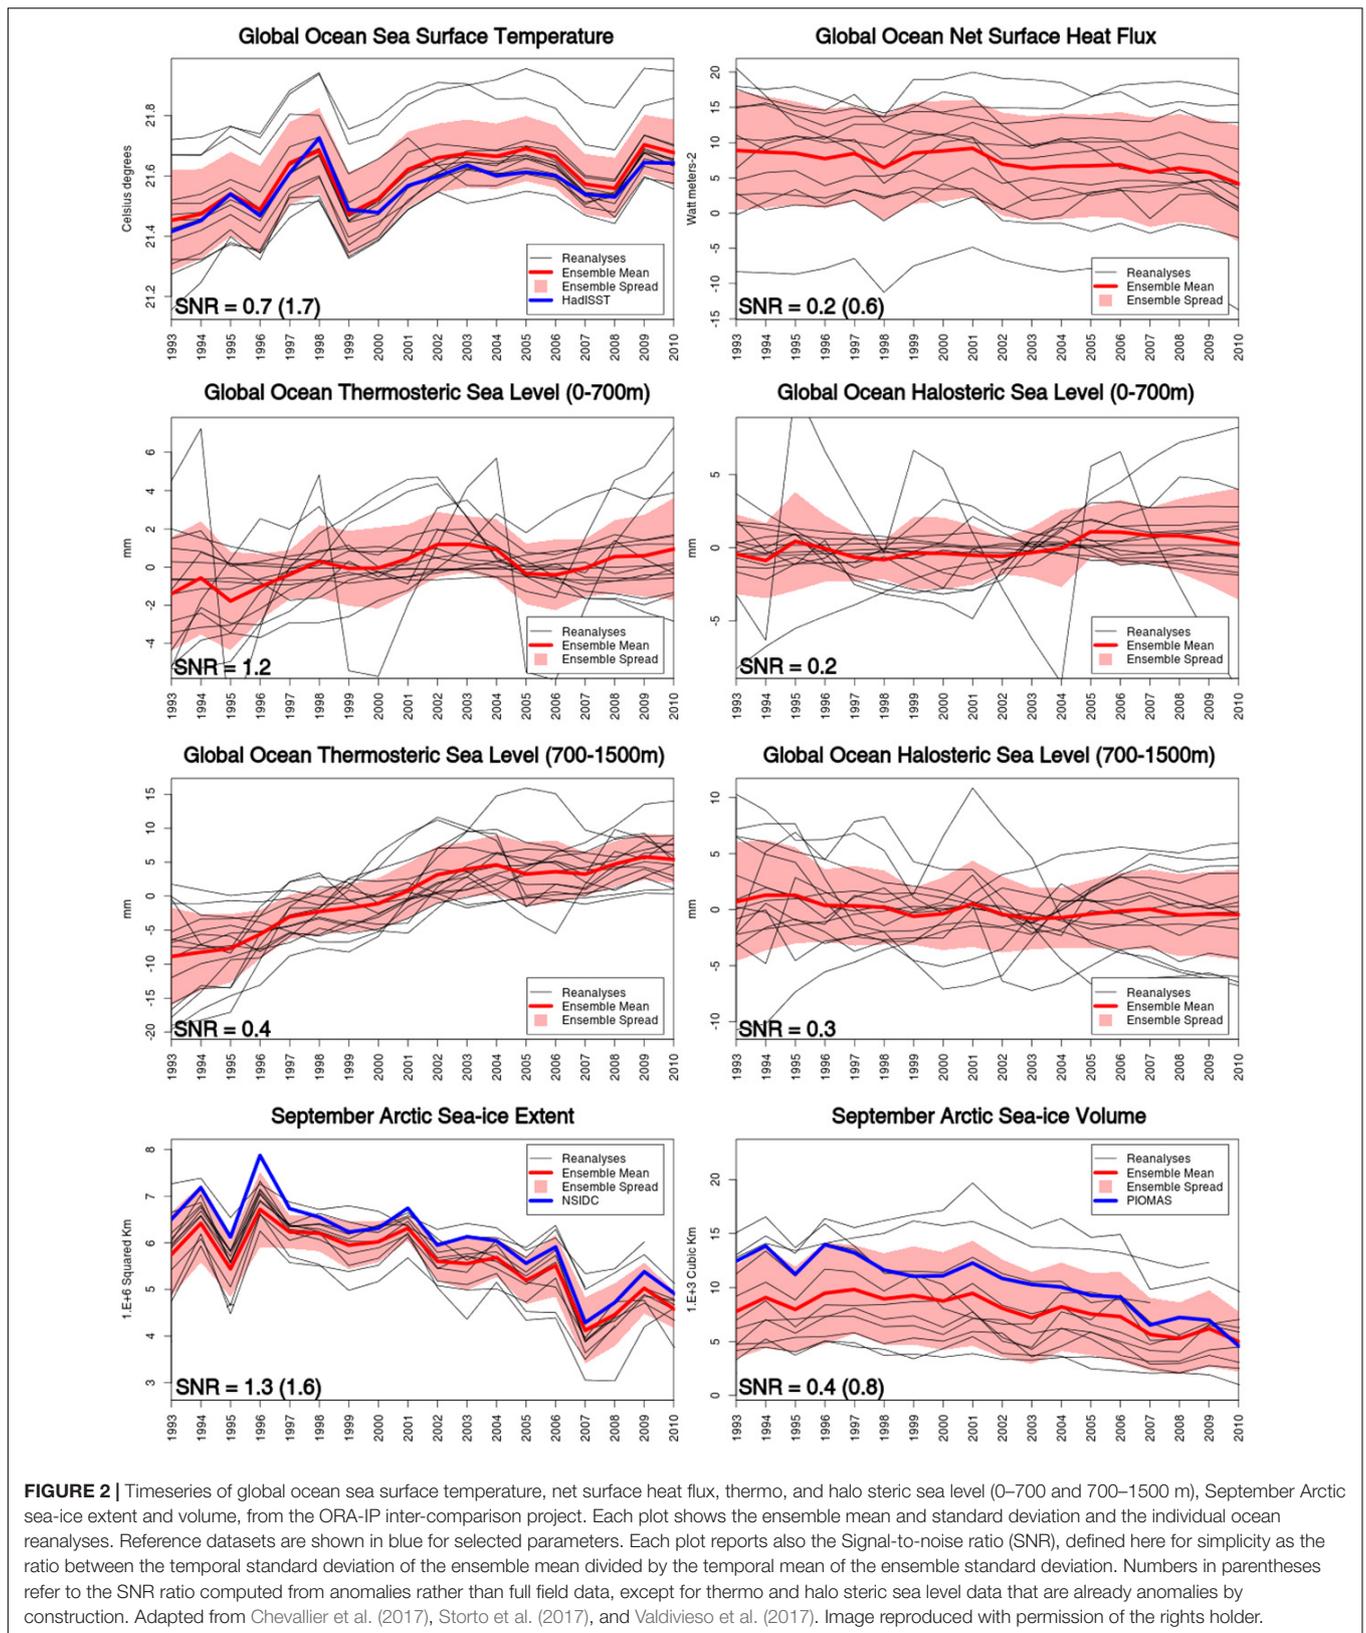

FIGURE 2 | Timeseries of global ocean sea surface temperature, net surface heat flux, thermo, and halo steric sea level (0–700 and 700–1500 m), September Arctic sea-ice extent and volume, from the ORA-IP inter-comparison project. Each plot shows the ensemble mean and standard deviation and the individual ocean reanalyses. Reference datasets are shown in blue for selected parameters. Each plot reports also the Signal-to-noise ratio (SNR), defined here for simplicity as the ratio between the temporal standard deviation of the ensemble mean divided by the temporal mean of the ensemble standard deviation. Numbers in parentheses refer to the SNR ratio computed from anomalies rather than full field data, except for thermo and halo steric sea level data that are already anomalies by construction. Adapted from Chevallier et al. (2017), Storto et al. (2017), and Valdivieso et al. (2017). Image reproduced with permission of the rights holder.

OBSERVATIONAL REQUIREMENTS

The need for sustained, long-term global observations to support climate monitoring and forecast activities has long been recognized (Karl et al., 2010), as well as the complementary need for reliable and sophisticated pre-processing procedures (bias-correction, redundancy checks, quality control, etc.). The impact of different observing networks on the quality of ocean reanalyses and forecast systems has been assessed in several studies. Observational networks like Argo and altimetry satellite data are crucial to correctly resolve the vertical structure of the water column and the mesoscale ocean circulation, respectively (e.g., Oke et al., 2015; Shao et al., 2015; Zhang et al., 2017). Their availability therefore has a direct impact in the quality of ocean reanalyses (Balmaseda et al., 2007a, 2013). Tropical observing systems, like the TAO/TRITON, RAMA and PIRATA arrays, provide important information for the accuracy of ocean forecast systems (see Oke et al., 2015 and references therein). The recent degradation in the TAO/TRITON arrays had a significant detrimental impact on forecast skill in the tropical Pacific (Fujii et al., 2015), showing that it is critical to quickly address such degradations.

Although the number of oceanic observations has increased in recent decades, high-quality observations remain scarce in places, especially around and underneath the sea ice (Pellichero et al., 2017). While remotely sensed ice concentration has had good spatial coverage since 1979, the amount of *in situ* measurements of sea ice thickness (SIT) is very limited (Worby et al., 2008), and long-term and large-scale data sets do yet not exist. Nevertheless, improved SIT estimates are crucial to improve Arctic seasonal forecasts (Blockley and Peterson, 2018) and to reduce climate-model uncertainties (Lisæter et al., 2007; Mathiot et al., 2012; Melia et al., 2015). To improve model confidence in predicting polar sea ice conditions, satellite missions aiming at retrieving information on SIT (such as CryoSat2 and SMOS, and their combination, see Ricker et al., 2017) have been found to improve the performance of reanalyses in polar regions (Allard et al., 2018; Mu et al., 2018; Xie et al., 2018).

For global estimates of key climate parameters such as ocean heat content, the depths below 2000 m are currently unobserved, leading to obvious deficiencies of reanalyses in the representation of deep water characteristics and variability (Storto et al., 2017). Repeated observational transects such as GO-SHIP (Talley et al., 2016), as a follow-up to the WOCE sections (Macdonald, 1998), are fundamental for multi-decadal climate monitoring, but may be inadequate to constrain the deep ocean. For example, when numerous upper ocean observations are available, the use of unreliable vertical covariances in data assimilation may induce the wrong response at depth. There is hope that the developing deep Argo program (Zilberman, 2017) will gradually fill the gaps between the upper and deep ocean observing networks.

For both coupled and uncoupled reanalyses, observations of air-sea fluxes, at the moment available from a small number of dedicated ocean stations (e.g., Curry et al., 2004), appear

crucial for understanding the coupled data assimilation paradigm and improving air-sea flux formulations. On top of all these observational requirements, independent research-quality validation datasets (e.g., research quality tide-gauge data, Caldwell et al., 2015) must be sustained and made available in standard format (e.g., ADCP data from vessel-mounted or fixed location instruments to validate currents from reanalyses) to ensure reliable estimation of reanalysis uncertainty. The same applies to the development of independent remote sensing capabilities, both from existing and new satellites, such as the use of Gravity Recovery and Climate Experiment (GRACE) data to verify steric sea level rise in ocean reanalyses (Storto et al., 2017), or the use of IceSat sea ice freeboard measurements to validate sea ice thickness in reanalyses (Chevallier et al., 2017; Uotila et al., 2018).

Finally, as important as the data availability itself and data rescue projects such as GODAR⁶, improvements to quality-control and bias adjustment procedures for reanalysis applications need to be maintained and supported. Efforts are on-going, testified by the recent release of the first interim version of the IQuOD⁷ temperature profile dataset (Domingues and Palmer, 2015)⁸.

A FUTURE OUTLOOK

Recent years have seen the pioneering production of Earth system reanalyses that simultaneously produce a dynamically consistent reconstruction of the atmosphere, ocean, land and sea-ice, although with varying complexity in the data assimilation coupling (e.g., Penny et al., 2017). These products are preliminary but provide promising results (e.g., Feng et al., 2018) and will likely be developed much further in the coming decade. Earth system reanalyses can potentially improve the representation of budgets (Mayer et al., 2017), although propagation and amplification of coupled biases and errors may occur (Zhang et al., 2013). The role of (uncoupled) ocean reanalyses is expected to focus on the added value of eddying resolution (tackling eddy energetics, including tides at global scale, and improving the representation and the impact of coastal and shallow water processes on the global ocean), as well as consolidating its role as a validation tool for assessing the ocean model component of Earth system simulations. Emerging multi-scale data assimilation schemes (e.g., Miyoshi and Kondo, 2013) may further reconcile the mesoscale and large-scale circulation variability, whose simultaneous correction is generally lacking in the current state-of-the-art reanalyses. The increase in resolution also poses the challenge of data infrastructures capable of handling these large datasets; cloud computing services, new format standards, extraction services, etc., should all be investigated to facilitate access to high-resolution reanalysis datasets.

⁶Global Oceanographic Data Archaeology and Rescue (GODAR), Information available at: https://www.nodc.noaa.gov/about/international_godar.html

⁸www.iquod.org

Flow-dependent error characterization for both rapidly evolving processes (marine weather) and low frequency processes (climate modes, changes in observational sampling, etc.) will likely become an important component of both long- and short-term ocean reanalyses, inheriting the positive experience from atmospheric reanalyses (Poli et al., 2013). In particular, the importance of flow-dependent ensemble based data assimilation methods, compared to prescribed error implementations, has recently been demonstrated at global scales by Penny et al. (2015) and Storto et al. (2018b), and regionally for sub-polar gyre variability (Counillon et al., 2016), and also for the assimilation of sea ice (Sakov et al., 2012; Barth et al., 2015; Kimmritz et al., 2018).

Changes in the observing network expected over the next decade will offer reanalyses the possibility to integrate a larger number of heterogeneous observing networks. Deep Argo, surface salinity, high resolution altimetry, gravimetry, coastal observing networks, together with conventional profile data, may all be ingested to improve the representation of heat, mass and freshwater budgets in uncoupled and coupled reanalyses.

Finally data rescue programs also increase the appetite for the backward extension of ocean reanalyses, but need to be complemented with realistic error estimates and sophisticated bias- and drift- aware data assimilation methods that currently lack sufficient robustness. Enhancing the ocean observing network will also enable better bias estimates to be developed and used. This appears particularly relevant in light of new projects aiming at producing millennial timescale reanalyses from multi-proxy data (e.g., PAGES2k Consortium, 2017).

AUTHOR CONTRIBUTIONS

AS coordinated the individual contributions and compiled them into the manuscript. All co-authors contributed to the text by proposing the text, points of discussion, and references, and provided the corrections to a preliminary version of the manuscript.

FUNDING

We are grateful to the “Evaluation of Ocean Synthesis (EOS)” COST Action ES1402, which provided support for visiting research periods and networking opportunities contributing to some of the cited ocean reanalysis inter-comparison works. CLIVAR through the Global Synthesis and Observations Panel (GSOP) has also provided support for the reanalysis inter-comparison and assessment activities. CMD was funded by the Australian Research Council (FT130101532 and DP160103130); the Scientific Committee on Oceanic Research (SCOR) Working Group 148, funded by national SCOR committees and a grant to SCOR from the U.S. National Science Foundation (Grant OCE-1546580); and the Intergovernmental Oceanographic Commission of UNESCO/International Oceanographic Data and Information Exchange (IOC/IODE) IQuOD Steering Group.

ACKNOWLEDGMENTS

We thank the two reviewers for their valuable help in improving the quality of the manuscript.

Natural variability and change of the Earth's climate have significant global societal impacts. With its large heat and carbon capacity and relatively slow dynamics, the ocean plays an integral role in climate, and provides an important source of predictability at seasonal and longer timescales. In addition, the ocean provides the slowly evolving

lower boundary to the atmosphere, driving, and modifying atmospheric weather. Understanding and monitoring ocean climate variability and change, to constrain and initialize models as well as identify model biases for improved climate hindcasting and prediction, requires a scale-sensitive, and long-term observing system. A climate observing system has requirements that significantly differ from, and sometimes are orthogonal to, those of other applications. In general terms, they can be summarized by the simultaneous need for both large spatial and long temporal coverage, and by the accuracy and stability required for detecting the local climate signals. This paper reviews the requirements of a climate observing system in terms of space and time scales, and revisits the question of which parameters such a system should encompass to meet future strategic goals of the World Climate Research Program (WCRP), with emphasis on ocean and sea-ice covered areas. It considers global as well as regional aspects that should be accounted for in designing observing systems in individual basins. Furthermore, the paper discusses which data-driven products are required to meet WCRP research and modeling needs, and ways to obtain them through data synthesis and assimilation approaches. Finally, it addresses the need for scientific capacity building and international collaboration in support of the collection of high-quality measurements over the large spatial scales and long time-scales required for climate research, bridging the scientific rationale to the required resources for implementation.

Keywords: ocean observing system, ocean climate, earth observations, *in situ* measurements, satellite observations, ocean modeling, climate information

INTRODUCTION

The ocean is an integral part of the climate system: understanding how climate change and variability have shaped it and how climate will be influenced by future changes is a major societal challenge. Key to understanding the ocean's role in the Earth's climate system is monitoring changes in the ocean circulation, heat and carbon content, freshwater, biogeochemistry and sea level, as well as studying the interactions of the ocean with the atmosphere, cryosphere, land, and ecosystems. In addition, a firm knowledge of the changing physical environment is fundamental to understanding the ocean's biogeochemistry and ecosystem functioning, variability, and change. Obtaining high-quality ocean climate observations on a sustained basis is also key to attributing the observed changes of the ocean state and therefore obtaining reliable climate predictions for a range of applications and users (Clivar, 2018 Science Plan¹).

Through OceanObs'99 (Koblinsky and Smith, 2001) and OceanObs'09 (Hall et al., 2010) and through a continuous discussion of the global climate observing system (GCOS) implementation strategy², the design of the ocean observing system has emerged. It consisted, initially, in a definition of essential climate variables (ECVs) and their sampling characteristics in the ocean and elsewhere, and has evolved from a platform-centric perspective to an integrated cross-platform,

parameter-centric observing system. The challenge now is for the climate-oriented observing system to evolve further into one serving the increasing needs for ocean climate information at refined spatial and temporal scales, particularly in the face of advancing anthropogenic climate forcing.

In this whitepaper we review in section "Observing Requirements for Climate" the observing requirements for major processes of climate interest organized around global considerations and basins-specific aspects with an emphasis on the open ocean. Challenges and opportunities for the ocean margins are discussed in section "Observing Requirements for Boundary Currents and Continental Margins," while needs specific to climate modeling, forecasting and to synthesis and reanalysis efforts are presented in section "Ocean Observations for Climate Modeling and Climate Information," followed by concluding remarks in section "Summary and Final Remarks."

OBSERVING REQUIREMENTS FOR CLIMATE

A key capability of the ocean is to store huge amounts of heat, freshwater, and carbon (Rhein et al., 2013). Without this capability, terrestrial anthropogenic heating would be more severe than it currently is. An excess of these quantities enters the ocean through its surface, eventually filling the deep ocean through ventilation in the high-latitude "windows." The heat, freshwater and carbon are then distributed through ocean

¹<http://www.clivar.org/news/clivar-released-second-generation-science-plan-and-implementation-strategy>

²https://unfccc.int/sites/default/files/gcos_ip_10oct2016.pdf

currents and mixing, and feed back into the atmosphere and the cryosphere. Many processes and mechanisms contribute to this redistribution over a wide range of scales in space and time. Understanding and monitoring them is needed to quantify ocean climate variability and change, as well as to constrain and initialize climate models and remedy model biases for improved hindcasting and prediction.

An ocean observing system for climate needs to provide essential information on a sustained long-term basis for monitoring, understanding, and forecasting within all ocean basins (The National Academies of Sciences, Engineering, and Medicine [NASEM], 2017). Specifically, its components should cover climate-observing parameters concerned with changes of the ocean circulation and its budgets of heat, freshwater, carbon, and nutrients, and the exchanges of heat, momentum, freshwater, and gases between the ocean, atmosphere, land, and cryosphere. Parameters concerned with sea level as an integral indicator for climate change (see also Ponte et al., 2019) should also be included. Several of the observing requirements are general in nature and concern the global ocean domain; others concern regional specificities and are presented separately in each ocean basin.

General Considerations Concerning the Global Ocean Domain

General observing requirements involve sustained *in situ* and space-based approaches that sample essential climate parameters over a broad range of spatial and time scales, as outlined in the GCOS implementation plan. Space-based measurements cover globally the surface expression of a broad spectrum of ocean processes. In contrast, *in situ* measurements provide the full-depth resolution required to monitor the vertical structure of climate changes in the ocean. They are also essential to climate-quality satellite data for calibration and inter-calibration purposes. The combination of *in situ* and space measurements is indispensable in regional and global process studies and estimates of anthropogenic heat and carbon uptake, among others (e.g., Palmer et al., 2019; Wannikhov et al., 2019).

Space-based climate monitoring requirements involve sustained satellite measurements of sea surface temperature (SST) (O'Carroll et al., 2019), surface wind and wind stress (Cronin et al., 2019), sea surface height (SSH) from which surface geostrophic currents can be derived and gravity changes (mass changes in the climate system), surface fluxes of heat (Cronin et al., 2019) and freshwater including rainfall, sea surface salinity (SSS), surface waves (Villas Boas et al., 2019) and ocean color. They should be sampled at least twice daily, ideally four times a day, and at a spatial scale that resolves accurately the ocean mesoscale [$O(1)$ km]. Technology developments, such as new sensors and satellite constellations, are key to improve and expand these measurements. One priority is pursuing the development of wide-swath altimeters to measure meso- and submeso-scale SSH variations in crucial energetic regions.

It is imperative to sustain these observations (satellite or *in situ*) over a long period with climate-quality stability and precision. This requirement is all the more important if the

physical signal deviates from a Gaussian distribution, since in that case the statistical moment of the time series may not be stable in time, reflecting the occurrence of extreme events. Global budgets of ECVs, such as heat, freshwater, and carbon rely on top-to-bottom *in situ* measurements using various platforms. A global full-water column Argo float array (Claustre et al., 2019) and high-quality ship-based CTD sections are therefore mandatory, and should include measurements under sea ice. Equally important is the monitoring of boundary currents through systems that continuously measure their transport – a recommendation formulated during OceanObs'09 but never implemented.

In situ measurements of the above variables are currently coordinated by the global ocean observing system (GOOS) and collected through the global tropical moored buoy arrays, Argo and global drifter programs, high resolution XBT transects, and Go-SHIP surveys.

The surface drifter array provides a Lagrangian view of ocean circulation, as well as surface temperature, and a growing number of barometric pressure measurements essential to weather forecasting. Argo profiling floats sample temperature, salinity, and derived geostrophic currents more or less homogeneously throughout the ocean subsurface, except in the polar regions, and sparsely below 2000 m depth (Roemmich et al., 2015).

During OceanObs'09 the expansion to routinely include biogeochemical parameters, such as O_2 , carbon, pH and nutrients, was recommended. BioArgo floats, while still low in number, are being implemented, contributing oxygen profiles and, in some cases, additional biogeochemical variables. Improving globally the spatial and temporal coverage of subsurface measures of biogeochemical tracers collocated with physical measurements is even more critical today with accelerating acidification, oxygen depletion, and ecosystem change. New Deep-Argo technology is also coming on line to increase observations below 2000 m.

Surface and subsurface mooring arrays augment these observations, primarily along the equator and in critical boundary regions, with high temporal and/or spatial resolution observations of surface fluxes and subsurface T, S, currents, and at times oxygen, nutrients, and fluorescence. Moorings require routine maintenance and hence datasets are often short with respect to the climate signals of interest. Basin-wide GO-SHIP transects are essential to provide full depth observations of climate variables, including a full suite of biogeochemical parameters that can only be measured through water collection. Paleoclimate proxy data, such as through ocean sedimentary cores and corals, provide critical extensions of the instrumental record.

Since changes in mass and heat content drive sea level changes, regionally and globally, their monitoring over the full water column and under sea ice is essential. These measurements, in combination with sustained altimetry and tide gauge data, form the basis for studies of sea level change, and its coastal impacts (a WCRP Grand Challenge).

Finally, water isotopes of seawater, rainwater, and water vapor are required to provide calibration datasets for satellite

water isotope retrievals, as well as benchmarks for isotope-equipped climate model simulations of the global water cycle (also a WCRP Grand Challenge), as they intersect with clouds, circulation, and climate.

The Atlantic Ocean

Background

The Atlantic Ocean, through its Meridional Overturning Circulation (AMOC; Frajka-Williams et al., 2019), plays a unique role in the Earth's climate. Different from the vertical overturning circulation in the other basins, the AMOC carries warm saline water from the South Atlantic northward in the upper 1200 m (deemed as the “upper limb”) that is then transformed into the North Atlantic deep water (NADW) in the subpolar North Atlantic and Nordic Seas, and returned southward in the “lower limb” (1200–4000 m). This circulation is far more complex than commonly portrayed and involves the whole water column, linking the upper, mode, intermediate, deep and bottom waters formed and transformed in this ocean, or imported from other basins. The AMOC influences the northward transport of heat (Bryden and Imawaki, 2001) and its release to the atmosphere, providing a significant fraction of the zonally integrated atmospheric energy flux northward of 30°N (Rhines et al., 2008). Additionally, it captures about 30% of the anthropogenic excess of heat (Häkkinen et al., 2015; Palmer et al., 2017) and carbon (Takahashi et al., 2009). It drives the inter-basin transport of freshwater, nutrients, carbon, oxygen and other biogeochemical quantities (Tagklis et al., 2017), impacts the marine ecosystem, and affects the global hydrological cycle, with a clear connection to predictability, from seasonal to decadal (Schludt et al., 2014; Fu et al., 2018).

The AMOC is thought to be a driver of Atlantic multi-decadal variability (AMV), whose sub-polar center of action is linked to ocean dynamics (Kerr, 2000). The AMV, in turn, impacts Sahel rainfall, North American and European weather, the South and East Asian Monsoons, and Arctic sea ice (Sutton and Hodson, 2005). Decadal AMOC variability is positively correlated with northward energy transport in the ocean, but anti-correlated with transport in the tropical atmosphere; regional dynamical feedbacks, however, are unknown. Atmosphere-ocean interactions have been extensively studied on interannual time scales, but are less understood at decadal scales. The spatial dynamical scales involved in the variability and change of the Atlantic Ocean are small, as all current systems of interest are significantly affected by fronts and eddies at the mesoscales (10–300 km).

Atlantic Observing Requirements

The scientific community is moving toward a better rationalization of the Atlantic Observing System as a whole (AtlantOS, deYoung et al., 2019). Being the ocean that receives a large portion of the oceanic excess heat uptake, and that hosts major modes of climate variability, the Atlantic should be observed adequately to accompany the society in adaptation to sea level rise (Ponte et al., 2019), ocean warming (Palmer et al., 2019), ocean acidification (Tilbrook et al., 2019), and the increased intensity of extreme events, including

hurricanes (Goni et al., 2019). It is necessary to improve process understanding (in particular, ocean interactions between the meso- and submeso-scales and the large-scale circulation, air-sea interactions at the meso- and submeso-scales, and heat, freshwater, oxygen and carbon uptake, transport and release to the atmosphere), monitor changes, and feed robustly model developments (Fox-Kemper et al., 2019; Subramanian et al., 2019) and predictions (Penny et al., 2019).

Because of the particular nature of the Atlantic Ocean circulation, observations of currents, salinity, and temperature fields are needed from the surface to the ocean floor. These variables are also mandatory to monitor climate change and enable robust numerical weather prediction, as well as intraseasonal to interdecadal forecasts. However, because of the different scales of variability, they could be sampled with reduced spatial and temporal resolution for depths greater than 2000 m.

The current Atlantic basin observing system (schematized in **Figure 1**) is composed of AMOC (Frajka-Williams et al., 2019) and Tropical Atlantic PIRATA mooring arrays (Foltz et al., 2018). The AMOC array covers the full depth of the water column near the continental slope; the PIRATA array is limited to the upper ocean but includes heat and momentum flux observations. An assessment on the evolution of the tropical Atlantic observing system (TAOS) to expand and rationalize observations in this region is ongoing (Johns et al., 2018; Foltz et al., 2019).

In the open-ocean upper 1500–2000 m, the core Argo program is well developed in the North Atlantic, but more sparse in the tropical, and even more so in the South Atlantic. In the North Atlantic, deployments of BGC Argo and Deep Argo have been

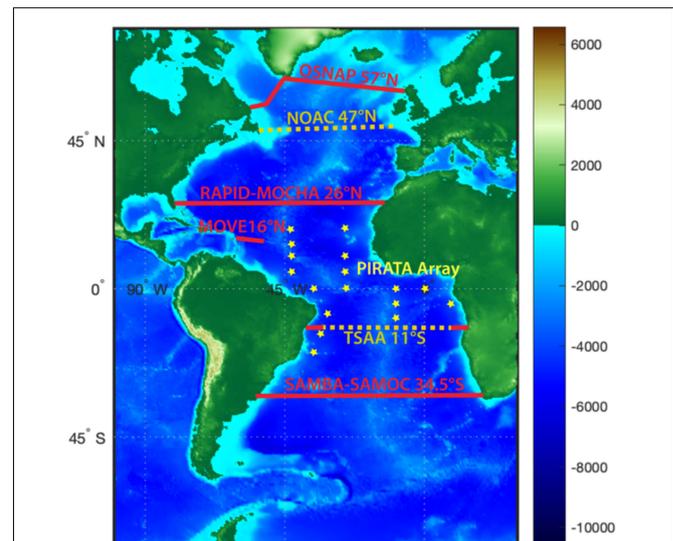

FIGURE 1 | Scheme of the moored observing arrays in the Atlantic with AMOC transports estimates from OSNAP 57°N, NOAC 47°N, RAPID 26°N, MOVE 16°N, TSAA 11°S, and SAMBA-SAMOC 34.5°S (see Frajka-Williams et al., 2019 for more details) and the Tropical Atlantic PIRATA mooring array (see Foltz et al., 2019 for more details). Argo and underwater glider arrays can be found in Roemmich et al. (2019) and Testor et al. (2019), respectively.

initiated but remain in an early development and coverage stage (Roemmich et al., 2019).

The Atlantic basin is regularly (on a 5–10 years base) surveyed by repeated GO-SHIP cruises (Sloyan et al., 2019), and other cruises servicing the various deep moorings and mooring arrays as well as oceanographic cruises organized by finite-time lifespan research projects. These cruises are essential in providing regular sampling of physical and biogeochemical properties over the full ocean depth not attainable by the Argo core floats nor by the mooring arrays alone.

The ship of opportunity program (SOOP) acquires measurements from volunteer merchant ships that regularly undertake shipping routes crossing the basin. This program helps to increase the *in situ* sampling of the surface ocean (temperature and salinity via thermosalinographs instrument mounted close to the water intake of the vessel) and the upper 700 m of the ocean temperature (mainly) by a high resolution (every 10–35 km) deployment of expendable bathymographs (XBTs).

A dense array of buoys drogued at 15 m of depth that measure SST, surface currents and barometric pressure, via the global drifter program (GDP), is also maintained across the basin, mostly through the ship-volunteering program (Lumpkin et al., 2017).

Ocean underwater gliders deployment has been occurring along and near the North American continental slope within the global ocean gliders program (Testor et al., 2019). Typically, gliders profile from the surface to the bottom (over the continental shelf), or to 200–1000 m depth in the open ocean. However, their spatial coverage remains marginal compared to the extent of the Atlantic slope boundary. Indeed, sustained projects in the Atlantic include only observations in limited spots of the western, eastern and northern boundaries of the North Atlantic (Testor et al., 2019).

Observations should be enhanced in key regions related to the AMOC (the Labrador and Irminger Seas and the North Atlantic passages overflows, the South Atlantic that interconnects actively the North Atlantic with the rest of the world ocean) (Frajka-Williams et al., 2019), in the Tropical Atlantic that plays an important control on weather extremes and climate modes (Foltz et al., 2019; Goni et al., 2019), and in the eastern and western boundary current systems (BCs) that are currently not sampled by the core Argo floats program, nor fully covered by the various Atlantic mooring arrays (Todd et al., 2019). Indeed, BCs not only regulate the meridional heat and fresh-water transports and cloud formation, but strongly influence atmosphere dynamics (Small et al., 2014; O'Reilly et al., 2017) and decadal variability (Gulev et al., 2013).

We recommend the continuation of all observing systems currently in place (core Argo and BGC Argo, AMOC, and PIRATA arrays, GO-SHIP cruises, surface drifters, VOS), and the enhancement of surface observations and observations in the atmosphere beyond current practices. In addition, we recommend enhancing subsurface ECV observations, as well as adding variables such as oxygen and pH, by maintaining and expanding the sensors equipping mooring arrays and observations undertaken by ships, and by implementing Deep Argo and BGC Argo.

The Pacific Ocean Background

The Pacific Ocean is the largest of the world's oceans and hosts the strongest interannual tropical climate mode, the El Niño Southern oscillation (ENSO), an ocean–atmosphere coupled phenomenon (Timmermann et al., 2018). ENSO exhibits huge worldwide socio-economical and environmental impacts (McPhaden et al., 2006). The Pacific basin accounts for much of the interannual variability of precipitation and tropical cyclones, inducing an elevated risk of drought in the western part of the basin and of flooding on the eastern side that cause widespread ecosystems disruptions, including severe bleaching of corals. Because of its remote influence through atmospheric teleconnections, ENSO also impacts the Indian and Atlantic oceans (Klein et al., 1999), and is in turn impacted by both (Kucharski et al., 2011; Terray et al., 2016).

At decadal to multidecadal timescales, the interdecadal Pacific oscillation (IPO), driven partly by decadal ENSO modulations (Power et al., 1999), is a major source for low-frequency climate variations, worldwide. The IPO affects the weather and climate in many regions of the globe (Dong and Dai, 2015), drives important state transitions observed in marine ecosystems across the Pacific Ocean (Mantua et al., 1997), and has been hypothesized as major cause of the recent slowdown in global surface warming (Kosaka and Xie, 2013). The observed warming trend in the past century has a complicated structure in the Pacific, with 'hot spots' along the western boundary currents (Wu et al., 2012). There are large uncertainties about the nature of this trend, calling for the need of sustained and uninterrupted monitoring, also with respect to its likely impacts on phytoplankton growth (Marinov et al., 2010).

The eastern tropical Pacific Ocean hosts two of the four largest oxygen minimum zones (OMZ) in the world, located to the north and the south of the equator. Significant global deoxygenation together with expansion of the OMZ in the tropical Pacific has been observed over the past 50 years (Stramma et al., 2008). This expansion will result in the transition, adaptation, and/or extinction of different marine species in the tropical Pacific Ocean (Breitburg et al., 2018).

Understanding and projecting climate changes induced by anthropogenic forcing in this region, including changes in background state and ENSO characteristics (Cai et al., 2015), are critical for assessing future socioeconomic and environmental impacts, as well as planning adaptation strategies. The latter are especially important for the highly populated coastal regions, including the Pacific island communities that are vulnerable to climate change through sea level rise, ocean acidification, and changes in storms characteristics.

Pacific Observing Requirements

Several regions of the Pacific Ocean require enhanced climate observations on top and above what stated already in the general considerations. Among them are the tropical Pacific for its unique role in seasonal to decadal changes, the Kuroshio and its extensions into the North Pacific, the eastern boundaries for their role in the hemispheric communication and radiative heat budget, and the complex low-latitude western boundary

systems, including the Indonesian throughflow (ITF) to the Indian Ocean. Because of the key role of the Pacific Ocean on global Earth's climate, it is also necessary to observe ocean surface wind stress and heat fluxes in the tropical Pacific at hourly intervals. Momentum and heat fluxes are essential for inter-calibrating satellite missions, driving ocean models and ocean reanalysis products, detecting ENSO precursors, and assessing and understanding tropical Pacific climate variations and climate change.

In the BCs of the Pacific heat and freshwater fluxes should be monitored through hourly observations of temperature, salinity, and velocity over the ocean's depth. These highly variable currents are indeed vital for predicting climate changes, for ENSO forecast and decadal prediction. Spatial and temporal coverage of subsurface measurements of oxygen, nutrients, chlorophyll, and pH should also be improved.

The parameters above could be observed by adding the necessary sensors to the existing Tropical Pacific Moored Array, which is a key component of the broader observing system. Eventual replacement of moorings with other observing technologies are being considered³ and should be done carefully, to ensure continuity of the climate records, e.g., with an overlap of the existing and new observing platforms over a sufficiently long time to allow a thorough examination of any consequences of the platform change. The existing Tropical Pacific Moored Array should be enhanced with additional direct surface flux measurements and biogeochemical and bio-optical sensors (pCO₂, chlorophyll concentration, particulate backscatter, oxygen, and nutrients). Furthermore, we recommend incorporating water isotope sampling/analysis on ships, including those servicing the Tropical Pacific Moored Array, as well as prioritizing island-based collection of rainwater, seawater, and vapor water isotopes wherever feasible, and deploying Argo floats with biogeochemical and bio-optical sensors, particularly in equatorial Pacific upwelling and OMZs regions. The current observing system, reviewed in this issue by Smith et al. (2019), would also benefit from an enhanced regional coordination in the far Eastern tropical Pacific where no mooring is currently available within the Tropical Pacific Moored Array albeit being the location of extreme El Niño development.

In general terms, we support developing a multi-platform approach for monitoring velocity, temperature, salinity, and biogeochemistry in the boundary currents of both the northern and southern hemispheres. This holds especially for the Pacific Ocean, building on the CLIVAR endorsed North Pacific Ocean circulation experiment (NPOCE) and the Southwest Pacific Ocean and climate experiment (SPICE). Finally, seasonal to interannual changes in the upper ITF that links the Pacific to the Indian Ocean should be monitored through direct observations and development of proxies for temperature, salinity, and velocity down to sill depths at hourly intervals. This can be achieved through enhancement of the IX1 XBT line with additional Argo floats and a pilot glider program, and maintaining multi-year mooring arrays to measure the full depth ITF of the major

inflow (e.g., Makassar, Maluku, and Halmahera) and outflow (e.g., Lombok, Ombai, and Timor) passages.

The Indian Ocean Background

Although the Indian Ocean is the smallest of the world's oceans, it has accounted for more than 50% of global ocean heat gain over the last decade (Vialard, 2015; Desbruyères et al., 2017) and harbors two of the most severe OMZs (Paulmier and Ruiz-Pino, 2009). Indian Ocean rim countries are home to almost one third of the global population. Many depend on fisheries and agriculture and have poor adaptive capacity, making them especially vulnerable to changes in ocean climate, including declines in fish catch, intensification of tropical cyclone intensity, increased drought (Roxy et al., 2015), and sea level rise. For instance, the Bay of Bengal accounts for 5% of tropical cyclones globally, but 80% of the associated fatalities (Paul, 2009).

The unique circulation and stratification of the Indian Ocean (Schott et al., 2009), driven by reversing monsoon winds, an influx of tropical waters from the Indonesian Seas, and massive run-off from the Asian continent, enhance important coupled modes of variability, such as the Madden-Julian oscillation (MJO) (Zhang, 2005), the monsoon intra-seasonal oscillation (MISO), and the Indian Ocean dipole (Webster et al., 1999), that have far-reaching impacts on rainfall, cyclogenesis, and ENSO. The recent rapid warming in the Indian Ocean has been attributed to an increasing trend in the ITF (Lee et al., 2015; Hu and Sprintall, 2017; Zhang et al., 2018) and an intensified Walker Circulation. Yet long-term variability in the ITF and in other dominant flux components of the basin-wide heat budget, e.g., the Agulhas Current (Bryden and Beal, 2001) or the upper-ocean overturning (Talley et al., 2003), remains poorly constrained. Modes of decadal variability also remain largely unknown in the Indian Ocean (Han et al., 2014), where the observing system dates back only 10 years.

The tropical Indian Ocean has a large warm pool (surface temperature >27.5°C), linked to the Pacific, that has a global reach, driving atmospheric convection, and the Walker Circulation. The warm pool, together with the thermocline ridge of the western tropical gyre, is strongly coupled with the atmosphere at intraseasonal timescales (MJO and MISO, Vialard et al., 2009; DeMott et al., 2015). Observing and simulating correctly these climate modes could improve monsoon forecasting and seasonal climate predictability throughout the tropics, yet measurements of upper ocean variability and surface fluxes have long been precluded in the western tropical Indian Ocean owing to piracy, while to the east, near the ITF exit, disagreements between flux products remain.

The OMZs in the northern Indian Ocean, together with changes in monsoon winds, are threatening marine ecosystems around the Asian subcontinent (Roxy et al., 2016). In the Arabian Sea, where hypoxia is well established, the OMZ has grown by 60% since the 1990s (Rixen et al., 2014), and may have already caused a dramatic shift in the ecosystem (Gomes et al., 2014). This OMZ could account for 20% of water column denitrification globally and may become a hotspot for outgassing of nitrous

³<http://tpos2020.org/>

oxide, a greenhouse gas with almost 300 times the potency of CO₂ (Naqvi et al., 2010). Observations of biogeochemical parameters to monitor subsurface expansion and impacts of these OMZs are lacking, and satellite ocean color proxies for tracking primary productivity have not been validated in this basin.

Indian Ocean Observing Requirements

The existing Indian Ocean sustainable observing system (IndOOS) is being reviewed under the leadership of the CLIVAR-IOC GOOS Indian Ocean Region Panel⁴. This review established that the current IndOOS system (see **Figure 2** for its components) resolves reasonably the equatorial variability associated with the MJO and MISO, monsoon circulation and Indian Ocean Dipole. Key phenomena or regions that require enhanced observations are the heat and freshwater transport of the ITF, Agulhas and Leeuwin BCs, air-sea fluxes, and the Arabian Sea including biogeochemical aspects such as its OMZ. Variability in the ITF could be captured through enhancement of the IX1 XBT line with additional Argo floats, a pilot glider program, and exploration of the use of tomography for monitoring heat transport in the main passages of Lombok, Ombai, and Timor. Monitoring the subtropical boundary currents can be achieved with a mixture of tall moorings, CRIES, and glider programs. Pilot hydrographic end-point moorings as part of these arrays, in waters 2000 m deep or more, will allow a better handle on the basin-scale variations in oceanic heat content. In the tropics, the RAMA (Research Moored Array for African-Asian-Australian Monsoon Analysis and Prediction) tropical observing system should be expanded westward into the Arabian Sea (now that piracy is resolved) and enhanced with more direct flux measurements and a new surface flux reference site northwest of Australia. Finally, Argo floats with biogeochemical and bio-optical sensors should be deployed throughout the Indian Ocean, particularly in the Arabian Sea upwelling and OMZ regions and in the Bay of Bengal. An overview of the IO observing system requirements is given in **Figure 2**.

Polar Oceans Background

The northern and southern polar oceans, present distinct, and at times shared, observational challenges and opportunities. The unique environment and the presence of sea ice complicate obtaining continuous, systematic observations, while promoting the development of new technology, and observational platforms. Polar oceans have experienced significant changes in heat/freshwater sources and fluxes from lower latitudes, sea ice melt, and river runoff. However, since the 1970s the decrease in Arctic sea ice cover has been widespread and dramatic (Vaughan et al., 2013), whereas Antarctic sea ice area changes have been strongly regional, with both increases and decreases (Richter-Menge and Mathis, 2017; Stammerjohn and Scambos, 2017). More recently, polar amplification, where the polar region warms to higher temperatures and more rapidly than lower latitudes, has become of major concern in the northern hemisphere, but is not (yet) realized in the Southern Ocean (Lind et al., 2018).

⁴<http://www.clivar.org/indoos-review-2006-2016>

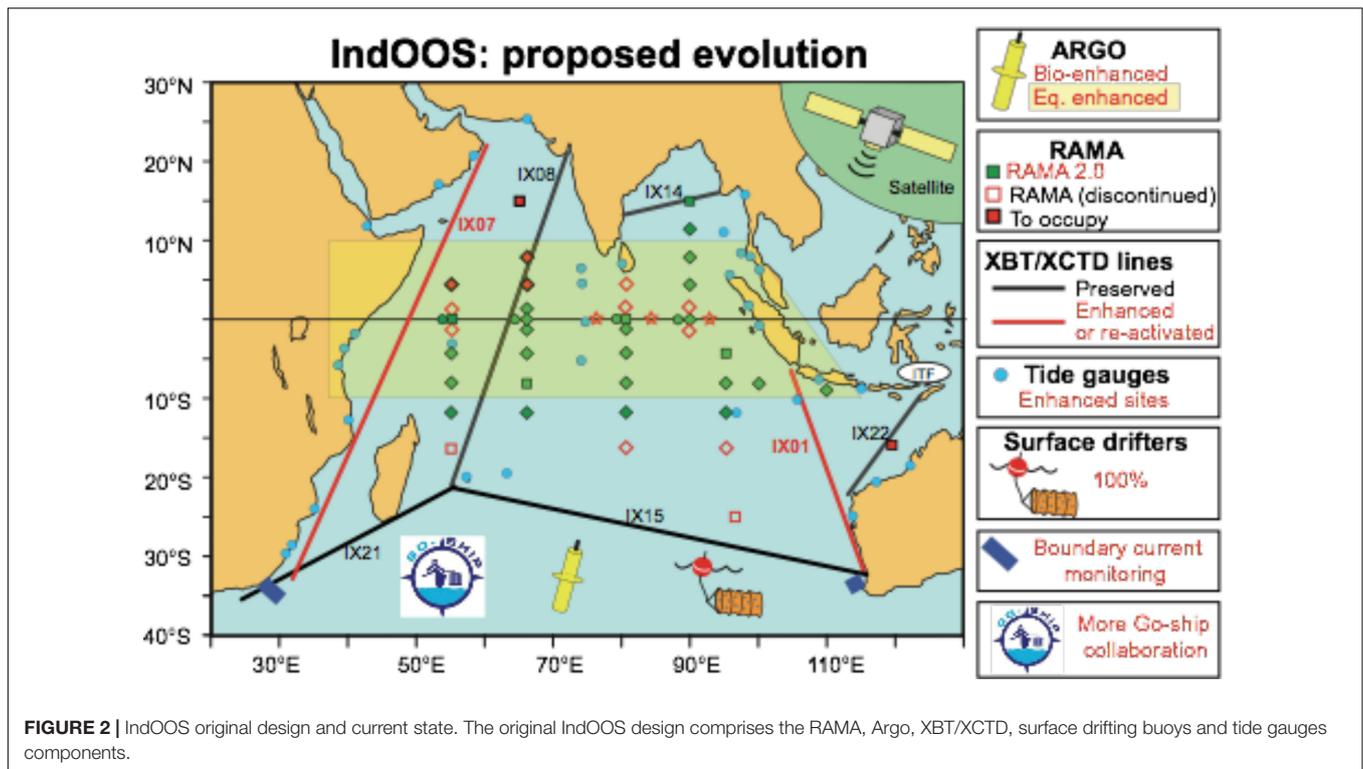

The Arctic Ocean plays a key role in the global overturning circulation and is a nexus of Atlantic Ocean variability, Pacific Ocean variability, and coastal environments, with run-off from ice sheets and large rivers being critical to ocean properties and circulation. A number of hypotheses for Arctic climate variability have been proposed but cannot be confirmed with current measurements. For example, how Atlantic water enters the Arctic, how it is redistributed within the Arctic interior, or the balance of forces that control the net outflow through the Canadian Arctic Archipelago. This complex system requires an integrated observational network to monitor and characterize sources and sinks of heat and salt into and out of the Arctic, and their changes. Direct observations of these sources are lacking, as in the case of fresh water inputs due to ice shelf basal melt and iceberg calving. However, in the broader region of the Arctic Mediterranean (Nordic Seas and Arctic Ocean), current meter arrays have been in operation at critical gateways or “choke points,” such as the Bering Strait and across the Greenland-Scotland Ridge, since the 1990s, providing monthly, if partly intermittent, time-series (e.g., Bringedal et al., 2018). Arrays operate also at key sections within the region, e.g., Svinøy Section, Barents Opening, and in the Fram Strait (Dickson et al., 2008), and in Davis Strait (Curry et al., 2014).

The Southern Ocean connects the Atlantic, Pacific, and Indian Oceans and, as explained in more detail in Newman et al., 2019, has a major impact on climate change signals. Recent estimates show that Southern Ocean circulation changes may account for 75% of the total excess heat linked to the airborne fraction of anthropogenic CO₂ and 50% of the anthropogenic CO₂ taken up by the ocean (Frölicher et al., 2015).

Decadal variability in heat and CO₂ storage in the “upper” and “lower” loops of the MOC in the Southern Ocean may modulate both anthropogenic and natural CO₂ reservoirs (Gruber et al., 2019). The Southern Ocean also plays a critical role in the ventilation of the low latitude ocean interior through mid- and deep-water masses. Freshening and volume decrease of the heaviest water mass in the world’s ocean, the Antarctic bottom water (AABW), are the two strongest decadal signals ever observed in the deep oceans (Rintoul, 2018). AABW is a mixture of high salinity brine rejected in coastal polynyas during ice formation and surrounding circumpolar deep water, but the mixing process has not been observed directly, and links between surface forcing and AABW remain speculative. These factors, combined with the seasonal variability in sea ice, intense meso- and submesoscale features and extreme synoptic scale winds, pose a challenge to resolving the seasonal to decadal variability in the storage, and ventilations through sustained observations.

High-Latitude Observing Requirements

In the polar oceans, observations are needed to monitor and characterize the ice-ocean system, the coastal-open ocean system, and the freshwater/heat transports into and out of these systems. Satellite observations of the polar oceans have provided a multi-decadal record of climate variability, but only for a limited number of fields. Remote sensing allows for monitoring sea ice concentration, thickness, age, and drift. Furthermore, it provides SST, sea surface salinity, and ocean

bottom pressure. However, *in situ* measurements of these remote sensing products are rare, making calibration and validation of satellite algorithms challenging.

Free-drifting profiling floats present challenges in the polar oceans due to the likelihood of being trapped under ice and damaged. Technology developments allow the floats to sense the ice presence and store data for a number of years, but failure rates remain high. Efforts are underway to improve this problem. New technologies are being tested, such as the NOAA autonomous sailing drone that measures the near-surface ocean and atmosphere environments, and a system of moored sound sources maintained by the Alfred Wegener Institute in the Weddell Sea.

In the Arctic, well constrained transport estimates of volume, heat, and salt/freshwater in and out of the basin exist. It is imperative to maintain such gateway observations at a time when the climate system is in flux. However, key branches of the circulation and exchange, e.g., the Arctic circumpolar boundary current (ACBD), remain mostly unobserved. Significant work has been done to characterize freshwater storage within the Arctic Ocean (Rabe et al., 2014; Prowse et al., 2015), but additional observations are needed to characterize heat storage, transport, and mixing in this basin. Buoys to measure ice motion, surface pressure, and air temperature have been deployed and monitored by the International Arctic Buoy Program since 1978⁵, but measurements in the vicinity of sea ice remain limited.

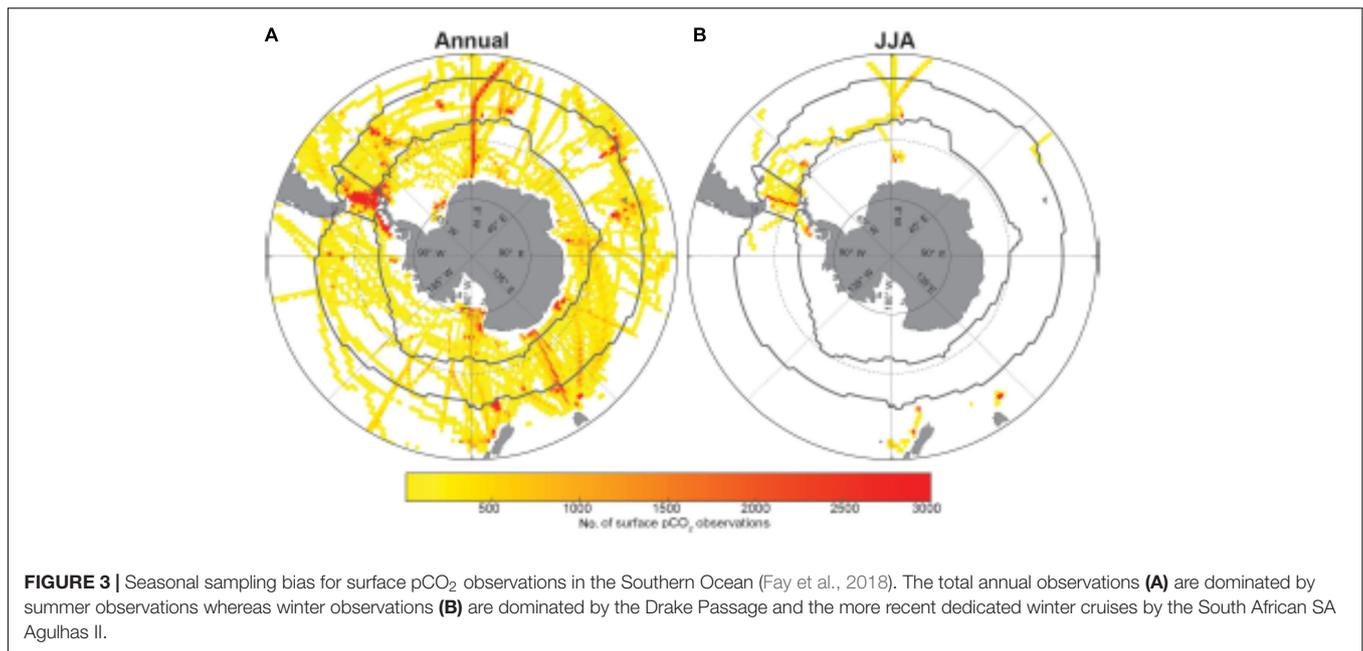

Observing the Southern Ocean presents additional challenges due to the distance from population centers and higher costs

to deploy ships and autonomous platforms. As in the Arctic, surface fluxes from the atmosphere and ice (both land-based and floating) need additional sustained observations. Among all climate variables, ocean-, and sea-ice surface flux estimates are simultaneously the most fundamental and uncertain (Bourassa et al., 2013). Their seasonal cycle is not well constrained and should be a focus for the next decade (Mongwe et al., 2018; Gruber et al., 2019). Seasonal biases in the observational record (Figure 3) pose significant challenges to constraining mean annual variability and trends (Fay et al., 2018). Significant gaps remain in observations of the ice-impacted oceans for non-summer seasons (Newman et al., 2019).

The continuation of the high-resolution full depth CTD lines as part of GO-SHIP, particularly the 3 choke points (SR01, SR03, and A12), is essential on a 5 – 10-year repeat cycle to constrain not only storage rates but also their decadal variability. Greater focus should be given to the winter Mode Water and Intermediate Waters subduction areas at the boundary between the ACC and the sub-tropical systems. Floats and deep-diving gliders may contribute to a future integrated observatory of the Southern Ocean, complementing the seasonal biased ship-based data.

Although the Southern Ocean MOC cannot be directly quantified, it is possible to estimate the transport of mass, heat and other physical and biogeochemical tracers at the edge of it, usually defined to be at 30°S. These transports are routinely computed in climate models, pointing to common biases such as the underestimation of bottom water and the overestimation of light water exports (Downes et al., 2015). Recent estimates of meridional transports of mass, heat and salt along the Atlantic sector at 32–35°S were obtained

⁵<http://iabp.apl.washington.edu>

through the SAMOC project⁶. Similarly, new observational estimates of ACC transport across Drake Passage reported values much larger than model estimates (Donohue et al., 2016). All these observations should be sustained and enhanced over the next decade. In this framework, we recommend establishing a Deep Ocean Observing System that would include instrumented sea floor cables, as routinely done in other regions.

Additional observations are needed to monitor the mixing and exchange of water masses between shelves and open ocean. Furthermore, sea-ice freshwater flux has been recognized as a key player in water mass formation and transformation in both data assimilating models (Abernathy et al., 2016) and a combination of observations (Pellichero et al., 2018). These unprecedented observations should be maintained and enhanced (Gray et al., 2018).

The paucity of Southern Ocean station data leads to relatively low accuracy in estimates of wind stress strengthening and poleward shift during the last decades, quantified as trends in the Southern Annular Mode (Swart and Fyfe, 2013; Swart et al., 2018). Reliable estimates of westerly winds and confidence in recent wind trends are fundamental. Accurate estimates of easterlies and katabatic coastal winds are also needed for understanding sea-ice extent and AABW production. Moreover, coastal winds may partially explain the subsurface warming to the west of the Antarctica Peninsula that is largely responsible for the glacial ice mass loss in the same region (Spence et al., 2017), and for significant changes in ACC transport (Zika et al., 2013).

Hydrographic observations since the 1950s in combination with earth system models indicate that the warming and freshening of the Southern Ocean over recent decades can be

attributed to a combination of greenhouse gas emissions and ozone depletion (Swart et al., 2018). It is critical that the Southern Ocean continues to be carefully monitored as the expectation is that warming and freshening will carry on into the foreseeable future with major implications for sea-ice, ice-sheets, as well heat and carbon uptake, in the region.

OBSERVING REQUIREMENTS FOR BOUNDARY CURRENTS AND CONTINENTAL MARGINS

Background

Tropical and subtropical coastal oceans host marine resources of great value to human societies and their sensitivity to anthropogenic change is amplified by proximity to growing population centers. The coastal oceans (e.g., areas within Large Marine Ecosystems; Sherman and Alexander, 1986) account for 95% of the global fish catch (Stock et al., 2017) despite covering about 22% of the ocean's surface area, and are exceptionally complex across a range of scales and steep gradients in physical and biogeochemical properties.

Over the past centuries interdisciplinary observations of the coastal oceans have offered unparalleled insight to the links among climate processes, fluid dynamics, ocean biogeochemistry, and marine fisheries (McCabe et al., 2016). Coastal upwelling, vertical mixing, and lateral and vertical transport of waters along and across coastal boundaries, combined with riverine delivery of allochthonous inorganic and organic matter (Liu et al., 2018), contribute to the biological production in the eastern BCs and broadly in tropical coastal systems. Canonical western BCs are characterized as oligotrophic

⁶http://www.aoml.noaa.gov/phod/SAMOC_international/

marine environments, in which mesoscale processes, coastal bathymetry, and continental runoff can locally enhance primary production.

On both eastern and western margins of tropical and subtropical basins, interactions between topographic features, coastal atmospheric jets, coastally trapped and internal waves, Ekman transport and submesoscale and mesoscale circulations (Figure 4) further complicate our ability to represent coastal dynamics in climate models (Richter, 2015). These model biases affect seasonal prediction and climate change projections through non-linear processes such as atmospheric deep convection (Belmadami et al., 2014), and cannot be easily corrected *a posteriori*.

Primary production and the fate of organic matter influence the capacity of the coastal oceans to capture atmospheric CO₂ (Fiechter et al., 2014). Currently, the net effect of coastal productivity and CO₂ flux on the global carbon cycle is highly uncertain. Closely coupled to CO₂ atmosphere-ocean exchange is growing concern for acidification and deoxygenation of coastal waters (Ito et al., 2017). While empirical relationships between climate conditions and marine ecosystems have been documented, their stationarity over long time periods is uncertain, particularly as coastal systems are forced by physical climate conditions never observed in the recent observational record (Rykaczewski and Dunne, 2010).

The upwelling that occurs in eastern tropical-subtropical boundary currents is highly sensitive, depending on latitude, to the adjacent surface and subsurface water masses and/or to the coastal wind stress, the so-called coastal low-level jet (LLJ) (Fennel et al., 2012). This sensitivity is reflected in the biogeochemical consequences of the upwelling. The representation of both water masses and coastal wind stress are challenging in numerical models, and observations are lacking and/or are collected at national level with limited international coordination. LLJs are located at the atmospheric low-level inversion capping the planetary boundary layer (PBL) and separate moist, cool marine air-masses from warm, dry continental air-masses. They separate prevalent mid-tropospheric westerlies and lower-tropospheric easterlies, and are due to atmospheric subsidence associated with subtropical anticyclones (Takahashi and Battisti, 2007; Toniazzo et al., 2011). Currently almost no *in situ* data is available on some of the LLJs, such as that of the Benguela (Patricola and Chang, 2016) and scatterometer satellite data have limitations within the coastal fringe (Astudillo et al., 2017). Even where regular measurements exist (e.g., Chile-Peru and California coasts) stations are land-based and lateral gradient information is sparse.

Western BCs of the subtropical gyres, such as the Gulf Stream, the Kuroshio, the Brazil, the Agulhas, and the East Australian Currents play important roles in climate system. They export heat, salt, and nutrients from the tropics, release vast heat and moisture to the atmosphere, and play important roles in a number of atmospheric phenomena such as precipitation (Minobe et al., 2008), positioning of the storm

track (Small et al., 2014), and blocking and positioning of the jet stream (O'Reilly et al., 2017). Alike eastern boundary upwellings, western boundary currents mediate the horizontal and vertical flux of water masses from the permanent thermocline to the mixed layer (Blanke et al., 2002). They can also have a strong influence on the uptake of carbon dioxide (CO₂) from the atmosphere (Takahashi et al., 2009), and thus be a key component of the carbon cycle. The ocean dynamics in the western boundary regions can control the local expression of large-scale sea-level rise on the eastern coasts of the continents (Minobe et al., 2017).

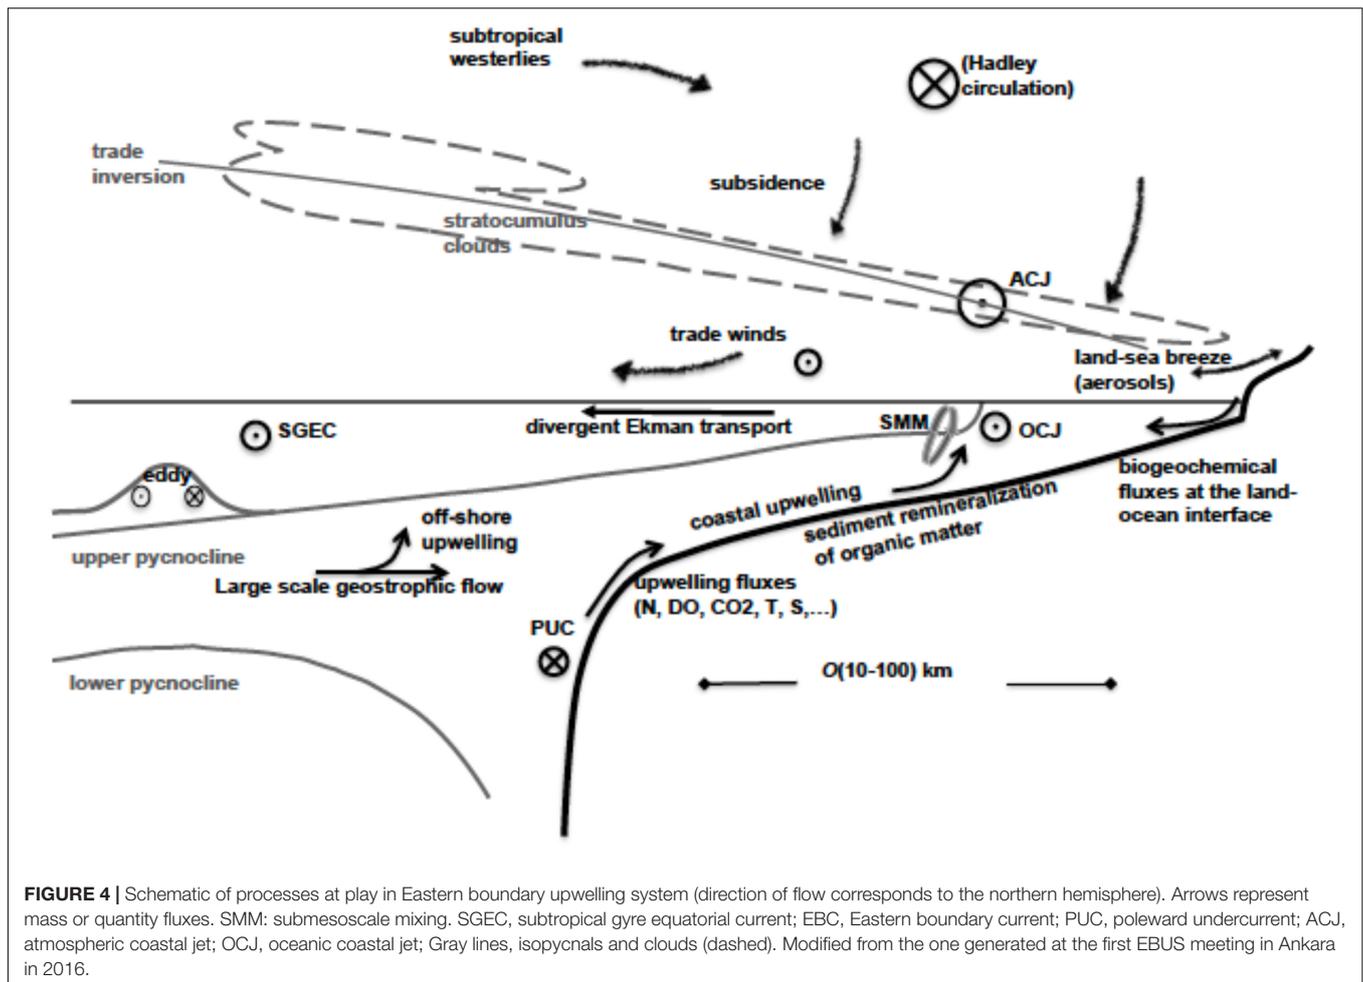

Observing Requirements

Major challenges in observing the BCs and the continental margins include elevated mesoscale and submesoscale variability, the heterogeneity across regions, and the complexity of processes affecting the dynamics and thermodynamics of the air-sea interface. Decades of consistent *in situ* observations are required to distinguish long-term anthropogenic change from changes associated with natural variability (Takahashi and Martinez, 2017). They are also necessary for better understanding extreme events, including marine heatwaves that often occur in the eastern boundary upwelling systems due to shallow thermocline associated with large-scale climate drivers and/or local air-sea interaction (Bond et al., 2015; Kataoka et al., 2018).

Multidecadal and interdisciplinary observations are available in some eastern BCs, such as the California (Goericke and Ohman, 2015) or Peru (Graco et al., 2017) Current systems and in all the western boundary currents. However, only baseline observations are available in most coastal oceans, particularly in the southern hemisphere. Given the coastal oceans' disproportionately large importance to human society and marine ecosystems, continued emphasis should be placed on increasing in-situ observations and sharing existing data collected within national programs.

Boundary current systems observing systems should be developed and implemented to cover the upper 1500 m continental slope in dynamical regions key to ocean-atmosphere interactions that are heavily undersampled (see Todd et al., 2019 for more insights). Enhanced the monitoring of both eastern and western boundary currents is required to more accurately characterize their variability and change, and campaign-type observational experiments are necessary to improve understanding of the mechanistic processes controlling them.

The accumulation of interdisciplinary oceanographic observations in boundary current regions make them central to CLIVAR's goals of understanding climate phenomena on a range of scales and informing adaptation and mitigation strategies regionally. Efforts, however, should be coordinated among countries, and data –for both ocean and atmosphere – made available to the scientific community. While the dissemination of open ocean observations has made exceptional steps in response to internationally coordinated programs, data collected in territorial waters remains subjected to observation protocols, and usage policies that differ widely between countries. They are often inaccessible to the international and even national community

due to their sensitive nature in terms of economic (e.g., oil exploration and fish stocks), military and border enforcement considerations. Restrictions also involve sovereign airspace, limiting *in situ* observations of the atmospheric boundary layer, and which is a critical component of the coupled coastal upwelling system. Height-resolved atmospheric observations are particularly scarce and a major limitation for the understanding of coastal dynamics of upwelling regions.

We argue for fostering finer and more integrated physical and biogeochemical *in situ* sampling that would naturally involve R/V surveys, autonomous sensors (drifters, profilers, and gliders), and moorings. Considering the general gap in coastal marine *in situ* data, a specific effort could target the ability of such communities to install and maintain long-term high-frequency ocean-atmosphere data-buoys at homogenous standards, especially in the tropics-subtropics. The ship time and sea-going capacity of various national laboratories for fishery assessment should also be better leveraged. Coordinated coastal process studies in different regions are required to document the relationship between coastal upwelling and meteorological conditions, and to improve understanding of the mechanical and thermal forcing of the near-surface ocean in coastal areas, of surface turbulent fluxes, air-sea exchanges, transport and mixing

at scale of kilometers or less, and biogeochemical exchanges, interactions, and cycling.

OCEAN OBSERVATIONS FOR CLIMATE MODELING AND CLIMATE INFORMATION

Background

One of the key communities that use ocean observations are the participating governments through the inter-governmental panel on climate change (IPCC). Since the Fourth assessment report the IPCC assessment cycles includes a chapter on oceans. IPCC Working Group reports focus on climate change, frequently at global scales, over long periods of time, and have common sets of principles with consequences for the observing system. There is demand for multiple lines of evidence to support conclusions with estimates of uncertainty, and the scientific conclusions have to be traceable to the observations or simulations that underlie them. One of the fundamental questions is whether the observed changes can be attributed to anthropogenic forcing and alternative natural forcing, like variations in solar radiation,

volcanic eruptions, and internal variability, can be excluded. There is also growing interest about ocean extremes and abrupt events, requiring the observational record to include time-scales of these extremes.

Since OceanObs'09, the role of ocean modeling and data assimilation in furthering understanding and enhancing prediction capabilities has increased to the point where today models and state estimations are integral to oceanography and climate science. In particular, models initialized from observed climate conditions through state estimation products are used in prediction or projection systems. State estimation involves a simultaneous analysis of the state of both ocean and atmosphere. These coupled state estimations will benefit from accurate and complete estimates of the exchange of heat and momentum at the ocean-atmosphere interface, noting the requirement for global balances.

Recent advances in the fidelity of models and their enhanced use arose through ongoing community efforts to improve the numerical and physical foundations of ocean models. These advances also concern the increased role of open source development: by embracing the input of any and all scientists and engineers, and offering a systematic and documented software framework to ingest that input, ocean model codes have been taken from the purview of a few experts circa 2009 into the light of an open and vigorous community circa 2019. Further details of the enhancements to numerics and physics are summarized in Fox-Kemper et al. (2019); here we focus on the role of observations for improving the skill of ocean models as part of assimilation/prediction systems.

From numerical schemes to parameterizations, ocean circulation models have improved over the last decade [see Griffies et al. (2010) for an assessment a decade ago]. New numerical approaches, including Arbitrary Lagrangian-Eulerian approaches to vertical coordinates and unstructured and nested horizontal grids, preserve large-scale budgets while allowing for regional specificity, and improved stability and accuracy. Coupled models – ocean-sea ice, ocean-atmosphere, and ocean-ice shelf – are evolving rapidly and reveal emergent phenomena that uncoupled models fail to capture. Consistent coupling requires numerical and parameterization advances that will lead to more robust estimates of oceanic and cryospheric changes, including sea level rise. Significant model biases have been reduced through improved parameterizations of mesoscales, submesoscales, boundary layers (Villas Boas et al., 2019), internal mixing, and other processes, in turn made possible by process-level understanding through high-resolution models and dedicated observational studies.

Requirements for Climate Modeling and Forecasting

As the community moves into higher-resolution and more accurate modeling, new observational challenges arise (Fox-Kemper et al., 2019). Continuous monitoring of global and process-level diagnostics is key to ensuring continued progress in model development. At the same time, coordinated sets of observing system simulation experiments (OSSEs) can help

optimizing cost and scale effectiveness of future long-term observational systems (Mazloff et al., 2017).

Key diagnostics and their observational requirements include the annual cycle at various latitudes. In the polar oceans, for example, challenges in observing it within the seasonal ice zone and a bias toward summer values in the observations cause large model uncertainties in surface momentum and buoyancy flux that are, in turn, among the largest sources of model spread (Downes et al., 2015; Farneti et al., 2015). Sea ice thickness, sea ice volume, AABW and High Salinity Shelf Water formation rates and processes, ice shelf basal melt (including rates of changes), iceberg calving rates, and ocean heat fluxes are also among the data-driven products required to meet WCRP research and modeling needs, and reduce divergence in ocean reanalyses (Uotila et al., 2018).

In addition, many new applications of ocean and climate models, especially state estimation, monitoring, and decadal predictions, require observational data that is high quality in representativeness, accuracy, precision, and sampling. Realistic models benefit from these observations, and at the same time provide help to identify gaps in observational schemes.

Observational Products for Climate Information

Ocean reanalyses (or syntheses) are a fundamental tool for present-day climate monitoring because they provide a dynamically consistent, four-dimensional view of the oceans. Although the propagation of the observational content into unobserved regions or periods is non-trivial, the use of ocean reanalyses products increased significantly during the last decade (Stammer et al., 2016). Ocean reanalyses that combine an ocean general circulation model with available ocean observations use new, improved methods for comparing observations and modeled data. Reanalyses, if consistent mathematically and dynamically, can provide information for key climate diagnostics that are mostly unobserved, such as deep ocean heat content changes and their contributions to sea level rise (Karspeck et al., 2017; Palmer et al., 2017). Synthesis efforts are widely used in climate studies such as the annual State of the Climate report (Blunden et al., 2018), and applications ranging from downstream (biogeochemistry, fishery, and energy) modeling to downscaling (high-resolution regional simulations) deployments, depend upon their availability.

The development and production of ocean reanalyses calls for coordinated efforts in disseminating quality-controlled observational datasets, which may in turn benefit from delayed time quality checks e.g., relying on feedback information from assimilation systems and/or sophisticated buddy checks (e.g., Cabanes et al., 2013). Among these datasets, IQuOD is a recently produced collection of marine sub-surface observations, which aims at processing and disseminating unbiased climate data of the highest quality, consistency, and completeness (Domingues and Palmer, 2015⁷). Among many existing datasets, *in situ* observations of biogeochemical parameters have been compiled and quality controlled by the global ocean data analysis project

⁷www.iquod.org

(GLODAP), that includes over one million seawater samples (Olsen et al., 2016⁸). Similar initiatives have been implemented by several space agencies for satellite parameters (e.g., the European Space agency climate change initiative (CCI), or the Making Earth System Data Records for Use in Research Environments (MEaSUREs) programs through the NASA Earth Science Data Systems). Finally, there is the need to sustain and maintain a large number of observational datasets (e.g., currents from drifters or ADCP, tide-gauge data, air-sea flux measurements, etc.) that are used for validation purposes and enable improvements of, and linkages among, ocean models, and assimilation systems (Balmaseda et al., 2015).

Investigating ocean heat content products, Abrams et al. (2013) concluded that a major source of error was in the interpolation-methods of the underlying time series. Cheng et al. (2017) identified the culprit in assuming in the interpolation that missing data can be treated as background climatological field. This assumption creates a low bias in the estimates, that for global heat content becomes a significant fraction of the trend (Figure 5). New estimates agree better with, and lie with the spread of, CMIP5 simulations of the historical period.

Controlling these biases demands high quality reference temperature data sets with expendable measurements from Argo and XBT lines from ship of opportunities as done in

the IQuOD project. Additionally, the analysis and gridding of the observations should be monitored through systematic reviews and assessments. Finally, it is essential that the observed records are tested against those from climate models (Figure 5, lower panel).

Critical for reanalyses and objective analyses is the provision of uncertainties for each observational based product, ideally in form of error covariances. However, uncertainty information needs to be provided also for model results, and in either case should account for omissions, sampling and systematic errors.

Finally, an important downstream application is the initialization of coupled subseasonal to decadal prediction systems (Marotzke et al., 2016), where improved data assimilation schemes have led to increased predictability (Bellucci et al., 2011; Polkova et al., 2014; Liu et al., 2017). However, model-consistent coupled assimilation schemes will ultimately be required to optimize prediction skills and improve model biases.

SUMMARY AND FINAL REMARKS

Climate monitoring requires long, sustained and high-quality measurements of essential and process-oriented climate parameters in the ocean, including surface fluxes of heat, freshwater, and momentum. For climate purposes, the

⁸www.glodap.info

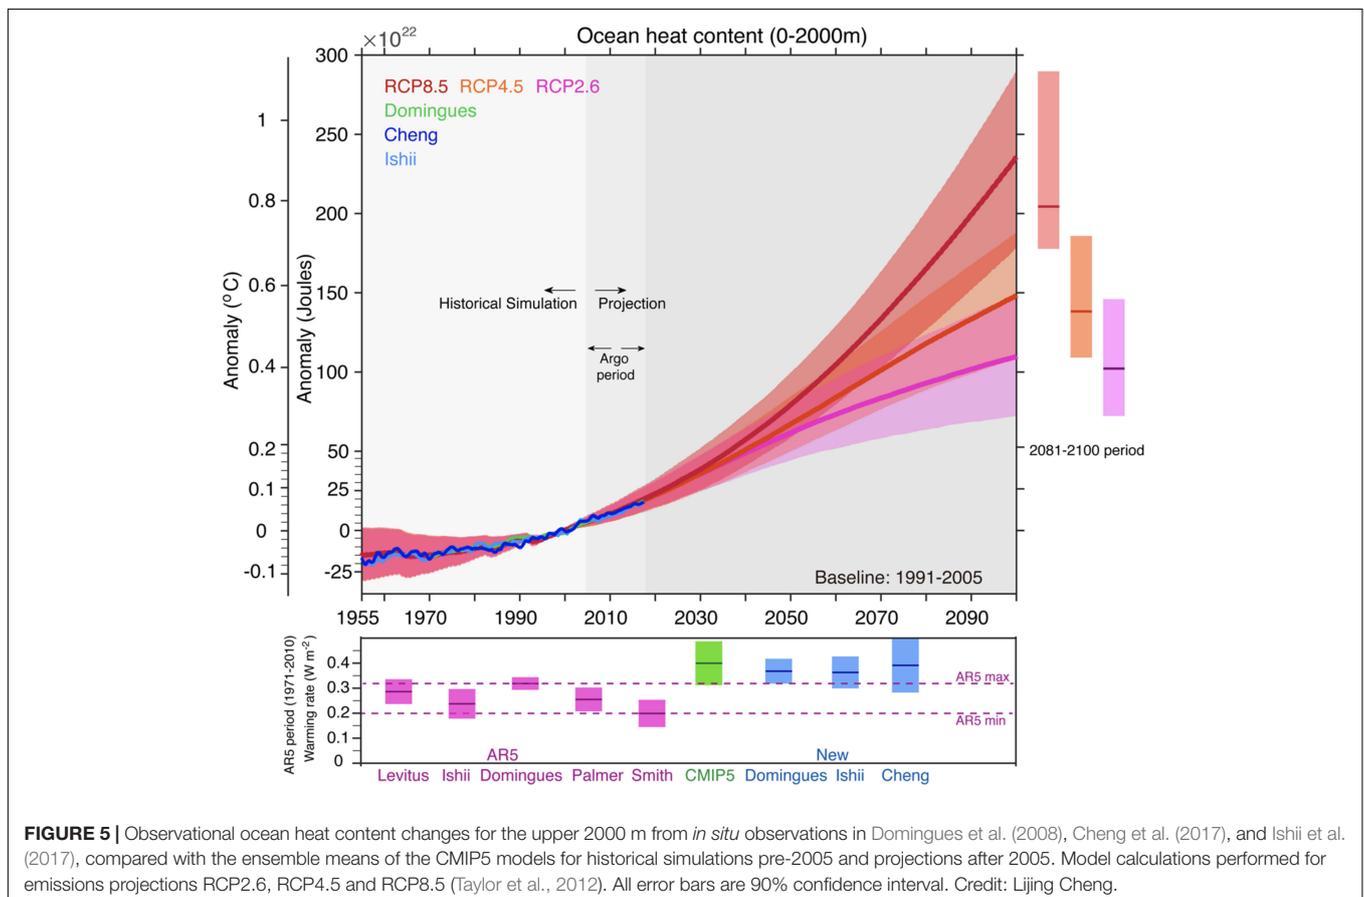

FIGURE 5 | Observational ocean heat content changes for the upper 2000 m from *in situ* observations in Domingues et al. (2008), Cheng et al. (2017), and Ishii et al. (2017), compared with the ensemble means of the CMIP5 models for historical simulations pre-2005 and projections after 2005. Model calculations performed for emissions projections RCP2.6, RCP4.5 and RCP8.5 (Taylor et al., 2012). All error bars are 90% confidence interval. Credit: Lijing Cheng.

length of uninterrupted timeseries, and the stability of the measurements are critical.

The climate observing system needs to include both satellite and *in situ* observations. A mix of platforms and technologies, in orbit and *in situ*, will greatly improve the chance to meet user requirements, regionally, and globally. Synergies between all components and platforms are fundamental also to insure the cross-calibration of parameters for quality purposes. Each satellite mission should have an in-situ counterpart that optimizes data calibration, stability and space/time sampling, and vice versa. Such a system is parameter oriented; to maximize its use and utility, the subsequent required step is the merging of observations into a parameter time series. Ocean and climate syntheses are therefore an integral part of this endeavor.

Subsurface measurements are critical to monitor and investigate the ocean role in the climate system. It is a priority to expand the Argo program to the full water column and under sea ice, and to augment high-quality sections and timeseries networks, especially in BCs. A global, continuous, *in situ* network of gliders would contribute effectively toward this objective. All existing elements should include O₂ and CO₂ sensors, as well as nutrient monitoring, a testimony of the increasingly interdisciplinary nature of climate science. Improving both quality and coverage of surface flux measurements of heat, carbon, freshwater, and momentum is mandatory. At the same time the existing satellite fleet should be sustained and expanded, to ensure that surface salinity, gravity, and winds etc are part of a long-term, stable monitoring system.

The climate observing system cannot be static, but needs to evolve scientifically and technically, considering new sampling needs, new sensors and technological advances. Reviewing the adequacy of present-day observing system and its future requirements will allow to focus research and innovation in areas where existing technologies do not meet expectations and needs.

Finally, building and sustaining a climate observing system in the ocean relies critically on capacity building, cooperation, and coordination among the international community. It is indispensable to motivate and support the scientific communities

in emerging and developing economies to take ownership for long-term, quality-controlled climate observations, and to use them to produce actionable climate information. This last step is indispensable to the generation of regionally relevant climate information.

AUTHOR CONTRIBUTIONS

DS and AB created the outline of topics and wrote the proposal of the manuscript. All authors contributed to the writing and editing processes of the manuscript, and recommended the references and examples.

FUNDING

This work was partly supported by the DFG funded excellence center CliSAP of the Universität Hamburg (DS). AB was supported by the National Science Foundation through award NSF-1658174 and by the NOAA through award NA16OAR4310173. SM was supported by the Earth Systems and Climate Change Hub of the Australian Government's National Environmental Science Program.

ACKNOWLEDGMENTS

Comments from the two reviewers are gratefully acknowledged. We thank all the CLIVAR panel members who contributed with helpful comments and suggestions to this work. The International Cooperation that CLIVAR enjoys would not be possible without the organizational leadership of the CLIVAR ICPO hosted by the First Oceanographic Institute (FIO) in Qingdao, China, the continuous support of the US-CLIVAR office, and the scientific leadership and support of the World Climate Research Programme. NCAR is sponsored by the US National Science Foundation. BD acknowledges supports from FONDECYT (project 1171861).

Turbulent and radiative exchanges of heat between the ocean and atmosphere (hereafter heat fluxes), ocean surface wind stress, and state variables used to estimate them, are Essential Ocean Variables (EOVs) and Essential Climate Variables (ECVs) influencing weather and climate. This paper describes an observational strategy for producing 3-hourly, 25-km (and an aspirational goal of hourly at 10-km) heat flux and wind stress fields over the global, ice-free ocean with breakthrough 1-day random uncertainty of 15 W m^{-2} and a bias of less than 5 W m^{-2} . At present this accuracy target is met only for OceanSITES reference station moorings and research vessels (RVs) that follow best practices. To meet these targets globally, in the next decade, satellite-based observations must be optimized for boundary layer measurements of air temperature, humidity, sea surface temperature, and ocean wind stress. In order to tune and validate these satellite measurements, a complementary global *in situ* flux array, built around an expanded OceanSITES network of time series reference station moorings, is also needed. The array would include 500–1000 measurement platforms, including autonomous surface vehicles, moored and drifting buoys, RVs, the existing OceanSITES network of 22 flux sites, and new OceanSITES expanded in 19 key regions. This array would be globally distributed, with 1–3 measurement platforms in each nominal 10° by 10° box. These improved moisture and temperature profiles and surface data, if assimilated into Numerical Weather Prediction (NWP) models, would lead to better representation of cloud formation processes, improving state variables and surface radiative and turbulent fluxes from these models. The *in situ* flux array provides globally distributed measurements and metrics for satellite algorithm development,

product validation, and for improving satellite-based, NWP and blended flux products. In addition, some of these flux platforms will also measure direct turbulent fluxes, which can be used to improve algorithms for computation of air-sea exchange of heat and momentum in flux products and models. With these improved air-sea fluxes, the ocean's influence on the atmosphere will be better quantified and lead to improved long-term weather forecasts, seasonal-interannual-decadal climate predictions, and regional climate projections.

INTRODUCTION

Societal Importance of Air-Sea Fluxes

The oceans impact weather and climate by heating (and cooling) the lower atmosphere. In particular, as seawater evaporates, the ocean surface cools; and when the moisture later condenses into cloud droplets, this heat is released, warming the atmosphere. This moistening, and then warming, makes the air buoyant, driving low-level baroclinicity and atmospheric convection, causing wind convergence at the surface and divergence aloft. At the equator, ocean heating of the atmosphere can result in towering convective clouds that reach the top of the troposphere. These disturbances in turn drive teleconnections in the atmosphere, affecting weather and climate remotely. Most dramatically, every 2–7 years, zonal shifts in the surface heating patterns along the equatorial Pacific, associated with El Niño Southern Oscillation (ENSO), lead to climate extremes across the world. Patterns of surface heat fluxes (Figures 1, 2) also affect large-scale atmospheric circulation patterns, with deep convection over the thermal equator forming the upward branch of the “Hadley Cell” that drives trade winds. Westerly jet streams in both hemispheres are likewise associated with vertical-meridional cells in the midlatitude and high latitudes. Again, their rising branches and storm tracks are aligned with the surface heating of the atmosphere associated with warm ocean western boundary currents that extend into the midlatitude ocean basins (Figures 1, 2). These surface wind patterns, e.g., westerly winds at high latitudes and easterly trades in the tropics, in turn drive the ocean general circulation. Western boundary currents associated with the wind-forced subtropical ocean gyres are particularly important as they carry warm water poleward, helping to transfer heat from the tropics (where there is greater heating of the earth's surface by solar radiation per area) to higher latitudes (where heat lost at the surface by latent and sensible heat flux and net infrared cooling is greater than that gained by solar radiation). As discussed in this paper, quantifying these air-sea fluxes, which represent the direct communication between the ocean and atmosphere, is challenging. Through the recommendations presented here, we believe that remaining large biases and uncertainties that result in differences in global fields (Figures 1C–F) could be reduced by up to an order of magnitude, enabling better resolution of phenomena on scales ranging from sub-diurnal and mesoscale to global and interannual.

Reducing inaccuracies (both biases and random uncertainty) in air-sea fluxes is important for improving long-term weather and climate predictions. Because the ocean's capacity to store heat is about 1000 times greater than that of the atmosphere, long-term weather and climate predictability has its origins in the oceans. Heat storage and release occurs on a range of time scales (Figure 2 and Supplementary Table S1) and can provide predictability out to 10–100 days (e.g., Madden-Julian Oscillation, Asian/Indian Monsoon), on seasonal-interannual time scales (e.g., ENSO), and out to decades (e.g., Pacific Decadal Oscillation, Atlantic Multidecadal Oscillation). Predictions of weather and climate on these time scales have great economic benefits for agriculture, water resource management, energy management, human and ecosystem health among others. Thus, to achieve useful predictions we must be able to quantify where, when and how much heat is released to the atmosphere. As a first step, here, we discuss strategies for improving our ability to quantify the amount of heat that at present is being exchanged between the ocean and atmosphere, regionally and globally. Because these air-sea heat exchanges are highly related to the surface dynamics and turbulent properties, we will also address quantification of wind stress.

Strong air-sea fluxes can occur on short time and space scales (Figure 2 and Supplementary Table S1), challenging both *in situ* (because of technical difficulties in extreme conditions and undersampling) and satellite observations (because of grid-averaging). The primary external time scales affecting air-sea fluxes are the diurnal cycle and the annual cycle associated orbital forcing. Internal dynamics lead to a range of other time and space scale variability in wind stress and air-sea heat fluxes. Sea-surface temperature (SST) fronts in the ocean are particularly critical to air-sea fluxes. The largest magnitude and temporal variability of air-sea fluxes is found in regions associated with SST fronts, specifically at western boundary currents such as the Gulf Stream, where intense poleward currents carry warm tropical water into the subtropics. In winter, large ocean heat loss is associated with cold air outbreaks, when cold and dry air blowing over much warmer water drive frequent episodic high flux events (e.g., Bond and Cronin, 2008; Shaman et al., 2010; Tilinina et al., 2018). Additionally, the intense SST gradients at ocean fronts result in strong heat flux gradients. These strong gradients in heat flux are known to be crucial for modulating both synoptic atmospheric variability and in turn the mean atmospheric state (Parfitt et al., 2016; Parfitt and Seo, 2018). Away from ocean fronts, whilst

turbulent mixing of colder and dryer air aloft generally results in a near surface air temperature cooler than the SST and relative humidity less than 100%, the net surface heat loss from the ocean is much weaker. As will be discussed below, there are many challenges associated with resolving air-sea fluxes in regions of strong ocean fronts.

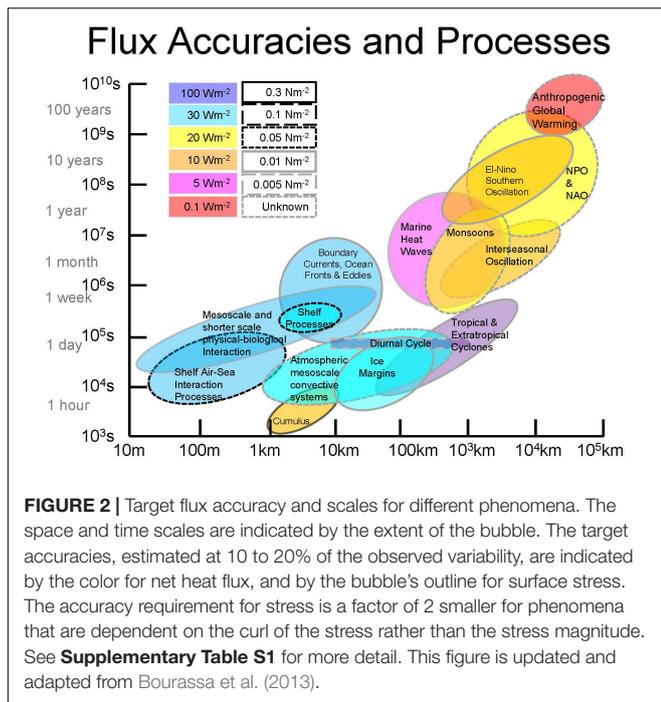

Because the specific heat capacity of water is considerably larger than that of land, air temperature is more variable over land than over the oceans, leading to a tendency for milder coastal climates than inland. Oceanic heat loss due to evaporation is associated with moisture fluxes that are an important source of water for agriculture and human consumption. Understanding and quantifying the exchange of heat and momentum between the ocean and atmosphere is therefore critically important for proper management of natural resources and reducing risks to vulnerable populations.

Quantifying Air-Sea Exchanges of Heat and Momentum

The net surface heat flux (Q_{net}) comprises net shortwave (i.e., solar) (Q_{sw}) and net longwave (i.e., infrared (IR)) (Q_{lw}) radiative fluxes, and surface turbulent (latent and sensible) heat fluxes:

$$Q_{net} = Q_{sw} - Q_{lw} - Q_{lat} - Q_{sen} \quad (1.1)$$

Surface latent heat flux, Q_{lat} , is the heat extracted from the ocean when seawater evaporates. This heat is released to the atmosphere when and where this vapor condenses, forming clouds. Likewise, sensible heat flux, Q_{sen} , is the heat extracted from the ocean associated with an air-sea temperature difference. The sign convention used here enables each term to be expressed generally as a positive value (i.e., as a magnitude) for most applications. When averaged over the global oceans and a full year, there

should be a near-balance between solar radiative heating of the ocean (reduced by net longwave radiative heat loss), latent heat loss due to evaporation and sensible heat loss induced by air-sea temperature and humidity differences. However, due to biases in flux estimates, existing products have difficulties closing the heat budget, as discussed in section “Current Capabilities for Gridded Flux Products.”

The net shortwave radiation flux, Q_{SW} , is the net difference between the incoming (i.e., downwelling, $SW \downarrow$, and reflected outgoing shortwave radiations, $SW \uparrow$, and is commonly computed using a surface shortwave albedo, $\alpha = SW \uparrow / SW \downarrow$, estimate:

$$Q_{SW} = SW \downarrow - SW \uparrow = SW \downarrow (1 - \alpha). \tag{1.2}$$

Likewise, because the outgoing surface longwave radiation $LW \uparrow$ comprises both the IR radiation emitted by the surface of the ocean and the portion of atmospheric downwelling IR radiation $LW \downarrow$ that is not absorbed by the ocean surface, the net longwave radiation flux, Q_{LW} , can be expressed as:

$$Q_{LW} = LW \uparrow - LW \downarrow = \epsilon \sigma_{SB} T_s^4 + (1 - \epsilon) LW \downarrow - LW \downarrow = \epsilon (\sigma_{SB} T_s^4 - LW \downarrow) \tag{1.3}$$

where ϵ is the IR surface emissivity ($\epsilon = 1$ for black-body emission) and is taken to be equal to the absorptivity, σ_{SB} is Stefan-Boltzmann constant, and T_s is the surface (skin) temperature that is emitting the IR-radiation, in degrees Kelvin. The skin temperature of the ocean is generally cooler than the water beneath, as the ocean is nearly always and everywhere giving heat to the atmosphere (Fairall et al., 1996a). On the aqueous side of the interface, viscosity and the air-sea density difference prevent the turbulent transfer of heat from ocean to

atmosphere and so the heat supplied to the interface to feed the latent and sensible heat fluxes and into the layer that emits infrared radiation to the atmosphere, is provided by molecular conduction, which requires a vertical temperature gradient. This temperature gradient is referred to as the thermal skin layer (Donlon et al., 2002; Minnett et al., 2011). As a result, the surface layer of the ocean is in nearly all cases cooler than at a depth of a millimeter or so. The thickness of the layer emitting infrared radiation that is subsequently measured by satellite radiometers to derive SST is comparable to the thermal skin layer (~ 0.1 mm; Wong and Minnett, 2016, 2018), and so the derived temperature is referred to as the ocean skin temperature.

The latent and sensible heat fluxes are typically estimated from state variables, using a “bulk flux algorithm” (e.g., Fairall et al., 2003). As described in section “Turbulent Momentum and Heat Flux EOv and ECVs,” the primary state variables for turbulent fluxes, including wind stress, are surface winds relative to surface currents, skin temperature, near-surface air temperature, and near-surface humidity. Because most *in situ* estimates of the oceanic near-surface properties are below the skin, as discussed in section “Parameterizations to Extrapolate Measurements to Air-Sea Interface,” parameterizations must be used to extrapolate the bulk sea surface measurements to the air-sea interface. Likewise, as described in section “Parameterizations to Extrapolate Measurements to Air-Sea Interface,” flux EOv and ECV for the surface radiation include downward solar radiation, upward solar radiation (or surface albedo), downward longwave radiation, skin temperature, and longwave surface emissivity. We refer to the variables listed here as the “flux Essential Climate Variables (ECVs)” and “flux Essential Ocean Variables (EOVs).”

Turbulent Momentum and Heat Flux EOv and ECVs

The surface momentum (aka wind stress), sensible heat and latent heat fluxes provide surface boundary conditions for turbulent flux profiles in the lower atmosphere and upper ocean. These surface turbulent fluxes are most directly quantified by measuring the direct covariance (aka eddy correlation) between the fluctuating vertical velocity that drives the exchange with the fluctuating quantity of interest within the constant flux layer above the air-sea interface. For example, the directly measured latent heat flux is determined from

$$Q_{lat} = \rho L_v \langle wq \rangle \tag{1.4}$$

where ρ is the density of air; L_v is the latent heat of evaporation, w and q represent the fluctuating vertical velocity and specific humidity, respectively, and the brackets denote a temporal average of, generally, an hour or less. The turbulent fluxes, however, are difficult to measure at sea due to challenges that include platform motion contamination, flow distortion, high power requirements, rain and sea-spray contamination. Additionally, numerical forecast models do not resolve near surface turbulence, so surface fluxes must be parameterized.

These parameterizations are typically based on the assumption that the flux of some quantity is proportional to the vertical gradient of that quantity, e.g., the latent heat flux is proportional to the gradient in specific humidity. This approach, commonly referred to as the gradient or profile method, provides first-order

closure in numerical models. The approach therefore requires vertical profiles of the observed or model-resolved non-turbulent state variables of temperature, specific humidity and velocity. The multiplicative factor that relates the flux to the gradient is known as the eddy viscosity for the momentum flux and the eddy diffusivity for the heat fluxes, e.g., the latent heat is determined from

$$Q_{lat} \approx -\rho L_v K_q \frac{\partial Q}{\partial z} \quad (1.5)$$

where K_q is the eddy diffusivity for moisture, and $\partial Q/\partial z$ is the vertical gradient of the mean specific humidity. Commonly used parameterizations of the eddy viscosity and diffusivity in the surface (constant flux) layer assume that the efficiency of mixing by turbulent eddies scales with the height above the ocean surface. The efficiency of mixing is also a function of atmospheric stability, where mixing is suppressed under stable (thermally stratified) conditions and enhanced in unstable (convective) conditions. These two considerations predict semi-logarithmic profiles that includes a function that accounts for atmospheric stability.

It is also difficult, however, to measure vertical profiles and implement the gradient method over the ocean due to many of the challenges given for the direct covariance method. Instead, the surface fluxes are generally estimated using sea-air differences in the mean “bulk” state variables measured (or modeled) at the surface and at some height within the surface layer. The bulk aerodynamic method links the turbulent fluxes to mean air-sea velocity, temperature and humidity difference using transfer coefficients:

$$\tau_x = -\rho \langle uw \rangle \approx \rho C_D S \Delta U, \quad \tau_y = -\rho \langle vw \rangle \approx \rho C_D S \Delta V, \quad (1.6a)$$

$$Q_{lat} = \rho L_v \langle wq \rangle \approx \rho L_v C_E S \Delta Q, \quad (1.6b)$$

$$Q_{sen} = \rho c_p \langle w\theta \rangle \approx \rho c_p C_H S \Delta \Theta, \quad (1.6c)$$

where c_p is specific heat at constant pressure; u and v are the fluctuating along-wind and cross-wind velocity components, respectively; and θ is the fluctuating potential temperature; C_D , C_E , and C_H are the transfer coefficients (known as the drag coefficient) for momentum, latent heat and sensible heat, respectively; S is the scalar wind speed relative to the ocean surface that includes gustiness; and ΔU , ΔV , ΔQ , and $\Delta \Theta$ are the sea-air differences in the along-wind, crosswind, specific humidity and potential temperature, respectively.

At low winds, convective conditions, large-scale eddies drive gustiness that results in differences between the vector average wind components, U and V , and the wind speed, S , that includes gustiness. Convective gustiness has been shown to drive surface fluxes even when the vector-averaged winds are close to zero (Beljaars, 1995; Fairall et al., 1996b). However, the wind speed is difficult to measure on a moving platform due to wave contamination of the anemometers (i.e., vector averaging is used to remove this contamination but at the expense of gustiness). Additionally, the momentum equations in numerical models generally predict the vector components. Therefore, a common solution is to add convective gustiness to the vector averaged winds such that $S^2 =$

$U^2 + V^2 + U_g^2$ where U_g represents the gustiness due to convection. This is the approach used in the COARE algorithm (Fairall et al., 1996b). However, gustiness parameterizations that provide a single value of U_g regardless of height are physically inconsistent as convective gustiness is expected to vary with height within the boundary layer. More work is needed on this topic.

Although difficult, direct covariance estimates of the fluxes have been successfully measured from a variety of over-ocean platforms or a wide range of conditions as described in section “Current Capabilities.” These fluxes provide direct estimates of the transfer coefficients after normalization of the appropriate bulk state variables as given by Eq. 1.6. The measured transfer coefficients are then used to develop parameterizations of these coefficients that take into account two principal effects: atmospheric stability and ocean surface roughness. For example, direct measurements of the momentum flux are used to parameterize the drag as

$$C_D = \frac{-\langle uw \rangle}{S \Delta U} = \left(\frac{\kappa}{\ln(z/z_0) - \psi_u} \right)^2 \quad (1.7)$$

where the middle term is the measured drag coefficient and the last term is a parameterization that includes a roughness length, z_0 , and a function that accounts for stability, ψ_u . This formulation is based on the assumption of a semi-logarithmic profile in the marine surface layer.

The impact of atmospheric stability is generally determined using Monin-Obukhov Similarity (MOS) scaling. MOS is used to develop functions (e.g., ψ_u) that account for the effects of stability in three overall stability classes: (1) neutral conditions, (2) unstable or convective conditions, and (3) stable or stratified conditions. Neutral surface layers are associated with high winds and little solar heating where turbulent mixing is driven by wind shear. The stability function equals zero under neutral conditions, i.e., $\psi_u(\text{neutral}) = 0$, in the absence of convection or stratification. Unstable surface layers range from situations where turbulent mixing is completely driven by convective processes (aka free convection) to more common situations where the mixing is driven by both buoyancy and wind shear (aka forced convection). Stable surface layers force the wind shear to do work against the stratification, thereby inhibiting mixing and turbulent exchange.

While the form of the stability functions can be guided by scaling arguments (e.g., in the free convective limit), the actual form of these functions must be determined empirically from direct measurements. Successful formulations are able to parameterize the entire range of stability classes. Reasonably consistent formulations have been determined through observations in a number of overland (e.g., Dyer and Hicks, 1970; Businger et al., 1971; Dyer and Bradley, 1982), over-ice (e.g., Grachev et al., 2007) and overwater (e.g., Edson and Fairall, 1998; Vickers and Mahrt, 1999; Edson et al., 2004, 2007, 2013) investigations, which have shown MOS scaling to be valid as long as the assumptions central to its application are not violated. These include a constant turbulent flux layer, stationarity and horizontal homogeneity.

Before developing parameterizations that account for the varying roughness of the underlying sea surface, the impact of

atmospheric stability must first be removed (e.g., Fairall et al., 1996b). This is done using the MOS stability functions by adjusting the transfer coefficients to neutral conditions where, e.g., $\psi_u(0) = 0$ and the neutral drag coefficient is defined as $C_{DN} = (\ln(z/z_0))^2$. The roughness length is commonly parameterized using the roughness Reynolds number for smooth flow to provide the surface “roughness” at low winds (Smith, 1988). Other low wind studies have suggested the use of Weber number scaling to parameterize the roughness as a function of surface tension (Wu, 1994). The low-wind roughness is added to another roughness length that accounts for the increasing roughness of surface waves at increasingly higher wind speeds. This roughness length commonly relies on a relationship suggested by Charnock (1955). The Charnock relationship effectively models the surface roughness due to wind-waves as the ratio of surface forcing (i.e., the surface stress) to the restoring force of gravity. This ratio is multiplied by a variable of proportionality known as the Charnock parameter.

The Charnock parameter is expected to account for the wide-range of physical processes that impact wind-wave interaction. Therefore, it should come as no surprise that there is a wide range of published parameterizations of the Charnock parameter. The transfer coefficients are known to have a wind speed dependence – strong for C_D and weak for C_E and C_H . This dependence has naturally led to the parameterization of the transfer coefficients as a function of wind speed (e.g., Large and Pond, 1981) or using a wind-speed dependent Charnock parameter (e.g., Fairall et al., 2003). Other bulk algorithms have explicit dependencies on sea state (e.g., significant wave height, wave period and wave steepness, wave-age, directional differences between the wind and wave fields), and fraction of ice cover. Such dependencies in measured fluxes are often modeled using Charnock’s relationship where the Charnock parameter is parameterized in terms of the wind-speed, wave-slope, wave-age and ice fraction. However, understanding the relation between the roughness parameter and the sea state, and likewise the effect of sea state on the relative winds, remains an area of active research (e.g., Liu et al., 1979; Large and Pond, 1981; Donelan et al., 1993; Fairall et al., 1996b, 2003; Mahrt et al., 1996; Bourassa et al., 1999; Brunke et al., 2003; Drennan et al., 2005; Edson et al., 2013; Hristov and Ruiz-Plancarte, 2014).

The impact of waves on air sea-fluxes also extends to the sensible and latent heat fluxes. For example, many formulations of the transfer coefficients for sensible and latent heat include the drag coefficient to the one-half, $C_D^{1/2}$, times a scalar component for heat and moisture; e.g., the transfer coefficient for latent heat can be defined as $C_E = C_D^{1/2} C_q$ where C_q is the scalar component of the moisture transfer. This formulation predicts that any wave-related dependencies in the drag coefficient will be included in these formulations in a somewhat muted form. Analogous to the aerodynamic roughness length used to define the drag coefficient, the scalar components are commonly defined using “thermal” roughness lengths. For example, the transfer coefficient for latent heat has been defined as

$$C_E = C_D^{1/2} C_q = \left(\frac{\kappa}{\ln(z/z_0) - \psi_u} \right) \left(\frac{\kappa}{\ln(z/z_{0q}) - \psi_q} \right) \quad (1.8)$$

where z_{0q} is the thermal roughness length for moisture and ψ_q is a MOS stability function for humidity. The thermal roughness lengths are often parameterized as a function of the roughness Reynolds number, which is defined using the aerodynamic roughness length (see Liu et al., 1979; Fairall et al., 1996b for details). As such, any wave-related parameterization of the aerodynamic roughness length will also be included in the thermal roughness lengths.

The more sophisticated algorithms account for the difference between a bulk water temperature and the interface temperature, wind gustiness, and surface currents, as discussed in section “Parameterizations to Extrapolate Measurements to Air-Sea Interface.” However, there is a balance between increasing parameterization complexity and hence dependence on additional variables that may be uncertain or unknown, and improvements that may be gained by considering additional physics. The COARE algorithm transfer coefficients are claimed to be accurate on average to approximately $\pm 5\%$ for C_D and C_E (set equal to C_H) for wind speeds from 2 to 20 m s⁻¹. By this we mean that some 15,000 h of direct flux measurements, converted to transfer coefficients, and averaged in wind speed bins will be within 5% of the COARE transfer coefficients at the same wind speed. The scatter of individual 1-h measured values is about 25% and are generally wind speed and certainly platform dependent. This scatter is principally sampling error and is well-understood in terms of turbulence statistical theory (Blomquist et al., 2014). Research challenges that could lead to improved bulk flux parameterizations include:

- Development of wave-dependent surface flux parameterization that outperform wind-speed dependent parameterizations under a wide range of wind, wave and current conditions.
- Development of flux-profile relationships that account for both stratification and wave-induced perturbations on the wind profile though the wave boundary layer (WBL) and beyond under a wide range of wind, wave and current conditions.
- Development of surface flux and flux-profile relationships that account for directional differences between the wind and wave fields.
- Development of Geophysical Model Functions (GMF) to provide remotely sensed surface stress estimates that match or exceed the accuracy of bulk fluxes using *in situ* measurements.
- Development of convective gustiness parameterizations that are valid through the surface layer to the lowest grid point in high resolution forecast models.
- Development of gustiness parameterizations for coherent structures such as roll vortices in forced convection.
- Validation and continued development of models to simulate evaporating sea-spray and their impact on momentum, heat and mass fluxes under high to extreme wind conditions.
- Development of scale-dependent flux parameterizations for nested high-resolution models down to Large Eddy Simulation (LES) scale.

- Development of coupled LES with sufficient accuracy to simulate wind-wave-current interaction near the ocean surface to provide output that can be considered data for parameterization and model development.

In summary, modern bulk algorithms need to better incorporate the impact of waves and currents on the magnitude and direction of the surface stress and their modulation of fluxes and mean profiles (e.g., Grachev et al., 2003; Hara and Belcher, 2004; Grare et al., 2013, 2018; Hristov and Ruiz-Plancarte, 2014; Buckley and Veron, 2016; Cifuentes-Lorenzen et al., 2018). The wavy boundary layer and shallow atmospheric boundary layers provide a number of additional challenges associated with sea-spray, gustiness, severe stratification and extreme winds. The impact of boundary layer processes on surface fluxes above the surface layer are best studied with additional boundary layer measurement in combination with numerical models and simulations. Therefore, resolving the main issues with bulk algorithms will require a combination of field observations and specialized atmosphere-wave models. Because of the many dependencies, detailed research models such as advanced wave codes (e.g., Kukulka et al., 2007; Banner and Morison, 2010; Kudryavtsev et al., 2014) and wave-LES models (e.g., Sullivan et al., 2014, 2018; Hara and Sullivan, 2015), in combination with observations in many different regimes, can provide a rational way to explore the phase space of parameterization variables.

Parameterizations to Extrapolate Measurements to Air-Sea Interface

While the transfer coefficients used in bulk algorithm introduce some uncertainty into the estimation of the surface air-sea fluxes, perhaps a larger uncertainty comes from treatment of the flux state variables used to estimate the flux. In particular, for most state-of-the-art bulk algorithms, the sea surface temperature (SST) and specific humidity are assumed to be ocean skin values. If instead, a bulk sea temperature is used (i.e., sea temperature measured at depths ranging between 0.01 and 5 m or even deeper), then it should be adjusted to the surface using either parameterizations or models. Fairall et al. (1996a), for example, uses first estimates of the net surface heat flux and wind stress to force a one-dimensional mixed-layer model of the diurnal warm layer relative to the pre-dawn conditions. This is then used to account for stratification (i.e., the warm layer) above the depth of the bulk temperature measurement. Fairall et al. (1996a) also provides a “cool skin” model to account for the surface cooling from non-solar radiative components of the net surface heat flux to compute the SST or skin temperature. Other methods exist for making these extrapolations. For example, the Webster et al. (1996) method relies upon a specification of wind speed and peak solar flux to compute the diurnal warm SST variability at the surface. Parameterizations in terms of wind speed lead to a simple thermal skin effect correction (Donlon et al., 2002; Minnett et al., 2011). For tropical open ocean environments, the average warm layer correction leads to about a 5 W m^{-2} increase in Q_{net} , while the average cool skin adjustment is a decrease of about 10 W m^{-2} . However, corrections due to the warm layer can lead to substantially larger fluxes when

the measurements are made at depth in the presence of large diurnal warming events.

Likewise, for these state-of-the-art bulk algorithms, surface current estimates are needed to compute the wind speed and vertical wind shear relative to ocean surface as given by ΔU and ΔV in Eq. 1.6. The resulting changes in stress are usually small compared to the stress except in regions of strong currents such as over western boundary currents. However, ignoring surface currents in the development of flux parameterization can lead to a systematic bias in the transfer coefficients (Edson et al., 2013) as the wind- and wave-driven currents are generally in the direction of the wind. As a result, the wind speed relative to water is generally smaller than the wind speed relative to earth. These differences are also large enough to cause substantial errors in the horizontal gradient of stress, which can have substantial impact on ocean circulation, upwelling, biology and biogeochemistry (Shi, 2017). Surface currents, however, are generally measured *in situ* at 10 m or deeper. There is growing appreciation that there can be non-negligible shear within the upper 10 m on timescales of the flux calculations. This can add to the errors in the relative wind, and potentially to errors in the flux parameterizations if the currents are not consistently adjusted to the surface. Brodeau et al. (2017) estimated the effect of surface currents on the wind stress to be on average within $\pm 0.005 \text{ N m}^{-2}$ with the largest uncertainties amounting to $0.02\text{--}0.025 \pm 0.005 \text{ N m}^{-2}$.

Radiative Heat Flux EOV/ECV

The net radiative component of the air-sea heat flux comprises a shortwave component that is emitted by the sun ($SW\downarrow$) and reflected from the ocean surface ($SW\uparrow$) in the spectral range of $0.3\text{--}4.0 \mu\text{m}$, and a longwave component that is emitted by the atmosphere ($LW\downarrow$) and surface ($LW\uparrow$) in the spectral range of $4.0\text{--}100.0 \mu\text{m}$ (Eqs 1.1–1.3). $SW\downarrow$ has a direct and a diffuse component that interacts differently with the underlying surface due to differences in their spectral composition and angularly dependent properties. About half of the solar radiation incident on the top of the atmosphere reaches the surface of the Earth after being transmitted through the atmosphere. Extinction of solar radiation in the atmosphere is mostly by ozone, water vapor, clouds, and aerosols. The vertical profiles of clouds, water vapor, and temperature largely determine the longwave emission by the atmosphere. Clouds play a major role in determining the net radiative balance at the surface, dependent on their amount and optical properties (e.g., optical depth, a general measure of the capacity of a cloud to control the amount of light that will reach the surface). Most atmospheric constituents (e.g., cloud, aerosols, and water vapor) can now be derived from satellite instruments. At the ground, $SW\downarrow$ is measured with pyranometers (spectral range of 0.310 to $2.800 \mu\text{m}$) and $LW\downarrow$ is measured with pyrgeometers (spectral range of 4.5 to $42 \mu\text{m}$). The upward component of the surface solar radiation, $SW\uparrow$, depends upon $SW\downarrow$ spectral composition controlled by the solar zenith angle, atmospheric and cloud properties, as well as the surface optical properties, which depend upon the sea state (i.e., wind speed) and chlorophyll concentration in the upper ocean (Jin et al., 2004). *In situ* measurements of $SW\uparrow$ are very rare and thus it is typically estimated from the $SW\downarrow$ and surface albedo, α (Eq. 1.2).

The strong albedo dependence upon solar zenith angle means that more reflection occurs at lower sun angles (during dawn and dusk, in winter and at higher latitudes). Payne (1972) used observations of both upwelling and downwelling shortwave radiation to develop a relation between albedo and solar zenith angle and atmospheric transmittance. At low solar zenith angles, the albedo is 0.03 to 0.06, but at high solar zenith angles it can approach 0.3. Li et al. (2006) examined wind speed and zenith angle dependent models of the albedo from the perspective of upwelling shortwave at the top of the atmosphere. They found that differences among models were less than 10 W m^{-2} and the difference in the global mean was within $\pm 2.5 \text{ W m}^{-2}$ compared with Clouds and the Earth's Radiant Energy System (CERES) data. In the TOGA COARE bulk formulae, Fairall et al. (1996a) use a fixed albedo of 0.055. Errors in albedo can introduce errors in the net shortwave radiation and air-sea heat flux. Further work is needed to improve albedo parameterizations for use in state of the art bulk algorithms, Numerical Weather Prediction (NWP), and satellite radiation algorithms.

In situ observations of longwave radiation at sea have become more common only in the last 10–20 years. Prior to that, various bulk formulae for net longwave radiation at the sea surface were used that depended upon air- and sea-surface temperature, humidity, cloud cover (and type), and latitude (Fung et al., 1984). While *in situ* observations are used for local radiation budgets and for validations of computed radiative fluxes, only satellite observations can provide surface radiative fluxes at a global scale. To estimate radiative fluxes from satellite observations, we need to rely on radiative transfer models. Inputs for radiative transfer models include temperature and water vapor specific humidity vertical profiles, and cloud and aerosol properties. The accuracy of these properties largely influences the accuracy of surface radiative flux computations. Surface radiative fluxes are especially sensitive to near surface temperature and humidity profiles and boundary layer cloud properties. Consequently, improvements to these near surface properties are critical for reducing uncertainty in satellite-derived surface radiative fluxes.

CURRENT CAPABILITIES

Quantifying the air-sea fluxes over the global ice-free oceans requires a hierarchy of observations specifically targeted for (1) improving understanding of processes controlling air-sea exchange and their relationship to atmospheric and oceanic state variables, and specifically, for improving the “bulk algorithm” for computing these fluxes; (2) measuring flux EOVs and ECVs over the global ice-free ocean with sufficiently high spatial and temporal resolution, coverage, and accuracy to generate the global flux products; and (3) obtaining high-quality long time series and regionally distributed measurements that can be used for validating and improving these flux products. Here we describe the current capabilities of the *in situ* networks for measuring air-sea heat and momentum fluxes, and remotely sensed capabilities. Each has its strengths and weaknesses and NWP models are commonly used to integrate these disparate observations into dynamically consistent fields.

We thus also describe current capabilities in NWP and hybrid NWP flux products.

Current Capabilities for *in situ* Flux EOV/ECV Measurements

ICOADS

The International Comprehensive Ocean-Atmosphere Data Set (ICOADS, Freeman et al., 2017, 2019) collates surface marine data extending back three centuries. Before about 1970 almost all ICOADS observations are from ship voyages but as ocean technology has developed, data from more platforms (surface moorings, drifters, floats) have been incorporated into the archive. At present, nearly all near-real time surface marine data available through the Global Telecommunication System (GTS) are incorporated into the database and periodically data from delayed mode archives are incorporated. Flux ECV and EOVs available through ICOADS include: SST, air temperature, humidity, wind speed and direction, barometric pressure, visually observed characteristics of sea state, and coded weather information. ICOADS contains few radiation measurements, but does contain visually observed cloud observations (Eastman et al., 2011). Sampling in ICOADS is very heterogeneous with observations concentrated in the major shipping routes of the Northern Hemisphere. Sampling errors in surface turbulent fluxes computed from ICOADS reports may amount to more than 60 W m^{-2} in poorly sampled regions (e.g., Gulev et al., 2007). ICOADS observations can be challenging to use, but if handled with care, ICOADS provides data for *in situ* flux calculations and global surface flux products (Josey et al., 1999; Berry and Kent, 2009). ICOADS also provides a major input data source for reanalyses (e.g., ERA-Interim: Dee et al., 2011; 20th Century Reanalysis: Compo et al., 2011; and CFSR: Saha et al., 2010). ICOADS is also the main *in situ* data source for the construction of gridded analyses of surface marine ECVs and EOVs including those used as surface boundary conditions for atmospheric reanalyses (e.g., HadSST3: Kennedy et al., 2011; ERSSTv5: Huang et al., 2017; COBE-SST2: Hirahara et al., 2014; HadNMAT2: Kent et al., 2013). Additionally, ICOADS data are used for satellite data calibration and evaluation (e.g., Jackson and Wick, 2010; Liman et al., 2018; Tomita et al., 2018), as well as long-term regional reconstructions of surface fluxes (Gulev et al., 2013). ICOADS is an archive for observations but requires access to expertly managed data from each different network type. Presently there is no international system for the expert management and archival of surface meteorological observations from the GTS although several national weather services maintain their own collections.

In situ Sensors for Measuring Fluxes

A typical set up to estimate the momentum, sensible heat and latent heat flux on a moving platform includes a 3-axis sonic anemometer/thermometer; a 3-axis motion package and an open path infrared hygrometer. Sonic anemometers/thermometers have become the tool of choice for marine research. Although they experience some dropouts and occasional spikes, particularly in rain, they are generally very reliable in the marine environment. Motion sensors are finding their way into

many (non-marine) applications. As a result, researchers now have a number of small, low-power, reasonably inexpensive and sufficiently accurate motion packages to choose from. The infrared hygrometer is ideally deployed alongside a system that flushes the optics between rain events. A closed-path hygrometer avoids many issues associated with contamination of the optics. However, experience has shown that they suffer from uncorrectable attenuation of the signal due to the sticky nature of water vapor within sampling tubes in high humidity environments. The fluxes should be measured using the wind velocity relative to water, which requires a 2-axis current meter. Investigation of wind-wave interaction requires surface wave information for the wave height, wave direction and wave period to compute variables such as wave-slope and wave-age from directional wave spectra. These estimates can be made from ships and surface moorings with some difficulty and limits in the frequency/wavenumber resolution due to the size of the platform. Instead, the latest generation of directional wave-buoys are recommended for these investigations. These buoys have onboard processing and near real-time data telemetry of key wave parameters. They are small enough to resolve a large fraction of the shorter wind-wave spectra in addition to the dominant waves. There is also a growing use of fast-response pressure sensors to investigate pressure-work and energy transfer primarily from fixed towers and specialized research platforms like the Floating Instrument Platform (*R/P FLIP*). The latest generation of these sensors appear to measure absolute pressure to sufficient accuracy for these studies. The main challenge, however, is in the design of the sensor head required to remove dynamic pressure fluctuations to isolate the desired static pressure fluctuations.

The meteorology sensors are best deployed at a height above the wavy boundary layer (corresponding to the height of the dominant waves or more about mean sea level) due to issues that arise when attempting to measure the fluxes too close to the ocean surface. Specifically, since the size of the turbulent eddies supporting the fluxes scales with the height above the surface, ever higher frequency measurements are required to capture the flux as one nears the surface (Kaimal et al., 1972). Similarly, stronger winds shift energy toward higher frequencies. However, there is an inherent limitation to the size of the eddies that can be measured with sonic anemometers and infrared hygrometers. This stems from the ~ 10 cm path length of these devices, which means that any fluctuations smaller than this length are path-averaged and unresolvable. This limits their ability to capture the flux and resolve the inertial subrange very near the ocean surface, particularly at high winds, no matter how fast the sampling is. High winds also produce sea spray that poses a number of measurement challenges (Andreas et al., 2008, 2015). Besides the challenge of actually measuring spray to investigate their modulation of the fluxes (e.g., Richter and Veron, 2016), the droplets are known to contaminate sensors used to measure the latent heat (moisture) flux. In fact, the direct measurement of latent heat flux under high wind and rainy conditions remains one of our greatest needs and challenges. Additionally, the measurement of surface fluxes under extreme wind conditions are complicated by additional considerations such as an increasing “pressure

stress” term reported in the LES study by Hara and Sullivan (2015). However, a major challenge for air-sea interaction research is to observe momentum, heat and mass exchange within the wavy boundary layer. The observational challenge is to minimize these issues through the use of innovative platforms and new sensors specifically designed for the near-surface environment.

***In situ* Platforms for Observing Fluxes**

Historically, ships have been the primary platform for marine surface observations over the open ocean. Prior to 2000, nearly all direct covariance flux observations that have gone into developing the state of the art bulk flux algorithms were from ship-based observations (e.g., Fujitani, 1981, 1985; Donelan et al., 1997; Fairall et al., 1997); notable exceptions being fluxes measured from the *R/P FLIP*; (Fisher and Spiess, 1963) and the Air-Sea Interaction Spar (ASIS, Graber et al., 2000; Drennan et al., 2003, 2005). Care was taken in the development of these algorithms to account for issues associated with making surface marine observations from ships. For example, the large profile of the ship can cause flow distortion so that wind measured on the deck is not characteristic of the ambient wind (Yelland et al., 1998). Likewise, micro-climates on the ship decks can affect air temperature (Berry et al., 2004), humidity, and even barometric pressure measurements. Ideally, ship-based measurements are made on a well-exposed mast, forward of any obstructions.

The flow distortion in the measured mean winds can then be accounted for using empirically, modeled and/or wind tunnel derived corrections. Limiting relative wind directions and using aspirated radiation shields (or using naturally aspirated radiation shield when the relative winds are above some limit) reduce the errors due to heat island effects (i.e., ship micro-climate). The motion of the ship can also affect the surface turbulence measurements (e.g., Landwehr et al., 2015). In particular, wind and ocean currents must be transformed into Earth coordinates using high quality navigation data. In the past few years, the quality of inertial motion sensors has increased significantly, making it possible to now do motion correction routinely at 20 Hz resolution. Such technology, however, is not always available and even when available, as for example for Voluntary Observing Ships, motion correction is not always applied. For further discussion on best practices for surface marine data, see Bradley and Fairall (2006), which can be found in the Ocean Best Practice repository website for GO-SHIP measurements: <https://www.oceanbestpractices.net/handle/11329/386>.

Many of these “field errors” are minimized in measurements taken from moored surface buoys. Progress has been made in both developing sensors suitable for unattended deployment at sea on surface buoys and in quantifying their uncertainties. As a consequence, in moderate conditions an accuracy of 8 W m^{-2} in net heat flux has been achieved over hours to days and longer (Tables 1, 2), and further improvements are possible. In wind speeds below $\sim 3 \text{ m s}^{-1}$ active ventilation is needed of air temperature and humidity sensors and radiometers. New generation humidity sensors offering better stability and improved accuracy should be phased in. Platform tilts should be monitored as mean tilt is a source of error for incoming shortwave and longwave radiation observations. New sensors are

TABLE 1 | Summary of flux EO/ECV uncertainties based upon ASIMET sensor uncertainties stemming from laboratory calibration, sensor drift, and field impacts with estimates of total uncertainties in instantaneous, daily, and annual values (after Colbo and Weller, 2009).

Flux EO/ECV	Lab Calibration	Drift	Field	Sensor Error (and contribution to Q_{net} error)		
				Instantaneous	Daily	Annual
Downwelling Longwave Radiation	Coefficients of fit: 1.5 W m^{-2} Noise: 0.5 W m^{-2}	2 W m^{-2}	Tilt: $< 2 \text{ W m}^{-2}$ Temperature gradients: 4 W m^{-2} Salt spray: $< 1 \text{ W m}^{-2}$ Solar: $< 1\% \text{ SW}_{in}$	7.5 W m^{-2}	4 W m^{-2}	4 W m^{-2}
Downwelling Shortwave Radiation	2 W m^{-2}	$< 2 \text{ W m}^{-2}$	Tilt: $< 2 \text{ W m}^{-2}$ Temperature gradients: $1\text{--}2 \text{ W m}^{-2}$ Salt spray: $< 1 \text{ W m}^{-2}$	20 W m^{-2} , more in broken cloud	6 W m^{-2}	5 W m^{-2}
Humidity	Linear: 0.16 \%RH Cubic: 0.1 \%RH	0.9	Under 95 \%RH : $\pm 1 \text{ \%RH}$ Heating in low winds: 3 \%RH	1 \%RH , 3.2 W m^{-2} 3 \%RH , low winds, 10 W m^{-2}	1 \%RH , 3.2 W m^{-2} 3 \%RH , 10 W m^{-2}	1 \%RH , 3.2 W m^{-2}
Air Temperature	$< 0.03^\circ\text{C}$	0.05°C	$> 1^\circ\text{C}$, wind $< 1 \text{ m s}^{-1}$ 0.7°C , wind = 2 m s^{-1} 0.4°C , wind = 3 m s^{-1}	0.2°C , more in low wind, 3.5 W m^{-2}	0.1°C , 2.2 W m^{-2}	0.1°C , 2.2 W m^{-2}
Barometric Pressure	0.06 hPa	1.5 hPa (max) 0.2 hPa	Temperature: 0.1 hPa Wind: $< 0.1 \text{ hPa}$ (wind $< 10 \text{ m s}^{-1}$)	0.3 hPa , 0.0 W m^{-2}	0.2 hPa 0.0 W m^{-2}	0.2 0.0 W m^{-2}
Sea Surface Temperature	0.001°C	0.05°C	Low wind: 0.1°C Cool skin: $< 0.02^\circ\text{C}$	0.1°C , 4.4 W m^{-2}	0.1°C , 4.4 W m^{-2}	0.04°C , 1.7 W m^{-2}
Wind Speed	1%	$+0.1 \text{ m s}^{-1}$	Tilt: $< 0.3\%$ Sea state: uncertain Very low wind: $\pm 1 \text{ m s}^{-1}$	max (1.5% , 0.1 m s^{-1}) more in low wind 1.7 W m^{-2}	max (1% , 0.1 m s^{-1}) 1.6 W m^{-2}	max (1% , 0.1 m s^{-1}) 1.6 W m^{-2}
Wind Direction	Raw compass: 1° Buoy spin: 4°	2°	Low wind: 1° Flow distortion: $< 5^\circ$	6° (more in low wind)	5°	5°

Flux uncertainties computed for tropical conditions using a database of ship observations and the COARE 3.5 algorithm; the uncertainty is the difference in fluxes averaged over the database (14103 tropical 1-h observations) with and without the perturbation in the mean variable. Because passive radiation shields are used for air temperature and humidity sensors, values are given for different ranges of wind speed; in low winds and high insolation, air temperature and humidity errors are larger.

TABLE 2 | Accuracy of long-term average of heat flux components, net heat flux, wind stress magnitude, and freshwater flux for an ASIMET system deployed in the subtropics, after Colbo and Weller (2009).

	Q_{LW}	Q_{SW}	Q_{lat}	Q_{sen}	Q_{net}	$ \tau $	E-P
% Error (covariance flux % Error)	10	2.5	6 (5)	16 (14)	20 (16)	20 (9)	10 cm
Typical Error (covariance flux typical error)	3.9 W m^{-2}	5 W m^{-2}	7 W m^{-2} (5 W m^{-2})	2 W m^{-2} (1.5 W m^{-2})	10 W m^{-2} (8 W m^{-2})	0.007 N m^{-2} (0.005 N m^{-2})	10 cm

These numbers reflect the typical magnitude of systematic errors after averaging a sufficiently large number of measurements so that random errors can be considered negligible (e.g., one year of hourly measurements). Numbers given for covariance are estimated assuming a single commercial sonic anemometer and infrared absorption fast hygrometer system. Some uncertainty will cancel out when combining data from an ensemble of covariance observing systems. For example, for the PSD ship database containing data from 41 cruises residual statistical uncertainty in mean covariance stress (averaged in wind speed bins) is described by $\text{sqrt}[(0.0003)^2 + (0.02 |\tau|)^2]$.

being developed that can distinguish diffuse radiation, allowing the computation of the direct solar radiation component and its correction for effective changes in zenith angle associated with platform motion.

Researchers have recently begun collecting year-long time series of direct covariance flux measurements of momentum, heat and mass fluxes from surface moorings (Weller et al., 2012; Bigorre et al., 2013; Farrar et al., 2015; Ogle et al., 2018). The instrumentation on these moorings experiences less flow distortion than ships and measures a wider variety of conditions given their longer deployments. For example, fluxes were measured on a 3-m discus buoy for 15 months during the NSF CLIMODE field program. The buoy experienced wind conditions spanning $0\text{--}23 \text{ m s}^{-1}$ over a wide range of stability

and surface wave conditions. The fluxes measured under these conditions were used to develop the COARE 3.5 algorithm (Edson et al., 2013).

Similar flux packages have been deployed as part of NSF's Ocean Observatories Initiative (OOI), which have been measuring motion-corrected winds for over 5 years, which will enable direct stress and buoyancy flux measurements. Recently, fast response hygrometers were used in the NASA SPURS programs (Farrar et al., 2015) to directly measure the latent heat flux. Similar work is underway to develop buoy CO_2 flux systems by drying the sample. Flux systems now exist that can compute and telemeter fluxes in near real-time to shore. In general, deployment duration on buoys is limited by battery power, although some sensors are subject to biofouling and

other issues that affect the calibrations. Surface buoys are also exposed to weather, vandalism, waves, and sea birds. Redundant installation of meteorological sensors is often necessary to avoid data gaps due to sensor failures. This is particularly important for flux calculations since failure of any one of the primary state variables will result in a data gap in the air-sea flux. Even with these precautions, however, surface moorings must be refreshed at 12–18 month intervals, requiring a ship to transit to these distant locations and adding to their expense. On the other hand, these mooring cruises provide an opportunity to do repeat sections to key locations in the global climate system.

Computational fluid dynamic flow studies of the buoy tower and sensors are recommended to identify errors due to flow distortion and guide improved sensor placement and tower design. Protection from marine birds is recommended. In freezing conditions, heated sensors are required to prevent ice buildup; and heating of the buoy tower may be required to prevent ice buildup leading to tipping or inversion of the surface buoy. Of course, adding heating and ventilation as well as additional sensors to measure the fluxes directly requires increased battery payloads. This has been done successfully using isolated battery packs to deliver power on a duty cycle. The buoys of the OOI provide continuous power using additional sources that include solar panels and wind generators with rechargeable storage batteries.

The success of buoy-based systems has led to the development and use of a wide variety of platforms for observing air-sea interactions, including Autonomous Surface Vehicles (ASVs), surface drifters and spar buoys (**Figure 3**). ASVs generally have propulsion powered by either waves (e.g., Wave Glider) or wind (e.g., Saildrone, Sailbuoy), and have electronics powered by solar energy and/or batteries. ASVs navigation can be controlled by setting corridor width and waypoints via satellite communication system (e.g., Iridium). With speeds of up to 2.5 knots for wave-propulsion ASV and 7 knots for wind-propulsion ASV (depending upon wind and ocean conditions), and endurance of 6 months to a year, ASVs can cover thousands of nautical miles. This gives ASVs the capability to either sample in a station-keeping mode, like moored buoys, to create a fixed time series, or in repeat section-mode, or adaptive sampling mode, to do surveys like a research vessel (RV). Recent examples include sampling through hurricanes/typhoons (Lenain and Melville, 2014; Mitarai and McWilliams, 2016) and in the harsh Southern Ocean (Monteiro et al., 2015; Schmidt et al., 2017; Thomson and Girton, 2017).

Nearly all components for calculating bulk EOV/ECV fluxes have been measured from ASVs, including wind speed and direction, air-temperature, humidity, solar and longwave radiation, bulk temperature, skin SST, and surface currents, although some of these measurements are less mature than others. While ASVs tend to have minimal flow distortion, their platform motion (pitch, roll, heading) must be removed when transforming their measurements into Earth coordinates. Improved Global Positioning Systems (GPS) enable corrections for platform motions at better than 10 Hz. With sonic wind sensors measuring 3-dimension winds at 10 Hz or faster (particularly at high winds near the surface), field tests are

underway to determine whether these platforms can be used to measure covariance flux wind stress directly in addition to the mean wind. The low height of sensors making atmospheric measurements on some of the ASVs remains a technical issue. The community also does not have a good handle on the effects of wave shadowing or distortion on the atmospheric boundary layer and its impact for example on the measured wind field (Schmidt et al., 2017) and further efforts are required to assess and address this. Quantification of the accuracy for measurements associated with air-sea heat and momentum fluxes are continuing.

ASV technology is new and currently at a pilot Technical Readiness Level (TRL) of 4 (“Trial”) – 5 (“Verification”) (Lindstrom et al., 2012). Before it can be expanded to a global array, the TRL needs to be increased to a mature TRL of 9 (“Sustained”). For this, all sensors and systems need to be validated against known standards under a wide range of field conditions on a routine basis. The platforms themselves must be understood with respect to flow distortion, height of the various instruments, and other complicating factors. Navigation needs to be automated in ways that maintain safety at sea, and enables coordinated work with other observational platforms, such as moorings, ships, and gliders (see Swart et al., 2019). Adaptive sampling of atmospheric (e.g., storms/hurricanes) or ocean (e.g., fronts and eddies) features require automatic identification and tracking by ASV. Such capability would enable optimal exploration of complex atmosphere-oceanic environments. Likewise, onboard data processing needs to be developed and tested, and sensor system, data, and metadata must be standardized. Finally, the ASV community must agree to common data delivery, archiving and best practice. An ASV governing body could help develop these standards and create an ASV network.

Drifting or Lagrangian platforms such as the ASIS (Graber et al., 2000) have been used to successfully measure the surface fluxes in field campaigns for decades. Drifting spar buoys generally require less motion correction, experience less flow-distortion and place sensors above the difficult-to-resolve processes within the wave-boundary layer (Hara and Sullivan, 2015); all of which results in accurate direct flux estimates (Edson et al., 2013; Drennan et al., 2014). Another advantage of a Lagrangian measurement of the air-sea fluxes in combination with oceanic temperature and salinity is that, to the extent the drifter follows the mean mixed layer currents, an ocean heat budget assessment can be simplified by reducing the advective flux divergence contribution to the budget (e.g., Silverthorne and Toole, 2013). Thus the surface fluxes measured by a drifter can be more directly constrained by changes in the upper ocean heat or salt content, and more directly compared to one-dimensional ocean models to evaluate the effects of surface forcing on the upper ocean (e.g., du Penhoat et al., 2002). Low-profile Lagrangian surface drifters provide reliable measurements of surface currents and waves over a wide range of conditions (e.g., Herbers et al., 2012). Recent advances in these platforms have included the ability to measure EOVs and subsurface turbulence with, e.g., SWIFT drifters (Thomson, 2012). Drifting versions of the traditional surface mooring are being developed at several institutions. These “minibuoy” provide flux measurements at

FIGURE 3 | Examples of different types of air-sea flux *in situ* platforms. Clockwise from upper left: Norwegian weather ship Polarfront (image courtesy of Norwegian Meteorological Institute) (Yelland et al., 2009); NOAA ship Ron Brown (from www.noaa.gov); WHOI Air-Sea Interaction Tower (image courtesy Jayne Doucette Woods Hole Oceanographic Institution); RSMAS “ASIS” spar buoy (Graber et al., 2000); Saildrone, Inc., “Saildrone” ASV (image courtesy of Saildrone, Inc.; www.saildrone.com), Liquid Robotics “Wave Glider” ASV (from www.liquid-robotics.com with modifications by UW/APL), UW/APL “SWIFT” drifter (Thomson, 2012); JAMSTEC TRITON buoy (from JAMSTEC, www.jamstec.go.jp); and, in the center, the WHOI SPURS buoy (Farrar et al., 2015).

significantly lower cost for field programs and could also be used to significantly augment conventional operational networks such as NDBC and TAO. The community should be encouraged to continue its efforts to design innovative platforms and flux systems while observing and developing best practices that include assessment against accepted standards.

OceanSITES Reference Time Series

The accuracy of fluxes from moorings approaches and in some cases exceeds that required for monitoring many of the ocean air-sea interaction phenomena (Figure 2). Moorings thus can provide “reference time series” for tuning satellite measurements and assessing uncertainties in satellite and NWP fields. The purpose of the OceanSITES network¹ is to collect, deliver and promote the use of high-quality multi-disciplinary data from

¹<http://www.oceansites.org>

long-term, high-frequency observations at fixed locations in the open ocean. These long time-series help to distinguish variations in EOVS due to temporal variability from that due to spatial variability. The large set of co-located EOVS at these sites (e.g., surface heat fluxes, ocean wind stress, subsurface temperature, salinity, velocity, surface mixed layer depth), allow many terms in the heat, momentum and salt equations to be evaluated and thus processes responsible for variability to be identified. Such analyses are critical for identifying causes of biases in NWP reanalyses and ultimately improving the model physics.

The OceanSITES network comprises moorings funded by individual principal investigators from oceanographic agencies in many different nations. Most sites were initiated through research process studies. For example, the Stratus mooring at 20°S 85°W, was initiated during a cloud feedbacks study (Mechoso et al., 2014; Weller, 2015), while the Kuroshio Extension Observatory

(KEO) was initiated during a field study of western boundary current physics (Cronin et al., 2013). Station Papa, a site of an ocean weather ship from 1940 to 1981 in the NE Pacific subpolar gyre, has been at the center of many oceanographic process studies (Freeland, 2007; Cronin et al., 2015). The NOAA surface mooring there was initiated during a process study of the carbon cycle. The WHOI Hawaii Ocean Timeseries (WHOT) mooring was initiated as an oceanic sentinel sister site to the Moana Loa “Keeling Curve.” Monterey Bay Aquarium Research Institute (MBARI) maintains a station in the California Current system. Its primary purpose is for monitoring and understanding the ecosystem productivity and biogeochemical cycling in this upwelling zone. The OOI Irminger Sea station is part of the Overturning in the Subpolar North Atlantic Program (OSNAP). The Southern Ocean Flux Station (SOFS) south of Tasmania monitors the ventilation and mode water formation in the Subantarctic Zone (Schulz et al., 2012). SOFS and the OOI Southern Ocean (50°S, 90°W) site west of Patagonia are the only two stations in the Southern Ocean. Both are subject to storms, waves, and strong currents. The Tropical Atmosphere and Ocean (TAO) mooring array in the Pacific was initiated to better understand, monitor and predict ENSO (McPhaden et al., 1998; Cronin et al., 2006), while the tropical array in the Atlantic was designed to monitor and predict both ENSO-like and meridional modes and the Indian Ocean tropical array was designed to also monitor monsoon variability (McPhaden et al., 2009). The commonality of these long time series sites is that they all are publicly available through the OceanSITES global data assembly center, in a common data format. **Figure 4** shows a comparison of a satellite-based latent and sensible heat fluxes and OceanSITES moorings. Not all these moorings carry radiation sensors and therefore only a subset of these OceanSITES moorings monitor net surface heat flux.

The long time series provided by the sustained surface moorings of OceanSITES have proven to be of high value, and continuation of the sustained observing sites is recommended. Merged, quality-controlled time series are produced at a number of such sites and have been sought after by the modeling community, by the remote sensing community (Pinker et al., 2018), and by those evaluating new hybrid flux products (Valdivieso et al., 2017). Some of the time series are just now entering a third decade of observing, and these time series are capturing accurate records of decadal variability as well as of trends. Testing whether or not models and flux products replicate the broad range of time scales in the fluxes, out to decadal and beyond, is critical and requires sustained surface flux time series of high quality. Further, detection of long-term trends and separation of trends from decadal and multidecadal variability also requires ongoing long time series. These sustained time series sites also become foci for process studies that will improve understanding of air-sea interaction and fluxes and support further improvement of models.

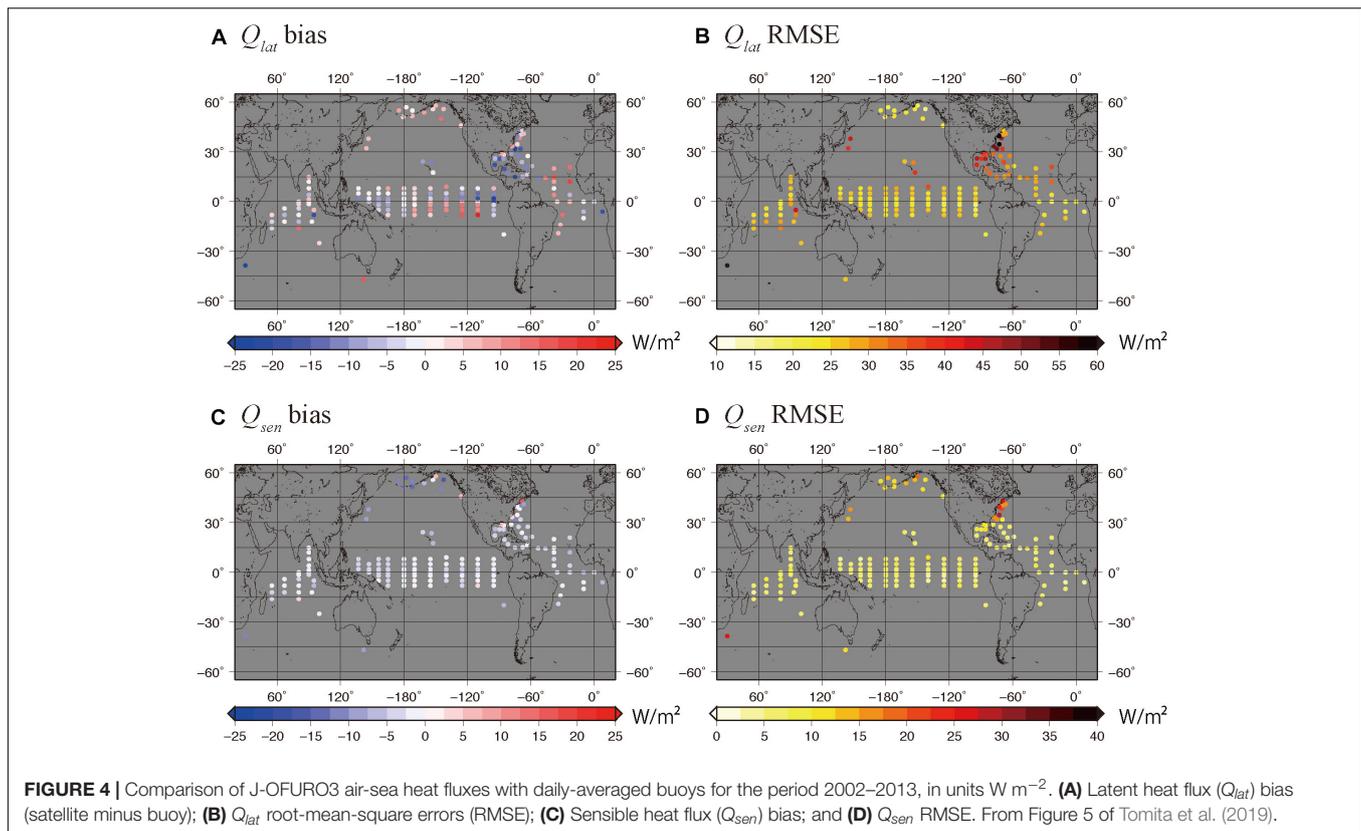

Within the global ocean observing system, data from OceanSITES reference stations moorings are particularly important for validating gridded products of fluxes as they provide long records of high-quality flux EOV and ECV at high temporal resolution, co-located with other EOVs and ancillary

ocean variables such as the surface ocean mixed layer. In this way, the sources of the biases can sometimes be determined, leading to improvements. The suite of sensors from OceanSITES flux moorings should include not only all flux EOV/ECV, but also, if possible, direct covariance flux estimates as well, although this may require technological development for the platforms. Likewise, sea state EOVs are being tested as flux EOVs and therefore should be included if possible. In addition, it is strongly encouraged to obtain additional environmental parameters which could help represent atmospheric and oceanic conditions that may affect the air-sea exchanges and their impacts. For example, Global Navigation Satellite System (GNSS) receiver, could provide precipitable water vapor, which has been shown to improve weather forecasts (Li et al., 2015).

Current EOV/ECV observations all suffer from different drawbacks. Comparison of point measurements from *in situ* instruments to satellite measurements, which inherently represent an average over some spatial footprint that is typically kilometers or more in extent, is made difficult by the differences in spatial and temporal sampling. These differences, caused by spatial variability on scales smaller than the satellite footprint, can be compensated somewhat by temporal averaging of the *in situ* data to effectively attenuate the small-scale variability (e.g., May and Bourassa, 2011; Lin et al., 2015), but the difference in time-space averaging in different observational approaches remains a fundamental difficulty. The *in situ* moored buoy data is accurate and has high temporal resolution, often for a long record, but these point measurements tend to be too sparsely distributed for mapping spatial patterns and understanding teleconnections. The moored buoys tend to be located along coastlines where they are easier to maintain, and in the three main tropical arrays. Furthermore, while the surface moorings that contribute to OceanSITES and coastal arrays and to research endeavors provide many flux EOV and ECV, few measure all. In particular, only a small subset of these moorings measure solar radiation and not all of these sites measure downward longwave radiation. Likewise, surface current observations are available at only a small subset of surface mooring sites. There are also large gaps in the center of ocean basins and at high latitudes, especially in the Southern Hemisphere (see Swart et al., 2019). There are currently only 22 operating sites in this global network that measure net surface heat flux, with only 7 of those being in the Southern Hemisphere. This drastically undersamples important ocean-atmospheric regimes that are known areas of high error for flux analyses. These long, high-quality time series are critical data for satellite algorithm developers, for model testing and development, and for analyzing critical processes in the climate system. These large gaps in coverage reduce the efficacy of the observation for the research and weather applications discussed in section “Introduction.”

Current Capabilities for Remotely Sensed Flux EOV/ECV Measurements

The current capabilities for remotely sensed flux EOV/ECV are summarized in **Table 3** and **Figure 5**. In particular,

typical uncertainty estimates for the highest resolution swath products as well as high resolution gridded products. These uncertainty estimates are presented along with their contribution to uncertainty in the net surface heat flux, estimated by linearizing Eq. 1.1 with respect to the EO/ECV following Cronin et al. (2014). It should be noted that these uncertainties are based upon comparisons to buoys, which are primarily located in the tropics. **Table 3** also describes the typical spatial and temporal resolution, and where technology developments are necessary. **Figure 5** shows the status of the constellation for each EO/ECV over the next decade, and actions needed for improvement. The status of each system is described briefly here.

The ocean surface roughness measured by satellite sensors is normally transformed into an ocean wind speed at 10 m height using algorithms developed through comparisons with ocean buoys and NWP products (Meissner and Wentz, 2012; Shibata, 2012; Meissner et al., 2014; Hirahara et al., 2015). In reality, the ocean surface roughness is related to the air-sea velocity difference, which is actually the variable of most interest for flux calculations. The measurement of ocean surface roughness from scatterometers (e.g., ASCAT, QuikSCAT, RapidSCAT) and passive microwave (MW) radiometers (e.g., SSMI, SSMIS, WindSAT, AMSR-E, AMSR2) is already at a spatial resolution and accuracy sufficient for most global flux estimates. At NDBC, TAO, and PIRATA buoys, monthly mean satellite wind speeds are found to have average biases of $0.3 m s^{-1}$ and RMS of 0.73 and $0.81 m s^{-1}$ (QuikSCAT and SSMI, respectively) (Wallcraft et al., 2009). RMS is a bit larger for the daily mean wind speed; RMS of

$1.25 m s^{-1}$ at TAO buoy is reported (Hirahara et al., 2015). It is even larger in the Kuroshio Extension region; RMS is $1.6 m s^{-1}$ at KEO buoy for AMSR2 (Tomita et al., 2015).

The recent generation of satellite SST sensors (e.g., VIIRS, AATSR and its successor, SLSTR) are close to meeting the global uncertainty of 0.3 K for surface skin temperature measurements, but the uncertainty has regional non-random characteristics that may not always meet the uncertainty requirements (Petrenko et al., 2014). There have been efforts to generate a stable SST record (e.g., ESA Climate Change Initiative for SST, NOAA Pathfinder AVHRR, MODIS – VIIRS). In regions with persistent, seasonal cloud cover, observations are simply not possible from IR instruments, which hinders the accuracy of daily and monthly SST analyses (Liu and Minnett, 2016). Other sources of error, such as water vapor and atmospheric aerosols have regional and temporal characteristics that will impact the uncertainty (Luo et al., 2019). Passive microwave SSTs approximate to the sub-skin value, but with simultaneous observation of wind speeds, and further research into transformation of these observations into a skin value, they can provide essential observations in regions where the IR observations are simply not available due to cloud cover (see section “Systematic Uncertainties Near Fronts and Regions of Persistent Clouds”). Donlon et al. (2002) found the skin to subsurface difference asymptotes to a value of $-0.14 K$ for wind speeds above approximately $6 m s^{-1}$. Since subsurface temperature measurements from buoys are widely used in IR atmospheric correction algorithm development and validation, an offset of $-0.17K$ is used as an estimate of the global thermal

TABLE 3 | Current capability in remotely sensed flux EOVs and corresponding error in net surface heat flux and wind stress.

Observable	Sensor	Horizontal Temporal Resolution	Sensor accuracy of swath (and contribution to Q_{net} uncertainty)	Uncertainty of gridded product at available daily or monthly resolution (and contribution to Q_{net} uncertainty)	References
Ocean surface wind speed and direction	Scatterometer and Passive Microwave Radiometer	25 km/12 h	0.6–1.6 m s ⁻¹ (13–26 W m ⁻²)	0.6–1.6 m s ⁻¹ (9.6–26 W m ⁻²)	Yu and Jin, 2012; Zhang et al., 2018
Skin SST	Infrared Radiometer; Passive Microwave Radiometer (which measures an approximation to the sub-skin temperature)	1 km/12 h	0.2–0.6 K (9–26 W m ⁻²)	0.2–0.6 K (9–26 W m ⁻²)	Corlett et al., 2014; Gentemann and Hilburn, 2015; Kilpatrick et al., 2015; Tu et al., 2015; Bulgin et al., 2016
Near surface air temp	Technology advancements needed	25 km/12 h	1.3–1.55 K (18–22 W m ⁻²)	0.5–1.55 K (6–22 W m ⁻²)	Jackson and Wick, 2010; Roberts et al., 2010; Yu and Jin, 2018
Near surface specific air humidity	Passive Microwave Radiometer	25 km/12 h	1–1.3 g/kg (20–26 W m ⁻²)	0.8–1 g/kg (16–20 W m ⁻²)	Roberts et al., 2010; Tomita et al., 2018; Yu and Jin, 2018
Surface solar radiation	Imagers (multi-channel), CERES, ancillary	100 km/3 h	55 W m ⁻² (55 W m ⁻²)	11 W m ⁻² (11 W m ⁻²)	Rutan et al., 2015; Kato et al., 2018
Surface longwave radiation	Imagers (multi-channel), CERES, ancillary	100 km/3 h	20 W m ⁻² (20 W m ⁻²)	5 W m ⁻² (5 W m ⁻²)	Rutan et al., 2015; Kato et al., 2018

Accuracy values estimated from comparisons with buoys. Contribution to error in net surface heat flux computed from the tropical database as per **Table 1**. Column 2 (Sensor) describes instrumentation and where technological advances are needed. Column 5 shows daily resolution of gridded fields for all variables except solar and longwave radiation. For these, monthly averaged resolution is shown. Unless otherwise noted, accuracies are total uncertainties, including random uncertainty. Also unless otherwise noted, accuracies are estimated from globally distributed comparisons. As the quoted effect of these uncertainty values on the net heat flux are based on Tropical/sub-Tropical measurements they may not apply at mid-high latitudes. Uncertainties of the gridded products do not include uncertainties due to sampling error, and therefore underestimate the true uncertainty by some unknown percentage.

skin effect, so the subsurface temperatures approximate to a skin SST (Kilpatrick et al., 2015).

Near-surface air temperature is an exceptionally difficult observation from satellite measurements, as existing instrumentation cannot adequately resolve the planetary boundary layer, which has thicknesses varying from ~500 m to 3 km over the ocean (von Engel and Teixeira, 2013). This observable is currently estimated using atmospheric sounders and hyperspectral sensors, both of which have drawbacks. The sounders have higher sensitivity to the upper, rather than lower, atmospheric temperatures and have low vertical resolution, making the measurement of near surface temperature exceptionally challenging. The hyperspectral instruments such as AIRS and IASI, have high spectral resolution and offer better vertical resolution, but still suffer from the fundamental physical problem that the vertical resolution of derived profiles is limited to ~1 km. The use of passive MW imagers to determine near-surface air temperature and humidity has been undertaken with some success, if a first-guess SST is used, with small (<0.1°C) bias and roughly 1.5°C RMS (Roberts et al., 2010; Clayson and Brown, 2016).

Near-surface air humidity is very difficult to infer accurately from satellite radiometers, for the same reasons as for near-surface air temperature. For both temperature and humidity, the weighting functions used for retrievals are dependent on the temperature and humidity profiles and, consequently, cannot be fixed for given wavelengths. Thus, there is a risk that the near-surface variables are artificially correlated with the sea-surface temperature and the state of the atmosphere, and distinguishing

the true physical correlations from those that are artifacts of the measurement is difficult. In addition, the retrieval algorithms for near-surface temperature and humidity are commonly trained with *in situ* buoy and/or ship measurements. The relationship between satellite measurements and near-surface variables is strongly regime dependent, displaying a step-like transition (or separation) from the warm/humid regime to the cold/dry regime (Yu and Jin, 2018). The evidence suggests that the skill of the retrieval algorithm is highly dependent of the vertical distribution of water vapor. Current remote-sensing algorithms to derive near-surface humidity using a satellite MW radiometer show RMS disagreements of ~1.0 g kg⁻¹ with smaller positive bias in mid-latitudes (Tomita et al., 2018). A recent regime-dependent approach that treats the warm/humid and cold/dry regimes separately shows noted improvement with RMS of 0.8 g kg⁻¹ for air specific humidity and 0.5°C for air temperature (Yu and Jin, 2018).

As discussed in section “Radiative Heat Flux EOV/ECV,” surface radiative fluxes are computed using radiative transfer models with input provided by cloud properties retrieved from satellites combined with temperature and humidity profiles. Comparisons of *in situ* surface observations and satellite-derived irradiances are used to estimate the uncertainty in satellite-derived irradiances; there are however, only a limited number of radiation measurements over the global ocean and most of these are in the tropics. Comparisons reported by Kato et al. (2018) show that surface monthly mean downward fluxes agree with observations to within a mean difference (RMS) of 5 (11) W m⁻², respectively for shortwave, and 2 (5) W m⁻² for longwave, when

Variable	Instrument type	Relevant Satellite Sensors - 2018-2030	Status and Actions
Ocean surface wind speed/direction	Radar scatterometers	ASCAT on MetOp-A, B, C; OSCAT on ScatSat-1 and OceanSat-2, -3, -3A; SCAT & SWIM on CFOSAT, <i>Follow-On mission from 2022</i> ; WindRAD on FY-3E, 3H <i>from 2019</i> ; SCAT on HY-2C, 2D, 2E, 2F <i>from 2019</i> ; SCA on MetOp SG <i>from 2022</i> .	Technology and algorithms are mature, but directional accuracy needs improvement . Technology improvements to include Doppler could give broad swath surface currents.
	PWM radiometers	WindSat* on Coriolis; AMSR2* on GCOM-W1; SSMIS on DMSP F16, F17, F18; GMI on GPM-Core Observatory.	Technology and algorithms are mature. Constellation is fragile. Sampling is poor. Speed only in most cases. Directional accuracy needs improvement.
	SAR	Sentinel 1 a & b, <i>followed by c & d</i> ; TerraSar-X, TanDEM-X & PAZ; COSMO-SkyMed; RADARSAT-2; <i>RADARSAT Constellation.</i>	Technology is mature, algorithm improvement needed. High resolution, but very poor global coverage. Directional accuracy needs improvement.
	GNSS reflectometry	CYGNSS.*	Technology is quite mature, but GPS satellites were not adequately intercalibrated, algorithm improvement needed . CYGNSS in tropics only. Launched 2015 for two-year mission. Speed only. Long-term prospects unknown.
	Doppler LIDAR	Atmospheric Dynamics Mission –Aeolus.	Experimental . 2D wind profile in flight direction, component in look direction. Should reach into PBL. Launched in 2018 for a 3-year mission. Large footprint, and poor sampling
Surface currents	SAR	Sentinel 1 a & b, <i>followed by c & d</i> . TerraSar-X, TanDEM-X & PAZ; COSMO-SkyMed; RADARSAT-2; <i>RADARSAT Constellation.</i>	Experimental , narrow swath, poor sampling , selected locations, current component only in look direction.
	Altimeters	Sentinel 3 a & b, <i>followed by c & d</i> ; JASON 3, <i>followed by JASON-CS-A and -B; SWOT in 2022.</i>	Mature technology and algorithms. Derived from surface topography along sub-satellite track using geostrophy. SWOT is experimental. Resolution is roughly 200 km and 5 days.
Sea-surface temperature	IR radiometers – polar orbiters	AVHRR on NOAA-19, MetOp-B, -C; MODIS* on Terra and Aqua; VIIRS on S-NPP & NOAA-20, <i>JPSS-2, -3</i> ; SLSTR on Sentinel 3 a & b, <i>followed by c & d</i> ; <i>METImage on MetOp SG from 2022.</i>	Technology is mature, algorithm improvement needed to reach required goals.
	IR radiometers – geostationary	Imager on GOES-15; SEVIRI on MSG-10; Imager on INSAT-3, -3DR, -3DS; AHI on Himawari-8, -9; ABI on GOES-16 (IR bands on GOES-17 have problems); AGRI on FY-4A, 4B, 4C; GIIRS on FY-4A, 4B, 4C, 4D, 4E; <i>AMI on Geo-Kompsat-2A; FCI on MTG-I.</i>	Technology is mature, algorithm improvement needed to reach required goals.
	PWM radiometers	WindSat* on Coriolis – current; AMSR2* on GCOM-W1.	Technology is mature, algorithm improvement needed to reach required goals. Constellation is fragile.
Near-surface air temperature	IR sounders – polar orbiters	AIRS* on Aqua; TES-N* on Aura; IASI on MetOp-B, -C; <i>IASI-NG on MetOp SG from 2022</i> ; CRIS on S-NPP & NOAA-20; <i>JPSS-2, -3.</i>	Technology and algorithms mature for coarse resolution sounding; new algorithms, and probably new technology, needed for PBL temperature.
	IR sounders – geostationary	Sounder on GOES-15; Sounder on INSAT-3, -3DR, -3DS; GIIRS on FY-4A, 4B, 4C, 4D, 4E; <i>IRS on MTG-S.</i>	Technology and algorithms mature for coarse resolution sounding; new algorithms, and probably new technology, needed for PBL temperature.
	PMW radiometers	SSMIS on DMSP series; AMSU on MetOp-B, -C, and NOAA-19; ATMS on S-NPP & NOAA-20, <i>JPSS-2, -3</i> ; <i>MWS on MetOp SG from 2022.</i>	Technology and algorithms mature for coarse resolution sounding; new algorithms, and probably new technology, needed for PBL humidity.
Near-surface air humidity	IR sounders – polar orbiters	AIRS* on Aqua; IASI on MetOp-B, -C; <i>IASI-NG on MetOp SG from 2022.</i>	Technology and algorithms mature for coarse resolution sounding; new algorithms, and probably new technology, needed for PBL humidity.
	IR sounders – geostationary	Sounder on GOES-15; Sounder on INSAT-3, -3DR, -3DS; GIIRS on FY-4A, 4B, 4C, 4D, 4E; <i>IRS on MTG-S.</i>	Technology and algorithms mature for coarse resolution sounding; new algorithms, and probably new technology, needed for PBL humidity.
Surface insolation	PMW sounders	AMSU on Aqua, MetOp-B, -C and NOAA-19; ATMS on S-NPP & NOAA-20, <i>JPSS-2, -3</i> ; <i>MWS on MetOp SG from 2022.</i>	Highly derived, needing frequent samples (1 hr or better) of top-of-atmosphere emitted radiance, 3D distributions of clouds, aerosols, water vapor and some trace gases. Wind-speed dependent surface albedo need to derive net insolation. Accuracy of input data and algorithms need improvement to reach goals.
	VIS/IR radiometers – polar orbiters & geostationary	CERES on Terra, Aqua, S-NPP, NOAA-20; <i>RBI on JPSS-2 & -3 from 2022</i> ; Imager on GOES-15; SEVIRI on MSG-10; Imager on INSAT-3, -3DR, -3DS, -3DS; AHI on Himawari-8, -9; ABI on GOES-16 (IR bands on GOES-17 have problems); AGRI on FY-4A, 4B, 4C; GIIRS on FY-4A, 4B, 4C, 4D, 4E; <i>AMI on Geo-Kompsat-2A; FCI on MTG-I.</i>	Highly derived, needing frequent samples (1 hr or better) of top-of-atmosphere emitted radiance, 3D distributions of clouds, aerosols, water vapor and some trace gases; cloud base emissivity. Accurate skin SSTs and surface emissivity needed to derive net IR fluxes. Accuracy of input data and algorithms need improvement to reach goals.
Net surface infrared fluxes	VIS/IR radiometers – polar orbiters & geostationary	CERES on Terra, Aqua, S-NPP, NOAA-20; <i>RBI on JPSS-2 & -3 from 2022</i> ; Imager on GOES-15; SEVIRI on MSG-10; Imager on INSAT-3, -3DR, -3DS, -3DS; AHI on Himawari-8, -9; ABI on GOES-16 (IR bands on GOES-17 have problems); AGRI on FY-4A, 4B, 4C; GIIRS on FY-4A, 4B, 4C, 4D, 4E; <i>AMI on Geo-Kompsat-2A; FCI on MTG-I.</i>	Highly derived, needing frequent samples (1 hr or better) of top-of-atmosphere emitted radiance, 3D distributions of clouds, aerosols, water vapor and some trace gases; cloud base emissivity. Accurate skin SSTs and surface emissivity needed to derive net IR fluxes. Accuracy of input data and algorithms need improvement to reach goals.

FIGURE 5 | Satellite sensors that are producing data that can be used in deriving estimates of ocean surface fluxes. Normal text indicates current satellites and sensors, with * indicating those that are beyond their planned lifetime. Italic font shows missions that are expected to be launched in the next decade. Bold text shows areas needing attention in coming decade; red borders highlight where significant action and progress are needed. Not all derived variables from all sensors will reach the accuracies given in **Table 3**.

the differences are averaged over 46 ocean sites. Rutan et al. (2015) using CERES Edition 3 3-hourly products found an RMS of 55 and 20 W m^{-2} for $\text{SW}\downarrow$ and $\text{LW}\downarrow$, respectively. These root-mean-square differences between observed and satellite-derived 3-hourly and monthly mean irradiances are used for the uncertainty shown in **Table 3**. These are within the reported monthly averaged uncertainty of observed radiative fluxes at buoys of $\sim 5 \text{ W m}^{-2}$ (Colbo and Weller, 2009). Comparison uncertainties are influenced by atmospheric, cloud and aerosol properties as well as temporal and spatial sampling issues. Ambient conditions, such as aerosol deposition, have also been shown to degrade buoy radiative flux measurements as well (Foltz et al., 2013). Although satellite derived surface radiative fluxes agree with observed radiative fluxes at buoys to within the uncertainty, most buoys are located in the tropics. To evaluate satellite derived radiative fluxes in a wide range of atmospheric conditions, observations in mid- and high-latitude regions are needed.

Systematic Uncertainties Near Fronts and Regions of Persistent Clouds

Because persistent clouds can form at fronts, IR satellite SST observations (e.g., AVHRR, MODIS, VIIRS ...) can be spatially patchy due to contamination by clouds. Conversely, IR data cloud screening algorithms can also mischaracterize actual IR-observed ocean SST variability near fronts as being cloud (Kilpatrick et al., 2019). A separate issue near fronts stems from the fact that the 25–50 km spatial footprint of microwave satellite SST retrievals often exceeds the frontal scale. Furthermore, these larger footprints and antenna side-lobes can allow land contamination to impact SST front detection in coastal regions. At present, many mapping products interpolate through these patches (e.g., Reynolds et al., 2013), leading to western boundary current fronts that are too smooth and that do not capture the mesoscale variability associated with the meandering of these fronts. Because the atmospheric response depends upon the sharpness of the SST gradient (Chelton et al., 2004; Minobe et al., 2010; Parfitt et al., 2016), this bias can result in a cascade of errors. Even multi-satellite merged data are unlikely to eliminate the gaps in surface variables completely in part because of land contamination in coastal microwave-based measurements, although a proposed higher resolution sensor could mitigate this problem (e.g., Bourassa et al., 2019; Rodríguez et al., 2019).

A strategy must be developed for handling patchy data in frontal and coastal regions, using alternative data sources. While drifters, ASVs and underway ship measurements may be able to fill these gaps at times, they are likely to be too sparse both in time and space to fill all gaps. Repeat sections from these platforms, however, may provide structure functions for sharp fronts, which when combined with information about the location of the front from altimeter and tidal data, could then help fill the gaps in the patchy data with properly located sharp fronts in flux EOF and ECVs fields. Ultimately, regional atmospheric modeling, preferably with non-hydrostatic model settings and high-resolution NWP products must be used to fill in remaining patches in data with dynamically consistent fields.

Systematic Uncertainties Due to Inadequate Sampling of Diurnal Variability and Episodic Events

Satellite instruments can provide global or near-global coverage, but the spatial coverage comes at the cost of reduced temporal resolution. Many of the satellites used for estimating surface fluxes are in sun-synchronous polar orbits. Polar orbits have the virtue of providing near global coverage, and sun-synchronous orbits have significant engineering advantages, as satellite observations are made within a narrow range of local times so that solar angles and sun glint are relatively consistent at all times. For some variables, such as SST, geostationary satellites are also useful, with the advantage of providing higher temporal sampling rates that can resolve the diurnal cycle of SST. SST can vary by more than 2–4 K over the course of a day in regions of high solar insolation and low winds. Resolving only nighttime SST can lead to biases of up to 5–10 W m^{-2} in the long-term mean heat fluxes (Clayson and Bogdanoff, 2013).

Resolving the diurnal cycle is particularly important since the diurnal cycle in solar radiation leads to an afternoon near-surface stratification that can trap surface forcing into a thin layer. As a consequence, rain-puddles formed during the daytime are fresher than ones formed at nighttime (Cronin and McPhaden, 1999). Likewise, “diurnal jets” can form, with anomalous wind-forced surface currents that are stronger in the afternoon than at nighttime (Cronin and Kessler, 2009, their **Figure 5**). The afternoon near-surface stratification also traps surface heat fluxes, making them more effective at causing SST change than at nighttime when the mixed layer depth is deeper. The diurnally varying mixed layer depth, in this way, causes rectification of diurnal variability into longer timescales (Bernie et al., 2005).

Satellite and NWP/reanalyses fluxes may also be biased due to poor representation of short-term extreme flux events associated with very strong winds and strong temperature and humidity gradients near the surface. In satellite-based fluxes these biases are likely due to poor sampling while in NWP and reanalyses they also might be associated with inability of atmospheric models to adequately simulate such conditions. Bentamy et al. (2017) using probability density function approach (Gulev and Belyaev, 2012) demonstrated that extreme fluxes derived from satellite products may deviate from flux extremes estimated from buoy measurements by tens of W m^{-2} , even if the mean flux estimates are comparable.

Except at high latitudes, a single polar orbiting satellite can provide a maximum of two measurements per day (e.g., at 10:30 am and 10:30 pm), which is inadequate for resolving atmospheric synoptic variability or for resolving the amplitude and phase of the diurnal cycle. The diurnal cycle can be resolved by either placing several satellites in different sun-synchronous orbit planes to sample several discrete local times or by a single satellite in a lower inclination orbit. In the latter case, the satellite will precess through the diurnal cycle for any location on the ground over a period of time (days to months) that is related to the orbit inclination. Placing several satellite in sun-synchronous orbits, while more costly, has the benefit of sampling the diurnal cycle daily at discrete local times and reduces the

overall re-visit time for resolving rapidly evolving storms and short-lived extreme events.

Current Capabilities for Gridded Flux Products

To create the global flux products, the flux EOVs and ECVs must be observed or estimated with sufficient resolution and coverage to map their fields, or to constrain NWP model solutions and reanalyses to produce realistic flux fields. For flux products that extend back to the early-mid twentieth century, these gridded products based upon observations and NWP rely exclusively upon *in situ* data, primarily from underway ships. In the past decades, a satellite constellation has been building that can provide several of the gridded EOVs necessary for creating the flux products. However, because satellites are at present unable to provide some EOVs (e.g., surface air temperature and humidity) with acceptable accuracy, for some “blended” products such as the OAFlux product (Yu and Weller, 2007), air temperature and humidity are instead based on bias-adjusted NWP outputs, while other flux EOVs and ECVs are derived from satellite data. Satellite measurements appear to provide sufficient signal-to-noise ratios to produce high-quality stress estimates; however, direct *in situ* measurements of stress are too sparse to provide adequate calibration. The common practice is to derive winds from satellite backscatter measurements by utilizing *in situ* wind measurements and compute wind stress from bulk flux parameterization.

Even NWP and blended flux products, however, have large biases and uncertainties (Cronin et al., 2006; Bentamy et al., 2017; Valdivieso et al., 2017; Tomita et al., 2019; Yu, 2019). Mean fields from 12 products show standard deviations of up to 30 W m^{-2} for net surface heat flux and $5 \times 10^{-2} \text{ N m}^{-2}$ for wind stress (Figures 1C,D). It should be noted though that agreement between the different products does not mean that there are no biases; it may mean that all products are biased in the same way. In this case, the standard deviation around the multiproduct mean is not an appropriate estimate of the uncertainty. Moreover, the standard deviation could be overestimated due to outlying products. Thus, independent reference data are required to determine the accuracy of these products.

For the global average, ocean heat content estimates show the net surface heat flux into the ocean to be less than 1 W m^{-2} (e.g., Roemmich et al., 2015); for most products, the global average of the net air-sea heat flux is up to an order of magnitude larger than this (Figure 6A and Table 4). Comparisons of the state variables against moored reference station data show that a substantial part of this mean bias is due to deficiencies in the bulk algorithm used by the NWP (Jiang et al., 2005; Zhang et al., 2016). Bias can also be associated with the radiative heat flux components (Figure 6B), highlighting the need to improve satellite radiative observations and the presence of clouds in NWP. In order to understand the regional distribution of these errors and diagnose their causes, *in situ* reference stations are needed (Figure 4).

To improve NWP fluxes, marine boundary layer physics in NWP must be improved, including their algorithms for computing air-sea fluxes. In addition, more *in situ* and remotely

sensed data with higher accuracy are needed to constrain the NWP. More accurate satellite-based moisture and temperature profiles and surface data would greatly improve remotely sensed estimates of surface radiation and latent and sensible heat fluxes, and if assimilated into NWP models, would likely lead to improved representation of cloud formation processes and thereby improved representation of the state variables and surface radiative and turbulent fluxes from these NWP models.

ASPIRATIONAL SAMPLING REQUIREMENTS AND TARGET UNCERTAINTIES

Air-sea fluxes are challenging to observe because high-frequency variability and gustiness rectifies into the longer time scales. To adequately represent the annual cycle of heat fluxes, synoptic variability associated with storms must be captured. Subdiurnal resolution is required to adequately represent fluxes associated with fast-moving storms or in regions with a large diurnal cycle in SST. Fast moving atmospheric synoptic transients are associated with surface flux extremes (e.g., Tilinina et al., 2018), which can only be resolved in high resolution data. A gridded air-sea flux product that has 25 km or better spatial resolution and at least 3-hourly temporal resolution with a random uncertainty of 15 W m^{-2} and a bias of less than 5 W m^{-2} would be able to capture most of the air-sea interaction phenomena shown in Figure 2. The corresponding wind stress product should have a random uncertainty of $\pm 0.01 \text{ N m}^{-2}$ (or a 5% noise-to-signal ratio, whichever is larger) and a bias of $<0.005 \text{ N m}^{-2}$. It is important though to realize that the native resolution of the source observations for this gridded product must be at least 2–4 times better – at least 10 km and hourly. While this represents an improved accuracy at this resolution for wind stress, for the heat flux product, achieving this accuracy would represent a breakthrough advancement. Table 5 summarizes the sampling requirements for each flux EOV/ECV needed to meet this aspirational target. Because SST is the primary ocean EOV that drives the air-sea flux, and can be controlled by ocean frontogenesis processes, SST must have the highest spatial resolution of all EOV/ECV. We set an aspirational target of 1 km. This aspirational target, even now, is partially met for many parts of the global ocean.

OPPORTUNITIES FOR IMPROVED FLUXES IN THE GLOBAL ICE-FREE OCEAN

For global ice-free ocean estimates of turbulent heat and momentum fluxes, it is necessary to measure the flux EOVs and ECVs with sufficient accuracy, coverage and resolution to meet the targeted uncertainty and stability. As described in section “Current Capabilities,” the primary state variables for computing turbulent air-sea fluxes of heat and momentum include near surface air temperature, ocean skin SST, near-surface humidity, and the surface wind relative to the ocean surface currents.

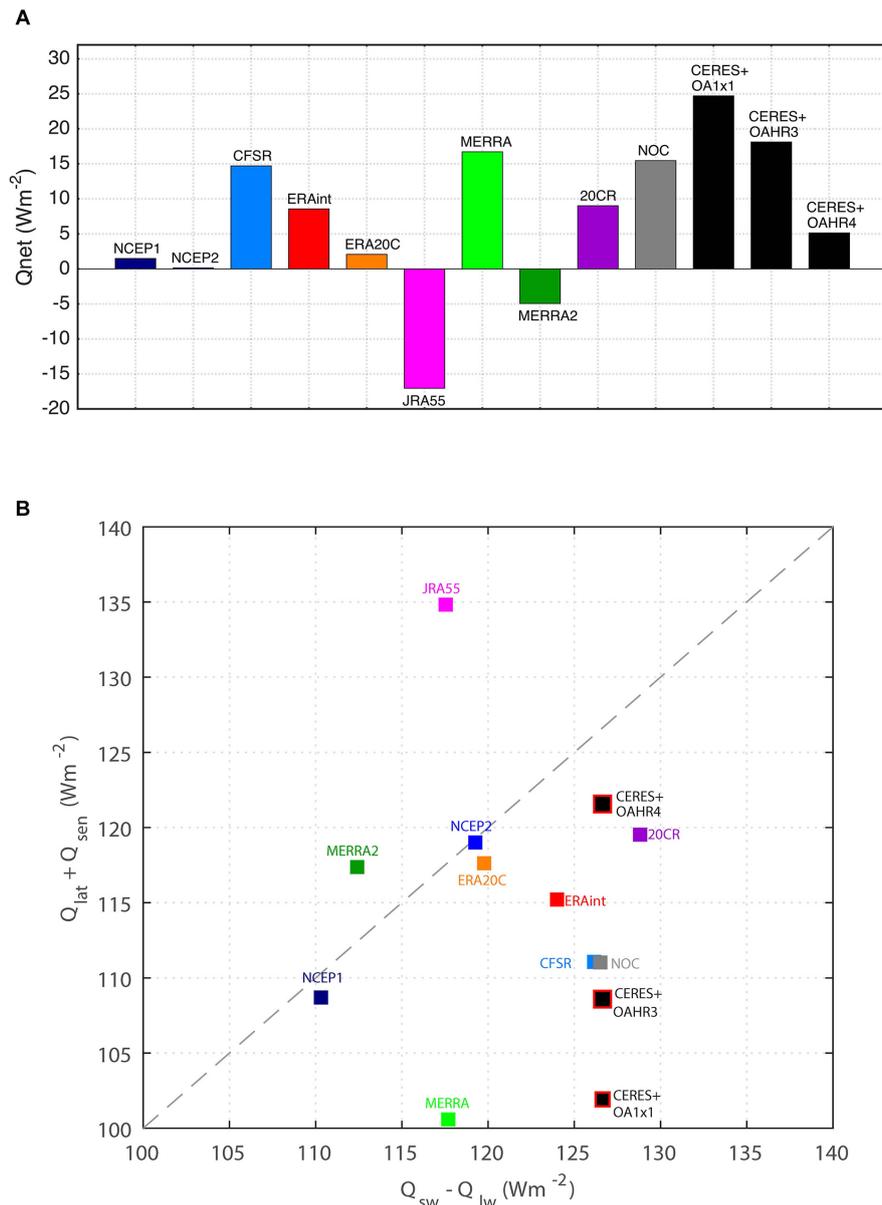

FIGURE 6 | (A) Global-ocean mean energy (Q_{net}) budget. **(B)** The ratio of the mean averages of $Q_{SW} - Q_{LW}$ to $Q_{lat} + Q_{sen}$; the dashed line denotes that this ratio equals 1.0. Abbreviations: 20CR, Twentieth Century Reanalysis; CERES, Clouds and the Earth's Radiant Energy System—Energy Balanced and Filled; CFSR, Climate Forecast System Reanalysis; ERA-20C, European Centre for Medium-Range Weather Forecasts Twentieth Century; ERA-Interim, European Centre for Medium-Range Weather Forecasts Interim; GPCP, Global Precipitation Climatology Project; JRA-55, Japanese 55-Year Reanalysis; MERRA, Modern-Era Retrospective Analysis for Research and Applications; NCEP, National Center for Environmental Prediction; NOC, National Oceanography Centre; OAFflux-1 \times 1, 1°-gridded Objectively Analyzed Air–Sea Fluxes; OAFflux-HR3 and -HR4, high-resolution (0.25°-gridded) Objectively Analyzed Air–Sea Fluxes analysis computed from Coupled Ocean–Atmosphere Response Experiment (COARE) version 3 and version 4, respectively. The 12 products used here are the same as used in Figure 1 from Yu (2019).

At present, humidity and air-temperature ECVs do not meet the requirements needed for global flux estimation (Tables 3, 5 and Figure 7). Our two major recommendations, described below, and our roadmap to flux improvement described in section “Roadmap for Improving Air-Sea Fluxes,” will address these deficiencies and others, enabling adequate sampling for all primary flux EO/ECV by 2030.

Space-Based Sensor for Near Surface Moisture and Air-Temperature Retrievals

A future remote-sensing measurement system designed for the boundary layer can address many of the issues that bedevil the present system. In particular, as described in section “Current Capabilities for Remotely Sensed Flux EO/ECV Measurements,” existing remote sensing

TABLE 4 | Various flux products information (based on Bentamy et al., 2017; Valdivieso et al., 2017; Tomita et al., 2018; Yu, 2019), including temporal and horizontal (in degrees) resolution, period of availability, flux components [Shortwave (Q_{SW}), Longwave (Q_{LW}), Sensible (Q_{sen}), Latent (Q_{lat}), Net air-sea heat flux (Q_{net}), Freshwater Flux (FW), and Momentum flux (τ)], and global ocean mean value for Q_{net} where available.

Near surface specific air humidity	Technology advancements/algorithm improvements needed	≤ 10 km	Hourly	Random: $0.5 g k^{-1}$ Bias: $0.3 g k^{-1}$
Sea surface current	Technology advancement needed	≤ 10 km	3 hourly	$0.3 m s^{-1}$
Upwelling/downwelling surface solar radiation	Technology advancements/algorithm improvements	≤ 10 km	Hourly	Random: $5 W m^{-2}$ Bias: $3 W m^{-2}$
Upwelling/downwelling surface longwave radiation	Technology advancements/algorithm improvements	≤ 10 km	Hourly	Random: $5 W m^{-2}$ Bias: $3 W m^{-2}$

This gridded product will likely use NWP to blend satellite and in situ observations to meet these targets. Some regions, such as ice margins, may need better resolution than these.

satellites are able to measure near surface wind speed and surface skin temperature with sufficient accuracy using either microwave or IR instruments, although further algorithm development is needed since these measurements are often tuned to bulk (rather than skin) SST and wind speed (rather than wind stress). Current atmospheric sounders are able to measure vertical profiles of temperature and water vapor, and these observations are the basis for deriving satellite-based near-surface air temperature and humidity.

Three major challenges need to be addressed to improve remotely sensed estimates of heat fluxes: improvements to retrievals, improvements to time coincidence of EO/ECVs, and improvements to algorithms. The first challenge is to improve the sensitivity and vertical resolution of microwave sounders in the boundary layer. Existing microwave sounders typically only have a few channels giving sensitivity at less than 10 evenly spaced levels from the surface to 20 km for temperature and to 10 km for water vapor. These channels are also fixed in frequency and often introduce biases due to the

shift of the weighting functions (see section “Current Capabilities for Remotely Sensed Flux EOV/ECV Measurements”). This may be overcome by adding additional channels, such as hyperspectral microwave sounding spectrometers at 50 and 183 GHz. Simulations of a notional hyperspectral sensor with a neural network retrieval algorithm predict uncertainties of 0.6°C for near-surface air temperature and 7% error for near-surface specific humidity, effectively doubling the accuracy of existing retrievals, for 1 km layers from the surface to 10–20 km altitude (Blackwell, 2005; Blackwell et al., 2011; Boukabara and Garrett, 2011). Assimilation of these better-resolved profiles into NWP should lead to additional improvements to the representation of near-surface conditions and thus air-sea fluxes.

The second challenge is to improve the time coincidence of the remotely sensed flux EOV/ECV measurements, which are typically made by independent systems and therefore usually not coincident in time, introducing de-correlation errors when computing fluxes from merged data. Time coincidence could be achieved by combining instruments on the same platform, or by using instruments on separate platforms flying in formation, which would most likely require a set of small satellite sensors to be cost effective. Alternatively, a passive microwave radiometer that combined low-frequency window channels used to measure SST and wind speed with atmospheric temperature and water vapor sounding channels would address the co-incidence issue with a single instrument. Radiometer instrument technology has made rapid strides in the past several years to miniaturize and lower the cost of the sensors envisioned

for this constellation, coupled with equal advancements in low-cost CubeSat and small satellites. The US Air Force plans to demonstrate a low-cost conical microwave imager (Brown et al., 2017) and NASA has two missions to demonstrate CubeSat microwave imager/sounders (Reising et al., 2016; Blackwell et al., 2018). In addition, launch costs have decreased through rideshare opportunities.

The third challenge is to improve the retrieval algorithms for near-surface air temperature and humidity. While SST and wind speed accuracies are typically better than 0.3–0.5°C (Gentemann, 2014; Kilpatrick et al., 2015) and 0.5–1.4 ms⁻¹ (Zhang et al., 2018), direct retrievals of near-surface air temperature and humidity a few meters above the sea surface remains challenging. Remote sensing retrievals provide average values for the lower 1 km. The relationship between this average and the air temperature and specific humidity at the sea surface requires an understanding of the vertical distribution of moisture within the atmospheric boundary layer and how this varies regionally and temporally. The suggested roadmap therefore includes a holistic program to improve and tune the retrieval algorithms and our understanding of their uncertainties, which will require improved remote sensing observations and a global array of *in situ* observation.

Globally Distributed *in situ* Network of Flux EOV and ECV

As discussed in section “Current Capabilities for Remotely Sensed Flux EOV/ECV Measurements,” the sparsity of the *in situ* network of flux EOV/ECV observations, particularly in large

regions of the Southern Hemisphere, stands as a major obstacle to progress. Lack of *in situ* data in these regions and other regimes lead to large uncertainties in satellite air humidity and temperature retrievals because retrieval algorithms are not sufficiently trained to represent various near-surface boundary conditions (Yu, 2019). In regions of low winds, where SST can have a large diurnal cycle and wind gustiness contributes significantly to the wind variance, *in situ* surface observations may capture the temporal variability of air-sea fluxes better than polar-orbiting satellite. Likewise, *in situ* observations may be better at capturing temporal variability of fast moving storms in the northern and southern hemisphere storm tracks. These tend to be regions with convective rainfall, which also can contaminate satellite IR scatterometer measurements. Finally, while satellite observations have a spatial resolution that a global *in situ* array could never meet, as discussed in section “Systematic Uncertainties Near Fronts and Regions of Persistent Clouds,” satellite can have data gaps due to persistent clouds in frontal regions precisely where air-sea fluxes are expected to be large. *Together, these strengths and weaknesses of remotely sensed vs. in situ observations argue for developing a global in situ flux-observing array to complement the global remote-sensing constellation.*

Mazloff et al. (2018, their Table 1) provide estimates for heat and carbon flux decorrelation scales in the Southern Ocean, sorted into low-pass and high-pass scales. The low-pass requirements need very sparse sampling (90° by 10° ; 11 measurements), but high-pass sampling is more substantial: 156 measurements in the 70° to 35° latitude range, or roughly one measurement per 4° by 4° box. Further work will need to be done to determine the optimal design of this regionally distributed plan. But at its center might be pairs or clusters of flux platforms within a regular grid (e.g., 10° by 10°) box. For reference, nodes of a 10° grid are shown in **Figure 8**, with 368 nodes in the global ocean. We envision a global network of flux observing platforms made up of ASVs, drifting and moored buoys, and R/Vs, with the exact choice of platform dependent upon conditions and scientific needs. This large-scale network of high-resolution sampling would ideally capture frontal structures that are critical to the generation of large exchanges of heat between the ocean and atmosphere.

These flux platforms could carry other sensor suites too, such as air-sea carbon dioxide flux packages and ocean acidification sensors. In this way, the network could be multi-functional and serve a range of communities and stakeholders beyond those described here. In the future, as true coupled data assimilation becomes standard for NWP, we would expect that this network of co-located surface ocean and atmospheric *in situ* observations would be particularly valuable for assimilations.

This globally distributed array should be built around an expanded OceanSITES network. At present, the OceanSITES surface flux array is too sparse, with 22 sites that measure net surface heat flux. Nineteen key regions needing OceanSITES time series stations are shown in **Figure 8**. These regions include eleven discussed in section “*In situ* Platforms for Observing Fluxes,” as well as regions in the western equatorial Pacific and western North Atlantic, and eight additional high priority regions

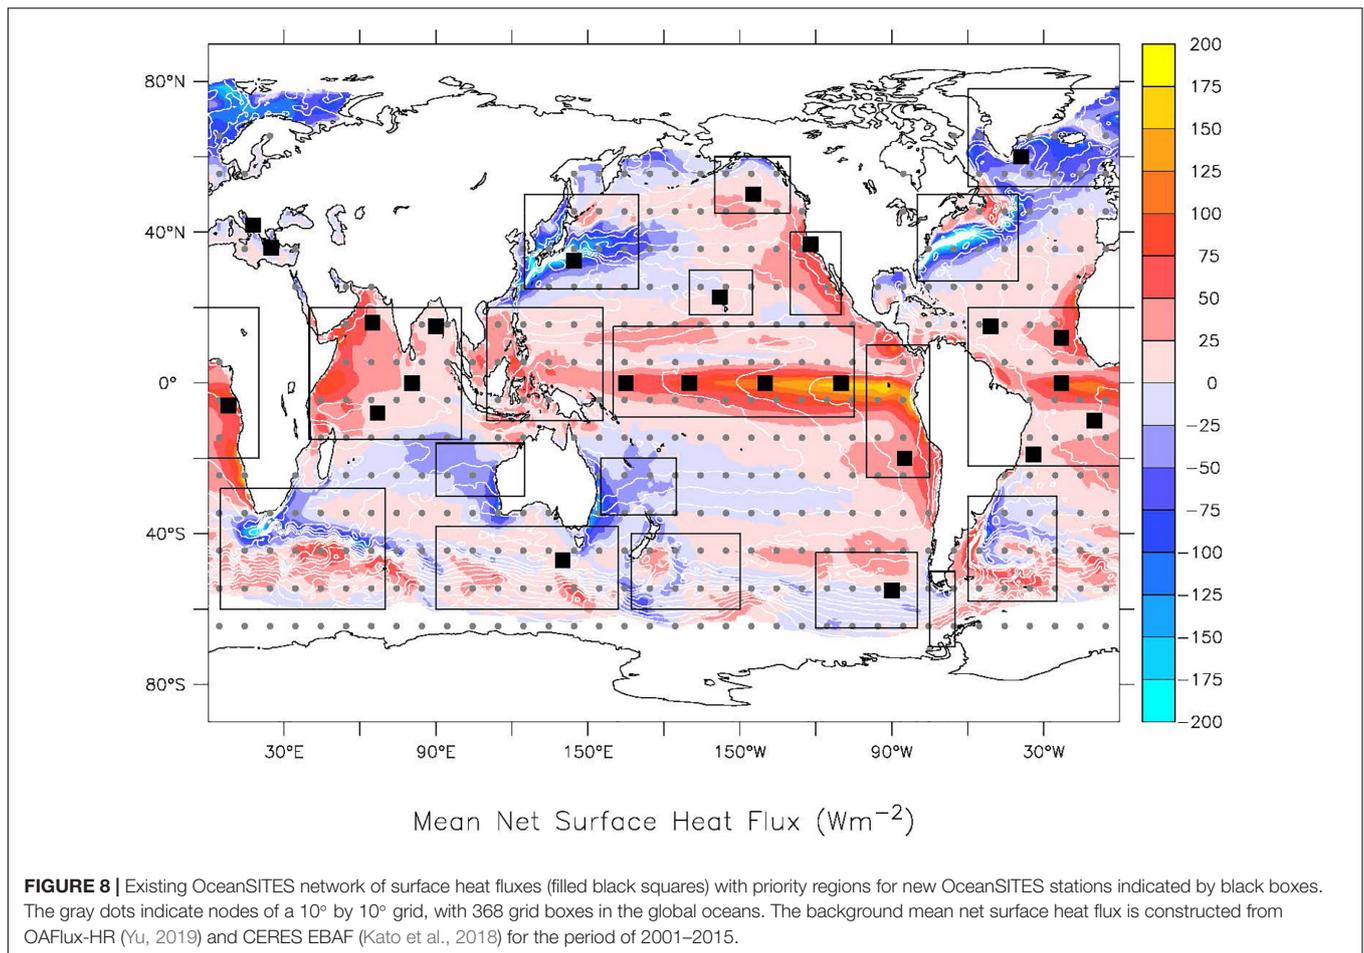

in the Southern Hemisphere. These regions have no OceanSITES flux reference station. As discussed in section “*In situ* Platforms for Observing Fluxes,” an OceanSITES station not only monitors the air-sea fluxes, but also the local response of the ocean, atmosphere, and ecosystem to these air – sea exchanges. Tozuka et al. (2018) have shown that the contribution of surface heat fluxes to surface frontogenesis/frontolysis depends not just on the flux gradients, but also on the distribution of mixed layer depth, which controls the effective heat capacity of the upper ocean. The OceanSITES flux network provides these co-located air-sea flux, mixed layer depth observations, and other EOVs so that budget analyses can be performed to determine causes for surface variability.

In some regions, such as the tropical Pacific, the number of OceanSITES flux reference stations could be increased simply by adding a few sensors to existing OceanSITES surface moorings. In other regions, new mooring stations are needed. The Tropical Pacific Observing System (TPOS)-2020 project is working to optimize flux measurements in the tropical Pacific, including the eastern and western boundary regions (Smith et al., 2019). Likewise, the Southern Ocean Flux working group is in the process of developing a deployment strategy to optimize the positioning of a sparse internationally supported array of flux moorings (Swart et al., 2019). Regional groups, like these, have the scientific expertise and local knowledge that are critical for making these long-term stations successful. Nevertheless, the following list of new sites are considered to be a high priority as they are all in regions that do not at present have any flux reference station:

New Flux Reference Sites for 8 Key Regions with no Flux Station at Present

- (1) Tropical Western Pacific (9°N , 150°E ; equatorial region west of 165°E): Typhoon corridor, monsoon, intraseasonal oscillations, and ENSO variability.
- (2) Southern Ocean (order 60°S , any longitude): Ice-edge conditions. Southern Hemisphere storm track.
- (3) Southern Ocean (40°S – 60°S , any longitude): Southern Hemisphere storm track.
- (4) Agulhas (40°S , 36°E): Intense heat loss region associated with S. Indian Ocean western boundary current (WBC), extratropical storms, interbasin eddy heat exchanges, mixed layer depth role in front gradient.
- (5) Southeast Indian Ocean (25°S , 110°E): Strongest ocean evaporation region (globally) in trade wind return flow, subject to “Ningaloo” mid-latitude marine heat waves. Subtropical mode water formation site.
- (6) Gulf Stream (35°N , 60°W): Intense heat loss associated with N. Atlantic WBC, eddy rich region, tropical-extratropical cyclones and interactions, cold-air outbreaks.
- (7) East Australian Current (35°S , 160°E): S. Pacific WBC, Tasman Front, tropical-extratropical interactions.
- (8) Brazil-Malvinas Confluence (42°S , 42°W): S. Atlantic WBC, eddy rich region, tropical-extratropical interactions.

These regions listed here are high priority because they at present have no OceanSITES flux reference station in them. Our

boxed regions, however, are large, covering major quadrants of each basin. Each have multiple regimes, sometimes separated by major fronts. For many regions, such as the tropics, multiple stations are justified. Careful array design studies by regional experts is recommended.

A subset of the long-term reference stations should be enhanced for process studies and to provide high resolution turbulent flux and mean profiles that extend 20 to 100 m into the marine atmosphere. These “super sites” would provide critical observations to validate and guide model physics and bulk flux and satellite retrieval algorithm development. Such a system, with multiple levels of fast-response sensors to directly measure momentum, heat and mass exchange, could be based on fixed towers, large moored spar buoys or other floating platforms, which are being developed and used by the offshore wind industry. Remote sensing systems deployed on the platforms and from nearby moorings (e.g., Lidar buoys) could provide further characterization of the coupled boundary layer, including cloud information, boundary layer height and mixed layer depth. Other key variables to be observed at these sites could include wave information, radiative fluxes (including both upwelling and downwelling fluxes), skin SST, precipitation, high-resolution upper ocean currents, fast static pressure, and a suite of oceanic boundary

measurements, among others. These supersites and their associated infrastructure would also serve as testbeds for validation of innovative platforms and systems, such as low-power sensors and remote sensing systems for deployment on buoys and mobile platforms. In addition, it is recommended that some of the ships servicing the moorings and supersites be enhanced to monitor the coupled boundary layer, and host unmanned aircraft systems for observing along-wind and cross-wind variations, obtaining data to improve albedo parameterizations, and for monitoring a wide-range of coupled boundary layer processes. The breakthroughs highlighted in **Figure 7** depend not only upon improved remote sensing and expanded *in situ* observations, but also upon improved models, algorithms and parameterizations. This ambitious goal is predicated upon vigorous research fed by these coupled boundary layer observations described here.

ROADMAP FOR IMPROVING AIR-SEA FLUXES

Quantifying air-sea fluxes is very challenging as multiple co-located flux EOJ/ECV must be measured at high temporal and spatial resolution, with high accuracy. At

present, the global ocean observing system does not meet the necessary requirements (Figure 7), mainly due to the lack of global coverage of surface humidity and air temperature. Our two major recommendations rectify this and other deficiencies:

Major Recommendation #1

Create a remote-sensing retrieval system designed for accurate boundary layer measurement of air temperature, humidity, SST, and surface stress. This would involve a holistic approach to improve resolution of satellite retrievals, time coincidence of remotely sensed surface flux EOVs/ECVs, and algorithms that relate the retrievals to near-surface conditions.

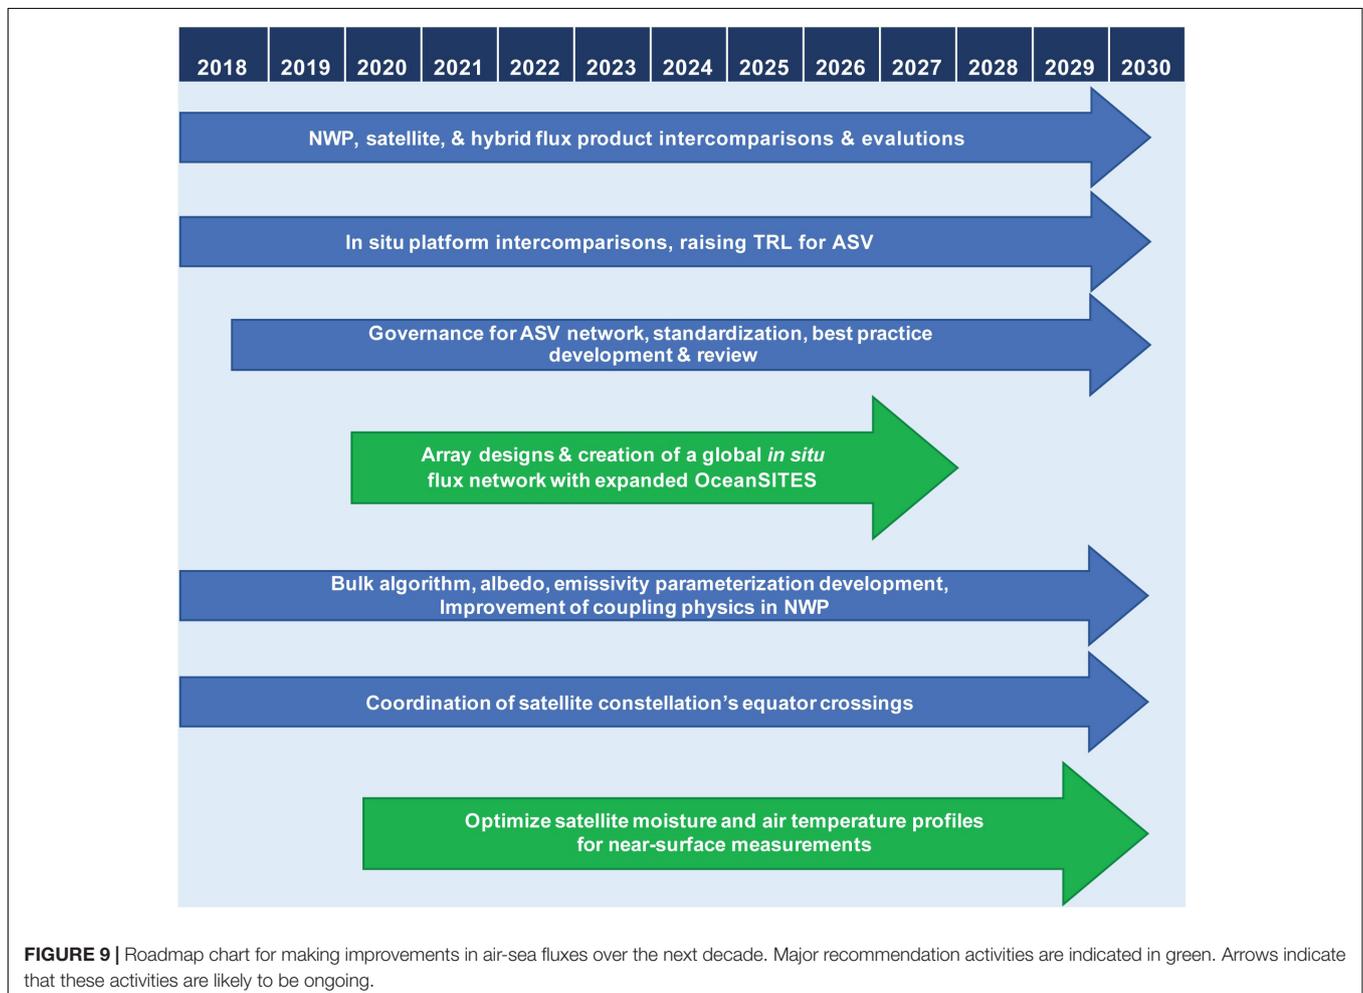

Major Recommendation #2

Create a global *in situ* array of flux observing platforms, built around an expanded OceanSITES network of time series reference station moorings. The global array would include ~500–1000 platforms including ASVs, moored and drifting buoys, and RVs, with 1–3 platforms in nominal 10° by 10° boxes. The OceanSITES network of 22 flux sites must be maintained and expanded in up to 19 key regions. In addition, the *in situ* array

should include a few super sites with enhanced observations of the coupled boundary layer.

These major recommendations depend upon a number of steps taking place, as shown in the Roadmap (Figure 9):

- The TRL for ASV and other new flux platforms must be increased before being used to form a large global network. These platforms must be continually evaluated against satellite and proven technology, including RVs, flux towers with vertical extent, and OceanSITES and OOI moorings. It is recommended that an international ASV expert group form to coordinate ASV data stream, evaluate data, and develop best practices and standardizations.
- Array designs for the *in situ* flux network must be studied. It is likely that a flux network would have some similarities to an Argo array in being globally distributed, but also have some distinct differences due to the importance of fronts and rapid variations in flux EOV/ECV. Likewise, in contrast to Argo, adaptive sampling capabilities of ASV could allow the globally distributed array to target certain phenomena and to sample in combination with other fixed platforms. Determining the optimal array design will require both model studies and pilot field studies.

- International coordination of data management and archival must be extended to flux-related data streams, including for all underway RV observations, ASVs, drifting and other flux platforms, and for observations transmitted in near real time in support of NWP on the Global Telecommunications System (GTS).
- With the expanded *in situ* array of platforms that measure all flux EOV/ECV including direct covariance flux estimates of the turbulent fluxes, the state of the art bulk aerodynamic flux algorithm can be improved, leading to reduced uncertainties. It is critical that the bulk algorithm in NWP be improved.
- Parameterizations for transforming bulk EOV/ECV into bulk algorithm state variables must be improved. These include (but are not limited to) extrapolation of bulk sea surface state variables to the air-sea interface, and parameterizations of albedo and emissivity.
- Cross-platform and cross-product intercomparisons must take place and differences must be reconciled. Sensors across all *in situ* platforms should have laboratory calibrations traceable to international standards, and field intercomparisons to verify consistency. Identification of field errors should lead to changes in best practices. Identification of model errors should lead to recommendations for improved physics and parameterizations.

CONCLUSION

In this paper, we lay out an observational strategy for producing 3-hourly at 25-km (and an aspirational goal of hourly at 10-km) gridded heat fluxes and wind stress fields over the global, ice-free ocean that have a breakthrough improvement in accuracy for heat flux and, for these scales, an improved accuracy in wind stress. The target for the net heat flux product is 1-day random uncertainty of 15 W m^{-2} (or 5% error for each radiative component and the sum of the turbulent heat fluxes) and a bias of less than 5 W m^{-2} . For the wind stress product the target is 1-day random uncertainty of $\pm 0.01 \text{ N m}^{-2}$ (or a 5% noise-to-signal ratio, whichever is higher) and a bias of 0.005 N m^{-2} . At present the heat flux uncertainty target is met only at OceanSITES reference station moorings and RVs that follow best practices. To meet these targets in the next decade, we make two major recommendations: (1) Create a remote-sensing measurement system designed for accurate boundary layer measurements of air temperature, humidity, SST, and surface stress; and (2) Create a complementary global *in situ* array of flux observing platforms, built around an expanded OceanSITES network of time series reference station moorings. The global array would include ~ 500 – 1000 platforms including ASV, moored and drifting buoys, and RVs, with 1–3 platforms in nominal 10° by 10° boxes. The OceanSITES network of 22 flux sites must be maintained and expanded in up to 19 key regions. The *in situ* flux array would provide globally distributed measurements and metrics

for satellite algorithm development and product validation. In addition, *in situ* flux EOV and ECV observations that also include direct covariance flux observations could be used to improve “bulk aerodynamic algorithm” for computation of air-sea exchange of heat and momentum. With improved coupling of the ocean and atmosphere in NWP, and constrained by the improved moisture and air temperature profiles, these NWP are expected to have improved representation of cloud formation processes and radiative properties. Together, these will lead to a more accurate satellite-based (and blended) flux product. This better quantification of the ocean’s influence on the atmosphere will lead to improved long-term weather forecasts, seasonal-interannual-decadal climate predictions, and regional climate projections.

AUTHOR CONTRIBUTIONS

MFC, CLG, JE, and IU were first authors for abstracts that were merged into the present version. MFC wrote the first draft of the manuscript. CLG, JE, SB, IU, EK, RAW, SAJ, RTP, SK, CWF, HT, PJM, JTF, SS contributed to text sections. LY, MB, PJM, and MFC contributed to figures. All authors contributed to manuscript revision, and read and approved the submitted version.

FUNDING

EK was funded by the NERC CLASS Program (NE/R015953/1). CLG was funded by NASA grant 80NSSC18K0837. SG was funded by MEGAGRANT P220 program (#14.W03.31.0006).

ACKNOWLEDGMENTS

The three reviewers provided insightful and detailed comments that significantly improved the manuscript. The authors gratefully acknowledge the contributions from Drs. Kentaro Ando, Tatsuya Fukuda, Yasuhisa Ishihara, and Makito Yokota (all from JAMSTEC, Japan), Dr. Aderrahim Bentamy (IFREMER, France), Mr. Shawn Smith (FSU, United States), Dr. Scott Miller (Albany University, United States), and Sandra Bigley (NOAA PMEL). This work benefited from discussions within the OOPC, AOPC, WRCP Data Advisory Council (WDAC) Surface Flux Task Team, National Academy of Science Workshop “The Future of Atmospheric Boundary Layer Observing, Understanding, and Modeling,” Southern Ocean Flux Working Group (SOFLUX), and Tropical Pacific Observing System (TPOS)-2020 Planetary Boundary Layer Task Team. This is PMEL publication 4842.

SUPPLEMENTARY MATERIAL

Conflict of Interest Statement: NOAA PMEL has had a Cooperative Research and Development Agreement (CRADA) with Saildrone, Inc., since 2014 that covers work with Saildrone ASV by MFC. This has involved in kind contributions from Saildrone, Inc., toward NOAA ASV missions. It is expected that this work will benefit NOAA's mission and the entire ASV industry. CLG had a contract for 6 weeks of her time from Saildrone, Inc. The contract was to coordinate a 2-month Saildrone cruise that occurred in Spring 2018. DV had a contract for 2 weeks of his time from Saildrone Inc., in 2018 to advise on the data collection and processing of turbulent flux measurements using their platform.

The remaining authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

Air-sea and air-sea-ice fluxes in the Southern Ocean play a critical role in global climate through their impact on the overturning circulation and oceanic heat and carbon uptake. The challenging conditions in the Southern Ocean have led to sparse spatial and temporal coverage of observations. This has led to a “knowledge gap” that increases uncertainty in atmosphere and ocean dynamics and boundary-layer thermodynamic processes, impeding improvements in weather and climate models. Improvements will require both process-based research to understand the mechanisms governing air-sea exchange and a significant expansion of the observing system. This will improve flux parameterizations and reduce uncertainty associated with bulk formulae and satellite observations. Improved estimates spanning the full Southern Ocean will need to take advantage of ships, surface moorings, and the growing capabilities of autonomous platforms with robust and miniaturized sensors. A key challenge is to identify observing system sampling requirements. This requires models, Observing System Simulation Experiments (OSSEs), and assessments of the specific spatial-temporal accuracy and resolution required for priority science and assessment of observational uncertainties of the mean state and direct flux measurements. Year-round, high-quality, quasi-continuous *in situ* flux measurements and observations of extreme events are needed to validate, improve and characterize uncertainties in

blended reanalysis products and satellite data as well as to improve parameterizations. Building a robust observing system will require community consensus on observational methodologies, observational priorities, and effective strategies for data management and discovery.

Keywords: air-sea/air-sea-ice fluxes, Southern Ocean, ocean-atmosphere interaction, climate, ocean-ice interaction

INTRODUCTION

Air-sea fluxes determine how properties, such as momentum, heat, freshwater, and gasses, exchange between the atmosphere and the ocean. They are essential to understanding the global energy budget (Trenberth and Fasullo, 2010), evaluating and improving weather prediction and climate models, and understanding oceanic and atmospheric processes that depend on the upper ocean [ocean heat uptake, mixed-layer temperature, Sea Surface Temperature (SST) variability] (Dong et al., 2007). This is exemplified in the Southern Ocean (SO), where extreme winds and sea states, strong temperature gradients, and strong seasonal changes (e.g., sea-ice cover) enhance air-sea exchanges in a region that is key to global climate (e.g., Sabine et al., 2004; Frölicher et al., 2015; Rintoul, 2018) and highly responsive to changing climate conditions (e.g., Andrews et al., 2015).

In situ observations of variables needed to estimate fluxes, in particular, meteorological measurements, are sparse in the SO (Figure 1), with almost no observations from autumn or winter months or at any time in the regions impacted by permanent or seasonal sea-ice cover. This results in large errors in SO reanalysis products (see section “Status of Flux Reanalyses and Requirements to Reduce Uncertainty,” Figure 2) and poor representation in climate models, with significant inter-related biases in SSTs, ocean thermal structure, winds and clouds, due to its strongly coupled dynamics (e.g., Thompson et al., 2011; Bodas-Salcedo et al., 2014, 2016; Hermanson et al., 2018; Hyder et al., 2018). The lack of *in situ* data also limits our ability to improve remote sensing products and optimize blending of model and remote sensing inputs (e.g., Objectively Analyzed Flux – Yu and Weller, 2007), and increases uncertainty in atmosphere and ocean dynamics and boundary-layer thermodynamic processes. The consequent uncertainties in climate projections further hinder our ability to develop climate mitigation and adaptation measures. To assess and improve flux estimates and understand key processes in the SO there is an urgent requirement for accurate, direct air-sea-ice flux observations, and the meteorological variables on which they depend.

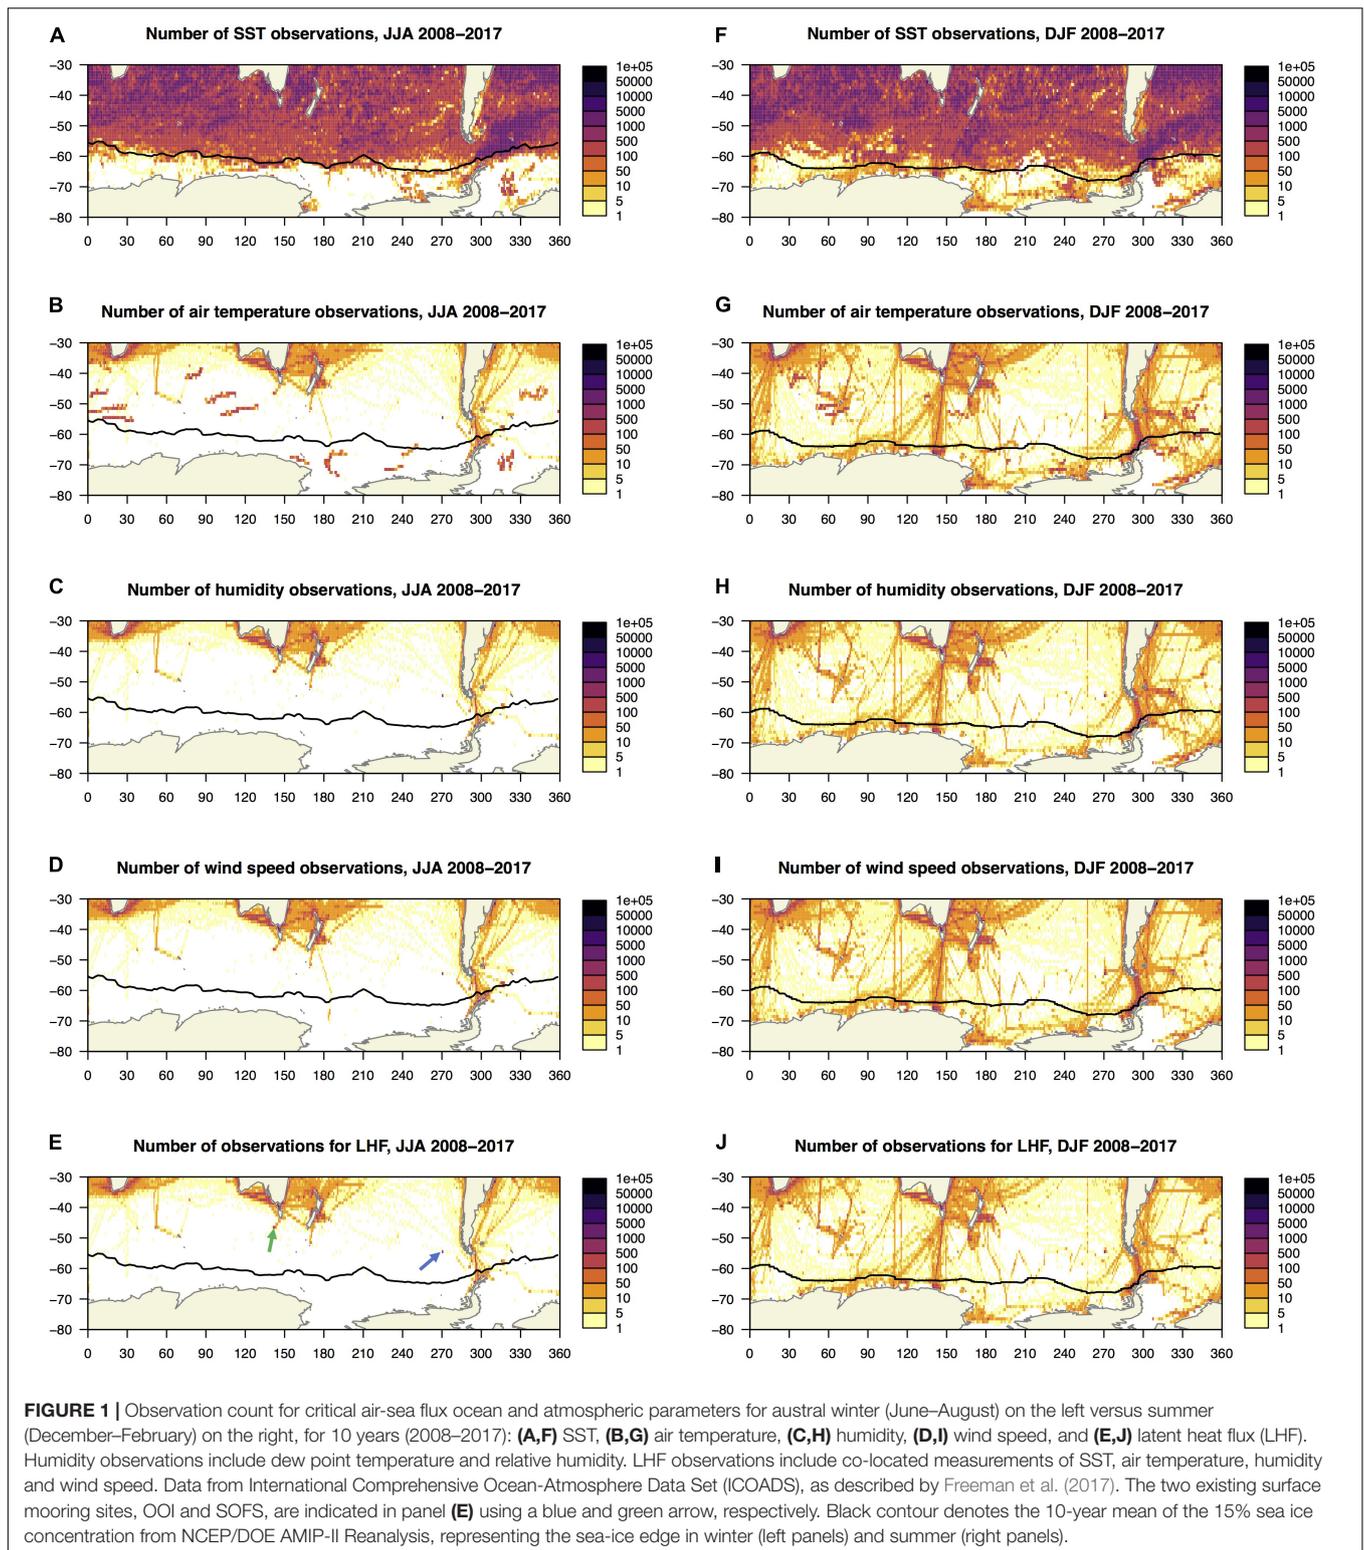

This paper builds on the high-latitude flux review of Bourassa et al. (2013). The objectives of this paper are to highlight the Southern Ocean-specific observational gaps, scales, and challenges in estimating air-sea-ice fluxes, to summarize key focus areas for future flux research, and to offer recommendations for improving estimates of fluxes. In particular, recent technological progress, such as surface flux moorings and autonomous surface vehicles, provide new mechanisms to improve high-latitude flux observations and

research in the coming decade. For details on broad-scale heat and momentum fluxes for the global ice-free ocean the paper by Cronin et al. (2019) should also be referred to. This paper articulates a charge for the SO air-sea flux community to come together to plan, collect and share air-sea-ice flux information, experience and knowledge. It is a product of the Southern Ocean Observing System (SOOS) international working group on SO air-sea fluxes (SOFLUX; Gille et al., 2016), which coordinates observing-system capabilities and requirements for SO air-sea-ice fluxes.

KEY SPATIAL AND TEMPORAL SCALES OF FLUXES

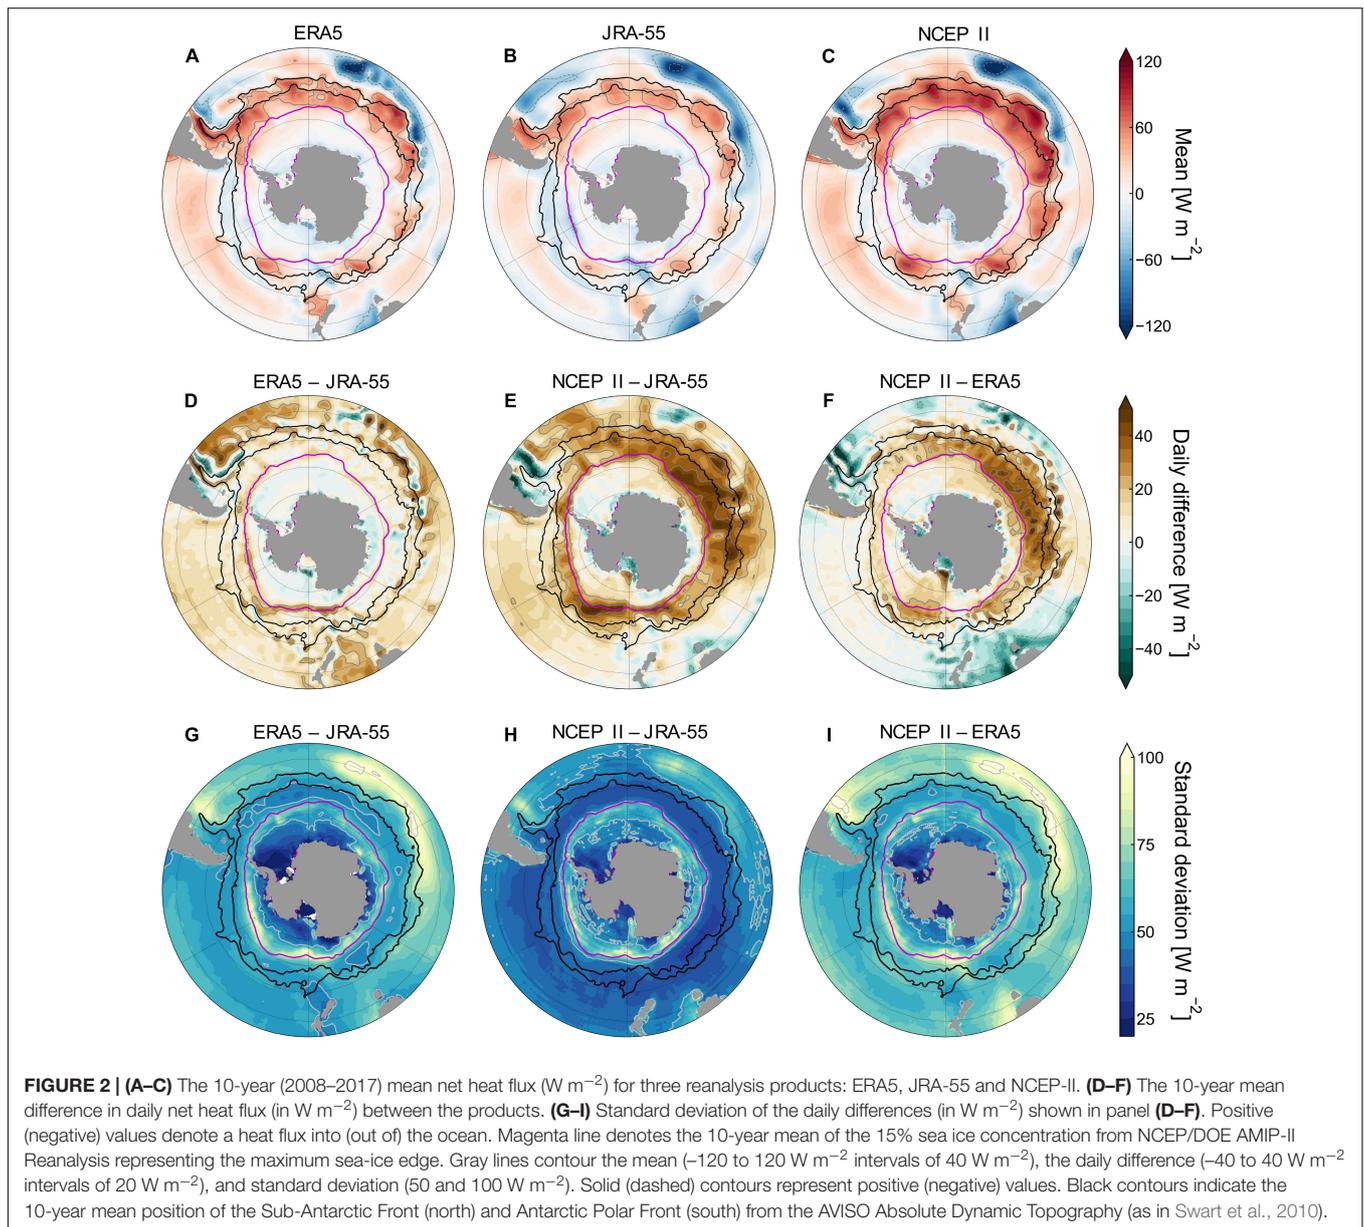

The short time- and length-scale variability of SO air-sea fluxes makes quantifying exchanges challenging (Lenton et al., 2006; Monteiro et al., 2015). This variability is predominantly driven by the high-frequency structure of winds (Yuan et al., 2009) and high-wavenumber structure of the ocean state (Chelton et al., 1998). However, one may exploit the low-frequency variability of ocean properties and low-wavenumber structure of the atmospheric properties to constrain the fluxes. For example, Observing System Simulation Experiments (OSSEs) show that the Argo float array is able to constrain the upper-ocean climate signals of heat, carbon, and freshwater content on seasonal timescales (Majkut et al., 2014; Kamenkovich et al., 2017; Mazloff et al., 2018). Spatial and temporal integrals of oceanic heat content change provide information on net heat fluxes, which can be used to assess biases in the bulk formulae derived from point measurements. Yet large-scale budgets do not provide information about the mechanisms driving small-scale air-sea fluxes, which are vital to understanding the system and can be revealed by *in situ* time-series observations (Ogle et al., 2018).

SOFLUX has prioritized the collection of high-quality *in situ* point measurements necessary to understand true small-scale flux variability, while also measuring the large-scale properties that reveal integrated flux values. High-frequency measurements suggest that Subantarctic air-sea CO₂ fluxes should be measured at a 3-day frequency to provide an unbiased constraint, particularly during the more stratified summer period. Sampling at lower temporal frequency would potentially alias the more rapid response of mixing and entrainment to storm events (Monteiro et al., 2015). Alternatively, Mazloff et al. (2018) suggest that maintaining platforms every 20° longitude by 6° latitude would constrain the climate-scale heat and carbon inventory, and validate integrated air-sea fluxes. While fluxes

themselves have significant high-frequency variability, the low-frequency component has large spatial scales of approximately 90° longitude by 10° latitude. Climate-scale fluxes for the ocean between 35°S and 70°S , could therefore be determined with 100

optimally spaced platforms. The current Argo array of >600 floats results in non-negligible uncertainty in estimating climate signals, with crucial gaps in the sea-ice impacted regions (Mazloff et al., 2018). Nevertheless, the results imply that reducing

uncertainty in fluxes and their parameterizations, is feasible. Statistical significance of observed trends will improve as fixed-point time series are sustained. Constraining the marginal ice zone (MIZ), however, remains a priority (Figures 1A,F).

STATUS OF FLUX REANALYSES AND REQUIREMENTS TO REDUCE UNCERTAINTY

Gridded satellite and reanalysis datasets in the SO suffer from a large inter-product spread in estimates of the net air-sea heat flux (e.g., Liu et al., 2011), stemming from insufficient observations, particularly in winter (Figures 1A–E), and the need to determine the net exchange as the sum of

four individual components (latent – Figures 1E,J, sensible, shortwave, longwave; Bentamy et al., 2017). Evaluation of the spread in net heat flux between atmospheric reanalysis products has revealed regional differences up to 60 W m^{-2} (Liu et al., 2011). These differences persist when zonally averaged and show ship-based and reanalysis products differing by $30\text{--}40 \text{ W m}^{-2}$ at a given latitude (e.g., Josey et al., 2013).

To further demonstrate first-order uncertainties around SO air-sea fluxes, a comparison is made between three commonly used reanalysis products of net heat flux (NCEP-II, ERA5, and JRA-55; Figure 2). Large mean state (10 year) differences (up to 50 W m^{-2} ; Figures 2A–C) and mean daily differences (reaching up to 40 W m^{-2} ; Figures 2D–F) exist between products for large swaths of the SO (e.g., in Figure 2E: mean daily differences $>20 \text{ W m}^{-2}$ for 35% of area south of 35°S),

particularly in the NCEP-II comparisons. These differences are highest in the central Antarctic Circumpolar Current (ACC) domains, at the boundaries to strong subtropical originating currents (Malvinas Confluence and Agulhas Return Current), and around the southern ACC to the edge of the winter sea-ice extent (especially in the Pacific and Indian sectors). The standard deviation of these daily differences (Figures 2G–I) emphasizes the larger range of differences (reaching $> 100 \text{ W m}^{-2}$) found in both the northern ACC domain and at the winter sea-ice edge and extending into the MIZ. The larger uncertainty associated with the edge or within sea-ice regions suggests complexities in constraining fluxes impacted by ice-ocean processes and/or the limitation of satellites/reanalysis products to estimate fluxes in ice-impacted domains (Yu et al., 2017). Strong ocean gradients at the boundary to the subtropical gyres could be leading to enhanced heat flux differences (Figures 2D–I; see section “Ocean Impact on Fluxes”) and these regions should be targeted for enhanced observational coverage to reduce uncertainty (see section “Specific Recommendations for the Coming Decade”).

The momentum (wind stress) flux is better determined in a climatological sense than the heat flux, as it is a function of fewer, more easily determined variables that are reasonably estimated from satellite observations. However, significant wind speed differences still exist between gridded products and *in situ* data (Schmidt et al., 2017) with biases of up to 7.5 m s^{-1} depending on the wind speed magnitude (higher wind speeds are subject to considerably higher errors). Consequently, there is only medium confidence that SO wind-stress forcing has strengthened on decadal timescales (Swart and Fyfe, 2012; Rhein et al., 2013) as is expected from coupled model-based studies (Russell et al., 2018).

Given the uncertainties noted above, improvement in SO heat and momentum flux accuracies is vital. This has long been recognized (e.g., OceanObs’99 and ’09 – Fairall et al., 2010) and the deployment of two surface flux moorings¹ is progressing towards this goal. The time-series are currently insufficient to evaluate whether reanalysis products accurately represent interannual and decadal variability, thus sustaining these time-series is key to reducing these uncertainties. Recently, analysis of ship data across the open ocean to the MIZ has enabled better understanding of air-sea interaction in this key transition region (Yu et al., 2017), although winter measurements remain lacking (Figure 1).

OCEAN IMPACT ON FLUXES

The exchange of tracers and energy across the air-sea interface is modulated by a complex upper-ocean “mixed layer” structure (Kilbourne and Girton, 2015). Instruments that quantify upper-ocean turbulence (e.g., Air-Sea Interaction Profiler; Ward et al., 2014) provide direct estimates of the mixing and mixed-layer depths from measurements of the dissipation rate of turbulent kinetic energy (ϵ) and density (ρ), respectively. Combined

¹Integrated Marine Observing System (IMOS) SO Flux Station (SOFS) south of Tasmania (Schulz et al., 2012) and the Ocean Observatories Initiative (OOI) mooring upstream of Drake Passage at 55°S , 90°W (Ogle et al., 2018).

with velocity scales associated with wind, wave, and buoyancy (e.g., after Belcher et al., 2012), improved parameterizations of mixing in the SO can be determined. It is anticipated turbulence from wave breaking and Langmuir circulation will play a dominant role in the turbulence generation and scaling (Esters et al., 2018). As ocean turbulence is a major driver for air-sea fluxes, such studies will lead to improved parameterizations in the SO.

Additionally, small-scale turbulence in the mixed-layer is influenced by oceanic motions spanning a few hundred meters (submesoscale) to hundreds of kilometers (mesoscale). For example, Arduin et al. (2017) show a strong covariance of mesoscale currents and surface-wave energy, especially in the Drake Passage. This implies a change in mesoscale surface roughness and thus effective surface-ocean stress (Small et al., 2008; O’Neill et al., 2012). This dependence impacts gas exchange via surface wave breaking (Brumer et al., 2017), although the magnitude remains to be directly measured. Furthermore, remote-sensing products indicate up to 20% of South Atlantic turbulent heat flux variance is explained by mesoscale eddies (Villas Bôas et al., 2015; Figure 2). Autonomous surface vehicles (ASVs) are key for augmenting *in situ* measurements of surface ocean variability, which is dominated by small-scale, submesoscale gradients (Thomson and Girton, 2017). Strong coupling exists between both waves and surface currents as well as between oceanic and atmospheric temperatures (Villas Bôas et al., 2015). This supports earlier work showing that fronts and eddies (and associated SST gradients) can substantially impact the air-sea exchange and near-surface atmospheric conditions in vigorous SO boundary-current regions (Pezzi et al., 2005, 2009; Messenger et al., 2012; de Camargo et al., 2013; Rouault et al., 2016).

Submesoscale (0.1–20 km) lateral density gradients in the upper ocean can also significantly modulate the depth of the mixed-layer on sub-seasonal time scales (Rosso et al., 2015; du Plessis et al., 2017, 2019), with implications for heat and carbon uptake, water mass modification due to surface buoyancy fluxes, and the timing of biological processes (Swart et al., 2015). The intensity of these features is strongly localized by the circulation of the ACC and its interaction with topographic features (Viglione et al., 2018). The MIZ may also be a site of enhanced vertical velocities due to the coupling between thin sea ice and near-surface oceanic flows (Manucharyan and Thompson, 2017). This can lead to enhanced lateral and vertical heat fluxes toward sea-ice, as well as modifying air-sea fluxes through, for example, changes in sea-ice concentration and floe size distributions (Horvat et al., 2016).

OBSERVING FLUXES THROUGH ICE

Sea-ice presence and concentration dramatically affect physical, gas, and aerosol fluxes (Bourassa et al., 2013), which in turn, provide a significant feedback to sea-ice state, extent, and thickness (e.g., Perovich et al., 2008). As sea-ice parameters change in a warming climate, a significant adjustment in the balance of the high-latitudes air-sea-ice fluxes is likely.

Ice-covered regions of the SO are acutely under sampled, especially in autumn and winter – with the hypothesis that open water in autumn before freeze-up is exposed to enhanced wind stress and mixing, amplifying air-sea exchange. Fluxes within open waters surrounded by sea ice (MIZ, leads and polynyas) can be estimated by classical approaches, but must account for (i) logistical constraints and (ii) ice-specific processes, such as reduced fetch area, wave attenuation and scattering, shear in the ice-ocean boundary layer, buoyant convection or stratification, short period gravity waves, and ice–flow interactions.

Air-sea-ice fluxes are ‘in this sense’ dramatically different from air-sea fluxes and often require separate methodology. For instance, heat flux budgets require assessment of sea-ice growth using ice mass-balance buoys, which provide spatially restricted point-measurements and require consolidated ice for deployment (i.e., not on unconsolidated ice formed in polynyas). While sea-ice processes drive gas fluxes at the air-sea-ice interface, assessment of these fluxes must take into account the unique gas dynamics and transport within sea ice, which are derived from techniques used for terrestrial fluxes. In addition, snow load and structure affect energy and gas transfer in different ways and are poorly constrained.

Finally, budgeting fluxes in ice-covered regions requires understanding of spatial and temporal variability of the sea-ice cover (Schröder et al., 2003; Matear et al., 2015), for which remote sensing is critical. However, deriving sea-ice volume, growth, type, temperature, snow load and structure, and momentum absorption from remote sensing is challenging. These properties are not measured directly and require models that are prone to errors. Further field process studies (see section “Specific Recommendations for the Coming Decade”) are needed in sea ice to constrain these uncertainties so as to improve the accuracy of fluxes that are reliant on satellite-derived information about sea ice characteristics.

TECHNOLOGICAL REQUIREMENTS FOR THE COMING DECADE

SO flux observations are almost exclusively collected by ships, with valuable time-series observations provided by two moored surface buoys (Figure 1). Expansion of these observing systems are necessary (see recommendation 1 below). Yet, ships suffer superstructure flow distortion effects on measurement accuracy (Yelland et al., 2002) and collect data for relatively short periods (days to weeks), while moorings provide point-location estimates and have significant maintenance costs. Detailed flow distortion calculations for research vessels operating in the SO would help improve the analysis of ship-based flux observations (e.g., Moat et al., 2006). Studies of the flow distortion around the towers of surface moorings shows minimal impact on wind velocity, although buoy position should be tracked to allow the wind observations relative to the buoy to be corrected to absolute wind velocity. More significant challenges involve coping with icing, surface waves and sea birds and so improvements to current surface buoy designs are recommended. These include phasing-in heating of key

sensors to prevent ice and frost build up, including anemometers and radiometers, adding cameras to document icing (being implemented on Irminger Sea Buoy) and actively ventilating air temperature and humidity sensor enclosures. In addition, incorporation of turbulent flux sensors (3-D sonic anemometers, fast response humidity, and temperature) and platform attitude and motion sensors can be done now to allow computation of the turbulent fluxes by the Direct Covariance Flux methods (Edson et al., 1998).

Recent advances in relatively cheap, small (2–7 m) and robust ASV with associated miniaturized sensors, improved battery capacity and energy harvesting, are demonstrating the capability to collect multi-month time-series of high-resolution air-sea flux and meteorology observations. The latest generation of ASV, such as Wave Gliders and Saildrone, have been deployed successfully in the SO (Monteiro et al., 2015; Schmidt et al., 2017; Thomson and Garton, 2017). Key technical issues for ASV flux measurements center on the low height of the atmospheric measurements and the effect of platform tilts on observations, such as incoming shortwave and longwave radiation. Bulk algorithms for estimating fluxes rely on the gradients beyond the ocean-atmosphere interface, which increase (and therefore are more reliably measured) with height. Very close to the surface, these measurements may have an insufficient signal-to-noise ratio. Further, measurements within the wave-affected portion of the atmospheric boundary layer may not be appropriate for comparison to the larger scale fluxes used in circulation models (e.g., Schmidt et al., 2017). These issues require careful calibration and validation over the full dynamic range of conditions.

The question now becomes how best to coordinate the distribution of these assets to ensure collection of high-quality data for end users, including agreement on data standards and management. To date, ASV deployments have been short-term project-based missions. A sustained and coordinated effort to deploy multiple ASVs (and Lagrangian platforms – SWIFT/drifting buoys) in the SO, potentially centered around key mooring sites, will require international resources and effort (see Newman et al., 2019). This type of system will address the data gaps between sparse vessel-based observations and achieve year-round presence in harsh/remote regions. In order to achieve this vision, recommended enhancements include; extending deployment duration (harness alternate forms of energy from current or wind; improved battery capability), autonomous piloting techniques (on-board route decision making), ocean/atmosphere feature tracking and automated coordination between platforms, and upper ocean profiling (e.g., automated hydrographic casts). Additionally, year-round flux observations in the seasonal ice-covered regions of the SO are required. Given that current ASV technology is limited to the ice-free ocean, new technologies need to be developed for the unique characteristics of Antarctic sea ice, which largely melts and reforms on an annual basis thereby not allowing for multi-season installations of platforms that are proven capabilities in the Arctic (e.g., Ice Tethered Profilers, Arctic Ocean Flux Buoys, and meteorological stations). One approach could be surface floating platforms that are able to withstand being frozen into the ice pack and then continue to operate once the sea ice melts and

releases the platform into the ocean until the next freezing period (e.g., UpTempO buoys).

Unmanned aerial vehicles (UAV) are a new platform supplementing flux sensing capabilities from existing platforms, with duration of fixed-wing missions of up to 24 h. UAVs, like satellites and aircraft, can provide a synoptic view of a relatively large area, while providing unprecedented ground resolutions (as fine as 1 cm) due to their slower speed, making for an exciting approach for process studies in particular. Significant progress has been made in developing cutting-edge UAV payloads for air-sea turbulent fluxes, radiative fluxes, surface albedo, SST variability, ocean surface waves, and ocean biogeochemistry (e.g., Reineman et al., 2016). Applications for UAVs in air-sea interaction have been demonstrated in polar seas, such as from polynyas (Cassano et al., 2010) and the MIZ.

SPECIFIC RECOMMENDATIONS FOR THE COMING DECADE

Targeted Field Observations

Enhanced flux observations are required almost everywhere (Figure 1), however, we particularly require them in (i) varying conditions (e.g., transient events/storms, different types of sea-ice, and sea state); (ii) regions with higher uncertainty and variability in reanalyses (marked on Figure 2, see section “Status of Flux Reanalyses and Requirements to Reduce Uncertainty”), which are predominantly in the boundary regions of the SO (e.g., Agulhas Return Current, Malvinas Current region), regions prone to higher energetics/eddy kinetic energy (e.g., downstream of Campbell Plateau, Drake Passage), and in the seasonal ice zone, especially in the region of the winter maximum sea ice extent. Further, SOFLUX recommends efforts towards achieving year-round time-series (i.e., mooring sites supplemented with new technologies, such as ASVs that can provide a spatial length-scale component to the time-series observations). Seasonally, the autumn and winter are priority periods to obtain even the most basic flux-related observations. Given that almost no flux-related observations exist in the seasonal and permanent sea-ice covered regions (approximately the entire SO south of 60°S), the community should see this as one of the highest priorities with potentially the most important priority being areas prone to abrupt flux events driven by spurious gaps in the sea ice (from coastal and open ocean polynyas down to the scale of leads in the pack ice). The SOCCOM float array is starting to address this, especially in the seasonal ice zone, but higher “carbon capable” (pH) float density is needed (further guidelines for density in Mazloff et al., 2018). OSSEs are valuable for optimizing the quantity and locations of time-series measurements, and flow distortion studies would enable better interpretation of vessel flux observations.

Dedicated Studies to Understand Air-Sea-Ice Flux Processes

Process studies are critical to improve flux and model parameterizations. Experiments from both poles would deliver

process information on fluxes under various conditions. Studies should leverage existing flux time-series provided by mooring sites to enhance understanding of annual and inter-annual flux variability. More specifically, observations able to resolve intra-seasonal processes and variability that impact fluxes are needed, such as those associated with oceanic eddies and fronts or the passage of atmospheric storms. This would provide insight into the temporal-spatial scales over which the atmosphere and ocean respond to changes imposed by the other. This justifies targeted process studies aimed at measuring flux differences over the scale of the first baroclinic Rossby radius (50 km or less) and over strong oceanic (temperature) gradients. Further detail can also be found in Newman et al. (2019).

Improve Satellite Flux Capabilities

Satellite retrievals of air-sea-ice fluxes pose a series of challenges, many of which are addressed by Bourassa et al. (2013). The challenges vary depending on the flux: (1) Momentum fluxes are well measured by scatterometers, but the global network of scatterometers does not provide the spatio-temporal coverage that is desired for tracking rapidly evolving and otherwise poorly sampled SO storms. The proposed SKIM (waves and currents) and WaCM (winds and currents) missions would be particularly valuable for assessing the direct transfer of momentum from atmosphere to wave and current fields. (2) Turbulent heat fluxes are typically inferred using bulk formulae from ship or buoy measurements. Satellites do not provide measurements of temperature and humidity in the planetary boundary layer that are necessary to apply bulk formulae, but they can measure properties of the ocean surface. Therefore, further work to develop reliable retrievals of turbulent heat fluxes would be valuable, particularly for the high wind, high sea spray conditions typical of the SO. The small Rossby radius in the SO means narrow frontal features (ACC fronts and eddies) have the potential to influence fluxes significantly, but are not necessarily well resolved in existing retrievals – high spatial resolution would be of value. (3) Freshwater fluxes depend on precipitation and evaporation. The Global Precipitation Mission estimates precipitation, but only in the latitude range from 65°S to 65°N (missing snow and rain within the Antarctic circle). Future satellite missions providing full coverage of the high latitudes would be valuable towards constraining air-sea-ice freshwater fluxes.

Accessibility of Data

Flux and meteorological data must be made more accessible, with uniformity of data processing and quality control. Polar-specific data discovery may be a way to address this (e.g., through SOOSmap). Likewise, the efforts of the Shipboard Automated Meteorological and Oceanographic System (SAMOS), which collects flux-related data from vessels and provides data collection standardization information and targets, needs to be supported/expanded (see Smith et al., 2015, 2019). Furthermore, increased field and vessels access to conduct flux measurements (e.g., available ship berth space or sensor installations) should be encouraged. The SOOS tool “DueSouth: Database of Upcoming Expeditions to the SO” provides support towards this end.

AUTHOR CONTRIBUTIONS

SS and SG conceptualized the manuscript with inputs from the SOFLUX working group and wrote the first draft of the manuscript. AT, BdS, JT, SJ, MM, and BW led the sections of the manuscript. SS, EK, MdP, and MM conceptualized and developed the figures. All authors contributed to the writing of the manuscript and read and approved its final version.

FUNDING

SS was funded by a Wallenberg Academy Fellowship (WAF 2015.0186). EK was funded by the NERC ORCHESTRA Project (NE/N018095/1). LP was funded by the Advanced Studies in Oceanography of Medium and High Latitudes (CAPES 23038.004304/2014-28) and the Research Productivity Program (CNPq 304009/2016-4). BdS was a research associate at the F.R.S-FNRS. PeH was supported by the Australian Antarctic Science Projects 4301 and 4390, and the Australian Government's Cooperative Research Centres Programme through the Antarctic Climate and Ecosystems Cooperative Research Centre and the International Space Science Institute Project 406. SG and

MM were funded by National Science Foundation awards OCE-1658001 and PLR-1425989. AT was supported by NASA (NNX15AG42G) and NSF (OCE-1756956).

ACKNOWLEDGMENTS

This manuscript is a contribution to the Southern Ocean Air-Sea Flux (SOFLUX) capability working group of the SCAR-SCOR Southern Ocean Observing System (SOOS). SOFLUX thanks the SCAR and SCOR for financial support in order to host meetings and support travel. The ICOADS data was acquired at the National Center for Atmospheric Research, Computational and Information Systems Laboratory, Boulder, CO, United States (available online at <https://doi.org/10.5065/D6ZS2TR3>). The three satellite-reanalysis products used include: (1) NCEP_Reanalysis 2 data provided by the NOAA/OAR/ESRL PSD, Boulder, CO, United States, available at www.esrl.noaa.gov/psd/; (2) ERA5 is generated using Copernicus Climate Change Service Information, available at www.ecmwf.int/en/forecasts/datasets/archive-datasets/reanalysis-datasets/era5; and (3) JRA-55: Japanese 55-year Reanalysis, available at: <https://doi.org/10.5065/D6HH6H41>.

The UN Decade of Ocean Science
for Sustainable Development.
Front. Mar. Sci. 6:470.
doi: 10.3389/fmars.2019.00470

Our civilization needs a clean, resilient, productive, safe, well-observed, documented and predicted ocean. “The ocean we need for the future we want” was the motto of the Intergovernmental Oceanographic Commission proposal to the United Nations to consider the merit of an Ocean Science Decade. By proclaiming the Decade, the UN General Assembly offered the oceanographic community a unique, once in a life-time, opportunity to change the way we do things, make oceanography fit for purpose of effectively supporting sustainable development, and energize the ocean sciences for future generations. The Decade is the chance to put in place a more complete and sustainable observing system and feed the resulting data into a science-based informed decision-making system allowing increased reliance of our civilization on the ocean, its ecosystem services and, at the same time, preserving ocean health. Strong and proactive engagement of the oceanographic community in the design of the Decade and its observing component and subsequent energetic implementation of the ideas are sought. Participants in OceanObs’19 are invited to consider the additional possibilities and requirements associated with the Decade in their contributions to and brainstorming at the Conference. It is essential to use collective wisdom of OceanObs’19 to help developing an ambitious and also realistic implementation plan for the Decade, with a strong observational component.

Keywords: ocean observing, science, observations, decade, sustainable development, societal, data management

INTRODUCTION

The Intergovernmental Oceanographic Commission (IOC) of UNESCO, a specialized organization of the United Nations system for ocean observations, data, services and related capacity development, proposed to the United Nations to proclaim in 2021–2030 an international Decade of Ocean Science for Sustainable Development. The idea of an ocean decade was directly linked to the 2030 Agenda adopted by the United Nations in 2015. The Decade can mobilize the ocean community behind the ideas of sustainable development and serve to focus the research and technological development in oceanography on existentially important issues of protection

and sustainable use of the ocean. This will be a decisive contribution by the ocean community to the implementation of the Sustainable Development Goals (SDGs) – not only the 14th (“Ocean”) SDG, but many others as well. Ocean observations are at the heart of this initiative.

The IOC proposal to the United Nations was successful and the UN Decade of Ocean Science for Sustainable Development was proclaimed by the United Nations General Assembly to start on 1 January, 2021. This decision potentially opens a new era in oceanography, implying a major change in the way the ocean community works and how it is organized and supported, and how it can contribute to the future of our civilization.

This article presents motivations for the Decade, gives background information and describes goals, anticipated societal outcomes, main areas of research and development, and the approach to use them in achieving societal outcomes. The IOC must present an Implementation Plan for the Decade to the UN General Assembly of 2020. This work is in progress. The plan will be a living document and will be adjusted in the future to accommodate new needs and undertakings, and, importantly, partners. Engagement of the ocean community, including ocean observation specialists, in designing the Decade and its subsequent implementation is strongly encouraged.

MOTIVATIONS FOR THE UN DECADE OF OCEAN SCIENCE FOR SUSTAINABLE DEVELOPMENT

The ocean, the largest ecosystem on our planet, provides our civilization with a range of existentially important services (Stocker, 2015; Visbeck, 2018). To continue benefitting from them, a globally shared information and knowledge system is needed that would inform, on one side, actions for the restoration and maintenance of the ocean’s health (Duarte et al., 2018), and on the other side, use of the ocean space and resources to achieve global sustainable development. At present, such a consolidated system is not in place. However, many elements that could be connected in a more synergistic way to build such a system either exist, are being designed, or being worked on. These seeds of growth reside in the ocean observing systems, research and development activities, advances in the domains of technology and oceanographic information services, scientific assessments, national and international legislation and policies, best practices, standards, capacities, and resources—including human and economic resources available to industries,—and the private sector.

There are numerous international agreements aimed at preserving the ocean, either in the form of treaties or frameworks, which have various degrees of being legally binding. The 2030 Agenda with its 17 Sustainable Development Goals (SDGs), including the SDG 14 on the Ocean and its 10 targets, was unanimously endorsed in 2015 by the UN General Assembly¹. The Paris Agreement of 2015 under the UN Framework

Convention on Climate Change refers to “the importance of ensuring the integrity of all ecosystems, including the oceans.”² The Sendai Framework for Disaster Risk Reduction of 2015 intends to address, *inter alia*, the risks to countries’ coastlines. The UN Convention on Biological Diversity of 1992, with its Protocols and Implementation Plan components³—such as Aichi Targets—refers to the need to manage marine and other aquatic ecosystems scientifically. The 1995 Code of Conduct for Responsible Fisheries⁴ and the Agreement on Port State Measures to Prevent, Deter and Eliminate Illegal, Unreported and Unregulated Fishing of 2009⁵ are key global instruments under the UN Food and Agricultural Organization to make fisheries sustainable. The Regional Seas Conventions of the UN Environment Programme and regional fisheries management organizations provide regional framework for conserving the ocean health and its living marine resources. The International Maritime Organization monitors the implementation of the UN Convention for Safety of Life at Sea (SOLAS Convention of 1974)⁶ and a series of international conventions against marine pollution. The UN Convention on the Law of the Sea (UNCLOS) of 1982 http://www.un.org/Depts/los/convention_agreements/texts/unclos/unclos_e.pdf provides overall regulatory framework for the conservation and sustainable use of ocean and its resources.

An United Nations Intergovernmental Conference is being held in the years 2019–2020 to agree an international legally binding instrument under UNCLOS on the conservation and sustainable use of marine biological diversity of areas beyond national jurisdiction. A number of important targets in relation to the sustainable use of the ocean are set in the Small Island Developing States (SIDS) Accelerated Modalities Of Action [S.A.M.O.A.] Pathway⁷, adopted at the Third International Conference on Small Island Developing States in Samoa in 2014. Since 1995, the Global Programme of Action for the Protection of the Marine Environment from Land-based Activities⁸ has been working to identify the sources of land-based pollution or harmful activities and prepare measures to reduce them. It is even more relevant now as we know about the huge amount of plastics transported to the ocean from the shore. Taken together, all of these and other frameworks provide building blocks for the potential ocean information and knowledge system aimed at supporting policies and actions for ocean health and sustainable use of the ocean.

At present, there is tremendous goodwill in the global community to protect the ocean. It strongly manifested itself at the first UN Conference to Support the Implementation of Sustainable Development Goal 14 that took place at UN

Headquarters in June of 2017 (the Ocean Conference⁹). More than 1,500 various commitments to that effect were received by the organizing committee of the Conference. Nine Communities of Ocean Action are following up on the implementation of those commitments. Another venue for seeking commitments is the series of Our Ocean annual conferences organized by national governments after the founding conference in 2014 called by the U.S. Ex-Secretary of State John Kerry. New networks and groups have been and will be created to conserve ocean health and promote sustainable means of using ocean resources. Engagement of the private sector holds a major promise in that respect and is stepping up.

The mobilization of the communities is the result of growing awareness and concern about the decline in ocean health. According to the First World Ocean Assessment conducted by UN¹⁰, due to the impact of multiple negative stressors, our civilization is running out of time to start managing the ocean sustainably. Symptoms of the decline in ocean health include warming of the ocean water at all depths, including submarine heat waves (Stocker, 2015), ocean acidification and its multiple consequences (Hoegh-Guldberg et al., 2014), reduced generation or depletion of oxygen, the massive scale of various types of ocean pollution including plastics and accidental pollution, dire consequences of the illegal, unreported and unregulated fishing and of fishing subsidies, ocean habitat destruction, harmful impacts of invasive species, and some other negative effects. The World Ocean Assessment lists some other impacts on the society: the sea-level rise, growing occurrences of more intense tropical (and, potentially extratropical) cyclones, harmful algal blooms, fish and human poisoning, inundation of the coasts by the Sargasso and some other factors. Migration of the population to the coast along with the continuing population growth exacerbate the risks to lives and property in the coastal zone, and earthquakes and tsunamis continue to represent a major threat.

According to the first Global Ocean Science Report, prepared by the IOC of UNESCO in 2017¹¹, the investment into ocean science is less than 4% of the global funding of natural sciences, with very large variations among countries. The current knowledge of the ocean, in terms of its physics and dynamics, might be close to sufficient for alerting the society and governments about many of the existing or emerging threats. However, there is a strong need for more specific knowledge and its systematic delivery and application to enable effective and efficient actions toward sustainability, at the global and regional levels. Mainstreaming oceanography and targeting it and ocean related components of natural and social sciences on practically assisting the sustainable development agenda were the main motivations for the IOC to develop the proposal to the UN to organize a Decade of Ocean Science for Sustainable Development (hereafter – the Decade¹²) in 2021–2030.

¹²<https://en.unesco.org/ocean-decade>

BACKGROUND AND MAIN GOALS OF THE DECADE

The proposal of the Decade came from a brainstorming meeting of the IOC Chair, Vice-Chairs and senior secretariat staff held in Gilleleje, Denmark in January 2016. Dr. Gunnar Kullenberg, a former IOC Executive Secretary, made significant contributions resulting in the meeting's success. During 2016 and first half of 2017, IOC Member States and many other interested parties were consulted on the concept and potential value of a Decade of Ocean Science. A proposal for the Decade was drafted for consideration by IOC Member States (IOC/INF-1341, 2 February, 2017) and a revised version of the proposal (IOC/INF-1341 REV) was presented to the twenty-ninth session of the IOC Assembly and subsequently endorsed through a Resolution (IOC Resolution XXIX-1, IOC-Unesco, 2017). In addition, recognizing the cross-cutting role of ocean science in SDG 14 of the 2030 Agenda, the Decade proposal was registered by the IOC as a voluntary commitment to the first UN Ocean Conference that took place in June of 2017 in New York⁹. In the middle of 2017, the IOC submitted the proposal for consideration of the 72nd Session of the UN General Assembly (UNGA).

It was proposed that the Decade start exactly fifty years after the International Decade of Ocean Exploration (IDOE) that took place in 1971–1980 (Holland and Pugh, 2010). IDOE was coordinated by the IOC and successfully stimulated oceanographic research and exploration, creating additional interest and support to the discipline. The IDOE was followed by several seminal developments in ocean management and sciences, including the preparation and signature of the UN Convention on the Law of the Sea (1982), the World Ocean Circulation Experiment (1990–2002) and several other major international undertakings in the domain of the ocean.

On 5 December 2017, the UNGA, within Part XI of the Omnibus Resolution for Oceans and the law of the sea (RES 72/73) relating to “Marine science,” decided (United Nations General Assembly, 2017, paragraph 292) to proclaim

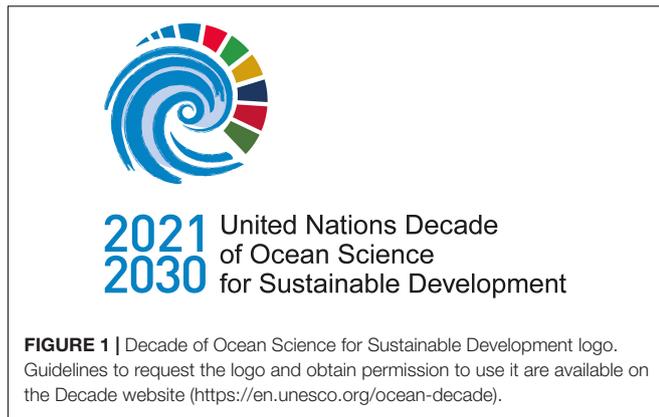

the United Nations Decade of Ocean Science for Sustainable Development for the 10-year period beginning on 1 January 2021, within existing structures and available resources.

The UNGA:

called upon the Intergovernmental Oceanographic Commission to prepare an implementation plan for the Decade in consultation with Member States, specialized agencies, funds, programmes and bodies of the United Nations, as well as other intergovernmental organizations, non-governmental organizations and relevant stakeholders.

Further, the UNGA:

- Requested that the Intergovernmental Oceanographic Commission provide information on the development of the implementation plan and regularly consult with, and report to, Member States on the United Nations Decade of Ocean Science and its implementation;
- Invited the Secretary-General to inform the General Assembly about the implementation of the United Nations Decade of

Ocean Science through his report on oceans and the law of the sea, on the basis of information to be provided by the Intergovernmental Oceanographic Commission;

- *Invited UN-Oceans and its participants to collaborate with the Intergovernmental Oceanographic Commission on the United Nations Decade of Ocean Science.*

The proclamation of the Decade by the UN General Assembly is an acknowledgment by UN Member States and their Governments of the importance, need for and role of ocean science, data and information exchange for sustainable development, and that science can play an important role in helping the ocean support the 2030 Agenda. The Decade requires response and delivery from the IOC and other UN bodies, the scientific community as a whole, working in close contact with governments, industry and business, as well as with the civil society.

The idea of the Decade is to achieve a major change in the knowledge and management of the ocean. It is reflected in the following two over-arching goals that provide the high-level motivation for the Decade:

Goal 1: To generate the scientific knowledge and underpinning infrastructure and partnerships needed for sustainable development of the ocean.

Goal 2: To provide ocean science, data and information to inform policies for a well-functioning ocean in support of all Sustainable Development Goals of the 2030 Agenda.

The design of the Decade should address both deep disciplinary understanding of ocean processes and solution-oriented research to generate the knowledge needed for reducing pressures on the ocean, preserving and restoring ocean ecosystems and safeguarding ocean-related prosperity for future generations. The Decade should turn the scientific knowledge and understanding into effective actions supporting improved ocean stewardship for sustainable development. The generation of societal outcomes of the Decade would trigger positive environmental and societal changes and would support peaceful cooperation of nations. The logo of the Decade (**Figure 1**) aims to demonstrate the role of ocean in all aspects of sustainable development.

SOCIETAL OUTCOMES

The Decade will aim to achieve considerable progress in a number of research and technology development areas with a view of generating the following six societal outcomes.

A clean ocean, whereby sources of pollution are identified, quantified and reduced and pollutants removed from the ocean in an efficient manner. Integrated research will assess the human and environmental shorter-term and long-term risks from ongoing and future types of ocean pollution and generate new ideas on how to reduce ocean pressures by recycling, improved waste management, and strengthening the governance regimes that encourage more sustainable production and consumption.

A healthy and resilient ocean, whereby marine ecosystems are mapped and protected, multiple impacts on them, including climate change, are quantified and, where possible, reduced and provision of ocean ecosystem services is maintained. The Decade will promote research aimed at elucidating impacts of cumulative stressors on the ocean, its seas, ecosystems and resources, hence providing required information to enable actions, which can reverse the ocean ecosystem degradation. Improved evaluation and appreciation of the economic and societal value of the ocean and its ecosystems will also be instrumental to stimulate marine spatial planning, marine protected areas, coastal zone management and other ecosystem-based management approaches.

A predicted ocean, whereby society has the capacity to understand current and predict future ocean conditions and their impact on human well-being and livelihoods. Under the Decade, sustained and systematic ocean observations would be expanded to all ocean basins and depths to document ocean change, initialize coupled models and facilitate improved ocean understanding. Knowledge of present and future conditions is a pre-requisite to the development of sustainable ocean economic policies and ecosystem-based management. More detailed and complete accounts of ocean processes can help to improve climate prediction in a significant way. The Decade will also build on advances in ocean robotics and the combination of remote and *in situ* ocean observations, which offer new opportunities and reduce operational costs; it will also promote multi-stakeholder contributions by governments, the private sector and citizens.

A safe ocean, whereby human communities are much better protected from ocean hazards and where the safety of operations at sea and on the coast is ensured. The Decade will promote research aimed at minimizing impacts of various changes and risk reduction through adaptation and mitigation. It will also support the development of integrated multi-hazard warning systems (MHWSs) in all basins, hence, contributing to enhanced preparedness and awareness of society with regard to ocean risks. Community resilience and adaptive capacity, with elevated education and awareness concerning the use of observations and data, will also contribute to reduced impacts and improved efficiency of early warning systems for natural and man-made hazards. This area of research will be of great interest for the insurance and reinsurance industries.

A sustainably harvested and productive ocean, ensuring the provision of food supply and alternative livelihoods. The Decade

should create a better understanding of the interactions and interdependencies of the ocean ecosystem and environmental conditions and processes, the use of resources and the economy. A major task in context of the development of the ocean economy will be in documenting the potential impacts from environmental changes on the established and emerging maritime industries and their ability to generate growth, especially for least developed countries and SIDS. Defining safe and sustainable thresholds for economic operations in the ocean will help policy-makers and stakeholders in implementing a truly sustainable blue economy (see for example, Smith-Godfrey, 2016; Visbeck, 2018). New research should develop and flesh out sustainable blue-green growth agendas and link it to efforts in ecosystem protection.

A “transparent and accessible” ocean, whereby all nations, stakeholders and citizens have access to ocean data and information technologies and the capacities to inform their decisions. The enormous need for more ocean information in the scientific, governmental, private and public sectors demands a step change in ocean education at all levels. New technologies and the digital revolution are transforming the ocean sciences; these will be harnessed to deliver data and information to all stakeholders. Science-policy interface for the ocean should be enhanced as well. Open access to ocean information, increased interactions between the academic and societal actor communities, and ocean literacy for all should capacitate all citizens and stakeholders to have a more responsible and informed behavior toward the ocean and its resources. Innovative capacity development schemes between south–south and north–south ocean actors as well as courses for ocean professionals will be key in raising ocean awareness and promoting better solutions.

The six societal outcomes of the Decade are holistic. In order to be achieved, most of them require actions by the society, governments, or by key stakeholders. However, there is no causal link to achieving them that would be entirely scientific. Nevertheless, progress in several thematic areas of ocean science is either necessary or very useful to achieve them. Scientific papers should not be the sole measure of success of the Decade. Impact to society, appropriately measured against clear objectives, should also be a measure of success. Such *initial* priority areas of research and technology development (R&D) are outlined below. There is no priority order among them. They are interconnected but allow focused design and planning. Progress in these areas is necessary to facilitate protection and the sustainable use of the ocean, on global and more localized scale.

R&D Priority Area 1: Comprehensive Map (Georeferenced Digital Atlas) of the Ocean

This R&D Area includes and goes beyond the domain of mapping the ocean bottom topography, and its importance can be illustrated by the deficiency of current global ocean depth maps. Current, largely satellite-based mapping of the global ocean renders a horizontal resolution between 2 and 5 km. At this resolution, many features are not detectable and result in only a coarse understanding of the ocean bottom. Technologies such as multibeam echo-sounders can deliver much higher

resolution, either as hull mounted on surface ships or on undersea vehicles that can be positioned closer to the seabed. At present the multibeam echo-sounder coverage of the world ocean is scarcely over 5%, leaving much work to be done and only a sketch of the true detail that exists under the ocean. The current map of the ocean does not represent therefore many important underwater features. If a parallel to the land surface is evoked, the equivalent resolution of terrestrial maps would level out almost all prominent topographic features. With the current level of knowledge, the recent searchers for missing aircraft simply did not know the true initial depth of water they were supposed to operate in.

Current efforts under the International Hydrographic Organization (IHO) and the IOC, particularly the IHO/IOC Project “General Bathymetric Chart of the Ocean” (GEBCO¹³) and its flagship Project Seabed 2030, sponsored by the Nippon Foundation, address the formidable task of mapping the ocean depth for most of the global ocean.

The task of mapping the ocean depth is being currently addressed through coordinated assembly of depth measurements made using various platforms, such as satellites, ship and autonomous underwater vehicle (gliders) echo sounding. It may be promising to review other sources of data, e.g., seismic information that is available from various seismic networks to enrich the volume of data, particularly for poorly covered regions. The feasibility of using new data and approaches needs to be studied.

A comprehensive map of the ocean should include much more information than just ocean depth. It requires other variables describing the physical, biological, chemical, and geological environments, ecosystems, cultural objects, boundaries, resources, etc. The shipping and transport community, weather and ocean forecasters, fishing industries and authorities, marine resource managers, and coastal cities and communities vulnerable to sea level rise, tsunami, and tropical cyclones are all dependent upon accurate ocean maps. Maritime spatial planning is a way of optimally putting many interdependent maritime activities on a single map. Establishment of marine protected areas is also based on mapping. Similar requirements exist in the coastal zone management. A common digital atlas of ocean information is necessary in order to address the prevailing and future societal pressures on the ocean. Advanced prototypes of such an atlas already exist in many regions of the world, sometimes encompassing high resolution maps.

Designing a digital georeferenced atlas of the ocean that would satisfy many of the future uses of the ocean and its protection is therefore a necessary and innovative scientific undertaking that requires consolidation of existing knowledge, review of requirements, new R&D, and comprehensive assemblage on regional and local scales.

R&D Priority Area 2: A Comprehensive Ocean Observing System

One cannot manage what one cannot measure. Ocean observations are the key to understanding weather, climate

¹³<https://www.gebco.net>

and the future state of marine ecosystems and resources. The Global Ocean Observing System (GOOS¹⁴) domain of competence is physical state variables in the upper 2 km of the water column and at the surface. It is expanding to include additional measurements in the deeper ocean and in the domains of biogeochemistry, biology, and ecosystems. The approach based on Essential Ocean Variables (Lindstrom et al., 2012) is effective and new variables should be taken on board, making the scope of observations capable to help monitoring and management of large marine ecosystems (LMEs) and coastal and offshore areas.

Global Ocean Observing System is a shared undertaking. All nations, even landlocked, benefit from the associated data products and services. United Nations Member States need to engage further to construct and sustain a global ocean observing system that covers all the world's major ocean basins and also addresses coastal and local interests. This system should be routinely maintained, with observations collected to a uniform and common standard of foundational or basic data, with information gathered made openly available to all and should be readily adaptive to both emerging circumstances and priorities as well as to local or regional needs, in addition to basic parameters. All the societal outcomes listed above would benefit from additional observations and parameters, and in particular, in the southern ocean and the Arctic that are currently under-observed. Efforts should also focus on expanding observations to the deep ocean in all ocean basins to characterize its physical state, biogeochemistry and ecosystems, and detect changes.

The Decade should produce a regime of international cooperation that fully monitors the major ocean basins of the world, at all depths, blending inputs into the GOOS, and maintained by the nations of the basin region, among others. It should synergistically use *in situ* and remotely sensed observations and strongly benefit from emerging observing technologies. The Decade should create conditions for involvement of downstream beneficiaries, such as the private sector, of the ocean observations (for example, as has been done for the tropical Pacific; Smith et al., 2019). Their input would provide very useful feedback on the quality and quantity of the observations information provided, and their interest in obtaining the data should create a “pull” and a better resource base for expanding and sustaining the ocean observations. It should be noted that such beneficiaries often operate on local scales and require information of high resolution.

R&D Priority Area 3: A Quantitative Understanding of Ocean Ecosystems and Their Functioning as the Basis for Their Management and Adaptation

The Census of Marine Life produced an inventory of species in the ocean, enhancing the scientific knowledge on what lived, lives, and will live in the ocean. This work is successfully continuing under the IOC Ocean Biogeographic Information System

(OBIS). The biological component of GOOS is approaching the pilot phase. Emerging technologies are becoming more mature and available, such as Environmental DNA sampling (eDNA; Ausubel et al., 2019). These new approaches will enrich more mature molecular methods and, combined, create a capacity for imaging life in the ocean in near real time. From viruses and plasmids to whales, and their interaction with each other, the new state of molecular and genetic science will reveal much of what has not been able to be measured or understood in the past. This knowledge will be instrumental to better understand the ecosystem services, including, for example, nitrogen fixation, primary production, nutrient cycling, and surface colonization (with thanks to the manuscript reviewer).

Increasingly, tools are available to replace the laboratory bound analysis with deployable laboratories that produce the resulting information, rather than simply collect the sample. A combination of methods exists to produce an ongoing measurement of micro- to the macro- and mega-sized components of the marine ecosystem inventory and assess its health. The new technologies will be able to help the researchers to better understand the functioning of deep-sea ecosystems, measure the cumulative impacts of ocean stressors and define the carrying capacity of ocean ecosystem to sustain human impacts and economic development. For the first time in history, this opens a possibility to meaningfully predict the evolution of ocean ecosystems, using biogeochemical and ecosystem models that are forced by modern climate prediction or projection models and are verified against a bulk of standardized *in situ* eDNA and other observations.

Availability of environmental predictions also offers potential to guide the adaptation to the new climatic and environmental conditions of certain valuable ecosystems (not only individual species), e.g., some coral reef ecosystems. The approach may consist of selective breeding of ecosystem components in a controlled basin of water with environmental conditions corresponding to the predicted regime of temperature (including estimates of its future variability and emergence of heat waves), salinity, water pH, oxygen, turbidity and, potentially, some other stressors. World aquariums possess significant potential to conduct such experiments.

Ecosystem monitoring with quantitative criteria of ecosystem health, enhancing knowledge of management solutions and availability of best practices and emerging predictive capacities hold promise to create a foundation for the science-based management of LMEs, with engagement of all key stakeholders, such as environmentalists and fisheries.

R&D Priority Area 4: Data and Information System

The IOC International Ocean Data and Information Exchange Programme (IODE¹⁵) focuses on the discovery, exchange of, and access to marine data and information including metadata, products and information. It sets international standards in that domain. The system, composed of an approximately 100 Data

¹⁴<http://www.goosocean.org>

¹⁵<https://www.iode.org>

Centers and associated data units, is capable of providing for long-term archival, preservation and documentation of marine data and information products, and facilitate related capacity development and the use of best practices.

Under the Decade, the oceanographic information system needs to be significantly expanded, upgraded and truly opened to the whole world to ensure flow of data and products between providers and users at different levels. The core of the future oceanographic data and information system is currently seen as a portal of ocean data that acts as a link between demand and supply and has a capacity to facilitate matching requirements for data and products. This engine is expensive to design and build, but it can be gradually created based on existing elements and advances in data processing and cataloging of data and product sources. Big data and cloud data processing and computing approaches offer additional perspectives to implement the portal. The initial steps toward creating the portal will likely consist of upgrading the current ocean data and information system while seeking resources and involvement of partners from IT industry and private sector to develop the future system in orderly manner, respecting the requirements of interoperability, the standards with acknowledgment of data originators. A Decade data policy will need to be developed and proposed. Compliance with the IOC data policy of free, unrestricted and open access to data should be considerably strengthened in the course of the Decade. A major international project on ocean data and information system development may be required, and, potentially, a global conference of the scale of OceanObs'19 to bring together known and new partners in the ocean data discipline, going beyond classical oceanographic data and starting to work with economic and social data.

R&D Priority Area 5: Ocean Dimension in an Integrated Multi-Hazard Warning System

Currently, there are a number of unconnected warning systems for ocean-related hazards. Some of them are operational, e.g., for tsunami generated by earthquakes, some are incomplete, e.g., for storm surges, and some emerging, e.g., for harmful algal blooms. Widely recognized and reflected in the Sendai Framework for Disaster Risk Reduction is the need to strengthen and harmonize the warning systems. An effective warning system has to be based on the knowledge of risks and corresponding emergency planning and warnings. The potentially affected communities need to be prepared to act appropriately on a warning. The hazard has to be detected, followed, and/or forecast. The warning then needs to be generated and timely, fully, and correctly transmitted, received, and acted upon.

This combination of actions and responsibilities necessarily involves more than one responsible agency. Experience shows a strong advantage of developing MHWSs able to act on more than one type of risk. During the Decade, a concerted effort should be made to incorporate ocean components into emerging or existing MHWSs and, as well, to more effectively use the ocean information for warnings of ocean-related hazards

at a variety of time scales, from immediate threats, such as tropical storms, to long-term, high-impact events like droughts, heat waves, forest fires, floods, etc. Until now, humankind has largely reacted too late to such hazards. There is significant progress in saving lives, but economic and infrastructural losses from natural disasters remain overwhelming and often strongly affect the capacity of a country or a region to recover after a natural hazard event.

The ocean-related warning systems, especially the one for tsunami, still require major methodological development, e.g., to embrace other sources of tsunami such as submarine landslides and volcanoes. Most importantly, the system needs to strengthen and upscale the preparedness of communities at risk. This quality of the system needs to be addressed during the Decade through involvement of appropriate governmental authorities and international mechanisms. The problem of “last mile” needs to be addressed so that the warning reaches the local community, which is prepared to act correctly, and community does so.

R&D Priority Area 6: The Ocean in an Earth-System Observation, Research, and Prediction

Ocean science is a part of the Earth system science. GOOS is a contributor to the Global Climate Observing System and, more widely, a part of the planet observing system of systems. To study and predict the future state of the ocean, one needs to incorporate it into various types of Earth system models. Industries, behavioral and societal changes, and economy all need to be eventually included in the observations and predictive modeling scope. As the time range of the prediction lengthens, more complexity is usually required to exploit the predictability of the interacting components of the Earth system. The longer the prediction range, the higher generally is the role of ocean processes in the prediction.

In addition, there exists an untapped potential in oceanographic observation and modeling that can help to improve a number of important services to humanity. This area of societal benefit includes many types and ranges of weather predictions, climate information services, various thematic assessments, and ocean space and resources management. Activities in the coastal zones and operations at sea are becoming more and more interdependent and need to be regulated accordingly. Activities require real-time decision making and anticipatory planning. Ocean modeling and prediction capacity that could meet such emerging requirements does not currently exist. Therefore, the Decade might engage at present unconnected modeling groups and industries into a design of a future multi-scale ocean observation and prediction system. Development of ethical principles of human interactions with the ocean, and short- and long-term economic analyses of ocean sustainability and the role of ocean science in it are urgently required. Quantitative assessments of tangible benefits and appreciation of intangible assets related to the ocean are needed for decisions to act on urgent issues including land-based sources of pollution, unsustainable ways of fishing and aquaculture and for ensuring protection of underwater cultural heritage.

R&D Priority Area 7: Capacity Building and Accelerated Technology Transfer, Training and Education, Ocean Literacy

All above R&D areas will move the cutting-edge of ocean science forward. They will augment the ocean science capacity and make it fit for the purpose of informing and even guiding sustainable development. The enabling elements for the progress are human potential, infrastructure, cooperation, resources and adequate social conditions of successful research and development. The IOC has started and will keep assessing the capacity of ocean science through the Global Ocean Science Report process. At present, the oceanographic capacities are highly uneven in the world, not only in terms of ability to contribute to the research but also in terms of ability to benefit from the scientific knowledge and technology, which is defined as also including ocean data and information. Based on ethical considerations and on the principle of common but differentiated responsibilities, all countries and communities should be able to benefit from the ocean life-supporting services, which requires capacity to act in a scientifically sound way. The Decade should strengthen the existing capacity development, training and education work and set in motion the transfer of marine technology (TMT) mechanisms. Infrastructure, training and teaching materials exist in many organizations. Their potential will be better sustained and potentially multiplied once the TMT Clearing House is put in place, linking supply and demand in capacity development, training and education.

One outcome of the Decade should be a major step forward in ocean literacy for various categories of people. The motivation for the Decade itself comes from the realization of the role of ocean for people and planet and from the understanding that the ocean is largely underexplored. A vigorous ocean literacy program of activities has to be designed. The major target audiences have to be students, which requires including ocean literacy in the school curriculum, decision makers—including governmental authorities—and the public at large (Santoro et al., 2017).

STRATEGIC APPROACH OF THE DECADE: TWO-WAY INTERACTION BETWEEN RESEARCH AND PRACTICAL APPLICATIONS

It is anticipated that progress in R&D will create new, more beneficial conditions for practical applications of new knowledge and technology. It is essential that ambitions of the private sector, governments and involved managers grow along with the progress in research. For that, active, intensive, and efficient communication of advances on ocean sciences will be a key enabling factor. The seven R&D priority areas listed above (or additional) will trigger accelerated development of the following means of using and protecting the ocean.

Protecting the ocean should employ the ecosystem-based approach, supported by observations and knowledge, with adequate regulation, and efficient and implemented policies including knowledge based establishment of marine protected areas in key locations.

The anticipation for the culmination year of the Sustainable Development Agenda, i.e., 2030, would be to have approximately 30% of the total area of the world Exclusive Economic Zones covered by scientifically-managed and governmentally approved maritime spatial plans¹⁶. This will bring multiple advantages for ocean “blue” economy and will facilitate management of ocean ecosystems and preserve ocean health. Similar progress is expected in the coastal zone management. It is essential that new MSP and coastal zone management approaches take into account not only the current state of the ocean and activities in it but are forward-looking, taking into account scenarios of future activities and appropriate environmental predictions.

Management of fisheries and aquaculture under the conditions of growing population, changing climate and the need to abate marine pollution, needs to fully capitalize on the multitude of ocean observations and on predictions of climate and ocean health and productivity. Observations and science can help increase transparency in managing the living marine resources and compliance with existing regulations, as well as stimulate countries to adopt progressive policies in the domain of fisheries and aquaculture.

Based on the analysis in the Intergovernmental Panel on Climate Change Special Report on the Ocean and Cryosphere in Changing Climate and gaps of knowledge and capacity to be identified in it, systematic work on adaptation solutions and search for climate change mitigation actions will be intensified.

WAY FORWARD, COMMUNITY AND UN ENGAGEMENT, RESOURCES

The Intergovernmental Oceanographic Commission was mandated by the United Nations General Assembly (UNGA) to lead the preparations of the Decade and develop its Implementation Plan in consultation with Member States, UN partners as well as other relevant stakeholders. The Implementation Plan must be submitted to the UN General Assembly in the second half of 2020. In the first part of 2018, a roadmap (IOC-Unesco, 2018b) was developed as an evolving document to guide the preparatory phase of the Decade by defining preliminary objectives, societal outcomes, governance and engagement processes.

In 2018, the 51st session of the IOC Executive Council welcomed the roadmap and decided to establish an Executive Planning Group (EPG) consisting of high-level experts to advise IOC governing bodies. The IOC convened the 1st meeting of the EPG from 17 to 19 December 2018 to brainstorm on scientific, governance, communications and engagement elements of the Decade. Beyond the scientific process itself, wide consensus was achieved within the EPG that the Decade must transform the way nations around the world invest in ocean science, both from the public and private sectors and how decision-makers use the available scientific knowledge to inform policies for ocean management. Experts also sought to lay out the basis for an effective strategy to communicate the objectives of the

¹⁶<https://en.unesco.org/mspglobal>

Decade, engage stakeholders, and ultimately influence behaviors and perceptions of scientists, decision-makers and the public around the value of ocean science for sustainable development. They stressed that capacity development and the TMT should be a key crosscutting priority, embedded deeply into the Decade planning process.

Executive Planning Group also agreed that early involvement of stakeholders in the planning phase would be key to achieving the objectives in an efficient manner and to secure broad and consistent implementation of the Decade. Stakeholders will be invited to contribute to the co-design of the Decade Implementation Plan through a consultation process that will be organized around Global Planning Meetings and a series of regional workshops foreseen in 2019 and early 2020 that will channel stakeholders' inputs into the preparatory process. Further to these consultative meetings, a Stakeholder Forum will be established and open to a broad range of communities (science, technology, ocean management, private sector, civil society) that are interested in contributing to the Decade.

UN partners with a focus on ocean are also associated to this consultation process. UN bodies were invited to contribute to the development of the Implementation Plan during a UN-Oceans' meeting (the UN inter-agency mechanism on ocean affairs) at UNESCO Headquarters in March of 2018. A dedicated task group was established at the UN-Oceans meeting held at the World Meteorological Organization in February 2019 to structure and reinforce its members' contributions to the Decade. The collaboration of the different UN bodies will also be encouraged through the development of both new and renewed partnerships with the IOC. It is essential to ensure that the UN agencies exercise leadership on aspects of the Decade that are relevant for their mandate. Communication and outreach efforts have intensified to present the objectives of the Decade and engage all these stakeholders.

The UNGA tasked the IOC with preparing the Decade Implementation Plan "within existing structures and available resources." Following the IOC Executive Council Decision, at its 51st session (IOC-UNESCO, 2018a), urging Member States to provide voluntary contributions for the preparation of the Decade, the IOC issued a Call for expression of interest in June of 2018. UN agencies and partners' organizations expressed strong support for the Decade and several Member States offered to host regional, global or thematic workshops scheduled during the Preparatory Phase of the Decade. More tangible support is still needed for the communication and outreach activities that will be developed for these consultative and planning meetings. Additional resources will be sought through alternative funding mechanisms such as public/private partnerships, as well as contributions of the philanthropic sector.

CONCLUSION: DECADE AND OCEANOBS'19 COMMUNITY

The Decade is a major chance for oceanography to put in place a more complete and sustainable observing system and feed the resulting data into a science-based ocean management system satisfying the increasing reliance of our civilization on the ocean, its ecosystem services, and, at the same time, preserving ocean health. The OceanObs conferences are also decadal but periodic events intended to give momentum and direction to developing ocean observing systems. The Decade responds well to the main goal of this OceanObs'19, which is to establish the value chain from ocean observations through research to long-term societal benefits and key stakeholders. It is hoped therefore that the OceanObs'19 community will see the Decade as a key opportunity to propose ideas for making ocean observations even more societally relevant and, hence, better supported, and will actively participate and strongly contribute to preparatory phase of UN Decade. In summer 2020 IOC will need to submit the Implementation Plan to the 75th UN General Assembly of United Nations. The opportunities to contribute are multiple. The proceedings of OceanObs'19 will be carefully studied in crafting the Plan. Regional and global meetings will be organized to further develop ideas and digest them into the plan. The Decade stakeholder forum is a platform to collect ideas. The link to it is at <https://en.unesco.org/ocean-decade/get-involved>.

AUTHOR CONTRIBUTIONS

VR wrote the first draft of the manuscript taking into account various documents, to which JB, GK, NS, and some other authors made an input. PP and JR wrote some individual sections of the manuscript. All authors contributed to the manuscript revision, and read and approved the submitted version of the manuscript.

FUNDING

Preparation of this manuscript was supported by IOC/UNESCO.

ACKNOWLEDGMENTS

We thank many people who contributed to preparation of the proposal to proclaim 2021–2030 an international Decade of Ocean Science for Sustainable Development and those who continue to work on the planning and support of it that is currently underway.

(2019) Observing Requirements
for Long-Term Climate Records
at the Ocean Surface.
Front. Mar. Sci. 6:441.
doi: 10.3389/fmars.2019.00441

Observations of conditions at the ocean surface have been made for centuries, contributing to some of the longest instrumental records of climate change. Most prominent is the climate data record (CDR) of sea surface temperature (SST), which is itself essential to the majority of activities in climate science and climate service provision. A much wider range of surface marine observations is available however, providing a rich source of data on past climate. We present a general error model describing the characteristics of observations used for the construction of climate records, illustrating the importance of multi-variate records with rich metadata for reducing uncertainty in CDRs. We describe the data and metadata requirements for the construction of stable, multi-century marine CDRs for variables important for describing the changing climate: SST, mean sea level pressure, air temperature, humidity, winds, clouds, and waves. Available sources of surface marine data are reviewed in the context of the error model. We outline the need for a range of complementary observations, including very high quality observations at a limited number of locations and also observations that sample more broadly but with greater uncertainty. We describe how high-resolution modern records, particularly those of high-quality, can help to improve the quality of observations throughout the historical record. We recommend the extension of internationally-coordinated data management and curation to observation types that do not have a primary focus of the construction of climate records. Also recommended is reprocessing the existing surface marine climate archive to improve and quantify data and metadata quality and homogeneity. We also recommend the expansion of observations from research vessels and high quality moorings, routine observations from ships and from data and metadata rescue. Other priorities include: field evaluation of sensors; resources for the process of establishing user requirements and determining whether requirements are being met; and research to estimate uncertainty, quantify

biases and to improve methods of construction of CDRs. The requirements developed in this paper encompass specific actions involving a variety of stakeholders, including funding agencies, scientists, data managers, observing network operators, satellite agencies, and international co-ordination bodies.

Keywords: marine, climate, measurement, uncertainty, ocean, atmosphere, ship, buoy

INTRODUCTION

Observations of environmental conditions near the ocean surface have been made from ships for centuries, and more recently from a wider range of observing platforms, including satellites. This paper will introduce the different types of measurements that have been made and describe the methods used to assemble the observations to generate records that can be used to characterize the changing conditions over the oceans. The most well-known long term marine climate record is that of sea surface temperature (SST), but there are also observations of air temperature, pressure, humidity, wind, clouds, waves, and weather conditions that have been used to generate climate records.

Most *in situ* surface marine climate records are based on the International Comprehensive Ocean-Atmosphere Data Set (ICOADS, Freeman et al., 2019), presently on Release 3.0 (Freeman et al., 2017). ICOADS is the most complete archive of its kind presently available and forms the basis for our discussion.

The requirements for data and metadata to construct long term climate records are hard to summarize in a simple form. Requirements for climate monitoring are collated by the Global Climate Observing System (GCOS) as part of the Observing Systems Capability Analysis and Review Tool (OSCAR) requirements database. The World Meteorological Organization (WMO) operate a “Rolling Review of Requirements (RRR)” in which user requirements for observations are compared with the capabilities of present and planned observing systems. For climate monitoring the outcomes of this review are published as reports on observing system status (GCOS, 2015) and requirements (GCOS, 2016). OSCAR considers a range of different application areas, other areas related to climate include climate science, applications and services, but climate monitoring is the most relevant to the construction of long-term climate records. The OSCAR/RRR process presents requirements for each variable as a desired accuracy at a chosen space and time resolution, plus a temporal stability. This is well-suited to measurements derived from satellites, but problematic for marine *in situ* measurements from mobile platforms (Berry and Kent, 2017). This paper therefore discusses the wide range of considerations underlying the development of accurate and stable long-term records in the context of an error model. Examples of the types of information that feed into the error model and therefore have an impact on the observing requirements are the availability of metadata describing measurement methods and protocols, and requirements for ancillary observations, for example for bias estimation or height adjustment. There are a range of other organizations concerned with the development of user requirements for surface marine data, for example the Copernicus Climate Change Service, the European Space Agency

Climate Change Initiative, and groups focused on particular variables such as SST (the Group for High Resolution SST) and winds (the International Ocean Vector Winds Science Team). Where relevant to climate monitoring and the development of long-term climate records requirements from such groups feed into the WMO RRR.

The GCOS defines three different types of observation networks: reference, baseline, and global (GCOS, 2016). These give a hierarchy of high quality traceable measurements at limited locations (reference network), through good quality measurements made more widely (baseline), to less accurate but widespread measurements to capture the important scales of variability (global). Such a suite of measurements can be combined to give the quality and coverage to provide stable, long term, climate records. The task is to assess the accuracy and sampling required for the different networks and how well the available historical observations map onto the requirements. Only then will it be possible to specify requirements for the continuation of long term records with the future observing system, and for prioritization of data and metadata recovery to improve the historical record.

Scope and Terminology

Here we consider the construction of climate data records (CDRs) of physical parameters observed near the ocean surface. These include the GCOS Essential Climate Variables (ECVs, Bojinski et al., 2014; GCOS, 2016) and Global Ocean Observing System (GCOS, 2018) Essential Ocean Variables (EOVs). Hereafter, we will refer to this combination of ECVs and EOVs simply as ECVs. Specifically we consider SST, marine air temperature (MAT), humidity, wind speed and direction, atmospheric sea level pressure (SLP) and also sea state and cloud parameters. Our criterion in this paper for considering a CDR to be long is greater than about 50 years, longer than the recent period with extensive satellite observations, and ideally centennial or longer.

This scope presently excludes the consideration of records derived from satellite data only as these have a maximum record length of about 40 years and are the subject of other papers in this issue (e.g., Arduin et al., 2019; Bourassa et al., 2019; O’Carroll et al., 2019). We note that many of the themes contained in this paper are relevant to both *in situ* and satellite data. It is critically important that high-quality satellite ECV records are maintained, evaluated and characterized with uncertainty estimates to create stand-alone CDRs, to enable the construction of long records jointly with *in situ* observations, to provide estimates of ECV variability and also data for evaluation. The Committee for Earth Observation Satellites (CEOS) and the

Coordination Group for Meteorological Satellite (CGMS) Joint Working Group on Climate provide coordination for activities related to the construction of CDR from satellites.

It is helpful to define some terminology for this paper.

Long term: about 50 years or ideally longer.

Large-scale: ranges from several degrees latitude/longitude to global scale.

Data: a collection of individual observations or measurements including information on date, time, and location.

Platform: any type of structure from which observations are made. Platforms providing records longer than 50 years include various types of ship, and fixed platforms such as rigs or coastal stations. Platforms providing shorter records include moored and drifting buoys, satellites, autonomous profilers, and surface vehicles.

Metadata: information describing characteristics of the platform, instrument, environmental conditions, observing protocols or data management that are helpful for interpreting the observations and estimating their uncertainty.

Climate data record: a time series of measurements of sufficient length, consistency, and continuity to determine climate variability and change and ideally accompanied by estimates of uncertainty and its correlation structure.

Gridded analysis: a timeseries of fields on a regular spatial grid, sometimes in-filled, typically at monthly or daily resolution, constructed from CDRs and ideally accompanied by estimates of uncertainty in the gridded values and the correlation structure of the uncertainty.

Data product: usually a gridded analysis, CDR or collection of data enhanced with derived variables or metadata.

Introduction to the Generation of Climate Data Records (CDRs) and Data Products

Figure 1 shows in schematic form the process involved in constructing a long-term dataset. In summary this consists of the following steps:

- Step 1 – understand what is required by different end users, prioritize
- Step 2 – gather together available data and metadata, or digitize new data
- Step 3 – determine the structure of the error model for each observation type and source and estimate contributing uncertainties and their dependencies
- Step 4 – clean up and bias adjust observations, propagating uncertainties and assessing uncertainty in the adjustments
- Step 5 – compare measurements from different components of the observing system in the context of their estimated uncertainties and user requirements, revisit steps 2–5 (and possibly 1) if needed
- Step 6 – produce data products tailored for particular applications
- Step 7 – evaluate products by comparison with withheld observations or independent reference data if available, and with other similar data products if available
- Step 8 – disseminate products with appropriate metadata, uncertainty estimates and documentation.

As shown in **Figure 1** this should be an iterative process, as changes to any part of the system will affect successive parts, and all can be refined by iteration.

Structure of This Paper

A general error model is first introduced along with an overview of approaches to uncertainty estimation and the generation of gridded and gap-filled data products (Section “An Error Model and Its Application”). The section “Overview of Available Data and Observational Metadata” describes the main types of platforms providing data and ancillary information relevant for the construction of surface marine CDRs, how each contributes to CDR construction and how the available observations might be improved and extended. The next section considers “User Needs for Data and Data Products” followed by an overview of approaches to the construction of CDRs, including summaries of specific issues for each ECV (Section “Considerations When Creating Internally-Consistent Records for Marine Surface ECVs”). The final sections look to the future and provide reflections and recommendations.

AN ERROR MODEL AND ITS APPLICATION

Introduction to an Error Model for Individual Observations

The observed value of measurand (O) at location co-ordinates (x, y), date and time (t) and observing height or depth (h), hereafter location (x, y, t, h) is an approximation to the true value (T) at a desired nearby location (x', y', t', h') . The definition of “nearby” will depend on the application, for example on the size of output grid or distance from a reference observation. The observed value will contain systematic and random errors (e.g., JCGM, 2008), and is an approximation for T . It may be possible to estimate the component due to systematic errors (B). Similarly, it may be possible to estimate the component due to differences in location or spatiotemporal representativeness (L). In each case we wish to correct the observations for bias or location, leaving residual errors ϵ_b and ϵ_l respectively. The local random errors, after any adjustment, can be represented by ϵ_o .

The systematic errors (B , hereafter bias) may depend on location, the general measurement method (m), the specific instrument used (i), the platform (p), the ambient environmental conditions at the time of the observation (a), and how the data were recorded, transmitted, exchanged, stored and archived (d) or other factors. The differences due to location (L) will depend on the gradients in the field of interest and on the distance. Examples of such location adjustments are to adjust observations to a common reference level (such as the adjustment of marine air temperature measurements to a common reference level, Kent et al., 2013), or time (such as the adjustment of satellite observations of SST to a common reference time to remove inhomogeneity in retrievals due to changing overpass times relative to local time of day, Merchant et al., 2014). Following correction for location differences and systematic observational

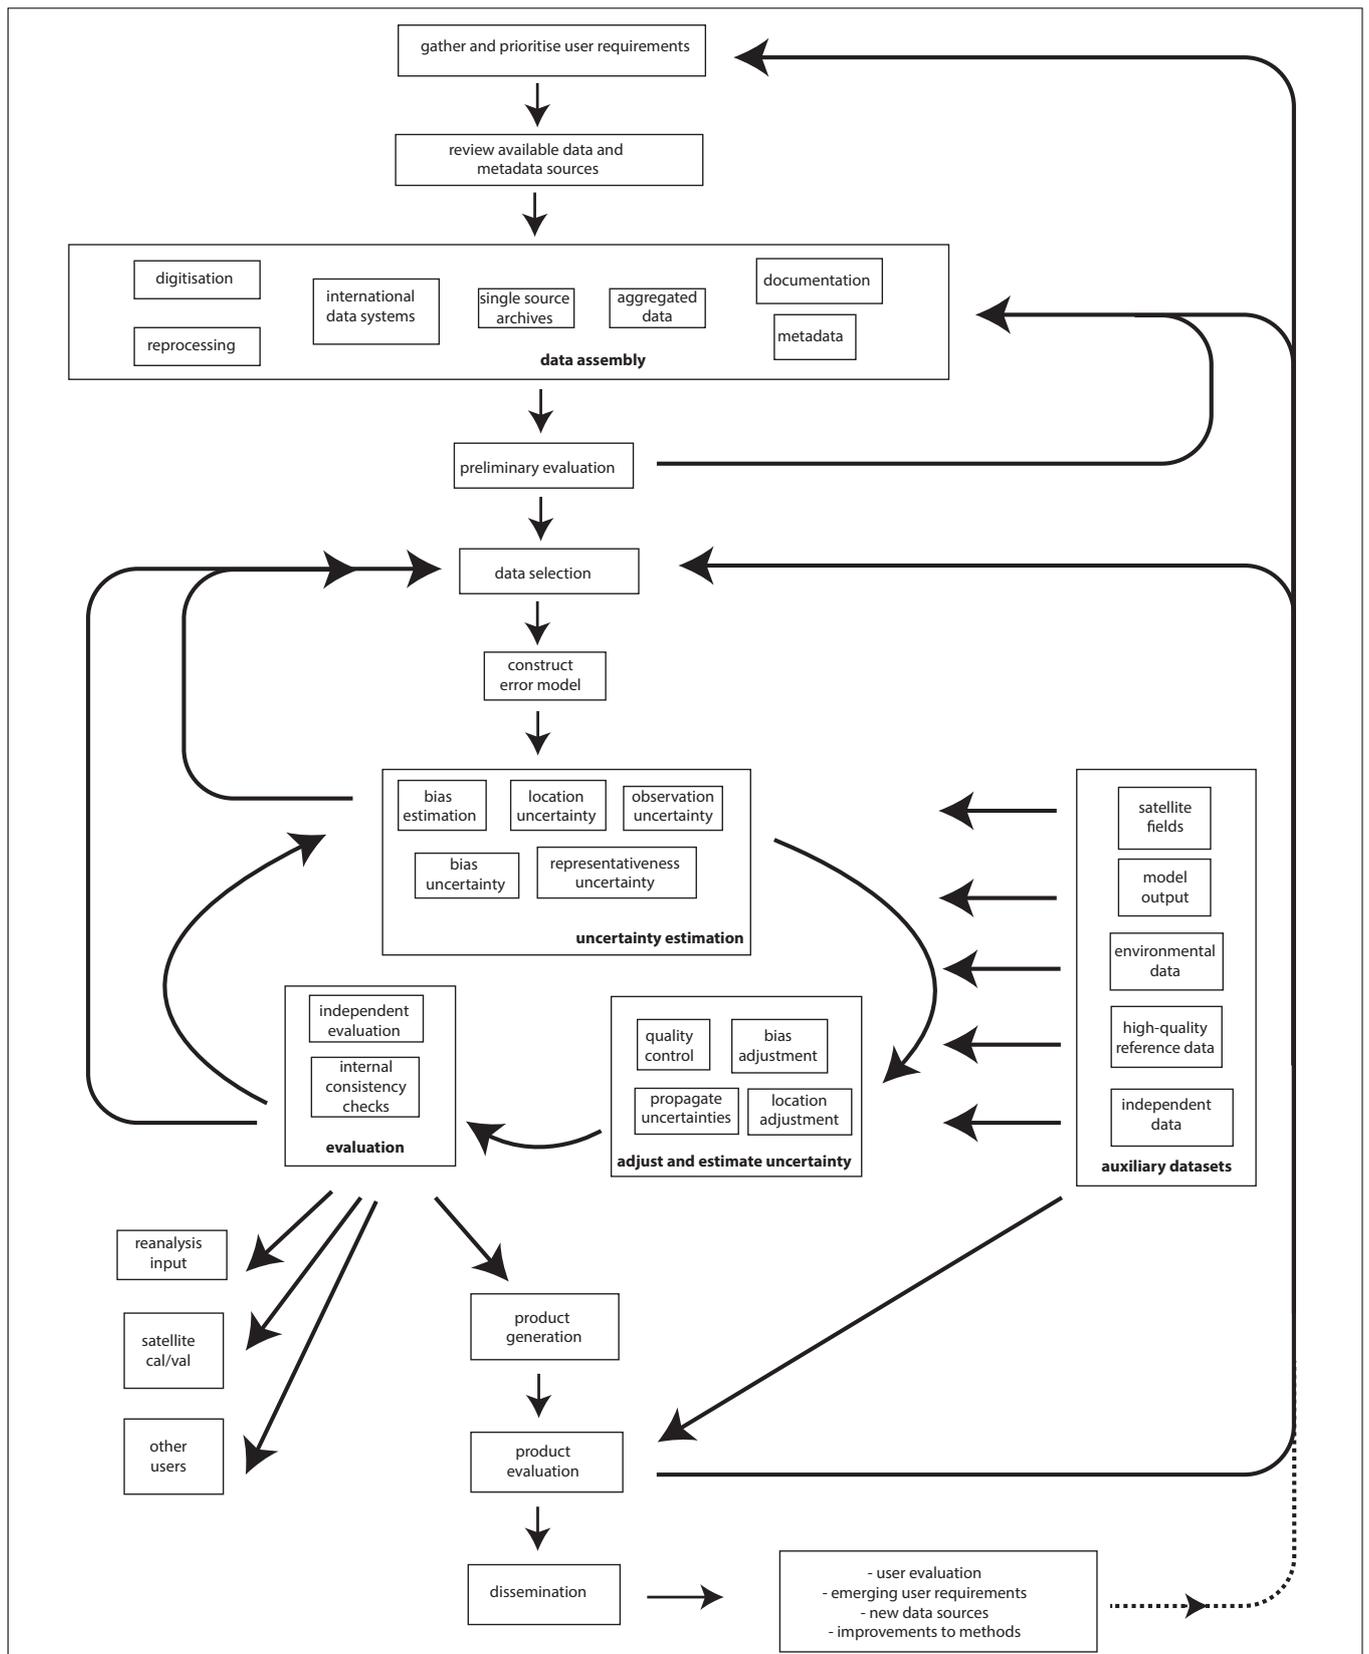

FIGURE 1 | Schematic of the development of *in situ*-based CDRs and other climate data products.

errors our best estimate is that all error terms ($\varepsilon_o, \varepsilon_b, \varepsilon_l$) will have zero mean across a large number of observations, but there may be structural relationships between subsets of errors that might be, for example, correlated across $x, y, t, m, i, p, a, \text{ or } d$.

This error model can be written:

$$O(x, y, t, h) = T(x', y', t', h') + B(x, y, t, h, m, i, p, a, d, \dots) \\ + L\left(\frac{\partial T}{\partial x}, \frac{\partial T}{\partial y}, \frac{\partial T}{\partial t}, \frac{\partial T}{\partial h}, \Delta x, \Delta y, \Delta t, \Delta h\right) + \varepsilon_o + \varepsilon_b + \varepsilon_l \quad (1)$$

With the residual difference between our observed and approximated value given by:

$$O(x, y, t, h) - \bar{B}(x, y, t, h, m, i, p, a, d, \dots) - \bar{L}\left(\frac{\partial T}{\partial x}, \frac{\partial T}{\partial y}, \frac{\partial T}{\partial t}, \frac{\partial T}{\partial h}, \Delta x, \Delta y, \Delta t, \Delta h\right) - T(x', y', t', h') = \varepsilon_o + \varepsilon_b + \varepsilon_l \quad (2)$$

Where the overbar indicates an estimated value of the systematic (\bar{B}) and location errors (\bar{L}). Estimates of T and gradients in T will have further dependencies, for example on $x, y, t, h, \text{ or } a$.

Typically we also need estimates of the expected error variances ($\langle \varepsilon_o^2 \rangle + \langle \varepsilon_b^2 \rangle + \langle \varepsilon_l^2 \rangle$) and their covariance structure. The random errors are usually considered independent and the covariance structure between observations takes the form of a diagonal covariance matrix. The covariance structures for the other error terms are more complicated. For example, the residual bias and location errors may be considered to be fully correlated across observations sharing particular characteristics (e.g., same m, i, p, a or d or nearby) and uncorrelated otherwise (JCGM, 2008).

The general error model informs data requirements. The most obvious requirement is for observations (O) of the parameter of interest at known dates, times, and locations. Next is for information on the methods and instruments used in order to accurately estimate any bias correction (\bar{B}) and any auxiliary information required to calculate the location adjustment (\bar{L}), for example atmospheric stability for the air temperature height adjustment. The number of observations required will depend on the objective (e.g., location or region, spatiotemporal resolution, and desired accuracy), and on the uncertainty in the observations (and its correlation structure). These requirements will be discussed further for specific variables in Section "User Needs for Data and Data Products." In addition to estimates of the adjustments required for biases and location differences we also need estimates of the expected variance of the residual errors, these are addressed in the next section.

Approach to Uncertainty Estimation

Historical data vary in quality and have a variety of errors. Understanding these errors, the degree to which they can be corrected, and the residual uncertainty associated with the adjusted measurements is essential for making use of the data. Quantification of uncertainties is likely to reveal complex dependencies of $\langle \varepsilon_o^2 \rangle + \langle \varepsilon_b^2 \rangle + \langle \varepsilon_l^2 \rangle$ (e.g., on $x, y, t, h, m, i, d, p, a$).

There are two primary ways of estimating the uncertainty in the observations, either through the direct observation and estimation of the probability density functions for the different errors (Type A) or through the use of assumed probability density functions based on other evidence (Type B) (JCGM, 2008). Instruments calibrated to international (and national or community) standards will conform with the Type A approach prior to deployment. However, even if international standards are followed and an instrument installed on a ship is accurate, siting of the instrument and misreporting can still lead to significant errors (e.g., Beggs et al., 2012). Drifting buoys are rarely recovered, so their calibration chain is effectively broken upon deployment. Moored buoys, such as those in the TAO array, are periodically recalibrated, but detailed calibration information is not presently delivered alongside the observations.

Typically, other solutions following the Type B approach are required. For example, one solution for detecting drifts in the calibration of sensors on drifting buoys is to fit each drifter with multiple sensors (Reverdin et al., 2010; Poli et al., 2018). Another solution is to compare coincident or nearly coincident measurements from different instruments such as using variograms (Kent and Berry, 2005). Triple co-locations (e.g., Stoffelen, 1998; O'Carroll et al., 2008) can be used in situations where errors can be considered to be independent. Application of such techniques requires redundancy in observing systems and consideration of the correlation structure of the errors. Comparisons between nearly coincident measurements are also important for quality control and bias estimation.

Quality control systems such as the *in situ* SST quality monitor (iQuam) Atkinson et al. (2013) and Xu and Ignatov (2016) use comparisons between *in situ* measurements and a reference field derived from a satellite-based analysis to quantify biases and standard deviations for individual platforms, which are effectively estimates of uncertainties. Others (for example Kent et al., 1993; Stoffelen, 1998; Ingleby, 2010) have used weather forecast fields as a basis for estimating measurement errors and uncertainties. More modern statistical infilling techniques can also be used to estimate and assess errors and uncertainties (see, e.g., Kent et al., 2017) but it is challenging to implement methods with complex dependencies globally and with high data volumes, for example, as associated with satellite data.

The Construction of Gridded and Gap-Filled Records

One of the main requirements for long-term CDRs is the creation of datasets containing summary statistics, such as the mean, on a regular grid. These gridded products tend to be more usable than the individual observations for many applications and are widely used. The simplest gridded products are based on the arithmetic mean of all observations within a grid box passing quality control. Examples include the ICOADS summaries (Freeman et al., 2017) and HadSST3 (Kennedy et al., 2011a,b). Such products are typically easy to use and maybe relatively easy to produce, but suffer from a variety of problems such as unresolved biases, incomplete coverage and inhomogeneous variance in time and space owing to the vastly different sampling density in

different times and places. Gridbox uncertainty estimation should account for all important components of the appropriate error model for the observation types used, and will typically require observational and platform metadata to correctly represent the expected error covariances. Kennedy et al. (2011a) showed large increases in the uncertainty in the global average SST associated with measurement error when covarying errors were taken into account.

Simple gridded products often form the basis of more sophisticated data treatments. A number of data sets interpolate or fill in gaps in the data, mostly for SST (e.g., ERSSTv5, Huang et al., 2017; COBE-SST2, Hirahara et al., 2014; HadISST, Rayner et al., 2003; Kaplan SST, Kaplan et al., 1998), but also for pressure (HadSLP2, Allan and Ansell, 2006). For filling of large-scale gaps as is required particularly in the 19th century (Figure 2A), these reconstruction methods typically use patterns (e.g., principal components or empirical orthogonal functions) derived from modern well-sampled data to reconstruct sparsely observed past climate states. The advantage of having globally or regionally complete fields is obvious and such analyses are widely used. A number of generic difficulties are expected and seen in such analyses including loss of variance, under-estimation of trends, over-fitting, and under-estimation of uncertainty. This highlights the difficulty of representing the broad spectrum of possible climate states from the relatively small and noisy sample of observed historical variability. In addition, these methods do not typically take into account the full range of error structures seen in the data and typically assume that errors are uncorrelated. Smaller-scale gaps and smoothing of data can also use techniques based on describing the expected local structure of variability such as optimal interpolation (e.g., Reynolds et al., 2002) or using a statistical model of the mid-scale variability (Karspeck et al., 2012).

One aspect of gap-filling that has not yet been widely used is exploitation of co-variability between different variables (except in the context of dynamical reanalysis production which exploits physical relationships between variables via assimilation into a weather forecasting model). Examples where this is likely to be useful include: joint analysis of winds and pressure; pressure or atmospheric circulation and temperature, humidity or cloud cover; and of SST, MAT, and humidity.

OVERVIEW OF AVAILABLE DATA AND OBSERVATIONAL METADATA

The Different Types of Observing Platforms

Figure 2 summarizes data availability based on the ICOADS Release 3.0 from each of the *in situ* observation types considered in Section “The Different Types of Observing Platforms.” Figure 2A shows sampling by ECV for 1800 to 1899, a period dominated by ship observations (Figure 3). Reports typically contain several ECVs with humidity and sea state reported less frequently than SST, MAT, SLP or winds. Numbers of observations and coverage generally increase over time,

with peaks associated with the start of international co-ordination (Maury, 1854) and the ingest of a large collection of US logbooks. Observation numbers and coverage both increase over 1900 to 1969 (Figure 2B) with decreases associated with the two world wars. There is an increasing contribution from meteorological observations associated with oceanographic measurements (Boyer et al., 2013). Humidity and waves remain less well-sampled than the other variables, their coverage depending on the sources of data in this period. Since 1970 the range of platform types diversifies (Figure 3) but while the number of observations increases, the coverage is lower by 2017 than in 1970 for all ECVs (Figures 2C, 3). This is due to a declining contribution by ships since the 1990s, partially compensated for SST and SLP by an increase in coverage from drifting buoys (noting that ICOADS is currently missing some drifting buoy observations from 2016 onwards).

Non-specialist Observing Ships

The creation of long records depends on combining many different types of observations. Many ship observations were originally made for ship operations or navigation, or in support of numerical weather prediction (NWP). Some observations arise from programs that did aim to understand marine climate variability, but typically to chart long term mean conditions (climatology) such as Maury (1854) or the WMO Marine Climatological Summaries Scheme (MCSS, WMO, 2012). The amount of information we have for such vessels varies dramatically with the data source. For observations digitized recently the value of multi-variate records with rich metadata is recognized and typically an attempt is made to recover all relevant information. However, in the past data and metadata are often lost through the many format conversions that observations may have been subjected to.

The earliest observations come from digitization of observations from individual voyages of discovery (Woodruff et al., 2005). The earliest systematic observations come from logbooks of the East India Company covering the period 1789 to 1834 (Freeman et al., 2017) and then from international co-ordination of marine observing by Maury (1854). This international co-ordination is now under the WMO Voluntary Observing Ships (VOSs) scheme (WMO, 2012). Presently data from VOS are collected in near real time (NRT) in support of NWP, via the WMO Global Telecommunications System (GTS). Archives of GTS-derived reports are kept by several National Weather Services (NWSs) but there is no systematic international system that ensures completeness and quality of these records that become the mainstay of the climate observing system.

Some VOS observations are also made available in delayed mode with additional parameters and improved quality control through dedicated WMO Global Assembly Centers (GDACs) in the United Kingdom and Germany. Over the years ICOADS has acquired major collections of surface marine observations from prior to the VOS scheme that were not collected by Maury, notable examples are from the United States, Japan (Kobe collection), Norway, and Australia (Manabe, 1999; Worley et al., 2005).

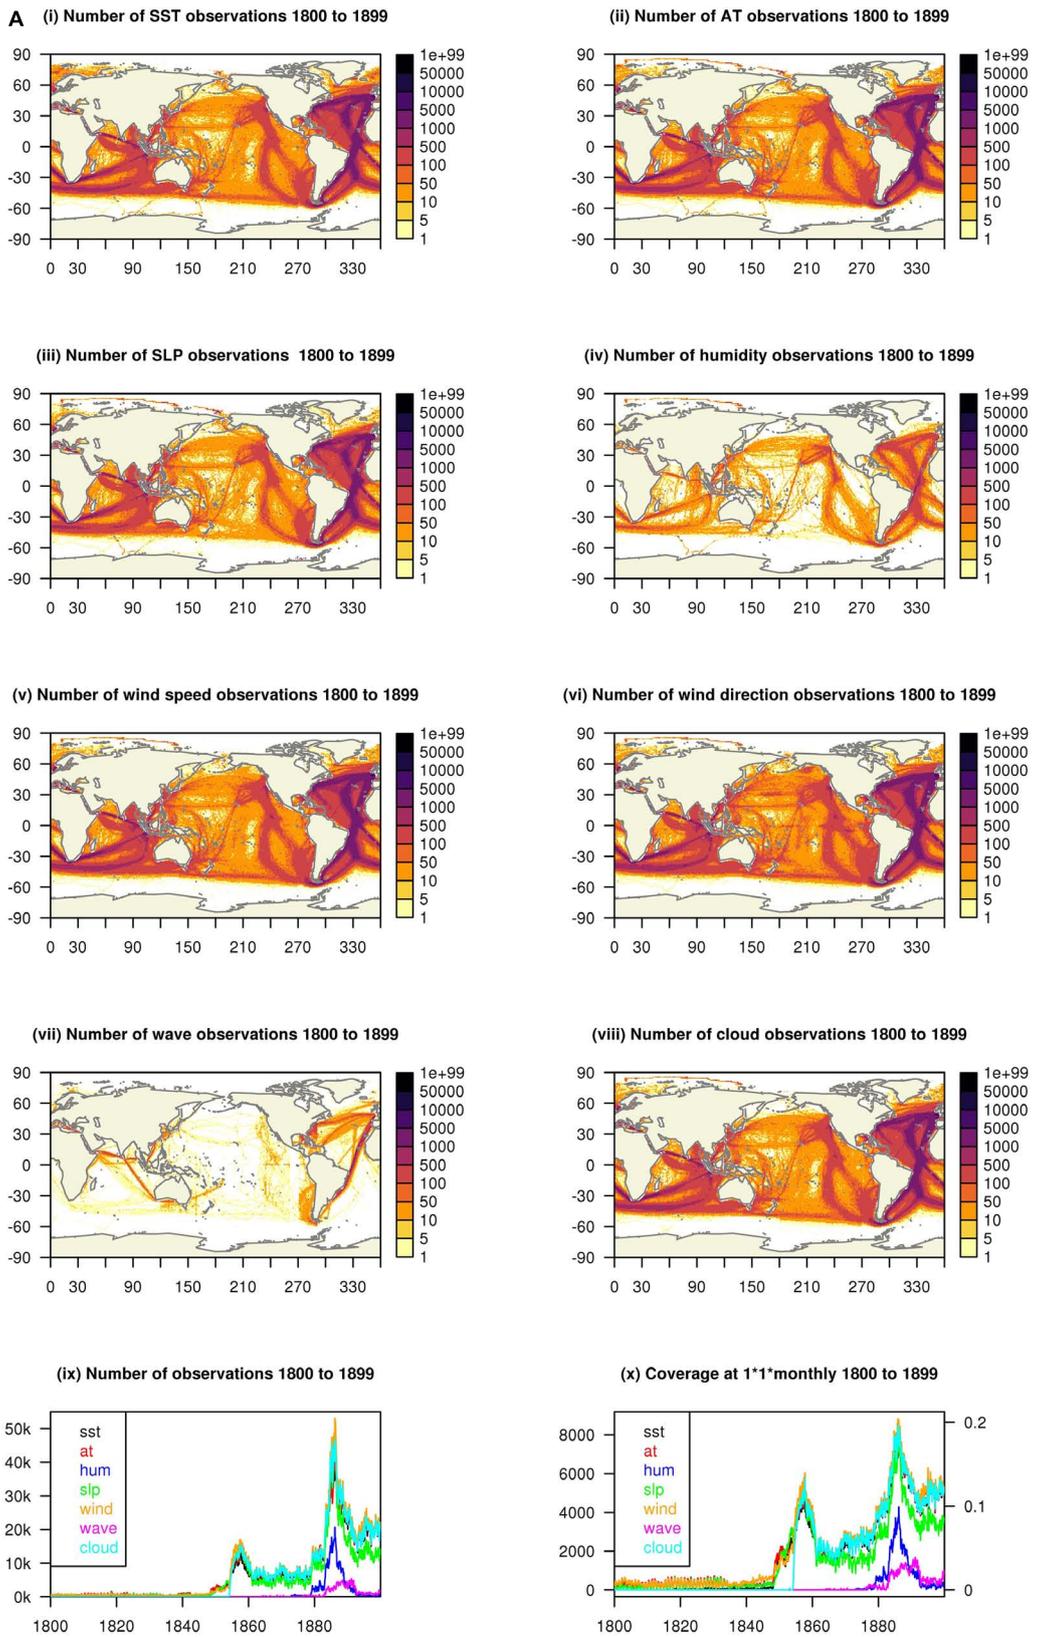

FIGURE 2 | Continued

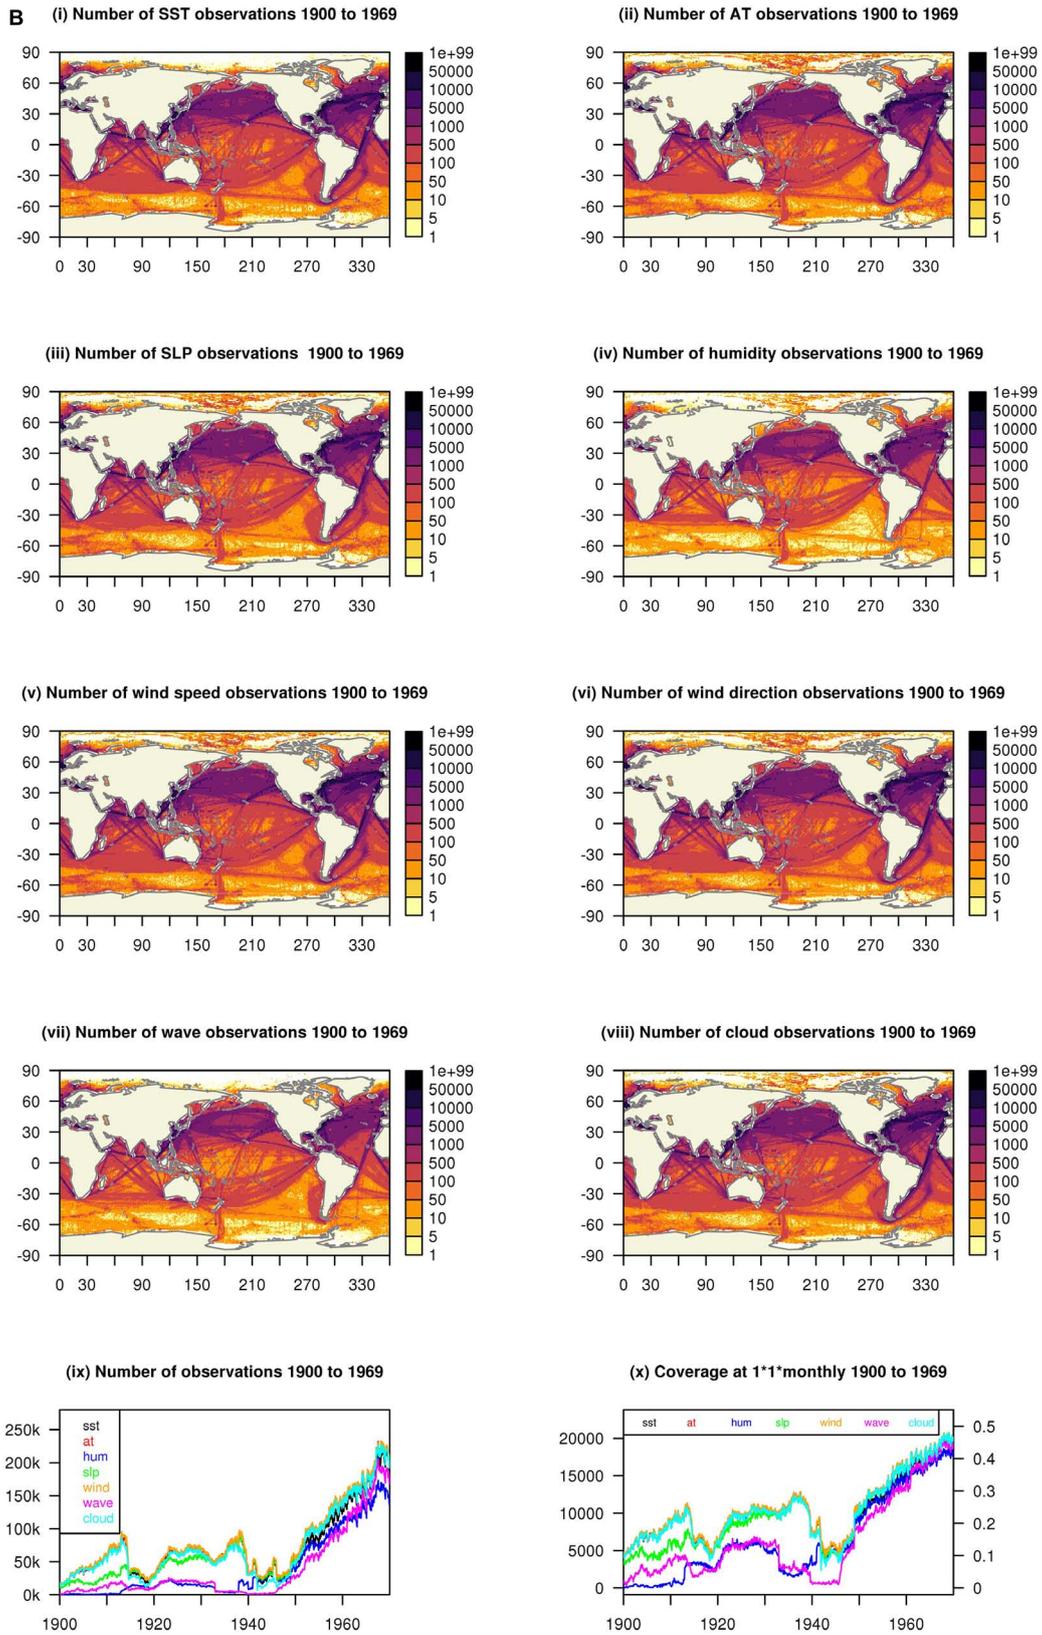

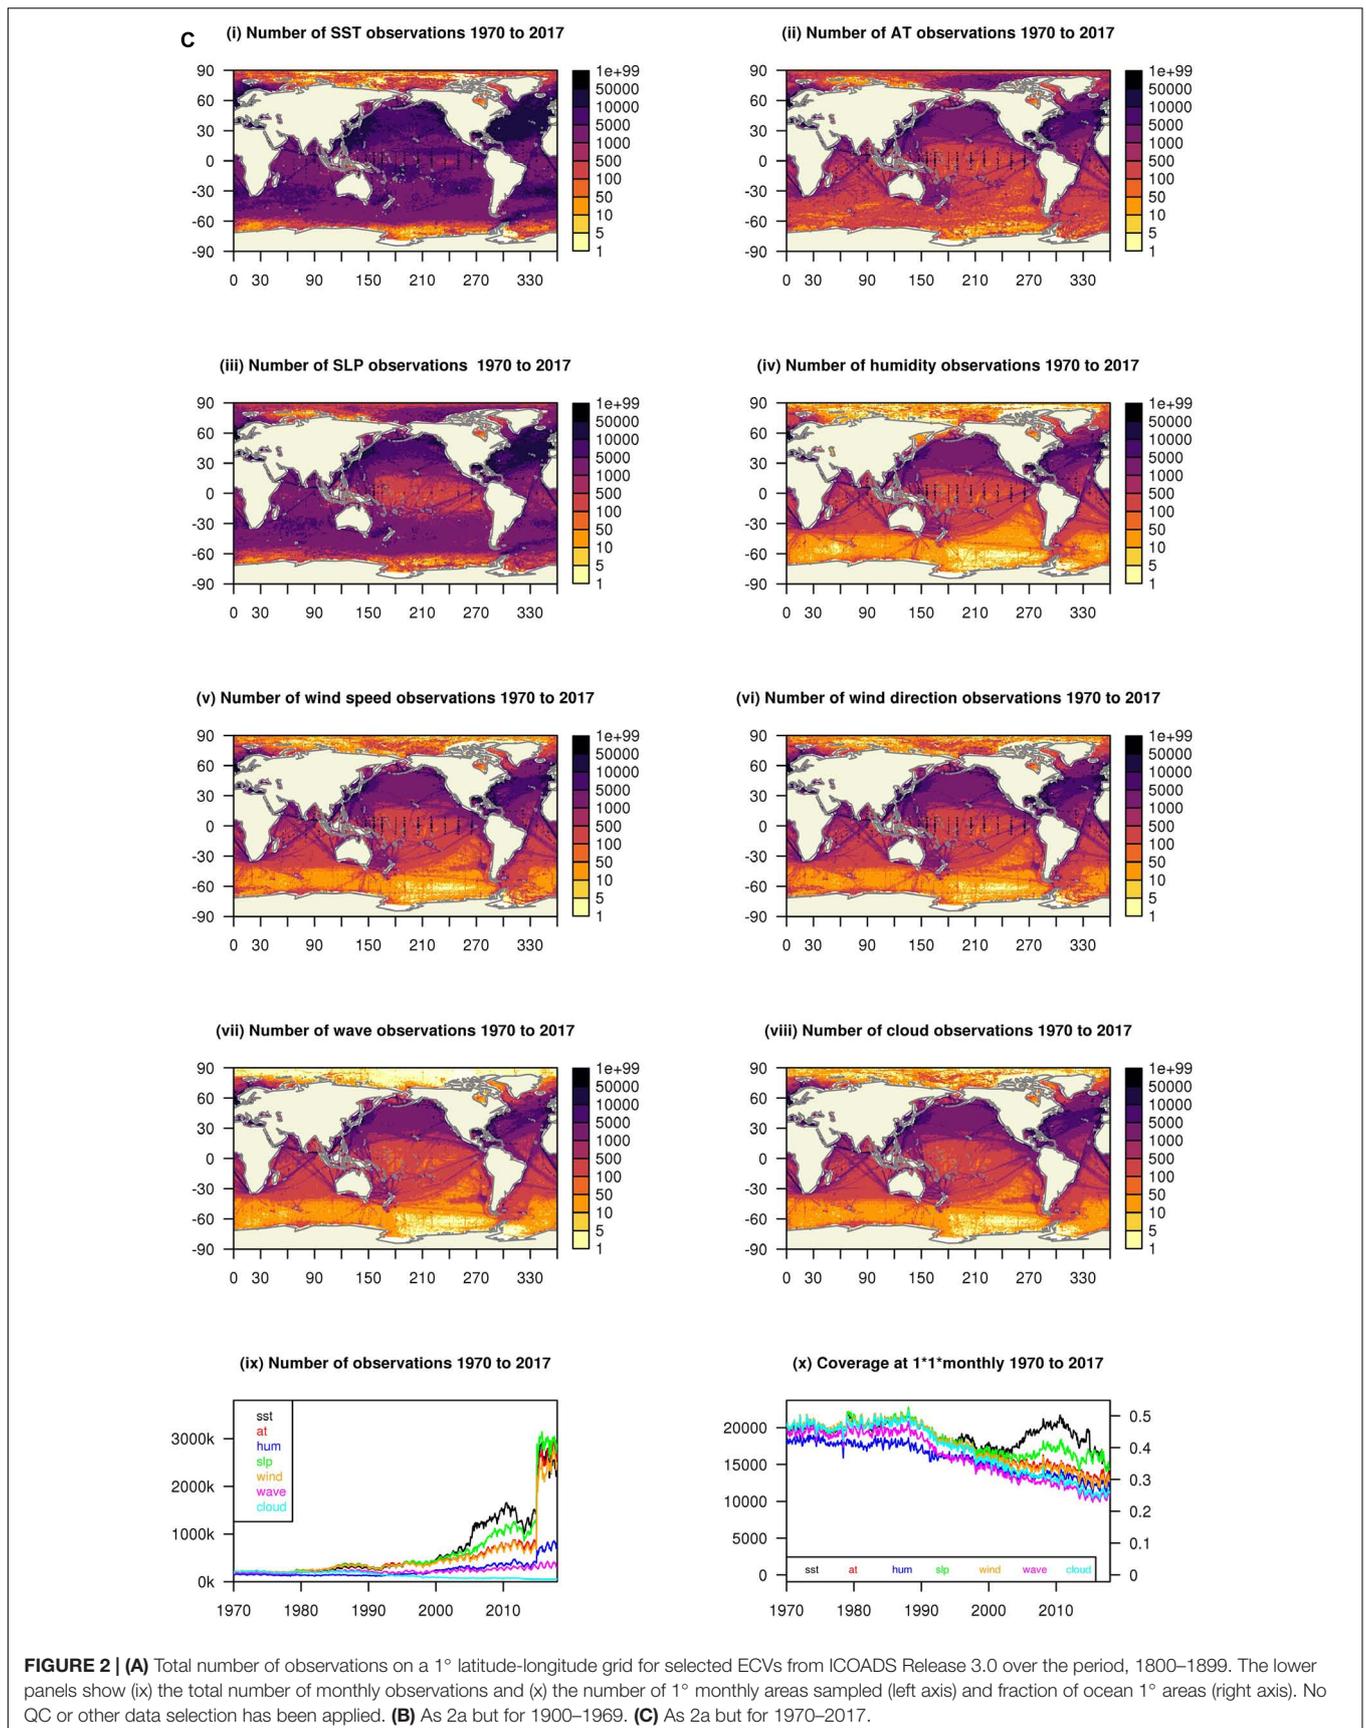

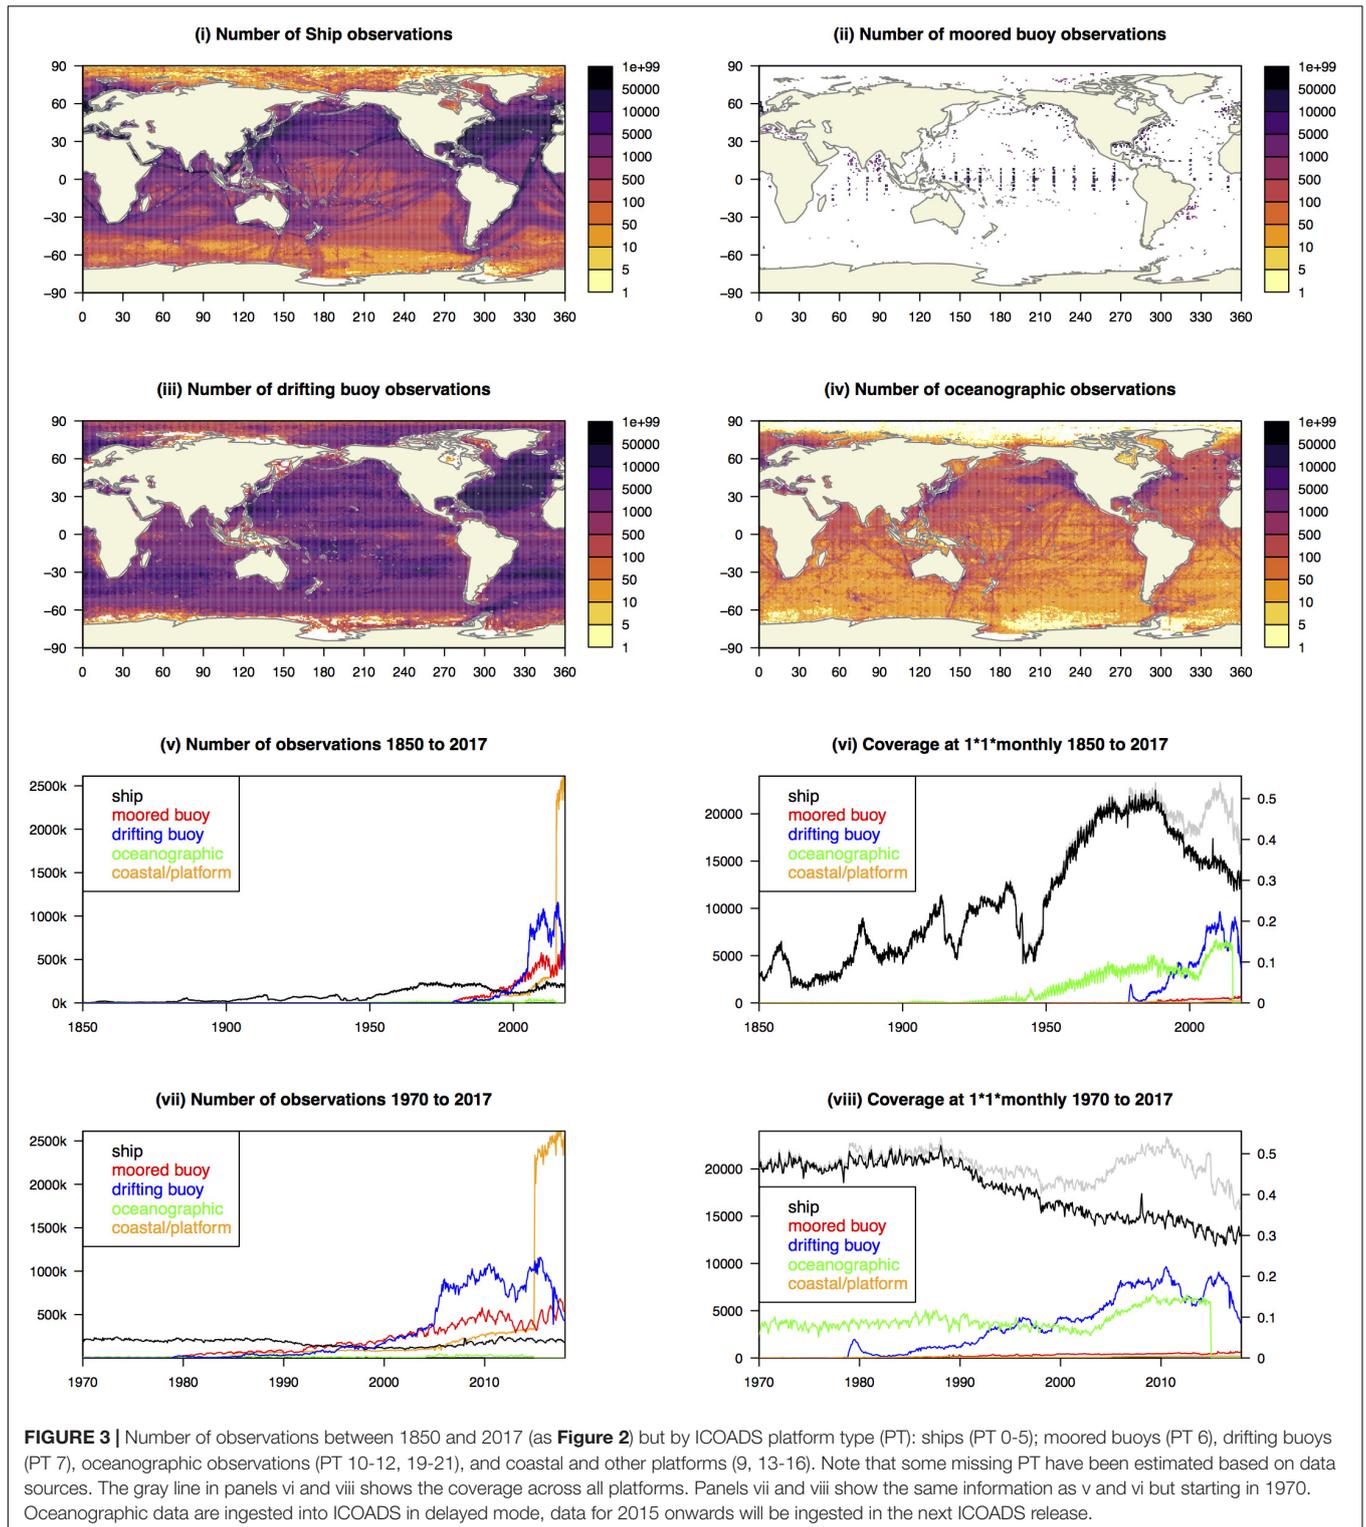

FIGURE 2 | Continued

Specialist Observing Ships

Observations from specialist vessels obviously have the potential for providing higher quality observations than non-specialist ships. However, in order for such observations to be most useful for the construction of long term records the data must

be clearly identifiable and accompanied by extensive platform and observational metadata. ICOADS contains observations from research vessels (RVs), ocean weather ships (OWSs), and light vessels (LVs) that have the potential to be used in a variety of ways either as a source of observations in sometimes

sparse ocean regions, or as high quality data for evaluation (e.g., Smith et al., 2001).

International Comprehensive Ocean-Atmosphere Data Set mainly contains observations from RVs operating as VOS and using a separate set of instruments from those used for research applications. In some cases, particularly in the US, VOS observations from RVs may come from the research instruments. Additionally, some RV data in ICOADS are from delayed-mode data sources that are focused on collection and quality evaluation of measurements from research instrumentation (e.g., Smith et al., 2018). There is the potential for some confusion as to the source of any observations identified as coming from RVs by their identifiers (callsign or ship name, hereafter IDs). In some cases, the same RV may provide VOS and delayed mode observations from two different instrument systems. A similar situation exists for OWS, which can be found in ICOADS in several different source data collections. Some OWS observations are clearly identified as such, either through being identified with a specialist source, or through the ICOADS “platform type” identifier (PT). However some ICOADS data sources contain mixtures of OWS and other data types, not always clearly identified, some duplicating observations in dedicated OWS sources likely to be of higher quality and completeness, and some that may be unique.

Data from RVs are typically managed at the national level with no dedicated international data management or archival system (Smith et al., 2019). Some nations do have dedicated data management systems for RVs including the US (Smith et al., 2018) and Australia [Integrated Marine Observing System (IMOS)], full international integration of such national RV data systems would enable the construction of high quality datasets for evaluation of a wide range of data and data products.

Data from specialist observing ships could have huge value for the development of long-term datasets, but the lack of an integrated international management system for RV data means that observations are not well-utilized for uncertainty estimation and quality evaluation.

Moored Buoys

Moored buoy observations have contributed to the global observing system since the 1970s (Figures 2C, 3) and are found in ICOADS in data sources deriving from both NRT and delayed mode archives. The two largest sources of moored buoy observations are the Global Tropical Moored Buoy Array (GT MBA) providing measurements in the Pacific, Atlantic and Indian Oceans (McPhaden et al., 1998) and the coastal network of buoys that make observations in support of NWP (DBCP, 2016). GT MBA data are curated by the NOAA Pacific Marine Environmental Laboratory (PMEL) who provide consolidated access to data from the full tropical array¹ (accessed 26 March 2019). ICOADS ingested the GT MBA archive as of February 2016 for Release 3.0 which included data collected up to the end of 2014 (Freeman et al., 2017). The PMEL archive is updated when improved information such as from post-calibration becomes

available, but updates and changes to the archive are not prominently publicized.

Observations from national coastal networks have not been a priority for historical curation, and no definitive archive for the data and metadata exist. Whilst potentially valuable, a combination of mixed data quality with many moorings sited in highly-variable coastal locations has meant that these moorings have not been widely exploited for climate applications (e.g., Wentz et al., 2017).

The OceanSITES aim is to collect, deliver and promote the use of high-quality data from long-term, high-frequency observations at fixed locations in the open ocean. Its scope is wider than considered here, including also biogeochemical and subsurface observations. OceanSITES funds a Technical Coordinator and IT staff who are based at the JCOMMOPS Project Office (OceanSITES, 2016). OceanSITES collates timeseries data from many different providers, and makes it available in a consistent format (OceanSITES, 2015) via two Data Assembly Centres. Several of the GT MBA moorings are designated as OceanSITES as are long-term moorings from the Woods Hole Oceanographic Institution.

Other Moored and Fixed Platforms

Observations made in coastal regions and from fixed platforms such as oil rigs can also contribute to the marine climate record (Figure 3). Land-based coastal observations are often excluded from CDRs and other data products as unrepresentative of open ocean conditions, but have a role to play for example for evaluation of datasets (see Hanawa et al., 2000; Kent et al., 2017; Cowtan et al., 2018 in the context of SST).

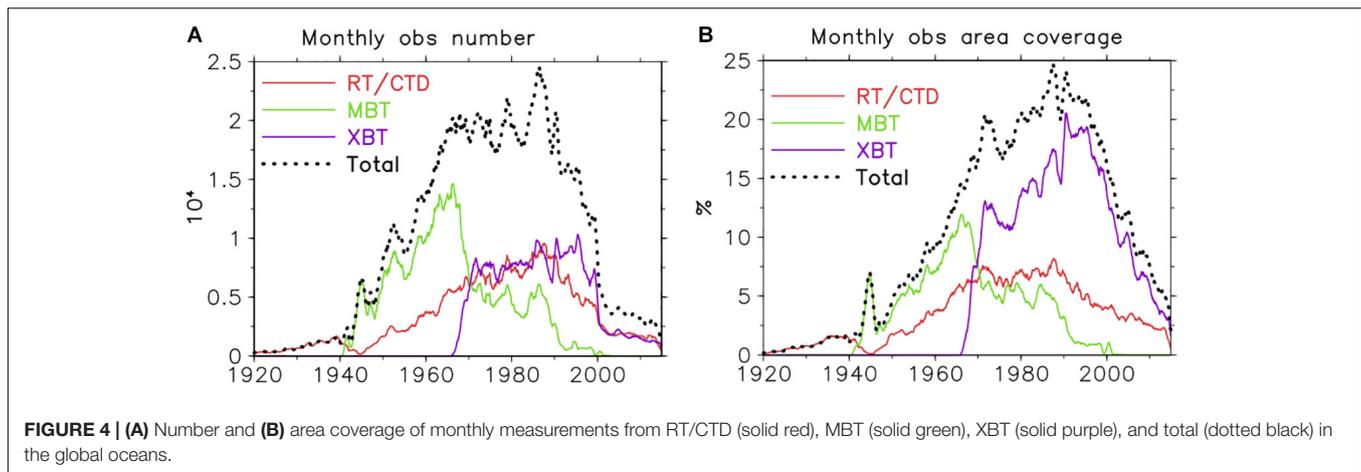

Surface Drifters

Surface drifters predominantly report SST and SLP (Figures 2C, 3), providing critical data for NWP and reanalysis (Centurioni, 2018). The development of the surface drifter observing system has been facilitated by clear user requirements (e.g., Zhang et al., 2006) and assessment of the impact of the data (e.g., Ingleby and Isaksen, 2018). However the reliance on surface drifters has led to a decline in observations of important ECVs such as MAT, humidity, wind, and cloud (Kent et al., 2006, also Figure 2C). Some drifting buoys have reported MAT, but their quality has not yet been evaluated. There is the potential for correlated sampling uncertainty as drifters may get trapped in eddies and will follow currents. They cannot provide good sampling in regions of divergence or areas of upwelling. Lack of multivariate sampling can be problematic for analysis, for example Morak-Bozzo et al. (2016) associated model output with drifting buoy measurements to characterize the dependencies of their diurnal cycles.

Oceanographic or Profile Measurements for Temperature

Historically, typically from 1950 to 2000s, ocean temperature was measured by reversing thermometers (attached to hydrographic bottles), conductivity–temperature–depth (CTD), mechanical bathythermographs (MBTs), and expendable bathythermographs (XBTs). Globally, there were 5000–20,000 measurements within 5 m of the ocean surface each month from 1950 to 2000s

¹<https://www.pmel.noaa.gov/tao/drupal/disdel/>

(Figure 4A), which covers 5–20% area of the ocean on $2^\circ \times 2^\circ$ grids (Figure 4B). Argo floats provide highly accurate temperature measurements but observations are sparse due to the typical 10 day sampling cycle. Argo data are only available for regions where the ocean is deeper than ~ 2 km.

These measurements were commonly used to estimate ocean heat content (e.g., Levitus et al., 2009), but XBT are problematic for SST analysis due to biases caused by the shock of entry into the water. Recent studies have however (e.g., Gouretski et al., 2012; Hausfather et al., 2017; Berry et al., 2018; Huang et al., 2018) have used these measurements to evaluate SST data products.

Satellites

Data from satellites have become an important resource for climate. Their record length is presently not yet sufficient on their own to meet our definition of a long term climate record. Increasingly CDRs will be constructed from satellite observations without blending with *in situ* observations, and the same considerations for stability and uncertainty will apply. *In situ* data are also required for calibration and validation of satellite climate records (e.g., Belmonte Rivas et al., 2007; Berry et al., 2018). As with *in situ* networks, satellite missions have not always been designed with climate applications foremost, so typically substantial work has to go into constructing stable records (Hollmann et al., 2013; Verhoef et al., 2017). However there are now efforts to establish and maintain traceability of global fiducial reference measurements, including for satellite-derived surface temperature (Snook, 2016).

Sea surface temperature is one ECV where satellite data has been most used for the construction of CDR, notably in the HadISST dataset (Rayner et al., 2003). Substantial effort has been put into the construction of stable and accurate SST records (Merchant et al., 2012, 2014). Other variables where satellites will play an important part in the construction of long-term CDR are for clouds and radiation (e.g., Loeb et al., 2012), winds (e.g., Verhoef et al., 2017), and waves (e.g., Young et al., 2011; Ardhuin et al., 2019). However, to date only SST has extended the satellite record back in time using *in situ* observations. Air temperature and humidity are hard to derive from space (e.g., Andersson et al., 2011; Prytherch et al., 2015) but doing so would

be valuable for estimation of air-sea exchanges (Weller, 2018; Cronin et al., 2019).

The satellite community are important users of *in situ*-measured surface ECVs (e.g., Belmonte Rivas et al., 2007; Stoffelen et al., 2015; Jackson and Wick, 2016; Kinzel et al., 2016; Berry et al., 2018; Liman et al., 2018; Thorne et al., 2018), and recommendations that aim to improve the quantity, quality, and consistency of *in situ* data will be of huge benefit for satellite calibration and evaluation.

Selection of Data Sources

Selection of *in situ* Observations for the CDR

The construction of long records inevitably means that a range of data sources needs to be considered and that there will be compromises on data quality to increase sampling. Most modern *in situ*-based surface marine climate records are built using the ICOADS (Freeman et al., 2017). ICOADS collates surface marine data from a range of different observing platforms, keeping the majority of available parameters and metadata together. Obvious requirements are measurements or visual estimates of the parameter of interest, along with information about the date and time of the observation and its location. Observations in ICOADS may have substantial uncertainty in their locations, dates, and times. Some data sources have positions recorded to the nearest degree, and some positions, dates and times have gross errors (Carella et al., 2017). Increasingly information on the identity of the measurement platform is used, for quality control, but also as part of bias adjustment and the construction of error covariances in gridded analyses. Observational metadata giving measurement methods, heights or depths of sensors is also valuable, but can be estimated (e.g., Kennedy et al., 2011a; Kent et al., 2013; Carella et al., 2018). It is also becoming more common to use information on the ambient environmental conditions as input to bias adjustment schemes and uncertainty estimation, which may further require estimates of ship speed and course, winds, cloud, temperature, humidity, pressure, wave conditions, and coded weather information. The availability of a full suite of estimates of environmental conditions also permits multivariate quality control.

Despite ICOADS providing all the information in a common format, the content and quality of records from different sources varies markedly. Much of the data provided in ICOADS (then COADS) Release 1 came from data that had been initially recorded in ships logbooks, then stored on punchcards and later transitioned to reel-to-reel tapes (Woodruff et al., 1987). Each format change and re-archival inevitably results in some degree of lost information, and the introduction of transcription errors. The present ICOADS format [International Marine Meteorological Archive (IMMA) format version 1] (Smith et al., 2016) allows the preservation of the entire record, but at cost of considerable complexity. Recently ingested data, such as that from the GTS or data recovery (Allan et al., 2011) therefore can retain a more complete record of the original data and observational metadata.

The amount of information we have for such vessels varies dramatically with the data source, summarized in ICOADS by the DCK (derived from a “deck” of punch cards) and SID (source identifier) indicators. Presently the information required to select observations from ICOADS based on an objective quantification of the quality of the data and metadata needed to construct CDRs is not available. A reprocessing of ICOADS to improve its compatibility with WMO Integrated Global Observing System (WIGOS) data and metadata standards would substantially improve this deficit.

Observations for Bias and Location Adjustment and Uncertainty Estimation

Methods for the estimation of data uncertainty such as the calculation of variograms (e.g., Kent and Berry, 2005) are based only on the variability of observations themselves, although these may be calculated for subsets of data, for example by measurement method. Bias estimation may use measures of internal consistency between subsets of measurements made using different methods (e.g., Folland and Parker, 1995; Kent and Kaplan, 2006; Kennedy et al., 2011a; Hirahara et al., 2014; Carella et al., 2018), between different platforms, or based on other characteristics (Chan et al., 2019), requiring metadata to identify appropriate subsets.

High quality observations are important for the detection and evaluation of biases (Hausfather et al., 2017; Berry et al., 2018). Specially designed datasets are also useful, often containing enhanced metadata (Kent et al., 1993; Berry and Kent, 2005), and/or co-located observations from different methods (James and Fox, 1972; Berry et al., 2004). Comparison of data products of similar ECVs that are likely to have largely independent errors (for example SST and MAT) can be used for bias adjustment (Huang et al., 2017) or evaluation (Cowtan et al., 2018).

Nearby observations are needed for some types of QC (see section “Quality Control”) but can also be used to diagnose relative data biases (e.g., Thomas et al., 2005; Chan and Huybers, 2019).

Observations of ambient environmental conditions which may be based on measurements or climatology are needed for estimation of B , L and their uncertainties, and may also feed into estimation of other components of uncertainty. Coded weather information is particularly useful for

identifying ambient conditions, for example whether or not it is raining.

Observations for Variability

Estimates of local ECV variability and gradients are needed for quantification of location uncertainty, as input to QC and for implementation of local gap-filling and smoothing algorithms. Estimates of large-scale variability are needed to provide patterns of expected modes of variability for reconstructions. Estimates of temporal variability are often based on *in situ* observations, moored buoys are particularly good for quantification of high-frequency temporal variability, and for understanding co-variability among different ECVs. Many ECVs show diurnal variability, both real and spurious. Real diurnal variations are often not considered, but ideally variations in local sampling time should be assessed as part of L . Satellite observations can be valuable for the estimation of spatial variability, but for variables such as MAT and humidity can only be assessed from VOS observations at present (Figures 2C, 3).

Observations for Evaluation

Ideally evaluation would use high-quality independent data widely distributed and spanning the entire period of record. These data would also be independent of those used for evaluation of biases and uncertainty. Examples where such evaluation has been possible are largely limited to SST using observations from Argo or other near surface measurements from oceanographic profiles (e.g., Hausfather et al., 2017; Huang et al., 2018), drifting buoys (e.g., Berry et al., 2018), moored buoys (e.g., Merchant et al., 2012). Evaluation for marine surface CDRs often relies on co-evaluation of different data products, which can provide important information on structural uncertainty (Kennedy, 2014; Kennedy et al., 2019) and be used to evaluate uncertainty estimates (Kent et al., 2017). Examples include: evaluation of SST using MAT from ships (Kent et al., 2013); coastal SST (Hanawa et al., 2000); or coastal air temperatures (Cowtan et al., 2018). Folland (2005) used a climate model to evaluate SST bias adjustments. Triple collocation (Stoffelen, 1998) is often used for evaluation of satellite winds, but has typically not been applied to historical *in situ* observations due to lack of collocated observations with independent errors.

An alternative, is to define subsets of data for evaluation that are excluded from the construction of data products. Near surface temperatures from Argo have often been excluded from analyses for use in validation (e.g., Martin et al., 2012) and the evaluation of air temperatures over land has also taken this approach by creating a separate version withholding a high quality subset (Hausfather et al., 2016).

When comparing different types of observation, or different gridded products, it is important to account for mismatches in spatiotemporal scales, known as representativeness. An example is when comparing *in situ* temporal average measurements at a single point with satellite measurements that are an almost instantaneous average across a spatial footprint. In order to estimate the expected uncertainty due to representativeness it is necessary to quantify the differences in scales and the variability of the ECV field across those scales.

Lack of independent high-quality observations is a barrier to the evaluation of long CDRs. As record lengths increase for timeseries stations such as OceanSITES and the GTMBA, and for satellite CDRs it will be possible to extend evaluation of *in situ* CDRs to other variables. The continuation and extension of OceanSITES will enable much evaluation of a wider range of ECVs with more independent data, at least for the modern period. RV observations are underutilized for evaluation, mainly because their data management is not internationally coordinated into quality-evaluated archives (Smith et al., 2019). Some potentially high-quality sources of data for evaluation, including from RVs, OWS and coastal stations, may require data rescue (see section “Data and Metadata Rescue”) or reprocessing (see section “Reprocessing of Existing Archives”).

Enhancing the Observational Archive Quality Control

Initial checking can identify reports with incorrect values for date, time and position, unphysical values for elements or incorrectly coded parameters or metadata. If these errors are systematic, it may be possible to re-translate the available observation source, or to provide feedback to the data provider and obtain a revised version. More often than not such problems are discovered too late for such remedial action (e.g., the original data may have been lost, or staff may no longer be in post) and the data source may be excluded from the analysis, but some values might be correctable.

Basic checks can identify unusable data or impossible values such as non-existent dates or locations, or observations made over land. Any data failing checks should be flagged rather than discarded as changes to tests may be required in the future, and analysis of reasons for data failing checks can be used in the refinement of QC. Simple tests for each variable include ensuring there is a measured value which is reasonable given typical conditions, usually tested against a monthly or daily climatology with allowances for a combination of the expected real variability in the parameter and observational uncertainty. Further checks may be possible, for example, cloud and weather codes can be checked for consistency (Hahn et al., 1988) and relative humidity should be close to saturation when it is raining or foggy.

More sophisticated checks may then be implemented such as evaluation of the tracks of individual ships or drifting buoys. Tests applied by Rayner et al. (2006) include limits on the inferred speed of the ship, consistency between actual and reported heading, consistency between interpolated locations and reported locations. Other tests that can be performed on individual ships include: checks for repeated values, repeated super-saturation, and counts of observations from the platform (ships which make very small numbers of reports are typically less reliable). More extensive checks can also be performed at this level (e.g., Atkinson et al., 2013; Xu and Ignatov, 2016) by comparing measurements from an individual ship or buoy to a reference field and making decisions based on metrics such as the average bias or standard deviation relative to the reference data set.

A further step may be comparison of nearby observations (Rayner et al., 2006). Typically, a single observation is compared to a mean of its neighbors. These “buddy checks” are of varying degrees of sophistication and effectiveness depending on the expected density and quality of the neighbors.

At each stage in the process, data which pass or fail individual checks are flagged and an overall decision is made based on some combination of these checks.

Following quality evaluation and flagging particular data sources or platforms that are identified as being of consistently low quality can be explicitly excluded from further analysis. Depending on the volume and characteristics of the observations that are flagged as erroneous or suspect, it may be advantageous to reevaluate parameters and limits within the QC process (Figure 1).

Enhancing Metadata

The amount of metadata that appears in ICOADS varies dramatically with data source (DCK and SID). Some sources have no platform IDs or observational metadata, some sources have IDs and rich metadata, particularly those that have been more recently digitized or processed. Most data sources have associated documentation, and a systematic review of this information is likely to substantially enhance ICOADS metadata availability. Examples of untapped metadata include mappings of ship numbers to ship names for some Japanese and Australian sources and documentation describing the transcription of data for punchcards. External documentary sources have also been used to infer metadata such as measurement methods (Kennedy et al., 2011b). Metadata from a WMO catalog has been associated with individual observations (Kent et al., 2007) based on IDs, and also used indirectly to infer metadata based on the recruiting country (Kent et al., 2010; Kennedy et al., 2011b). However to take full advantage of new information an improved data system and more flexible data models will be required.

Availability of IDs makes track checking possible (see section “Quality Control”) which can identify mispositioned observations. Recent masking of ship callsigns (Woodruff et al., 2011) in response to ship operators concerns about security and commercial interests, has led to a degradation of data in ICOADS and other archives. If no ID information is available then it is not possible to fully apply QC, to easily identify mispositioned or duplicate reports, to appropriately propagate uncertainty and to associate external metadata (Kent et al., 2007). Coded IDs have been adopted by some operators, which avoid some of these issues, but it may still not be possible to associate existing external metadata, and may preclude association of information that becomes available in the future.

It is possible to extend metadata using the characteristics of the data themselves. Examples include: the clustering of reports likely to be made on the same platform by ship tracking (Carella et al., 2017); the inference of data units or reporting precision from the distribution of reported values (Rhines et al., 2015); or the assignment of observing methods based on the data characteristics (Carella et al., 2018). Ideally such indirect methods of deducing metadata should be supported by full descriptions including observing instructions, information on instruments, their locations and installation and also documenting each stage of report coding and recoding.

There is useful information available from a wide range of other sources that have not yet been systematically integrated with marine observations. Where ship names are available it

is often possible to determine a wealth of information about the ship, including pictures and quantitative information on size and tonnage from the internet. It may also be possible to infer ship names for reports with a numerical ID based on ports of departure and arrival from online sources. Many other sources of information exist that might provide relevant metadata, for example databases held by Lloyds Register of Shipping or metadata transmitted with Automatic Identification System (AIS) vessel tracking.

Merging Different Sources and Archives

If data from different sources are to be combined and analyzed together then clear metadata is required to indicate the data sources and typically effort will be needed to harmonize data formats, particularly metadata and data flags. Documentation of all steps is essential to avoid misinterpretation.

The identification of any reports that may derive from the same original observation may be required. Examples include where observations may become available in delayed mode in enhanced formats or with additional checks. In this case, any NRT version of the same report should be identified and is usually flagged as inferior (although in some cases inadequacies in the archival process may have degraded the data). This may be straightforward, but in some cases, especially where corruption has occurred, different versions of the same observation can only be identified with uncertainty. For example, prior to ICOADS Release 2.5 (Woodruff et al., 2011) reports identified as inferior duplicates are only available in depreciated data formats, so it is not easy to test the efficacy of the duplicate identification procedures applied. Another issue arises where newly-digitized data sources should replace older versions, but it is not always possible to clearly identify previous digitizations of the same source material.

Ideally the identification of data likely to be derived from the same original observations should allow for a specified tolerance for the permissible degree of difference between candidate reports. This should be based where possible on known recording, conversion, and data management practices (ideally from metadata flags). Where this is not possible the classification of expected differences can be built up from a comparison of the data sources themselves. This classification of expected differences should feed into uncertainty estimation and be used when selecting the preferred version of observations thought to be duplicates.

Data for ICOADS Releases prior to 2.5 (Woodruff et al., 2011) for sources that have been given low priority for selection in the ICOADS “dupelim” duplicate elimination processing and are not available in the present archive should be prioritized for recovery and reprocessing. This will provide improved information on likely differences between data sources and also information on typical errors/miscoding.

The Need for Expert Data System Design and Management

The modern observing system is diverse and each data type requires careful management, documentation, evaluation and quality control. Observations collected primarily for applications

other than climate monitoring, typically for NWP, form the majority of the surface marine climate observing system. It is therefore critical that the needs of climate monitoring are considered in observing system design, and that observations needed for climate monitoring have dedicated data management systems and centers, whatever their origin. Whilst single variable repositories are used for some applications, observations made on the same platform should primarily be managed together and with adequate resources to allow expert evaluation, QC, and bias estimation.

USER NEEDS FOR DATA AND DATA PRODUCTS

Understanding the Needs of Different Applications

Needs for observational climate records have in recent years been discussed in a number of contexts, for example under the ESA Climate Change Initiative, the Copernicus Climate Change Service and the 5th International Conference on Reanalyses.

In general, these experiences yield a requirement for:

- (1) More data, i.e., existing observing arrays should be maintained, and sparsely observed regions should be better monitored and the potential of past measurements needs to be unlocked via digitisation and wider data sharing;
- (2) More research to be undertaken into creating consistent records so that multi-decadal records can be used for the evaluation of decadal re-forecasts, for example;
- (3) More research to be undertaken into quantifying uncertainty components and their covariance structures; and
- (4) Better statistical modeling techniques to create analyses and allow better representation of the full data distribution to allow, for example, provision of observational constraints on future climate projections.

As the need for higher resolution information (in space and time) grows, there needs to be continued development of long-term products from *in situ* and satellite which are consistent to support the optimal combination of these different data types. This growing requirement for higher resolution information places high demands on the historical and current observing systems.

To support services with frequent updates, such as seasonal forecasting, and in short delay, such as short-delay event attribution, short-delay updates to monitoring and SST and sea ice boundary forcing data sets (and their underpinning data bases, like ICOADS) need to be developed which are consistent with the long-term record (e.g., Schwab et al., 2015). ECV products need to be developed with consistent coverage through time (in-filled) and good uncertainty estimates.

The adequacy of observing systems for variables that are not yet associated with requirements for operational services has declined in recent years (Figure 2C, e.g., Kent et al., 2006; Berry and Kent, 2017). An example is air temperature

where a need has been identified for long term records for comparison with climate model output (Richardson et al., 2018). Observations of air temperature from VOS are required to extend coverage to enable the continued production of global air temperature analyses. To resolve this sampling deficit it will be necessary to relate observation requirements for gridded datasets to requirements for numbers and sampling strategies for VOS and other observing networks.

In the following, we explore two specific experiences: gathering of user requirements for sea-surface temperature and the needs for observations of dynamical reanalysis development.

Gathering User Requirements for Marine Climate Data

The development of user requirements covering a broad range of applications is increasingly important, and it is necessary to ensure that a narrow specification of requirements for a particular application does not lead to a degradation for other applications. An example of such a broad approach to gathering user requirements is that of the European Space Agency (ESA) Climate Change Initiative (CCI) SST project which aims to improve SST satellite data records to meet the requirements of the climate research community. A User Requirements exercise undertaken by the project (Good and Rayner, 2010) and then repeated 5 years later (Rayner, 2017) gathered the needs of the climate research community for observed SST information in general (not just for satellite SST products) via six methods:

- (1) a literature review of relevant documents from bodies such as the GCOS;
- (2) review of lessons learned information provided by other projects;
- (3) a questionnaire, which asked about:
 - (a) currently available SST data; and
 - (b) future needs for SST data, 5 years from now;
- (4) discussion sessions;
- (5) review of user requirements found in other related projects; and
- (6) a user workshop on uncertainties².

Current and future users of SST data were invited to enter their requirements into an online questionnaire and over 100 people responded on each occasion from all over the world. Respondents' work spanned the full range of climate applications, together with air quality modeling, fisheries, atmospheric chemistry, agricultural research, etc.

In general, different applications require different levels of data and the SST CCI User Requirements Document (URD) supports this conclusion. At least half of the users of SST information surveyed each time stated a need for information which has been made complete using a statistical infilling technique. However, it is also important to provide both individual observations and gridded, but not infilled, information for the other types of application such as data assimilation and climate change detection and attribution

respectively. Furthermore, data from different instruments should be combined where this will allow weaknesses in individual datasets to be overcome. For example, there is a requirement for SSTs retrieved from infrared and microwave satellite instruments to be combined to reduce biases and data gaps in particular regions. By making available single-sensor records, sensor-series datasets, and multiple-sensor analyses and extending records back before the satellite era using *in situ* measurements, the needs of different users can be met.

A large majority of survey respondents needs global information, but different applications require different resolutions of information, both spatially and temporally. The full range of options from <1 km to >1 degree latitude-longitude and <3-hourly to monthly were required, which indicates that the climate observing system needs to be able to support some very exacting requirements for some climate applications and with a sizeable minority needing information about diurnal variability. The most common response in terms of length of record needed was >30 years, but as an objective >100 years would be ideal for many applications with compatibility between satellite and *in situ* data being extremely important. Analysis of decadal variability and the study of climate extremes, detection of long-term trends and the study of long-term changes associated with coral systems, fish growth or genetic changes all need long records. These potential users want to be able to use data before the satellite era but also want to take advantage of satellite-derived products, so it is important that the two are consistent.

The concept of interim CDRs, i.e., short-delay updates to CDRs consistent with the long-term record, is relevant to many users. For some, a delay of less than a day is needed until data receipt. Some climate monitoring applications ideally need data within just a few days, but some can tolerate longer delays. This continuing need for climate quality data can be addressed by ensuring that the data record is extendable in the future when new instrumentation is available, but also requires conversion of data processing systems from research to operational, supported by the convergence of climate and operational requirements.

Typically, biases in SST data are not tolerated above about 0.1°C and precision is required to be 0.1°C or better. Strict stability requirements of better than 0.05°C/decade are stated. Users require these statistics to be demonstrated over spatial scales of ~100 km, which is not typically possible everywhere and certainly not unless large high-quality data subsets are reserved for evaluation.

The SST CCI User Workshop on Uncertainty³ identified a significant interest within the user community of the provision of uncertainty information via an ensemble (a set of plausible realizations of each SST field which span the uncertainties in the data). Respondents to a second questionnaire were asked if SST uncertainty information were to be represented by an ensemble, how many ensemble members would they need for their application? Over half of respondents indicated they would require more than 10 ensemble members, and a similar number also felt they would benefit from the provision of uncertainty

²<http://www.esa-sst-cci.org/PUG/pdf/CombinedSSTUserWorkshopReport.pdf>

³<http://www.esa-sst-cci.org/PUG/workshop.htm>

information via a parameterized error covariance matrix. These responses indicate a movement amongst the SST user community toward much more consideration of observational uncertainties.

Users also felt that confidence in uncertainty estimates needs to be stated and that uncertainty characteristics should be verified by comparison against independent observations. As with the evaluation of bias, precision and drift over time, this places strict requirements on the availability of independent, high quality reference data.

Observational Needs for Reanalysis

Many climate users access information about the climate system from dynamical reanalyses. Historical marine observations are key data sources for the production of climate-quality reanalyses. At the Fifth International Conference on Reanalysis (Buizza et al., 2018), the session on observations discussed the needs for observations of reanalysis production and the processing required to ensure a climate-quality outcome. These processing steps (data assembly, data rescue, quality control, bias correction, and data assimilation feedback analysis) and stated needs echo, in many cases, the processing and the SST needs discussed above, and demonstrate that they are generalizable to other variables.

Work on observations for reanalyses requires a sustained, well-supported effort involving cooperation with reanalysis producers; operational services are inadequate to support this work alone. Operationally-produced reanalyses are susceptible to changes in observing practice or transmission practice, such as the recent general move to the use of BUFR format for message transmission. Operationally-sustained production of underlying key data sets, consistent with the climate record, is essential to avoid discontinuities that affect downstream services.

Ongoing data rescue and recalibration, both of satellite and *in situ* data sources are very important for improving the quality of reanalyses and extending their quality back in time. In particular, data rescue is crucial for preserving data currently on fragile tape or paper. Reprocessing and making observational [both ECV and parameters used to generate Fundamental Climate Data Records (FCDRs) such as radiance (GCOS, 2011)] series more consistent allows more of the information to be included in a reanalysis and allows our reanalyses to better reflect the observations. This requires a sustained program (Brönnimann et al., 2018a,b).

The fundamental observational record needs to be carefully preserved for future reanalyses and for every other activity we may need it for now and in the future. This needs ongoing, adequate support. Previous experience demonstrates that once observational holdings become fragmented, it requires a great deal of effort to correctly reconstruct them.

Development of future assimilation systems needs to consider how best to use observations and information on their uncertainties and this effort needs to be supported. End-to-end propagation of uncertainties through observation processing is required to enable this.

The reanalysis community need to clearly state their ongoing requirements for the observing system, considering also the known downstream needs of applications. For example: a

subset of the observations used are particularly key and reduce uncertainty so much that they could be considered akin to reference series – these should be defined and particularly cared for; resolution of boundary/constraining SST fields is key to reproducing precipitation over frontal zones and reducing tropical biases – microwave SST data should be continued and its resolution increased; and funding for new satellite missions should be continued, since that provides for future innovation.

How Do User Needs Impact on the Construction of CDRs?

Producers of CDR and other climate data products have responded to user requests for more frequent updates, particularly important for climate monitoring. There is inevitably a tension between the speed with which products are made available and their quality. Observations may not be available in time for cut-off deadlines, improvements in data quality from delayed mode processing are not available, and assumptions must be made that data quality is similar to that seen previously. For those products aiming to meet the needs of users with requirements for fast data delivery, updates are typically made a few days after the end of every month. Except where particular problems are apparent, revision of these fast delivery products is usually every few years. This is a compromise between having relatively stable versions, and ensuring the highest quality.

Other trade-offs that may occur between different user needs are between quality, resolution and completeness. Infilled datasets are needed for some applications but uncertainty is bound to increase in unsampled regions. Need for increased coverage, or higher resolution, may require that lower quality data sources are utilized, perhaps without the desired metadata. In all these cases careful consideration of the terms in the error model will guide data selection, and provide estimates of data uncertainty that can guide user choice.

CONSIDERATIONS WHEN CREATING INTERNALLY-CONSISTENT RECORDS FOR MARINE SURFACE ECVs

Air Temperature

Observations of MAT have been made on ships since about 1750, but observation numbers increased with availability of measurements from the East India Company in the late 18th Century (Freeman et al., 2017) (**Figure 2A**). Early in the record measurements of MAT are more common than SST, which only become consistently observed following Maury (1854). Measurements are made with thermometers with a transition between mercury thermometers to electronic sensors over time (Kent et al., 2007). The most important factors for MAT data quality are thought to be the location, ventilation, and degree of sheltering from the sun (Kent et al., 1993).

Marine air temperature observations need to be adjusted to a common reference height (Kent et al., 2013), requiring information on the actual observing height (*h*) and an estimate

of the stability of near surface atmosphere which depends on ambient conditions (a). h may be available from Publication 47 (Kent et al., 2007), but only from around the 1970s, prior to this some rather broad generalizations must be made (Kent et al., 2013). A further source of uncertainty is the difference in measurement heights and depths that occurs with a change in ship loading. Elements of a required are wind speed, air-sea temperature difference, and ideally the humidity. Present adjustments applied to ICOADS use climatological estimates of a and its uncertainty. For high-quality data sources it is likely that using observed values would be an improvement, but this will require further research to quantify uncertainties for each data source and their impact on height adjustment. Improvements are likely to be possible for MAT without high-quality a through, for example, further constraining the likely climatological distribution of atmospheric stability with additional information such as wind direction.

The most prevalent source of bias (B) in MAT is due to the daytime influence of spurious heating by the ship infrastructure (Berry et al., 2004). This effect will be larger for sensors that are installed close to the deck as is required for manual reading of thermometers installed in Stevenson Screens (Berry and Kent, 2005). The move to remote reading electronic thermometers enables sensors to be installed in well-exposed locations should reduce the magnitude of B , but this has not yet been evaluated across ICOADS. Additional metadata, for measurement method (m), instrument (i), ship size and type and height above deck may in the future provide valuable information for more refined estimates of B and ε_b that may depend on proximity to the heat source and the ventilation of the sensor (for example an estimate of the ambient air flow and i , m). An estimate of \bar{B} (Berry et al., 2004) has been implemented with ICOADS from 1973 (Berry and Kent, 2011), but existing longer records minimize B by selecting night-MAT only (Rayner et al., 2003; Kent et al., 2013), restricting the record to start after 1850. Other B specific to particular data sources, periods or regions are treated *ad hoc* (Rayner et al., 2003; Kent et al., 2013).

Humidity

Humidity observation records exist intermittently from the late 1800s, reaching reasonable monthly coverage (~ 30 – 40% ocean area) from around 1960 onwards (Figure 2). Likely, many more observations exist but these have not typically been prioritized in data rescue efforts. Ships are the most prolific, and arguably most reliable, platform providing humidity observations given that they are manned and sensors are located further from sea level, and therefore from sea spray contamination, than moored buoys. However, since the 1990s moored buoys have steadily increased in number, rapidly from around 2010 to now almost double the number of ship observations (Figures 2C, 3).

Humidity has been typically measured using paired wet-bulb and dry-bulb thermometers (psychrometers) in either a hand held sling or within a ventilated screen. Humidity is then often converted and reported as dew point temperature, any such conversions should be documented (d). Since the 1990s, available metadata (40–60% of ships) shows that capacitance and electric sensors have steadily increased in number to approximately 40%

of the ships with metadata combined. These typically measure relative humidity which is then converted and reported as dew point temperature.

Sources of error for humidity observations depend on m . For wet-bulb thermometers the wick surrounding the thermometer can dry out or become contaminated with sea spray. Relative humidity sensors are also prone to contamination and can drift relatively rapidly, particularly in humid environments (Ingleby, 2010). While psychrometers tend to have better accuracy in moist environments, relative humidity sensors perform better in drier environments. Field evaluations of relative humidity sensors in the marine environment, extending the Ingleby et al. (2013) study of the United Kingdom land station network, are urgently required. If not well-ventilated, through active whirling or artificial ventilation, sensors will be biased humid. Adjustments have been applied for naturally ventilated screens (Berry and Kent, 2009, 2011), but require knowledge of m or i . Errors in MAT due to daytime heating of ship structures may not directly lead to biased humidity measurements (Kent and Taylor, 1996), but both sources of bias are likely to be larger for poorly exposed or ventilated sensors. As for MAT, humidity observations need to be adjusted to a common reference level requiring h and a . Sources of B for humidity largely follow those for MAT but are more complex owing to the derived and non-linear nature of humidity.

Sea-Surface Temperature

Sea surface temperature provides the marine component of global surface temperature, combined with air temperatures measured over land (Hartmann et al., 2013) and is the marine variable that receives the most attention because many activities in climate science and service provision rely upon it. Its uncertainties and bias adjustment have been recently reviewed (Kennedy, 2014; Kent et al., 2017). A wide range of different types of SST data are available, from satellites (e.g., Merchant et al., 2014), and *in situ* from ships, drifting buoys, moored buoys, platforms and coastal stations and the upper parts of temperature profiles from XBTs, CTDs, and Argo floats. There are several long-term global SST data sets (HadSST3, Kennedy et al., 2011a,b; HadISST, Rayner et al., 2003; ERSSTv5, Huang et al., 2017; COBE-SST2, Hirahara et al., 2014). This redundancy enables an estimation of structural uncertainty (Kennedy, 2014), demonstration that differences in B for different datasets exceeds their joint uncertainty (Kent et al., 2017) and that significant biases likely remain at the scale of individual ocean basins (Davis et al., 2018).

There is a need to reconcile near-surface and sub-surface measurements of temperature. The near surface layer is complicated (Kawai and Wada, 2007) and sampling just below the surface is worse than that close to the surface (Figures 2, 4). Despite this upper measurements from temperature profiles have been used to evaluate SST products (e.g., Gouretski et al., 2012; Hausfather et al., 2017; Berry et al., 2018; Huang et al., 2018).

Estimation of B for SST is relatively mature (Kent et al., 2017) and ideally requires knowledge of p , m , d , and a . The need for improved estimates of m and p for SST has driven improvements in metadata estimation (see section “Enhancing Metadata”). Improved estimates of B will need further improvements to m

and p , better documentation of past data management (d) and ambient conditions (a), facilitated by a reprocessing of ICOADS to improve duplicate identification and uncertainty estimation. Measurements from sensors attached to the hulls of ships are yet to be evaluated for uncertainty.

Availability of data for evaluation is better than for most ECVs, but improvements through data rescue and reprocessing would still be valuable (Kent et al., 2017).

Wind Speed and Direction

Wind speed observations based on the Beaufort scale and derived either from descriptions on the sails carried, or of the sea state, are available from the 18th century (Figure 2A). The transition from these visual observations to measurements by anemometers (Kent and Taylor, 1997) resulted in a spurious trend in mean wind speeds (Cardone et al., 1990; Thomas et al., 2008). This is compounded by an overall increase in h over time, and biases due the disturbance of air flow around ships (Moat et al., 2006). True wind speed and direction (relative to the earth or ocean surface rather than to the frame of reference of the ship) needs to be calculated from measured or estimated relative wind speed and direction and the ship motion. The procedure is different for measured and visually estimated winds and is not always performed correctly (Smith et al., 1999). There are also stronger diurnal variations in visual wind estimates from ships than in those measured with anemometers, probably due to the difficulty of observing sea state when it is dark (Thomas et al., 2008). To minimize inhomogeneity Tokinaga and Xie (2011) generated a long-term wind product based only on visual wind estimates and anemometers with known heights.

Measurements from buoys also contain uncertainties: any averaging applied needs to be documented, including whether scalar or vector averaging was used (Thomas et al., 2005), and measurements made close to the sea surface may be affected by waves. The moored buoy network provides calibration for satellite winds (Wentz et al., 2017) and helps to anchor wind products such as the Cross-Calibrated Multi-Platform (CCMP) winds (Atlas et al., 2011). Comparisons between *in situ* satellite winds should account for geophysical differences between the records such as the effects of surface currents (Plagge et al., 2012; Rodriguez et al., 2019).

Atmospheric Pressure

An extensive review of historical atmospheric pressure observations was conducted by Allan and Ansell (2006) and Ansell et al. (2006). Pressure observations need adjustment to sea level (L) requiring information on h and temperature. Mercury barometers need adjustment for local gravity and thermal expansion (requiring m , x , y and temperature) and also information on whether these adjustments have already been applied and if so how (d). Diurnal variations are significant (Ansell et al., 2006).

Lack of clarity on past data management remains a substantial problem for the use of pressure observations, with examples of adjustments having been applied twice, incorrectly, or not at all. A comprehensive review of available documentation, reprocessing of ICOADS original data sources and comparison

between those sources would be particularly beneficial for the historical pressure record, including for reanalysis.

Waves and Sea State

Visual observations of sea state have been made for centuries (Figure 2), observing practice was defined in the 1850s (Maury, 1854) and constitute the longest record of wind waves. Visual observations can identify several wave systems when a well-trained observer estimates a number of sea state characteristics along with atmospheric parameters. The observer's estimation is dependent on surrounding parameters (weather conditions, place of observation, type of vessel, stationary point, etc.). Even though the approach is essentially qualitative, it is possible to integrate all of these factors into a comprehensive observation. VOS data provide basic wave characteristics, such as wind sea, first and second swell heights, periods, and the directions of propagation of those wave components. Reported parameters enable the estimation of significant wave height, dominant period, wave age, steepness and wavelength (Gulev et al., 2003; Grigorieva et al., 2017) and have been used in extreme waves analysis (Grigorieva and Gulev, 2008), and for the assessment of long-term tendencies in wave parameters (Gulev and Grigorieva, 2004, 2006).

Observational practice has not changed, however, significant changes to the coding system occurred in 1950 and it is important to account for this when developing consistent climate records (Gulev et al., 2003; Grigorieva and Badulin, 2016; Grigorieva et al., 2017). Evaluation of the internal consistency of the wave record over time is critical for the identification of coding changes and their impact. Fitting of Weibull distributions to available data can produce more reliable gridbox values. Using these methods a century long record of wave parameters has been developed, that has not yet been fully exploited for applications such as comparison with satellite-based wave records or with model output.

Cloud Type, Cloud Cover, and Coded Weather Information

Visual cloud observations from human surface observers (Figure 2) contain a great deal of information about the atmosphere, interacting with radiation and modifying weather. The structure, height, and shape of clouds, which can be quantified by weather observers at the surface, can be used to assess the atmospheric state (Norris, 1998). The cloud record has been used to study how cloud cover interacts with the SST and changing meteorological variables such as lower tropospheric stability as well as to examine long-term trends in ocean cloudiness whilst revealing some spurious long-term variations (Eastman et al., 2011).

Visual cloud observations board ships throughout the oceans have been recorded using the same methodology and format, since the 1950s, 20 years before satellites. The Extended Edited Cloud Reports Archive (EECRA, Hahn et al., 1988; Hahn and Warren, 2009) contains millions of visual cloud reports from 1954 through 2008, based on observations in the synoptic code of the WMO that have been assessed for internal consistency

and QCd. The EECRA provides a measure of lowest-level cloud cover and total cloud cover along with a cloud type at three levels: high, middle, and low. At least 10 cloud types are defined at each level and selected meteorological information is also included in the record. EECRA methodology has been applied to ICOADS reports from 1950 to 2014 to provide an enhanced cloud record, but this has not yet been used to derive gridded estimates. VOS reports contain coded weather information that can be used to provide context of the environmental conditions that may be used in uncertainty or bias estimation. Precipitation data products have been produced using such codes (Petty, 1995; Josey et al., 1999).

FUTURE IMPROVEMENTS

Ensuring the Future Record

Reference Observations

OceanSITES provides the most consistent source of surface marine data presently available with unified access and common data formats. Whilst it does not strictly conform to the definition of a reference network used for observations over land (Thorne et al., 2017b) the maintenance of a high quality array of moored observations is critical for the maintenance of long-term records. The number of OceanSITES currently providing most of the ECVs in the scope of this paper is about 20, but an extension of similar size has been recommended in support of air-sea fluxes (Cronin et al., 2019), sampling regions thought to be particularly important for understanding the mechanisms of air-sea interaction and providing validation observations for satellites. Such an extension to approximately 40 sites would be extremely valuable for the construction of CDRs.

Select RVs have the potential, based on their level of technical personnel onboard and typically research-quality instrumentation, to act as mobile reference stations, provided a high-level of quality assessment can be achieved (Smith et al., 2019). This would be extremely valuable to link up fixed point high-quality OceanSITES, particularly if the same RVs are used to service OceanSITES, and provide more distributed data.

Argo provides a reference network for SST, but suffers from large sampling uncertainty due to the relatively short time spent at the surface. Surface drifters with higher quality sensors have been deployed to quantify sensor drift (Reverdin et al., 2010; Poli et al., 2018) and if deployed systematically in the future might provide a reference network for SST. Satellite missions such as the ATSR-series (Merchant et al., 2012) that are designed with stable orbits and sampling strategies such as dual view to enable the removal of artifacts such as aerosol contamination should be maintained and extended to provide stable long-term global records.

Baseline Observations

Baseline observations should be of good quality, widespread, and provide observations to link the reference and global networks. RVs that do not meet the criteria for reference observations are an obvious choice, but presently their data

and metadata are not collected and managed systematically, and there is no globally integrated data management system (Smith et al., 2019). Moored buoys other than OceanSITES are also candidates for contribution to baseline networks, but as for RVs there is no integrated data and metadata management system. Enhanced VOS, once evaluated, may also provide baseline observations.

Global Observations

Global networks are those data types that may not reach accuracy requirements for baseline networks but provide widespread measurements to capture the important scales of variability. Standard VOS form such a network, and data from AIS may in the future add to the global network of ship observations. Autonomous observations from Argo and drifting buoys contribute to the reference and baseline networks, but data from emerging autonomous vehicles will initially contribute to a global network. Observations from satellites have the potential to extend sampling to data sparse regions and can provide observations to quantify variability. Long term records blending satellite and *in situ* data to extend records prior to the satellite era should be developed for ECVs beyond the presently-available SST. New technology, especially from autonomous vehicles will also provide valuable observations for long term climate records. Such data can improve our knowledge of ECV variability over the oceans which will contribute to improved CDRs throughout the record and allow the extension of reconstruction methods to a wider range of ECVs. It also needs to be recognized that single variable observations are not as useful as multivariate ones which typically provide more of the ancillary information needed to quantify *B*, *L* and quantify uncertainty and its correlation structure.

Construction of long term records means that new observing technologies need to be continually incorporated into the record. This is made substantially easier when the changes are well-managed, there is co-located overlap between old and new types of observations, and all observations are described by appropriate metadata. It is critical that we retain a network of high quality observations, and evaluations of existing and new technologies are designed to exploit these high quality data.

Data and Metadata Rescue

The digitization of marine observations has dramatically extended the climate record (e.g., Freeman et al., 2017). Most data and metadata rescue activities are presently overseen by the Atmospheric Circulation Reconstructions over the Earth (ACRE) initiative (Allan et al., 2011). International co-ordination of data rescue is needed for several reasons, most obviously to avoid duplication of effort but also because those countries or organizations with the resources or requirements for data digitization may not be the same as those with holdings of undigitized data. The first step is the identification and cataloging of suitable material, typically ships logbooks, observing instructions, or other documentation. This may involve visits to libraries, archives or other institutions. If resources are identified then the material will be imaged, the

resulting images digitized, the data or metadata evaluated, QC applied and data made available for ingestion into climate archives such as ICOADS. The prioritization of resources for imaging will depend on the likely quality and quantity of data, the parameters available, the period and region covered, the match to user requirements and the level of risk for deterioration of the original material. Best practice is that as much information as possible should be digitized from each image along with all of the relevant metadata and ancillary data.

In the past all data digitization was performed by manual keying. Often the output data format was severely restricted, such as that for punchcards. In these cases it is particularly valuable to have documentation describing the procedures used. Sometimes the more complete original sources were then destroyed, but there may be examples where it may be possible to recover data from original sources. Automatic techniques for digitization do not yet work well with most data sources, but this likely to improve in the future, for example with tailored post-processing of output from standard optical character recognition algorithms. Recently crowdsourcing has been used with good success (Brohan et al., 2009; Burt and Hawkins, 2019). Crowdsourcing can be very effective, but requires substantial preparation of material so is most suitable for large volumes of data in similar formats. It is also necessary to maintain the enthusiasm of volunteers, and to demonstrate the value of their contributions.

Much recent digitization has been driven by requirements for reanalysis (e.g., Allan et al., 2011; Brönnimann et al., 2018a,b), and records containing pressure observations are most valuable for this application, especially in data sparse regions or periods. However there are many other applications that would also benefit from data recovery. Of particular value for the construction of long-term records are high-quality independent validation data, especially those that are expected to be consistent through periods of rapid changes in the observing system, for example during the World Wars.

Much marine data rescue has focused on old ships logbooks and metadata such as observing instructions, but there are other data sources that need to be integrated into international archives. Some RV operators have data archives on archaic media or in proprietary formats that could be lost and should be cataloged and prioritized for rescue. Many national services hold collections of GTS data that might provide additional observations, or if duplicating existing archives, information about uncertainty. Early satellite data also exist that need painstaking rescue from at-risk media.

Reprocessing of Existing Archives

The surface marine climate community has long benefited from the ICOADS integrated archive, the value of which is widely recognized (Thorne et al., 2017a). However compromises made during past data management are now reducing the potential for application of advanced methods for estimation of bias and location adjustments, thereby degrading gridded analyses and limiting further improvement. ICOADS has retained original data sources and the available

documentation, so it is possible to re-ingest these data, without constraints on formats or data volumes and in a way more compatible with international standards (see section “An Integrated Data System”).

Advantages of reprocessing selected ICOADS original data sources include:

- Recovery of observations thought to be duplicates and excluded from further analysis. This will allow the development of improved approaches to duplicate identification, and the quantification of differences between versions of the same measurements due to past data management.
- Improved identification of data from sources likely to be useful for evaluation, such as OWS or RVs.
- Recovery of data and metadata that were not retained in past data formats.
- Extension of metadata through a comprehensive review of documentation.

A further advantage would come from a reprocessing of GTS accessions to better identify reports that should be replaced with higher quality data from delayed mode sources.

An Integrated Data System

As noted above, the observing system is made up of a diverse range of platforms, observing systems and data streams, each with their own issues. In order to efficiently use the observations in the generation of CDRs a number of basic requirements need to be met:

- Observations from identifiable sources at the platform level
- Instrument metadata (methods, error characteristics, etc.) associated with the observations
- Open data sources for reproducibility
- Consistent conventions and format used to represent the observations (and metadata)
- Timely access to the observations (and metadata)
- Redundancy of NRT data streams and archive access.

These requirements are beginning to be addressed for surface ocean data through a number of initiatives. For example, within JCOMM a database containing the instrumental and platform metadata for all observing platforms contributing to the JCOMM programs (e.g., VOS, DBCP, etc.) has been developed and populated. Similarly, a Marine Climate Data System is under development to improve the timely flow of delayed mode and real time data as well as promoting best practices and standards. For the VOS the JCOMM metadata database has been built based on the WMO Publication 47 metadata and, in part, been driven by development of the WIGOS and metadata requirements from the WIGOS Metadata Standard. Integrated data management and archival systems are needed for all components of the GOOS and GCOS providing ECVs for the construction of CDRs. WIGOS, if used fully, provides an appropriate framework for the provision of data and metadata together. Whilst the developments of the JCOMM and WMO systems has focused on operational data flows other systems are being developed for climate data. An

exemplar is the C3S Climate Data Store part of the European Union funded Copernicus Climate Change Service.

REFLECTIONS AND RECOMMENDATIONS

Reflections

The construction of CDRs for all ECVs has been made more difficult by the lack of availability of good platform and observational metadata. This has in the past been compounded by a focus on rather narrow user requirements, for example for NWP, reanalysis or satellite bias adjustment. This has led to a narrowing of the range of ECVs that are typically measured together, and in some cases to truncated data formats and lack of metadata. Each set of observations has a non-trivial error model and this is linked with everything done to the data. Understanding, documenting, and encoding in metadata everything relevant about the platform, instruments, observing protocols, coding and recoding helps to reduce the uncertainty in CDRs and enables reconciliation between different measurement types (GCOS, 2016).

New data systems under development, for example at JCOMM and for the C3S Climate Data Store, should enable the relevant information to be captured and provided to users. But having the ability to record metadata is only part of the story. Data providers need also to be diligent in ensuring that metadata are reported, and archival formats need to preserve it.

Compromises are inevitable when the needs of CDR construction interact with the needs of real users, particularly in the area of timeliness vs. quality. The impact of any compromise will be minimized if the data system understands these potentially conflicting needs from the start.

The decline in the number of VOS reports has had a severe and detrimental effect on the sampling for several ECVs, in particular MAT, humidity, winds, clouds, and waves. The resulting decline in the number of multivariate records also has an impact on ability to bias adjust and quantify uncertainty those ECVs that are reported.

Rescue through digitization of data and metadata are key to the extension and improvements of CDRs. In many cases the priorities for CDR construction are similar to those for applications such as reanalysis which target data sparse regions and periods. But other requirements for CDRs include recovery of metadata and documentation, high quality and consistent timeseries, data with measurements of the same ECV made by different methods, and might prioritize reports that do not contain pressure measurements.

User requirements for GCOS are typically expressed in terms of a required accuracy at particular spatiotemporal resolutions⁴. Requirements for CDRs are often described in terms of quite strict stability of anomalies over large space and time scales. An example is a need for SST data sets which are global and demonstrably stable to much better than $0.1^{\circ}\text{C decade}^{-1}$, ideally with deviations less than $0.01^{\circ}\text{C decade}^{-1}$. This has been achieved for satellite SST (Merchant et al., 2012) but requires complementary and independent data for evaluation. SST and winds are the only record for which the community is able to demonstrate compliance with stringent user requirements, and typically only for relatively short periods and limited regions (e.g., Verhoef et al., 2017; Berry et al., 2018). SST is the only ECV where there are multiple long term data products with uncertainty estimates which

Recommendations

	Recommendation	Outcome	To whom directed	Supporting information section
1	Extensions to observations			
1.1	The OceanSITES network of high quality time series data should be maintained as an ocean reference network and expanded to approximately double its existing number of sites.	Provision of adequate reference observations for a wide range of ECVs	Network managers Funding agencies	Reference observations Observations for evaluation
1.2	RVs evaluated as providing high quality measurements of ECVs should be managed as a reference network and field comparisons with OceanSITES data regularly performed.	Increased availability of high quality data for a wide range of ECVs	RV operators	Reference observations Observations for evaluation
1.3	All RVs should aim to contribute to the provision of ECVs for climate archives, keeping sensors running at all times whilst at sea. Data should be evaluated and RVs designated as providing data suitable for reference, baseline and global networks identified and managed appropriately.	Increased availability of high quality data for a wide range of ECVs	RV operators	Reference observations Observations for evaluation

(Continued)

Continued

	Recommendation	Outcome	To whom directed	Supporting information section
1.4	The coverage of ECV observations from VOS needs to be expanded, as coverage of observations of MAT, humidity, clouds, waves has substantially declined since the 1990s.	Adequate records of MAT, humidity, cloud cover, etc. for use in climate science	JCOMM VOS network managers GCOS	Understanding the needs of different applications Considerations when creating internally-consistent records for marine surface ECVs Global observations
1.5	Data rescue needs to be continued, designed to meet a wide range of user requirements.	Increased information content of long-term surface marine records to support higher resolution applications	GCOS Holders of relevant archive material Funding agencies	Data and metadata rescue
1.6	Continuation of a dual-view reference satellite sensor series (e.g., in the family of ATSR/SLSTR) in a stable orbit with fixed Local Equator Crossing Time.	Stable, accurate SSTs, particularly in the presence of dust or other high aerosol loading	Satellite agencies	Reference observations
2	Enhancement to data management and QC systems			
2.1	Distributed but interoperable data centers, affiliated with JCOMM should be established building on national activities, for the archival, quality evaluation and distribution of surface marine data from RVs. All RVs should run measurement systems continuously whilst at sea and contribute their data and metadata	Establishment of a WMO/IOC Global Data Assembly Centre (GDAC) for RV surface marine observations Increased availability of RV observations	Funding agencies GCOS	Reference observations Observations for evaluation
2.2	Distributed but interoperable data centers, affiliated with JCOMM should be established, collecting and archiving GTS data for all surface marine ECVs and EOVs. One center should have responsibility for integrating and evaluating GTS data across data centers for each platform type (e.g., ships, moored buoys, drifting buoys).	Establishment of Data Assembly Centres (DACs) and Global Data Assembly Centres (GDACs) for real time data, contributing to the JCOMM Marine Climate Data system. More consistency in GTS holdings	Funding agencies GCOS	Merging different sources and archives Reprocessing of existing archives
2.3	Ensure that data from new technologies (e.g., autonomous vehicles) and systems (e.g., AIS) have appropriate data management systems in place, recognizing the needs of downstream users including climate.	Avoidance of the need for future reorganization work Reduced uncertainty	Funding agencies	Introduction to an error model for individual observations Enhancing the observational archive
2.4	Review and enhance data and metadata management for networks established in support of NWP to ensure that observations of ECV meet the requirements for climate applications.	Avoidance of the need for future reorganization work Reduced uncertainty	Funding agencies JCOMM	Introduction to an error model for individual observations Enhancing the observational archive
2.5	Recognize the value in terms of enhanced data quality and traceability of the management of delayed mode archives by those with expertise with particular types of measurements and systems and ensure that adequate funding is provided for this.	Reduced uncertainty	Funders of Global Data Assembly Centres	The need for expert data system design and management
2.6	Multi-variate reports should be managed together, and data subsequently pushed to single variable repositories if required. It needs to be easier for users to select and access data subsets.	Improved access to data for users	Network data managers	The need for expert data system design and management

(Continued)

Continued

	Recommendation	Outcome	To whom directed	Supporting information section
2.7	Approaches to QC should be shared and open source code and systems for implementation developed according to best practice.	Reduction in uncertainty	QC developers	Quality control
3	Field evaluation of sensors			
3.1	The uncertainty of surface ECV data from all observing systems and instrument types should be quantified in the field, and periodically re-evaluated. Examples where such field evaluations are urgently required are: humidity from relative humidity sensors SST from hull sensors MAT sensors with remote reading	Better quantified uncertainty	Network managers	Observations for evaluation Humidity Sea-surface temperature Wind speed and direction
4	Improvements to ICOADS and the surface marine archive			
4.1	The data format used by ICOADS predates WIGOS standards, and needs updating (Freeman et al., 2019).	Better communication of metadata	ICOADS	Enhancing metadata
4.2	A reprocessing of ICOADS sources from the most original sources available. This will enable better identification of duplicate observations, vessel tracking, uncertainty estimation and the better identification of data from different types of observing system.	Reduction of uncertainty	ICOADS Funding agencies	Merging different sources and archives Atmospheric pressure Reprocessing of existing archives
4.3	A systematic review of documentation and coding practice for the accession of data into ICOADS should be undertaken alongside an evaluation of data and metadata content, to ensure that documentation, data and metadata are consistent.	Greater consistency in information Reduced uncertainty	ICOADS Funding agencies	Specialist observing ships Merging different sources and archives
5	User requirements			
5.1	Engage with user groups to establish their requirements, recognizing that resources are required both to gather those requirements and to establish whether or not they are being met.	Products better suit the needs of users Adequate observing system	Network operators Funding agencies WMO/GCOS/JCOMM	User needs for data and data products
5.2	Develop observing requirement statements in terms of network design including for observation accuracy, sampling, coverage, and accompanying metadata.	Improved information for observing network design and monitoring Adequate observing system	GCOS Funding agencies	User needs for data and data products
6	Research to improve quantification of bias and uncertainty in ECVs			
6.1	Research to quantify biases and uncertainty in surface marine ECVs and EOVs and to construct improved CDRs and other data products needs to be adequately funded.	Better quantified uncertainty Improved products	Funding agencies	Observational needs for reanalysis

enables us to also evaluate uncertainty estimates and state that uncertainties are underestimated (Kent et al., 2017; Davis et al., 2018).

AUTHOR CONTRIBUTIONS

EK and NR wrote the first draft of the manuscript. All authors provided text and comments and approved the final draft.

FUNDING

EK and DB were supported by the NERC under the grants NE/R015953/1 and NE/J020788/1. NR, JK, and KW were supported by the Met Office Hadley Centre Climate Programme funded by the BEIS and Defra. VG was supported by the Russian Ministry of Science and Education under the Project 14.W03.31.0006.

Over the past decade, measurements from the climate-oriented ocean observing system have been key to advancing the understanding of extreme weather events that originate and intensify over the ocean, such as tropical cyclones (TCs) and extratropical bomb cyclones (ECs). In order to foster further advancements to predict and better understand these extreme weather events, a need for a dedicated observing system component specifically to support studies and forecasts of TCs and ECs has been identified, but such a system has not yet been implemented. New technologies, pilot networks, targeted deployments of instruments, and state-of-the art coupled numerical models have enabled advances in research and forecast capabilities and illustrate a potential framework for future development. Here, applications and key results made possible by the different ocean observing efforts in support of studies and forecasts of TCs and ECs, as well as recent advances in observing technologies and strategies are reviewed. Then a vision and specific recommendations for the next decade are discussed.

Keywords: tropical cyclones, extratropical bomb cyclones, upper-ocean temperature, ocean heat content, global ocean observing system, weather extremes, natural hazards, coupled ocean-atmosphere forecasts

INTRODUCTION

Extreme weather events are natural hazards that affect marine and terrestrial areas around the world and are associated with different temporal and spatial scales (Elsner et al., 2008; Menkes et al., 2016; Zhou et al., 2018). Tropical cyclones (TCs) and their extratropical counterparts, often referred to as extratropical “bomb” cyclones (ECs), are deep low pressure systems that produce and sustain high intensity winds. TCs develop exclusively over the ocean (e.g., Knapp et al., 2010), while ECs predominantly form in the land-ocean margin, in the vicinity of western boundary currents (e.g., Sanders and Gyakum, 1980), and can also occasionally develop over land (e.g., Hakim et al., 1995). TCs and ECs are among the deadliest and most destructive types of extreme weather, often causing widespread damage due to strong winds, storm surge, and heavy precipitation. Understanding their dynamical mechanisms and having the ability to accurately forecast them is a critical societal need but remains a challenge.

The understanding of upper-ocean processes leading to extreme weather events has largely benefited from the climate-oriented sustained ocean observing system (e.g., Legler et al., 2015) and observational process studies. Clearly, ocean observations are vital in ECs and TCs research and forecasts, since they enable examining the details of air-sea interaction processes that can lead to the formation and intensification of these systems (e.g., Leipper and Volgenau, 1972; Sanders and Gyakum, 1980; Mainelli et al., 2008; Kuwano-Yoshida and Minobe, 2017). In addition, ocean observations have been increasingly acknowledged by the forecast community as a critical piece to improve extreme weather forecasts (e.g., Dong et al., 2017). Their important role will likely continue to increase in light of improvements in coupled model capabilities (see below), and future extreme weather projections, which expects intense weather systems to become more frequent (e.g., Colle et al., 2015; Bacmeister et al., 2018). In fact, more and more occurrences of record-breaking “Cat-6” types of TCs were observed over the last decade, with three Cat-6 storms ($> = 165$ kts) forming during 2008–2018 (Haiyan, November, 2013; Patricia, October, 2015; and Meranti, September, 2016), and no Cat-6 TCs recorded globally in the earlier decade during 1999–2008. These recent changes and projections in occurrence of intense TCs and ECs emphasize the need for a sustained observing system in support of extreme weather studies and forecasts.

Recent advances in research and ocean observing efforts during the past decade have largely addressed specific recommendations identified by the scientific community during OceanObs’ 09 (e.g., Goni et al., 2010) about key areas to focus in support of TC studies and forecasts. Since then, new technologies, pilot networks, and targeted deployments have further expanded the reach of the global observing system and have been used in weather analyses, outlooks, and improved ocean-atmosphere numerical forecasts models. For instance, (i) extensive synergies between the scientific and operational communities continue to facilitate transitioning of research results into operations (e.g., Shay et al., 2014); (ii) networks

specifically designed in support of TC studies and forecasts have been implemented (e.g., Domingues et al., 2015; Miles et al., 2015); (iii) targeted airborne profiling observations ahead of forecasted TCs have been extensively implemented (e.g., D’Asaro et al., 2014; Meyers et al., 2015; Jaimes et al., 2016; Zhang et al., 2018); (iv) substantial progress has been made toward understanding the role of upper ocean salinity (e.g., Balaguru et al., 2012a,b; Domingues et al., 2015) and temperature stratification (Price, 2009; Lin et al., 2013a,b; Balaguru et al., 2015, 2018; Glenn et al., 2016) in controlling TC intensity and development; (v) real-time assimilation of ocean observations into coupled weather forecast systems continues to provide critical information for improved ocean representation (e.g., Chen et al., 2017; Dong et al., 2017); and (vi) new, state-of-the-art, coupled numerical weather models have evolved and are now being used in experimental and operational forecasting modes (e.g., Kim et al., 2014).

On a broader context, recent advances in ocean observations in support of extreme weather were accompanied by an overall improvement of global coverage based on *in situ* and satellite ocean observations, and in their analysis. For example: improved sensor technology and satellite coverage enabled substantial advances in satellite altimetry (Verrier et al., 2018); satellite-derived salinity measurements (Meissner et al., 2018), now available with the launch of the Aquarius and the Soil-Moisture Active Passive (SMAP) missions, have produced unprecedented spatial coverage of sea surface salinity observations (Meissner et al., 2018); advances in *in situ* observing systems and networks (e.g., Foltz et al., 2019; Goni et al., 2019; Roemmich et al., 2019; Todd et al., 2019) have also enabled many groundbreaking research of the global oceans and climate system. In addition, community-wide efforts aimed at advancing data availability, and data assimilation within high-resolution numerical models through the US GODAE (Chassignet et al., 2009), the GODAE/Mercator-Ocean forecast system (Drévilion et al., 2008), and other similar efforts, have also provided significant advances in oceanic forecasting capabilities. Currently, there are also ongoing efforts from the Environmental Modeling Center (EMC) within the National Oceanic and Atmospheric Administration (NOAA) to implement a global data assimilation scheme into the Real-Time Ocean Forecast System (RTOFS), and a similar scheme more specifically in support of hurricane modeling systems. Some examples of such systems include the regional scale coupled HYbrid Coordinate Ocean Model – Hurricane Weather Research and Forecast (HYCOM-HWRF), and the HYCOM – Hurricanes in a Multi-scale Ocean-coupled Non-hydrostatic model (HYCOM-HMON). Additional details of such hurricane models are explored further in Section “Impact of Ocean Data in Tropical Cyclone Intensity Forecasts” of this manuscript.

In this community white paper, we describe some of the most important advances in the observational efforts in support of studies and forecasts of TCs and ECs since OceanObs’ 09, and present and discuss some potential enhancements to ocean observing strategies for the upcoming future, as well as provide specific recommendations. This manuscript is organized

as follows: Sections “Tropical Cyclones” and “Extratropical Bomb Cyclones” provide detailed descriptions of TCs and ECs, respectively, and discuss the role of the ocean in their genesis and intensification; in Section “Ocean Observations and Parameters in Support of Extreme Weather Studies and Forecasts,” key components of the ocean observing system, products, and pilot networks in support of TC and/or ECs studies and forecasts are described; Section “Highlighted Applications and Results” presents selected applications of ocean observations in support of research into TCs and ECs; in Section “Impact of Ocean Data in Tropical Cyclone Intensity Forecasts,” the impact of ocean observations in the forecast of TC is specifically addressed; Section “Data Management” describes recent advances and needs concerning data management; and in Section “The Vision for the Next 10 years,” the recommendations from the scientific community and the vision for the upcoming decade are provided.

Tropical Cyclones

A TC is a fast-rotating storm system that is characterized by a low pressure center that forms in the tropics. TCs are observed in seven ocean basins worldwide (**Figure 1**), namely the: North Atlantic, Northeast Pacific, Northwest Pacific, Southwest Indian, North Indian, Southeast Indian, and South Pacific. In the North Atlantic Ocean basin, for example, 11–12 named TCs, 6 hurricanes, and 2–3 major hurricanes develop between June and November in a typical year (e.g., Landsea, 1993). TC development is associated with unstable atmospheric conditions, which are primarily linked with boundary layer temperature [i.e., sea surface temperatures (SST) under the eyewall], and to a lesser extent to the upper-level temperatures (see discussion in Balaguru et al., 2015). In addition, favorable atmospheric conditions for TC genesis and intensification, in order of importance, include: (i) relatively little variation in the vertical profile of the environmental winds (low vertical wind shear); (ii) an atmosphere characterized by lower-level convergence and upper-level divergence; (iii) sufficient environmental mid- and upper-level moisture; and (iv) relatively slow (less than 8 m s^{-1}) deep layer steering. Favorable environmental conditions for TC intensification have been thoroughly documented in many studies (e.g., DeMaria and Kaplan, 1994; Knaff et al., 2005, 2018; Kaplan et al., 2010; DeMaria et al., 2014).

Under favorable atmospheric conditions, SSTs above 26°C are needed for development and maintenance of TCs (e.g., Leipper and Volgenau, 1972; Dare and McBride, 2012). The vertical structure of the upper ocean plays a key role in the intensification and weakening of TCs with both thermal structure (e.g., Leipper and Volgenau, 1972; Shay et al., 2000; Mainelli et al., 2008; Goni et al., 2009; Shay and Brewster, 2010) and stratification (e.g., Lin et al., 2008; Price, 2009; Balaguru et al., 2012a,b, 2015, 2018; Domingues et al., 2015; Emanuel, 2015; Huang et al., 2015; Seroka et al., 2016; Rudzin et al., 2017, 2018) being important. The upper ocean heat content (OHC) is an indicator of how much energy is potentially available for TC intensification, while the stratification can act as a barrier to TC-induced mixing, suppressing upper ocean cooling, and helping maintain enthalpy fluxes from the ocean into the TC. Intense upper ocean mixing events caused

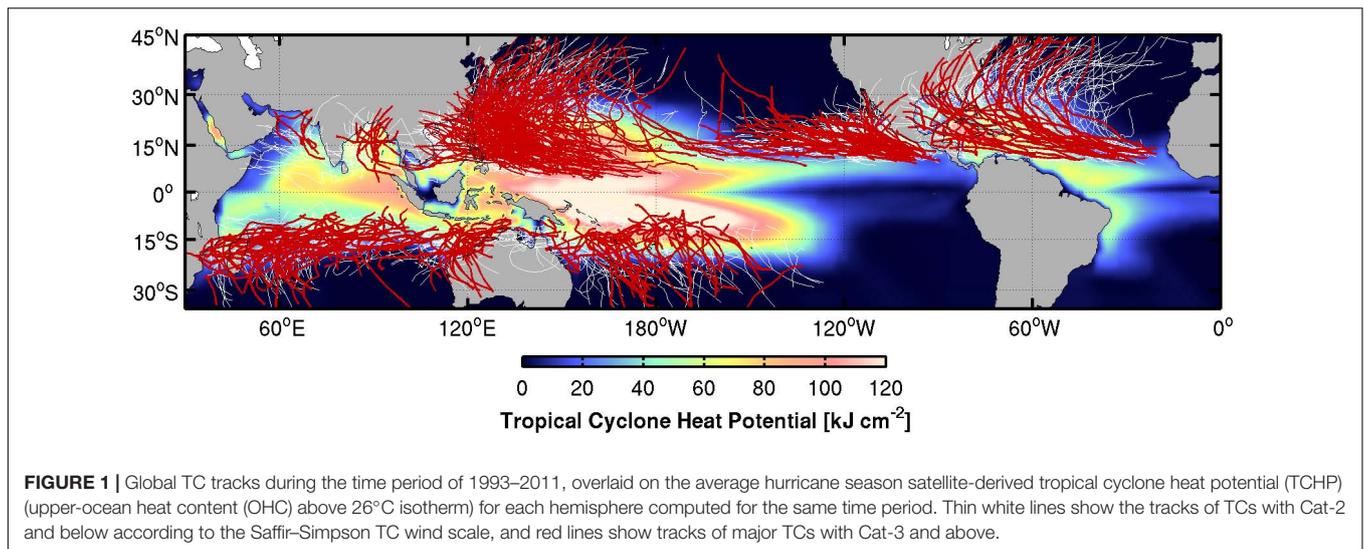

by the strong hurricane winds can quickly erode the thermal signature of subsurface warm or cold features (Pickard and Emery, 1990), leading to SST misrepresenting the ocean thermal energy, and potential TC intensity. Several studies (e.g., Mao et al., 2000; Shay et al., 2000; Ali et al., 2007, 2013; Mainelli et al., 2008; Lin et al., 2013b) demonstrated the importance of ocean thermal energy, represented by warm ocean features.

Tropical cyclone intensification involves the interaction of very complex mechanisms at a range of scales, such as internal TC dynamics, upper ocean interaction, and atmospheric circulation. Rapid intensification is often associated with TCs moving over warm ocean features (i.e., upper-OHC values larger than 60 kJ cm^{-2} , **Figure 2**), which maintain warmer SSTs (due to suppression of TC-induced sea surface cooling) near the convective center of the TC (Shay et al., 2000; Lin et al., 2005, 2009). The thermal energy across the sea surface is central to the enthalpy fluxes that transport heat and moisture from the ocean to the atmosphere, fueling the TC. For this reason, OHC estimates from a variety of datasets and methodologies are routinely used to provide operational guidance and carry out studies for intensity change and rapid intensification (e.g., Goni and Trinanes, 2003; DeMaria et al., 2005; Kaplan et al., 2010; Shay and Brewster, 2010; Meyers et al., 2014; Rogers et al., 2017; Knaff et al., 2018; Yamaguchi et al., 2018).

Despite these advances in understanding the role that the upper ocean plays in TC intensification, officially-issued short-term intensity forecast errors have not been significantly reduced over the past two decades in any basin (e.g., **Figure 3**; DeMaria et al., 2007, 2014). One of the factors contributing to the lag in improvement of TC intensity forecasts relative to TC track forecasts may be the lack of a dedicated ocean observing system with sustained and targeted ocean observations to correctly represent the ocean component in ocean-atmosphere coupled intensity forecast models. Nonetheless, operational intensity forecast tools and models have been improving and are starting to reduce official intensity errors (DeMaria et al., 2014), which may, in part, be due to improved atmospheric and ocean data assimilation (DA).

Extratropical Bomb Cyclones

An EC is an extratropical cyclone that undergoes rapid deepening of its low pressure by 24 hPa or more in a period of 24 h (i.e., ‘explosive cyclogenesis’; Sanders and Gyakum, 1980). This process is predominantly maritime, with seldom occurrences over continental land masses. Though they are typically winter events, and their genesis involves processes distinct from those associated with TC development, ECs produce winds as strong as hurricanes and are often associated with large rainfall and storm surges. Explosive cyclogenesis is mainly observed within the four basins, namely the Northwest Pacific, the North Atlantic, the Southwest Pacific, and the South Atlantic (Black and Pezza, 2013). Though ECs in the North Atlantic basin occur preferentially along the east coast of North America, in the vicinity of the Gulf Stream current (Sanders and Gyakum, 1980), several cases of ECs have occurred offshore of western Europe (e.g., Young et al., 1987; Burt and Mansfield, 1988). Additionally, ECs do occasionally occur over continents.

Examples include the “Cleveland Superbomb” in January 1978 (Hakim et al., 1995) and the more recent Colorado EC of March 2019.

Atmospheric baroclinic instabilities, upper-level vorticity coupling, and diabatic processes have been acknowledged as the main atmospheric mechanisms causing ECs genesis (Shapiro et al., 1999; Yoshida and Asuma, 2004; Kuwano-Yoshida and Asuma, 2008). Over the North Atlantic ocean, the number of explosive cyclogenesis events is modulated by the North Atlantic Oscillation (NAO), with positive NAO favoring a larger number of ECs due to stronger atmospheric baroclinicity (Pinto et al., 2009). Large-scale heat convergence linked with the Atlantic Meridional Overturning Circulation is also thought to influence atmospheric baroclinicity and modulate EC activity (Gómara et al., 2016). While these atmospheric and ocean conditions are mostly linked with the number of ECs developing, the strength, intensification and trajectory of the ECs are known for being directly influenced by upper ocean conditions (Kuwano-Yoshida and Minobe, 2017), with their genesis often associated with oceanic frontal systems. For example, the maximum frequency of explosive cyclogenesis and deepening is found to occur near the Kuroshio or the Gulf Stream; these oceanic western boundary currents are associated with large heat fluxes from the ocean to the atmosphere (Sanders and Gyakum, 1980; Ulbrich et al., 2009; Hirata et al., 2015, 2016, 2018; Kuwano-Yoshida and Minobe, 2017). Future projections suggest that strong ECs will tend to increase, while the total number of ECs is expected to decrease (Colle et al., 2015; Chang, 2017). Some of these climate model projections, however, cannot fully resolve sharp gradients linked with the Kuroshio and the Gulf Stream currents, and may lack in the accurate representation of the number of ECs forming (Haarsma et al., 2016). Further studies based on observations, or on high-resolution numerical simulations will likely be needed to confirm these trends.

In addition, the intensities of ECs that develop over warmer ocean regions are usually underestimated when compared to

those that develop over cooler ocean regions (Kuwano-Yoshida and Enomoto, 2013). This is because cloud condensation associated with latent heat release over warm ocean areas is more important for rapid development than the upper-level vorticity forcing (Catto et al., 2010). For example, recent analyses using satellite-based high-resolution SST measurements suggest that ECs are affected by SST fluctuations associated with fronts and mesoscale eddies around western boundary currents (Booth et al., 2012; Hirata et al., 2015, 2016, 2018; Kuwano-Yoshida and Minobe, 2017). Considering that the western boundary currents such as the Gulf Stream and the Kuroshio are warming more rapidly than the global average rate (Wu et al., 2012), the ocean’s effect on ECs generation is likely to increase in the future. With respect to ocean response to ECs winds, recent ocean simulations suggest that ECs can induce surface horizontal divergence and upwelling reaching depths of 6,000 m, which can impact the deep ocean circulation and ecosystems through mixing and biogeochemical transport (Kuwano-Yoshida et al., 2017).

OCEAN OBSERVATIONS AND PARAMETERS IN SUPPORT OF EXTREME WEATHER STUDIES AND FORECASTS

The Global Ocean Observing System (GOOS) provides measurements from a diverse suite of observing platforms that enable studies of the complex dynamics of extreme weather systems and help improve the overall skill of extreme weather forecast models. Accurate TC and EC forecasts based on coupled models, for example, require a correct representation of the upper-OHC, vertical density structure, and the mesoscale eddy field. This in turn requires upper ocean observations with high spatial and temporal resolution.

Analyses of ocean observations in the vicinity of TCs and ECs have led to improved understanding of their development and

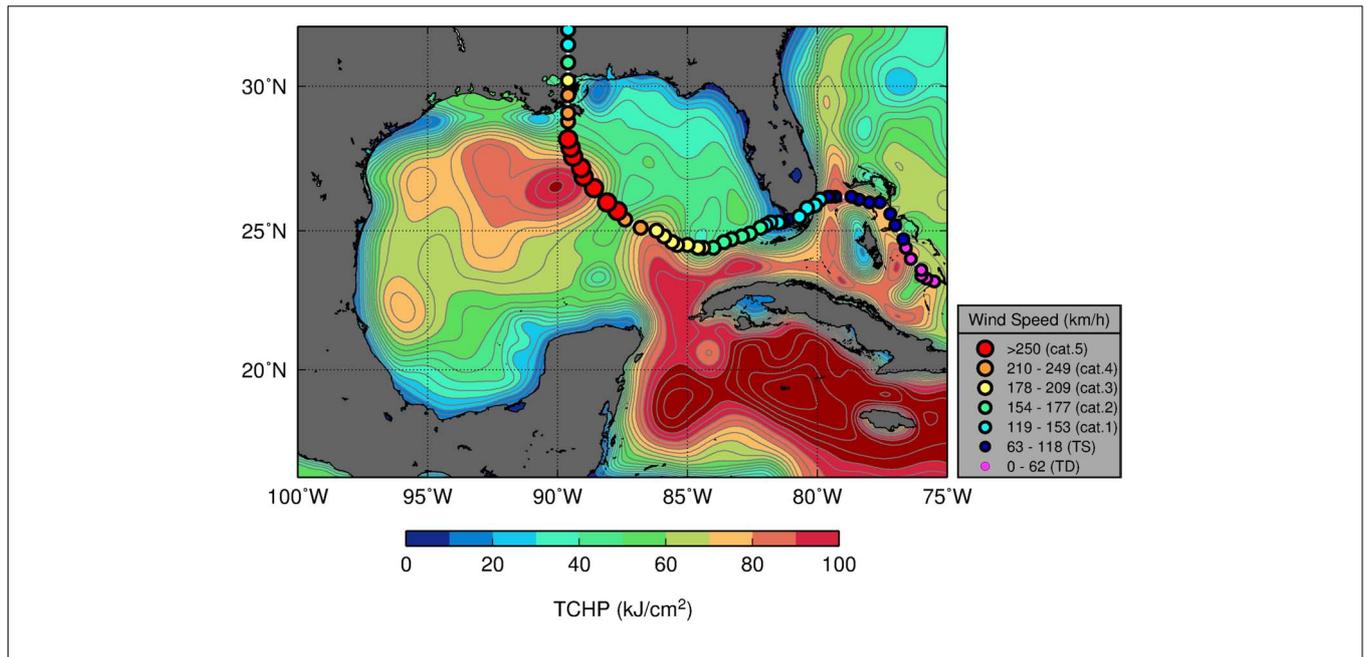

FIGURE 2 | Track of Hurricane Katrina (2005) overlaid on tropical cyclone heat potential (TCHP, upper-OHC) conditions in the Gulf of Mexico on 08/20/2005 (prior to the passage of Katrina). Gray contours are displayed every 5 kJ cm⁻² units.

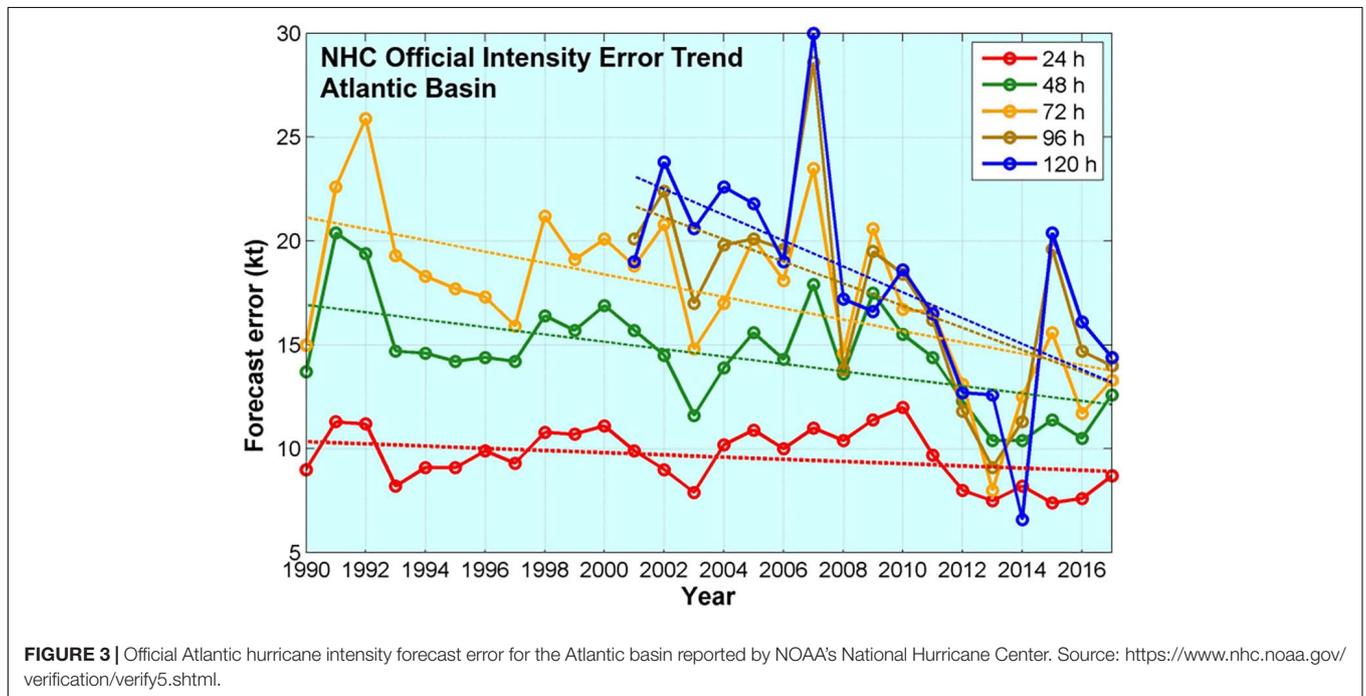

FIGURE 3 | Official Atlantic hurricane intensity forecast error for the Atlantic basin reported by NOAA's National Hurricane Center. Source: <https://www.nhc.noaa.gov/verification/verify5.shtml>.

intensification, which occur over distinct geographic domains and during different seasons. The GOOS includes several multi-national ocean observing efforts that support studies and forecasts of both TCs and ECs. While the observational requirements and needs for TCs and ECs are different, some of the observing platforms are used in support of studies on both types of storms, and some are specifically used to provide observations for TCs or ECs.

Here we discuss the importance of the integrated ocean observing system and of targeted ocean observations, focusing on their application to TCs and ECs. We also provide an overview of these various components based on several successful examples, which illustrate applications that are helping understand the dynamics of these extreme weather systems, and are also helping to improve the overall skill of their forecast. To be most effective for operational forecasting, observing

platforms should transmit their data in real-time via the Global Telecommunications System (GTS).

Ocean Observations

Satellites

Satellite-derived fields of SST¹ and sea surface height (SSH)² are used to estimate the upper-OHC (Leipper and Volgenau, 1972), which is sometimes also referred to as Tropical Cyclone Heat Potential³ (TCHP; Goni and Trinanes, 2003). The TCHP is defined as the excess heat content in the water column from the sea surface to the depth of the 26°C isotherm. TCHP fields can provide key qualitative and quantitative spatial information about areas where TCs may intensify, mainly by identifying the location and thermal characteristics of the oceanic upper layer, including warm eddies and current frontal regions (Meyers et al., 2014). For example, high values of TCHP (larger than approximately 50 kJ cm⁻²) have been shown to be linked to intensification of Atlantic hurricanes (e.g., Mainelli et al., 2008). It should be acknowledged, however, that TCHP from satellite-derived SST and SSHA can sometimes result in inaccurate estimates in regions that are strongly influenced by freshwater sources. In the Bay of Bengal, for example, where river water can persist in the near surface layer, salinity can have a dominant role in determining the subsurface density structure and the SSH (e.g., Yu and McPhaden, 2011); this can have a detrimental effect on the TCHP derived from satellite observations. Nevertheless, comparison of TCHP values derived from satellites and *in situ* observations in the Bay of Bengal has shown that satellite-derived estimates are generally unbiased, and estimates with a precision better than 20 kJ cm⁻² are often obtained (Nagamani et al., 2012).

Fields of SST and TCHP are routinely used by the NOAA National Hurricane Center (NHC) and the Joint Typhoon Warning Center for their subjective TC intensity forecasts and quantitatively in the Statistical Hurricane Intensity Prediction Scheme (SHIPS; DeMaria and Kaplan, 1994; DeMaria et al., 2005) and rapid intensification aids (Kaplan et al., 2010; Knaff et al., 2018). Notable examples of use of satellite fields to assess links between the ocean and hurricane intensification include Hurricane Opal (Shay et al., 2000), super-typhoon Maemi (Lin et al., 2005), Hurricane Katrina (**Figure 2**; Goni et al., 2009), and “killer cyclone” Nargis (Lin et al., 2009).

Underwater Gliders

Autonomous underwater gliders (Rudnick, 2016) provide measurements of temperature and salinity in the upper several 100 m and are becoming key components of the ocean observing system (Liblik et al., 2016; Testor et al., 2019). In addition to the standard measurements of temperature, salinity, and depth-average currents, gliders can be equipped to measure

current profiles (e.g., Todd et al., 2017), bio-optical properties, dissolved oxygen, and turbulent microstructure. Because of their adaptability and versatility, gliders fill important observational gaps in the ocean observing system (Liblik et al., 2016), particularly with respect to TC intensity forecasts. Glider observations are, for example, frequently assimilated into ocean-atmosphere coupled models and used for hurricane intensity forecasts. Sustained glider deployments monitor upper ocean conditions in areas frequently impacted by TCs (e.g., Domingues et al., 2015; Miles et al., 2015; Todd et al., 2018) and are part of the NOAA Hurricane Field Program⁴. Gliders also have particular utility measuring ocean processes on continental shelves before and during landfall of TCs, where alternative ocean observations are scarce (e.g., Glenn et al., 2016; Miles et al., 2017). In addition to measuring physical variables, gliders can carry specialized sensor payloads; sensors for key biogeochemical variables offer the promise of advancing our understanding of the role of TCs and ECs on ecosystems. For instance, dissolved oxygen measurements could help to characterize the storm-driven ventilation of subsurface waters in areas with oxygen minimum zones (e.g., the Arabian Sea; Morrison et al., 1999).

Since gliders move slowly (about 25 km/day) compared to most atmospheric cyclones *O* (300 km/day), actively piloting them into the paths of storms is generally not feasible due to the short lead times of forecasts. Thus, sustained deployment of gliders at locations prone to TCs or ECs (e.g., Domingues et al., 2015; Glenn et al., 2016; Perry et al., 2017) or along oceanic boundaries as part of boundary current observing systems (Todd et al., 2018, 2019; Testor et al., 2019) is preferable. Compared to rapid response deployments (e.g., Miles et al., 2015; Goni et al., 2017), sustained glider surveillance has the distinct advantage of providing critical high-resolution observations in the open ocean and over the continental shelf prior to storm arrival; these observations have been shown to improve the representation of the ocean in operational coupled forecast models of hurricane intensity (e.g., Dong et al., 2017). Most underwater glider data collected in support of Atlantic Hurricane studies and forecasts are transmitted in real-time to the GTS and U.S. Integrated Ocean Observing System (IOOS) underwater glider data assembly center⁵, and made available for immediate use by operational forecast centers.

Surface Drifters

Different types of drifters provide observations of ocean current velocities, SST, and sea level pressure (SLP) that are also used in support of weather forecasts, including TCs and ECs. Sustained global observations from drifters are used for constraining satellite SST errors and biases (e.g., Zhang et al., 2009) and have had a positive impact on global weather forecast throughout the troposphere thanks to assimilation of *in situ* SLP observations (Centurioni et al., 2017; Horányi et al., 2017; Ingleby and Isaksen, 2018). Horányi et al. (2017) showed that, in the case of intense cyclogenesis, SLP observations from drifters made

⁵U.S. Glider Data Assembly Center: <https://gliders.ioos.us/data/>.

possible large reduction in forecast errors, sometimes the largest among all the other assimilated observations. Furthermore, targeted deployments of drifters are sometimes carried out in front of TCs. During the Atlantic hurricane season, for example, Surface Velocity Program (SVP), Surface Velocity Program Barometer (SVPB) and Autonomous Drifting Ocean Station drifters (Centurioni, 2010; see also Centurioni, 2018, for a complete description of the drifter technology) are often air-deployed in front of TCs that may impact the US mainland. New drifters capable of measuring the directional wave spectra of surface gravity waves, termed Directional Wave Spectra Drifters (Centurioni et al., 2016, 2019) have also been deployed ahead of TCs. Successful deployments of various drifters have been carried out in the Atlantic Ocean during the following TCs: Fabian (2003), Frances (2004), Rita (2005), Dean (2007), Gustav (2008), Ike (2008), Isaac (2012) and Michael (2018), and in the western Pacific Ocean during Hagupit (2008), Jangmi (2008), Fanapi (2010), and Malakas (2010). In addition, drifters that are part of the Global Drifter Program⁶ array, often come close to TCs and provide valuable SST and SLP observations. In the 2013–2018 period a total of 116 SVP and SVPB drifters were located within 55 km of the tracks of systems that eventually developed into hurricanes (Centurioni et al., 2019). However, the effect of SLP drifter observation in improving TC track forecast has yet to be studied.

Air Deployed Profiling Instruments

Airborne profiling instruments are often deployed in targeted sampling mode in front of TCs in the Atlantic and Pacific basins. In the Atlantic, deployments of Airborne eXpendables Bathythermographs (AXBTs), Airborne eXpendable Conductivity Temperature and Depth (AXCTDs), and Airborne eXpendable Current Profilers (AXCPs) are generally conducted to sample ocean conditions ahead and under TCs as part of the NOAA Hurricane Field Program (Meyers et al., 2015; Jaimes et al., 2016; Zhang et al., 2018). Paired deployments of AXBTs and dropsondes, for example, provide collocated measurements of SST, air temperature, humidity and TC wind speed that allow for the estimation of bulk air-sea fluxes. Exchange coefficients used in such computations are based on direct flux data (Zhang et al., 2008). These data provide valuable information that is used to evaluate and improve TC model physics such as boundary-layer parameterizations (e.g., Zhang et al., 2015). In recent years, the following Atlantic TCs were sampled: Edouard (2014), Harvey (2017), Irma (2017), Maria (2017), Nate (2017), and Michael (2018). In the Pacific, paired deployments of AXBTs and dropsondes were also carried out during the 2010 Impact of Typhoon on Pacific (ITOP) international field experiment (D'Asaro et al., 2014, see section “The 2010 ITOP Field Campaign”).

More recently, the Air-Launched Autonomous Micro-Observer (ALAMO) (Jayne and Bogue, 2017) profiling float was developed to be deployed from an aircraft Sonobuoy-A size tube, similarly to AXBTs (Sanabia et al., 2013). A key distinction

between ALAMO floats and other airborne expendable profiling instruments is that these floats are capable of sampling 100s of profiles continuously before, during, and after the passage of TCs for up to 6 months, depending on instrument configurations. During the 2014–2018 period, a total of 60 ALAMO floats were deployed in support of the NOAA Hurricane Field Program in both the Atlantic and eastern North Pacific basins.

Profiling Floats

Profiling floats (e.g., Riser et al., 2016; Roemmich et al., 2019) offer the advantage of providing a sustained long-term and large-scale record of most of global oceans. Temperature and salinity observations from Argo floats⁷ are routinely assimilated into operational ocean models (e.g., Chassignet et al., 2009) that are used to initialize the ocean component of hurricane forecast models. In addition, operational Argo floats have been found to be very important in regions where routine and/or opportunistic airborne AXBTs observations are lacking, e.g., in the case of “Cat-6” supertyphoon Haiyan which devastated the Philippines in 2013 (Lin et al., 2014).

Profiling floats also offer valuable information of upper ocean processes contributing to ECs formation and intensification. The typical observation interval for individual Argo floats, however, is 10 days, which is generally too long to capture the rapid air-sea interactions associated with enthalpy fluxes and exchanges. High-frequency and adaptive fine scale profiling float sampling are generally needed to fully capture mesoscale ocean features usually associated with storm intensification, and also to characterize the storm-induced upper ocean response in detail. Argo floats under developing ECs were used to obtain 73 high-frequency profiles of the upper 700 m at 6-h intervals during the 2015/2016 and 2016/2017 winters. These data were critical to understanding ocean changes under ECs in the Northwestern Pacific (Kuwano-Yoshida et al., 2018) and emphasize the advantage of adaptive profiling float sampling using two-way communication systems. Observation interval and depth of modern Argo floats can be controlled using two-way satellite communication. Interactive operation of the floats with satellite and assimilated data enables high-frequency and high-resolution observation at fronts, i.e., the floats observe short interval if satellite and assimilated data suggest that the floats are located near the SST fronts. These *in situ* observations will complement satellite observations, increase temporal sampling, and enable resolving the fine structure associated with SST fronts that may help improve EC and TC forecasts.

In addition, expanding coverage of Biogeochemical Argo float observations also offer opportunities for evaluating phytoplankton response to mixing forced by TCs and ECs (e.g., Chacko, 2017) and studying the role that these extreme weather events play in ventilating subsurface waters in oxygen minimum zones. These new applications of profiling floats will enable detailed investigations of the upper ocean processes involved in EC intensification and the role that these extreme weather events play in the ocean biogeochemistry within their main formation basins, such as the Northwest Pacific and North Atlantic ocean.

EM-APEX (Electromagnetic Autonomous Profiling Explorer) Floats

EM-APEX were developed to measure profiles of upper ocean temperature, salinity and currents. Velocity estimates are based on measuring the voltage induced by seawater moving through the earth's magnetic field as first pioneered with expendable current profilers (Sanford et al., 1987; Shay et al., 1992) and later added to standard profiling floats (Sanford et al., 2007, 2011). EM-APEX floats were successfully air-deployed in front of Hurricane Frances (2004), during the ITOP missions in the western Pacific (2010), and more recently during Hurricane Michael (2018). The EM-APEX floats can profile to depths of 2000 m or over a specific depth region such as the mixed layer through the seasonal thermocline. Profiling configurations (i.e., sampling rate, and depth) can be changed via two-way Iridium communications, allowing for significant flexibility in an adaptive sampling before, during, and after storm passage, capturing air-sea interactions, and the oceanic response for several weeks following passage. For example, during Hurricane Michael (2018), a EM-APEX float sampled from 30 to 300 m during the storm at 1 h intervals to assess the role of current shear in vertical mixing processes to evaluate model parameterizations. With the high-resolution measurements, the evolution of the Richardson numbers could be determined at vertical resolution of 2–4 m in an active entrainment zone. In addition, the momentum flux from the surface wind stress into the surface mixed layer provides a method to back out the surface drag coefficient that are needed in examining the complex air-sea interactions that occur during TC passage (e.g., Shay and Brewster, 2010).

Biologging

It has also been used to collect *in situ* meteorological and physical oceanographic observations. Marine mammals (Campagna et al., 2000; Boehlert et al., 2001; Boyd et al., 2001), seabirds (Koudil et al., 2000; Watanuki et al., 2001; Charrassin et al., 2002; Wilson et al., 2002), sea turtles (Fukuoka et al., 2015; Narazaki et al., 2015) and fish (Block et al., 2001) have been adopted as autonomous samplers of oceanographic parameters such as temperature, conductivity and depth (Koudil et al., 2000; Block et al., 2001; Watanuki et al., 2001; Charrassin et al., 2002; Wilson et al., 2002; Fedak, 2013). These animals often live around western boundary currents and frontal systems where TCs and ECs are often observed (Figure 4). For example, biologging by sea turtles observed daily temperature profiles in surface layers in the northwestern Pacific (Fukuoka et al., 2015; Narazaki et al., 2015). The profiles were collected during 77 EC events in 6 consecutive winters. Both Argo floats and biologging captured rapid temperature changes under ECs. These ocean observations are crucial to identify near-surface baroclinic zones and ocean-atmosphere fluxes of heat and moisture. Such processes are crucial to the successful predictions and simulations of ECs.

Ocean Metrics for TC/EC Intensification Studies

Various parameters derived from *in situ* and remotely sensed observations that describe energy available in the upper ocean have been used to estimate the potential for TC and EC

development and intensification. The TCHP is one example, but it has dimensions that differ from SST and so cannot be used in place of SST in numerical models. Moreover, Price (2009) demonstrated that depth-averaged temperature is a more robust metric of hurricane-ocean interaction than is TCHP. Ali et al. (2015) then used satellite-derived TCHP and the depth of the 26°C isotherm (D26) to estimate ocean mean temperature (OMT) with a few assumptions. This OMT estimate was a better predictor for Indian monsoon rainfall than SST (Ali et al., 2015; Venugopal et al., 2018). Use of OMT in place of SST in numerical models offers potential for improvement in cyclone forecasting.

Thermodynamically, the subsurface ocean affects TCs through its control of TC-induced cold SST wakes. When the cold wake is weak (less than about 0.5°C), TCHP is a very good predictor of TC intensification, exceeding the skill of other predictors such as SST and vertically-averaged temperature (Figure 5; Balaguru et al., 2018). However, when the cold wake is strong (>0.5°C) (e.g., when SST is very warm and temperature stratification is shallow) ocean dynamic temperature (Tdy) performs significantly better (Figure 5; Balaguru et al., 2018). Tdy is defined as the ocean temperature averaged from the surface to the post-storm mixed layer depth, which depends on the upper-ocean stratification as well as the TC intensity and translation speed (Balaguru et al., 2015). An additional limitation of temperature-based metrics such as TCHP and OMT is that they do not account for salinity, which has been shown to be important in all TC basins (Wang et al., 2011; Balaguru et al., 2012b, 2016; Grodsky et al., 2012; Neetu et al., 2012; Domingues et al., 2015; Foltz and Balaguru, 2016). Satellite-based sea surface salinity measurements, when combined with subsurface *in situ* observations, can provide further information about the salinity stratification. This additional metric, when incorporated into Tdy may result in further improvements to statistical TC prediction schemes and enable more meaningful validation of operational ocean analyses and forecasts.

HIGHLIGHTED APPLICATIONS AND RESULTS

In this section, key results, sampling strategies, and applications of ocean observations in support of studies and forecasts of TCs and ECs are described. These case studies provide additional information on some of the successful examples of employing data derived from the GOOS, new pilot networks, and targeted deployments to enhance our understanding of the ocean-atmosphere interaction processes that can lead to TC and EC intensification.

The 2011 and 2012 Atlantic Hurricane Seasons: Hurricanes Irene (2011) and Sandy (2012)

Over the broad continental shelf of the Middle Atlantic Bight along the US East Coast, research carried out with gliders observations has shown that cool subsurface waters (i.e., the “Cold Pool”; Houghton et al., 1982) can be mixed with the

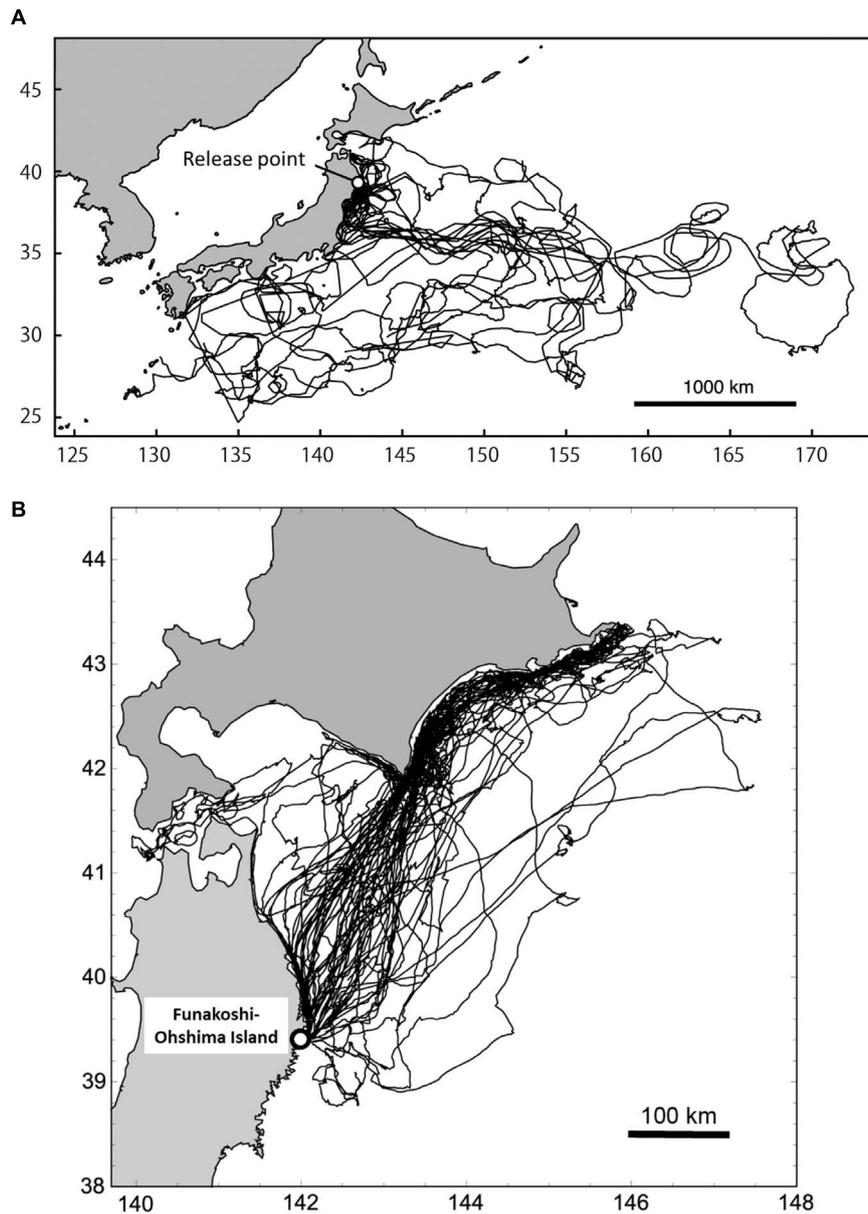

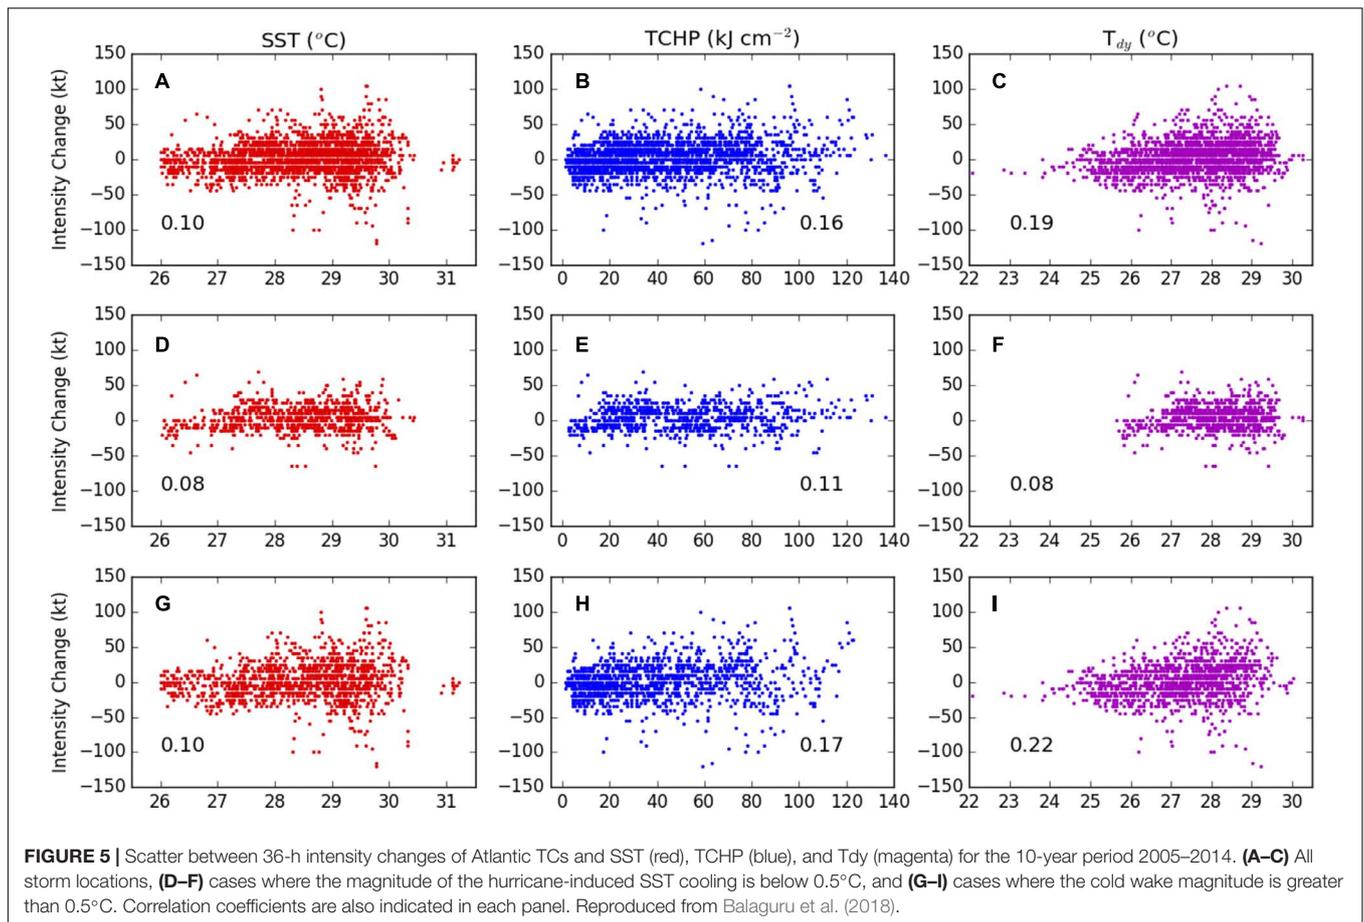

FIGURE 4 | (A) Satellite tracks of 15 loggerhead turtles released from Sanriku coast, Japan (open circle) between 2010 and 2014. **(B)** Tracks of 33 streaked shearwaters from a breeding colony in Funakoshi-Ohshima Island, Japan (open circle) between August and September in 2013 and 2014.

surface waters under intense wind conditions, thereby impacting storm intensity. Since the Cold Pool is obscured from the view of satellites, *in situ* observations, such as those obtained by gliders, are needed to capture its properties and impact on cyclone intensity (Glenn et al., 2016; Seroka et al., 2016). For example, a glider deployed ahead of Hurricane Irene (2011) observed larger than usual ahead-of-eye-center cooling of over 6°C (Seroka et al., 2016) caused by intense mixing of surface waters with cold subsurface waters forced by the hurricane winds. Subsequent ocean and atmosphere model sensitivity studies identified this process as the missing component necessary to capture Irene's rapid weakening just prior to landfall. In contrast,

glider observations collected during Hurricane Sandy (2012) showed that the storm winds were downwelling favorable and led to offshore advection of the subsurface Cold Pool waters, which prevented upper ocean cooling and favored the sustained intensity of Sandy (Miles et al., 2015, 2017).

The 2014 Atlantic Hurricane Season: Hurricanes Gonzalo (2014) and Fay (2014)

Studies carried out using all ocean observations, including those from underwater gliders, in the western tropical Atlantic and Caribbean Sea, were used to assess the pre- and post-storm

ocean conditions associated with Hurricanes Fay and Gonzalo (2014). When Hurricane Gonzalo passed north of Puerto Rico, the general background ocean conditions were provided by Argo floats and satellite-derived SST and SSH fields. In addition, there was one glider surveying upper ocean temperature and salinity structure in the vicinity of the projected path of Gonzalo (**Figure 6A**). This glider was the only observing platform to capture the presence of a 20-m-thick barrier layer (Domingues et al., 2015), a salinity stratified layer (e.g., Sprintall and Tomczak, 1992) within the deeper isothermal layer. This layer inhibited vertical mixing and limited surface cooling forced by Gonzalo's winds to only 0.4°C, allowing the storm to intensify to Cat-4 (Domingues et al., 2015). When Gonzalo subsequently crossed the path of Fay near Bermuda (**Figure 6A**), it weakened from Cat-3 to Cat-2 due to the upper ocean cooling of approximately 4°C observed in the wake of Fay (Goni et al., 2017).

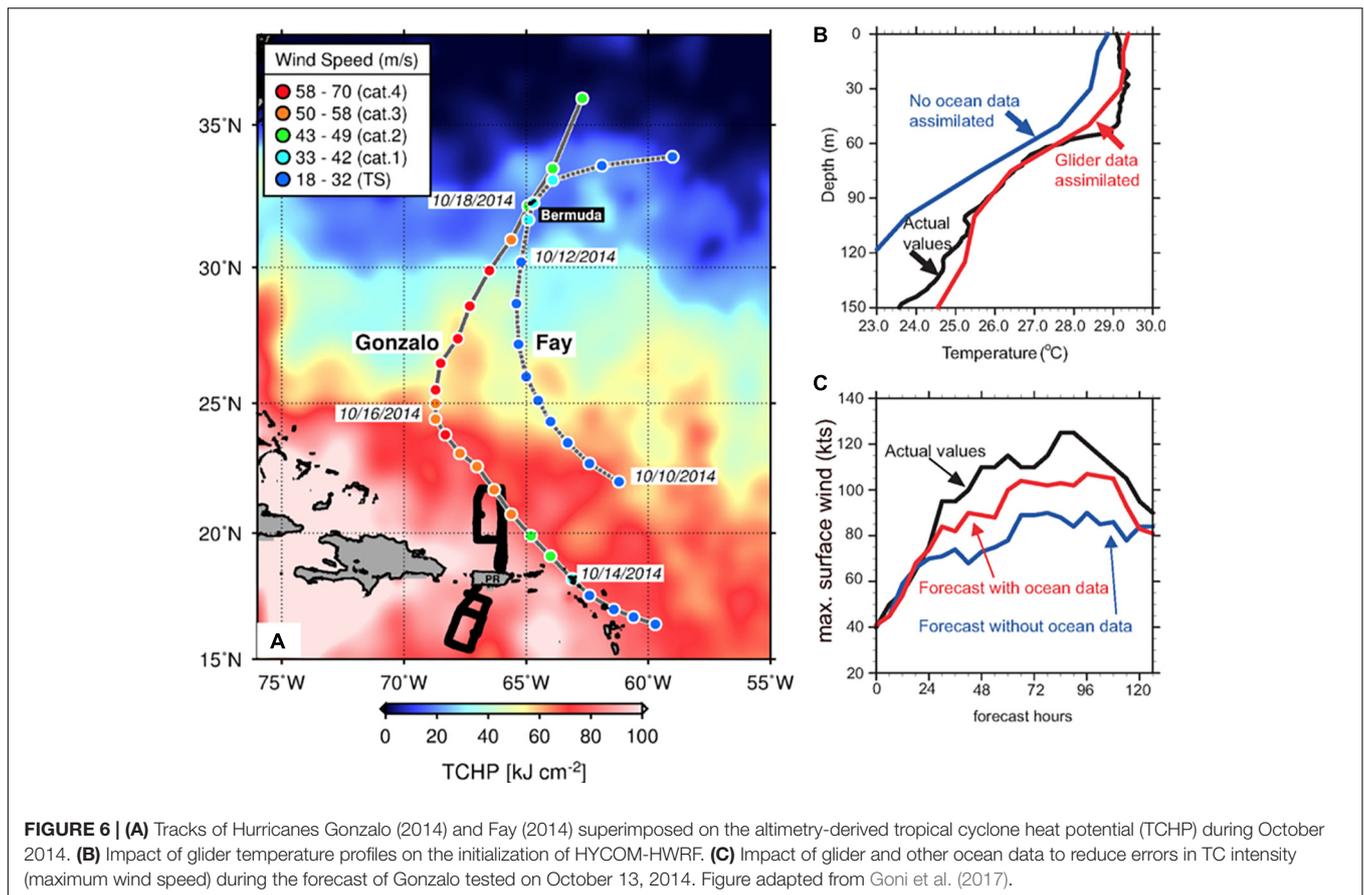

The 2017 Atlantic Hurricane Season: Hurricanes Harvey, Irma, Jose, Maria, and Nate

The 2017 Atlantic hurricane season was one of the most active in recent history with 17 named storms, and six major hurricanes. Underwater gliders, profiling floats, XBTs, airborne observations, and other observing platforms collected crucial ocean data to

assess upper ocean conditions and changes before, during, and after the passage of multiple hurricanes. Here we describe ocean observations and key results from Hurricanes Harvey, Irma, Maria, Jose, and Nate. Data from the ocean observing system were used in support of operational hurricane intensity forecasts.

In August, Hurricane Harvey developed in the tropical Atlantic and passed through the Caribbean Sea south of Puerto Rico. In this area, observations from one underwater glider showed that a relatively shallow mixed layer favored cooling of the upper ocean. Together with the moderate wind shear, this contributed to Harvey's lack of intensification within the Caribbean. Once Harvey reached the Gulf of Mexico, where TCHP derived from Argo floats was at a record level and SST exceeded 30°C (Trenberth et al., 2018), it intensified from a tropical depression (16 m s⁻¹/56 km h⁻¹ sustained winds) into a Cat-4 hurricane (59 m s⁻¹/212 km h⁻¹ sustained winds) in less than 48 h before making landfall along the Texas coast with devastating effects.

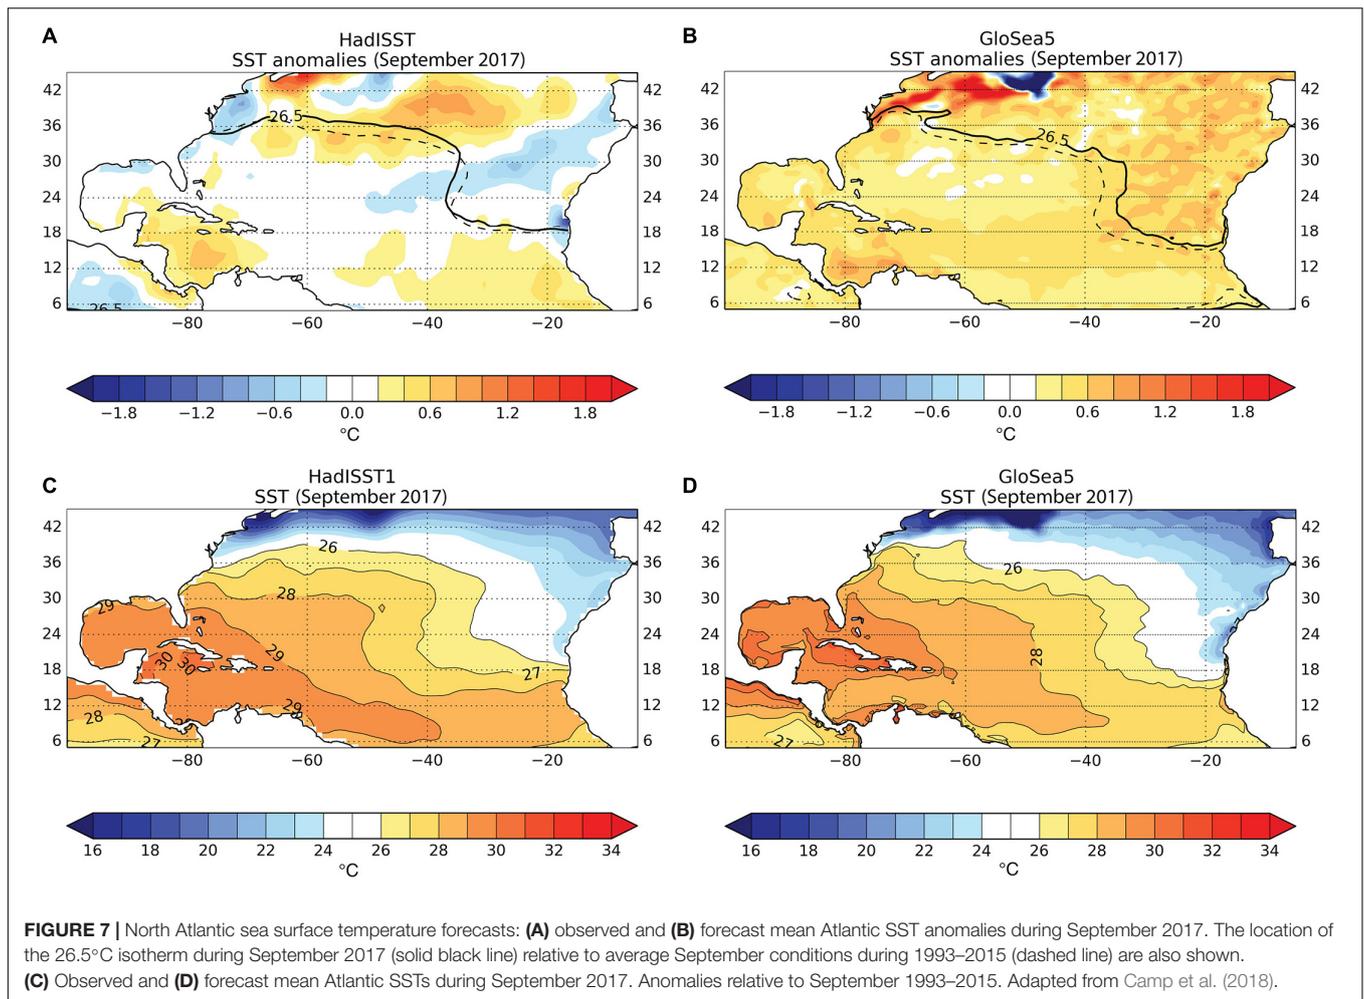

In September, SST values of ~30°C were observed across the western Atlantic and Caribbean (**Figure 7**), which, along with low wind shear, helped sustain the development and intensification of Hurricanes Irma, Maria and Jose (Camp et al., 2018). Hurricane Irma, the strongest TC globally in 2017, reached its maximum intensity (Cat-5) on September 6, while traveling over waters north of Puerto Rico and Hispaniola.

Observations from underwater gliders showed that a fresh water barrier layer ~ 15 m thick (**Figure 8A**) inhibited mixing between the upper ocean and colder underlying waters, similar to Hurricane Gonzalo (2014; Domingues et al., 2015; Dong et al., 2017). These observations also revealed that the upper 50 m of the ocean cooled by approximately 1°C as a result of storm-induced mixing. A few days after Irma, Hurricane Jose passed 2–3 degrees of latitude to the north of Irma's track. Jose's trajectory coincided with the cold wake left by Hurricane Irma, so it interacted with a relatively cooler and well-mixed upper-ocean as observed by underwater glider data. These cooler ocean conditions may have contributed to its weakening from Cat-4 to Cat-3. Later in the month, Hurricane Maria passed through the Caribbean Sea and then the same area as Irma in the tropical North Atlantic. Following a landfall in Dominica, Maria reached peak intensity on September 20 with maximum sustained winds of 78 m s^{-1} (280 km h^{-1}). Underwater glider observations revealed the existence of a very stable barrier layer that was approximately 30 m deep along the path of Maria (**Figure 8A**), providing favorable ocean conditions for intensification. On September 20, Maria made landfall in Puerto Rico as an intense Cat-4 hurricane. By the end of September, positive SST anomalies recorded before the passage of these hurricanes had dissipated due to the intense mixing caused by these major storms, and SSTs closer to neutral conditions were observed (**Figure 7A**). Farther north, Todd et al. (2018) used

glider observations and volume transport measurements in the Florida Straits to show that the Gulf Stream exhibited a large freshwater anomaly that was attributable to rains from Irma and also a transient reduction in volume transport that was attributable to wind forcing associated with the passing storm; further studies with numerical simulations are needed to better understand the dynamics of the storm impacts on the western boundary current.

In October, Hurricane Nate developed and steadily gained strength over warm waters of the northwestern Caribbean Sea. Once Nate reached the Gulf of Mexico, EM-APEX floats located near the projected track (**Figure 9**) were reprogrammed to profile every 2 to 4 h, returning vertical profiles of temperature, salinity, currents, dissolved oxygen, chlorophyll fluorescence, backscatter as a proxy of particle concentration, and chromophoric dissolved organic carbon. In addition, 140 AXCPs and AXCTDs were deployed from the NOAA WP-3D aircraft prior to, during and after Nate (**Figure 9**). These observations showed an upper ocean velocity response with magnitude of $0.5\text{--}0.75\text{ m s}^{-1}$ and rotation of the current vectors with increasing depth that led to strong current shear at depths of 40–60 m. The development of strong shear favored the deepening of the oceanic mixed layer under Nate by 10 to 15 m and mixed layer cooling of $1.5\text{--}2^\circ\text{C}$. The observed response was predominantly near-inertial in character, and likely impacted the air-sea fluxes and the intensity and structure of the storm (e.g., Jaimes et al., 2016).

Impact of Riverine Outflows on Tropical Cyclones

Areas in the Caribbean Sea and Tropical North Atlantic, where hurricanes commonly intensify, are sensitive to different freshwater sources, including major rivers such as the Amazon and Orinoco (e.g., Kelly et al., 2000; Balaguru et al., 2012a; Johns et al., 2014), and the Mississippi River (Goni and Domingues, 2019), which can contribute to the formation of barrier layers. In regions under the influence of strong fresh water sources, such as in the Bay of Bengal, low salinity conditions at the surface may sustain thermal inversions in the upper layer, which may further help suppress the TC-induced SST cooling (e.g., Sengupta et al., 2008). Barrier layers can be tens of meters thick, and have been indicated as a potential contributor to the rapid intensification of several TCs worldwide (e.g., Balaguru et al., 2012b).

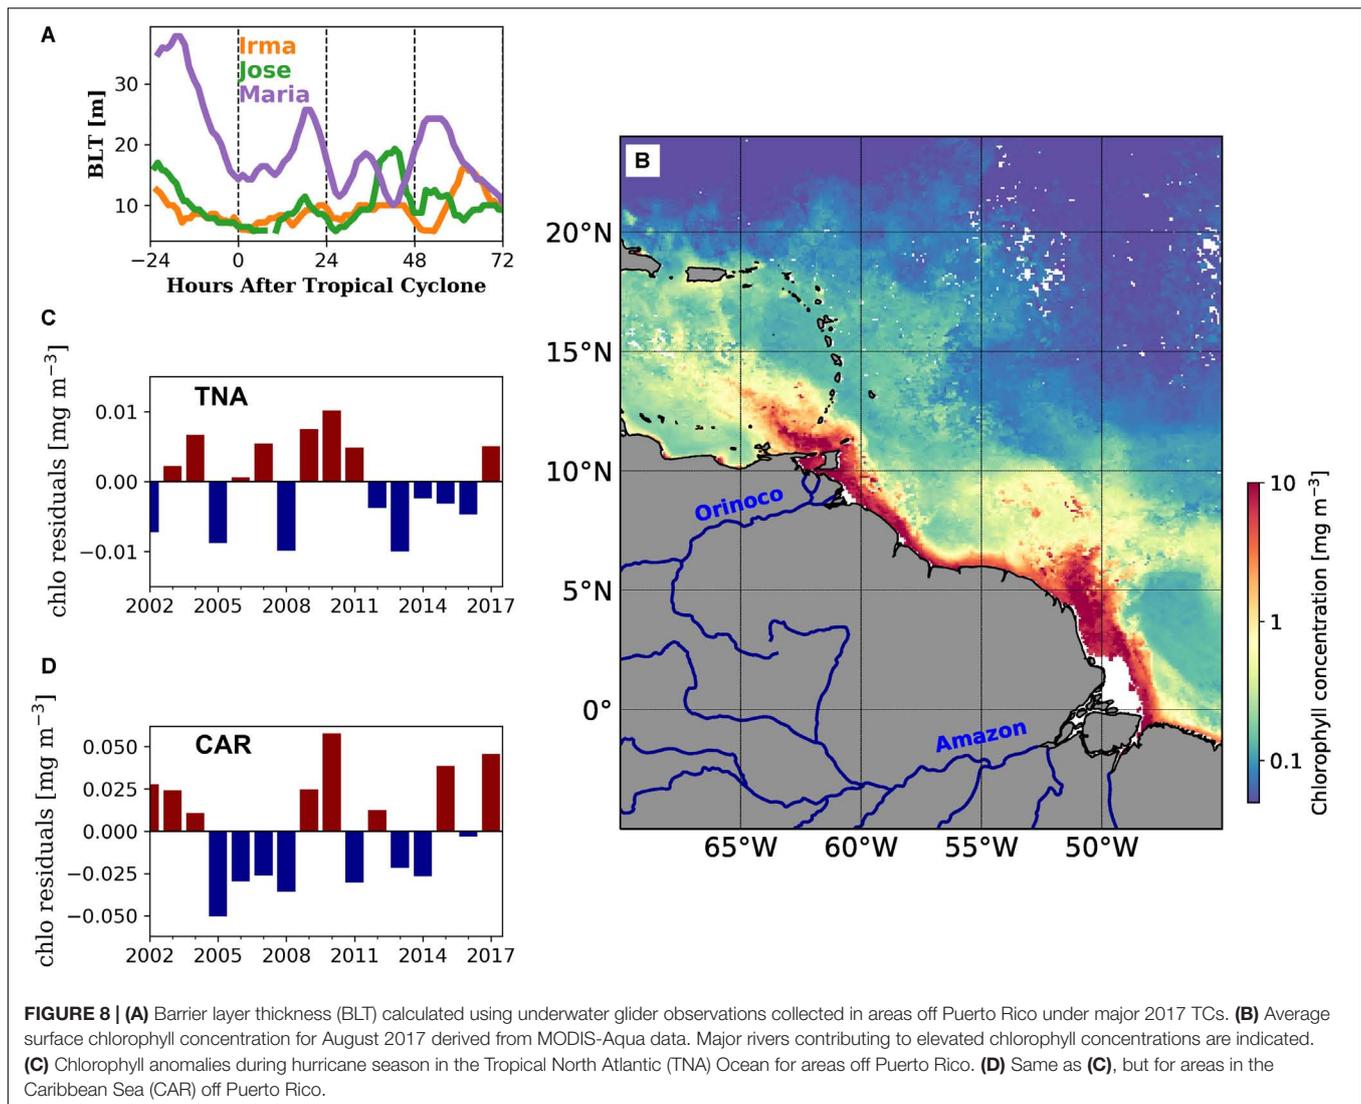

Several major Atlantic hurricanes in 2017 encountered pre-existing barrier layer conditions along their trajectories (see section “The 2017 Atlantic Hurricane Season: Hurricanes Harvey, Irma, Jose, Maria, and Nate,” **Figure 8A**). Analysis of satellite-derived chlorophyll data⁸ for August 2017 (**Figure 8B**)

⁸NASA Ocean Color website: <https://oceancolor.gsfc.nasa.gov/>.

indicates that freshwater plumes from the Amazon and Orinoco rivers were advected into the Caribbean basin, contributing to barrier layer formation. Comparison with historical chlorophyll data for the tropical North Atlantic Ocean and Caribbean Sea (**Figures 8C,D**) suggests that entrainment of freshwater plumes from these rivers into the basin-scale circulation in 2017 may have caused unusually strong freshwater transport into these areas. While investigation is still ongoing to assess the potential impact of these freshwater conditions on the 2017 hurricanes, these results emphasize that the correct representation of salinity conditions within coupled TC forecast models can be key to produce accurate hurricane predictions. This may be especially true for areas that are particularly sensitive to large freshwater sources, such as the Caribbean Sea, Gulf of Mexico, and tropical North Atlantic Ocean.

Development of Biologging as an Ocean Observation Platform for ECs

Flight and drift paths of sea birds soaring and floating over the ocean surface enable measurement of fine-scale winds and currents. Yonehara et al. (2016) and Goto et al. (2017) found

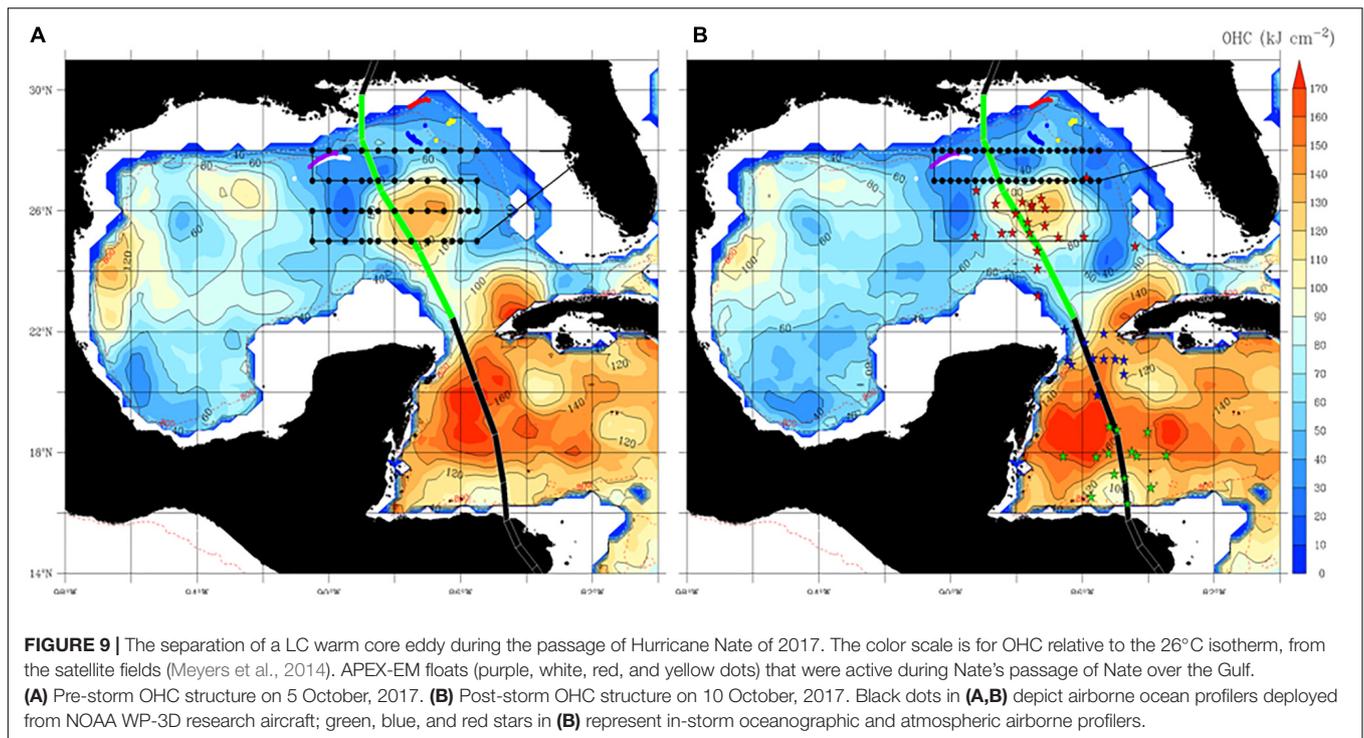

out that fine-scale flight trajectories by recording one position per second and minute provide 5-min to 1-h interval surface wind direction and speed along the trajectories. The bird-estimated wind directions showed good agreement with those from satellite, although wind speeds were slower than satellite winds because sea birds flew at lower altitudes than 10 m at which satellite winds were calibrated. Only the wind estimates from three birds had meaningful impact on data assimilation when severe rainfall occurred in Japan associated with two typhoons using regional numerical forecast system (Wada et al., 2017). Yoda et al. (2014) developed a new method for obtaining *in situ* ocean current measurements by using sea birds with GPS/GNSS loggers floating at the surface as Lagrangian current sensors akin to drifting buoys. The sea birds forage boundary areas between two oceanic mesoscale eddies where primary productivity and prey density are thought to be high. The current data from sea birds improved reproducibility of eddies through data assimilation into an operational ocean nowcast/forecast system (Miyazawa et al., 2015).

Biologging of temperature and salinity measurements derived from turtles also has the potential for improving numerical simulations in support of EC forecasts. Loggerhead turtles, for example, favor waters warmer than 15°C, which corresponds to the northern edge of the Kuroshio and its extension near the surface in winter. A feasibility study for data assimilation of temperature measurements by the turtles suggests that the turtle measurements captured the warm core rings separating from the Kuroshio Extension better than the Oyashio intrusion branches (Miyazawa et al., 2019). The improved ocean representation of such features may allow for better EC forecast through a more accurate simulation of air-sea interaction fluxes associated with these warm ocean rings and meanders.

The 2010 ITOP Field Campaign

The ITOP international field campaign in the western North Pacific Ocean is an important example for future field observation strategy and planning (Figure 10; D'Asaro et al., 2014). The western North Pacific was chosen because this basin is where

the largest number and the most intense TCs are usually recorded (**Figure 1**). In the summer of 2010, the ITOP field campaign used targeted aircraft AXBT observations to collect the pre-storm temperature profiles ahead of three TCs of distinct intensity: Megi, Fanapi, and Malakas. Supertyphoon Megi (with peak intensity $82 \text{ m s}^{-1}/296 \text{ km/h}$, Cat-5) was the most intense TC recorded globally until 2010, while Fanapi was a Cat-3 moderate TC and Malakas was a Cat-2 TC. The pre-TC ocean conditions were different for these three TCs (**Figure 11A**). Among the three, Megi intensified over warm ocean temperatures, characterized by TCHP values larger than 140 kJ cm^{-2} , and D26 of 120 m. In contrast, both Fanapi and Malakas traveled over waters with shallower D26 and TCHP values lower than 100 kJ cm^{-2} . Analysis of the available ocean observations revealed that these large differences in upper-OHC played a key role in the intensification of these TCs (Lin et al., 2013a; D'Asaro et al., 2014).

In addition to assessing the pre-TC ocean conditions using AXBT profiles, the paired ocean-atmosphere observations during TC intensification were also collected. These observations were used to evaluate the SST and air temperature at the TC core (**Figure 11B**), and their derived air-sea sensible and latent heat fluxes. The correct representation of these fluxes is needed to obtain accurate TC intensification forecasts. Direct observations of air-sea fluxes were obtained deploying co-incident/co-located atmospheric dropsounders and ocean AXBTs during TC-penetration flights (see **Figure 11C**). With these unique observations obtained during ITOP, accurate air-sea sensible and latent fluxes were obtained (Lin et al., 2013a; D'Asaro et al., 2014), revealing that enthalpy fluxes were substantially larger during Supertyphoon Megi as it reached Cat-2 (**Figure 11C**)

and then continued to intensify into a Cat-5 Supertyphoon. Results from ITOP emphasize the value of paired, co-located, ocean-atmosphere observations to improve model prediction performance and for improving our understanding on the role that different types of ocean conditions can play in the TC intensification processes.

IMPACT OF OCEAN DATA IN TROPICAL CYCLONE INTENSITY FORECASTS

A variety of observations collected near TCs in recent years have impacted the fidelity of TCs forecasts, typically by reducing errors and biases in analyses used to initialize the ocean component of coupled prediction models. For example, Halliwell et al. (2011) analyzed the impact of multiple factors toward reducing errors in HYCOM ocean analyses in the Gulf of Mexico prior to Hurricane Isaac (2005). They determined that assimilation of ocean observations is a leading-order factor in reducing initialization errors in comparison to ocean model attributes such as vertical mixing and surface flux parameterizations, along with model resolution.

More recently, Dong et al. (2017) conducted observing system experiments (OSEs) focused on the influence of conventional ocean observing systems plus underwater glider data on prediction of Gonzalo's intensity. A twin experiment was performed comparing an analysis that assimilated underwater glider data from July 15 to October 13 along with other *in situ* and satellite observations to an analysis produced by an unconstrained (ocean observations not assimilated) model simulation. These two analyses were then used to initialize the

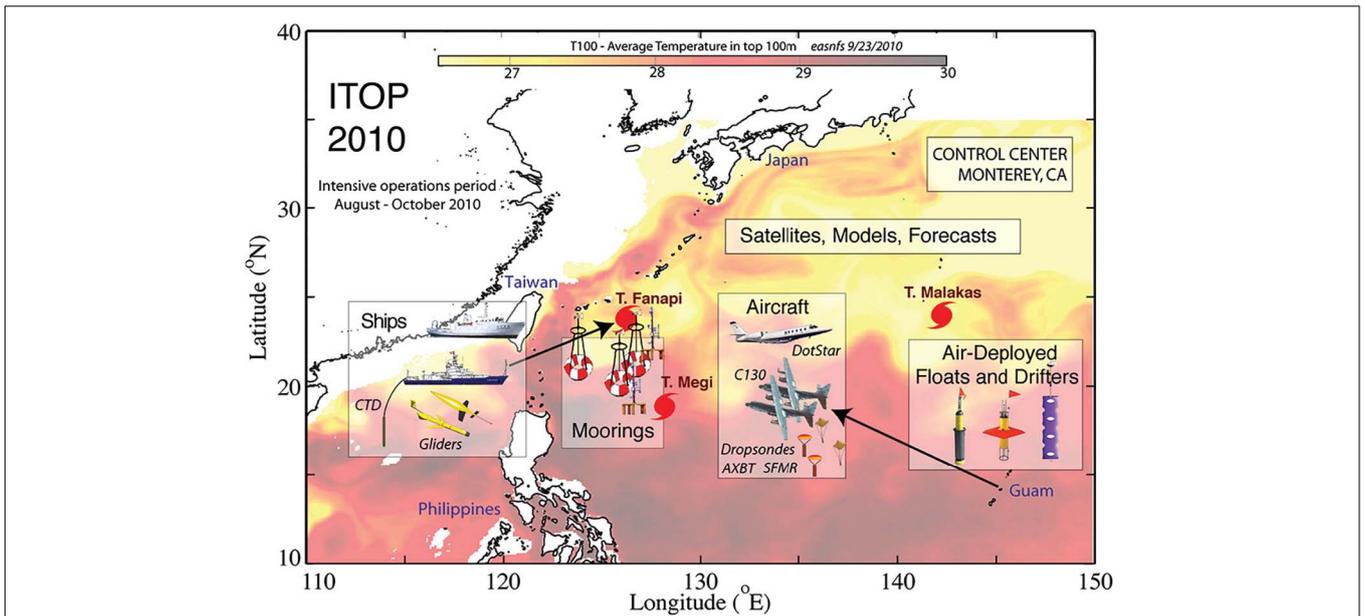

FIGURE 10 | Background color map of average temperature for the upper 100 m (T100) from the East Asia Seas Nowcast/Forecast System on 23 September, 2010. Overlaid are graphical representations of the ITOP operations area, experimental tools, and strategy. Locations of the three major ITOP storms at the time of maximum sampling are shown by storm symbols. Figure originally from D'Asaro et al. (2014), © American Meteorological Society. FIGURE 11 | Evolution of temperature and air-sea fluxes for three ITOP TCs (Megi, Fanapi, and Malakas). **(A)** Pre-TC temperature profiles from ARGO floats. **(B)** Symbols: SST and air temperature at the core of each TC as measured by dropsonde/AXBT pairs. Lines: results of an ocean model (Price et al., 1994) driven by the observed TC (solid) and extrapolated to higher wind speeds (dashed). **(C)** As in **(B)**, but for estimated total enthalpy flux (after Lin et al., 2013a).

high-resolution HWRF-HYCOM coupled forecast system (Dong et al., 2017). Assimilation of subsurface observations from gliders improved the representation of pre-storm vertical structure of both temperature (Figure 6B) and salinity, capturing the barrier layer previously observed in the region (Domingues et al., 2015). Consequently, forecast intensity errors (e.g., Figure 6C) were reduced by approximately 50% as a result of assimilating all available observations, enabling a substantially improved forecast for Hurricane Gonzalo.

Observing system experiments are now being conducted for the 2017 North Atlantic hurricane season. The fields of mean TCHP and D26 presented in Figure 12 demonstrate the impact of assimilating all ocean profilers (Argo and Alamo floats plus underwater gliders). Comparing fields produced by an unconstrained model simulation (Figures 12C,D) to observation-based estimates provided by the NOAA/AOML TCHP analysis product (Figures 12A,B), the unconstrained model produces TCHP that is too small and an upper-ocean warm layer that is too thin across the entire North Atlantic hurricane development region. Assimilation of all available ocean

profiles (Figures 12E,F) substantially corrects these large-scale biases. The planned next step in this analysis will be to assess the impact on intensity prediction by using these fields to initialize the HYCOM-HWRF forecasting model.

Observing System Simulation Experiments (OSSEs) have also been performed over the North Atlantic hurricane region. Given that the Nature Run, a validated, unconstrained, and realistic ocean simulation by a state-of-the-art ocean model, is known, it is possible to evaluate new observing systems and alternate deployment strategies for existing systems. Previous OSSEs have quantitatively assessed the positive impacts of existing observing systems and different deployment strategies for systems, such as underwater gliders and picket-fence deployments of thermistor chains (Halliwell G. R. H. et al., 2017), and also for pre-storm airborne ocean profiler surveys (Halliwell G. R. et al., 2017). More recently, OSSEs were performed to demonstrate the advantages of collecting ocean profiles from moving platforms such as gliders compared to collecting profiles from stationary platforms. These results are summarized by Fujii et al. (2019). Moving forward, OSSEs will continue to be an important tool

for the design and implementation of optimized ocean sampling strategies in support of both TCs and ECs forecasts, while OSEs will also continue providing further quantitative information on the impacts of different components of the existing ocean observing system.

DATA MANAGEMENT

Efficient data management, including data transmission is critical for ensuring observations are available in real-time or near-real-time for assimilation into forecast models. Latency in data availability can have unwanted downstream effects on the use of observations for operational purposes.

For weather forecasting, it is critical that Data Assembly Centers (DACs) and operators transmit data in real time to systems such as the GTS to ensure data availability for forecasters and to validate models. In order to make the data available for assimilation into forecast numerical models, most of the data obtained by the different observational platforms considered here need to be transmitted in real-time or near-real time through different satellite networks. After reception on land, the data typically undergo platform-dependent quality assurance (QA) and quality control (QC) procedures that are designed to identify possible inaccuracies in the observations. For most platforms these QA/QC procedures include tests designed to identify data gaps or missing values, spikes or unrealistic gradients in the data, and invalid dates or locations, among other error sources. The data are normally not modified during QA/QC, but individual records are flagged according to the results of the tests applied, or the data from a malfunctioning platform may be blacklisted and removed altogether from GTS distribution. The data are then encoded into different traditional alphanumeric formats (e.g., FM 63-XI Ext. BATHY for XBTs and AXBTs, FM 64-XI Ext. TESAC for Argo floats and underwater gliders; World Meteorological Organization (WMO), 2015a – Part A), or into binary universal form for the representation of meteorological data (FM 94-XIV BUFR, World Meteorological Organization (WMO), 2015a – Part B). For example, the data format TM315009 is used by the Lagrangian Drifter Laboratory at the Scripps Institution of Oceanography, by MeteoFrance, and by the UK Met Office for their contribution to the Global Surface Drifter Array, and for submission into the GTS (World Meteorological Organization (WMO), 2015b) for near real-time distribution and numerical model assimilation. Other data centers includes the Global Temperature and Salinity Profile Program (GTSP; XBT, Argo floats, underwater glider), the U.S. IOOS Glider Data Assembly Center (GDAC), and NOAA/NCEI (XBT, Argo, underwater glider) as part of long term archival and for distribution for other delayed-mode scientific applications. At this step the data may be submitted to delayed-mode QC that may result in flags for individual records or in modifications to the data set to ensure the highest possible data quality for all applications.

For research and retrospective analysis, data management is important to ensuring collected observations from various platforms, operated by diverse organizations, is easily available,

QA/QCed, and compatible with relevant standards. DACs can be leveraged to provide a diverse observation platform community a single place to store, share, archive, and quality control their data. In addition to providing standardized, easy to access, QA/QCed ocean observations critical for extreme weather events.

THE VISION FOR THE NEXT 10 YEARS

Ocean Observations in Support of Tropical Cyclones Studies and Forecasts

An integrated multiplatform ocean observing system for studies and forecasts of TCs is not currently in place. Analysis of ocean observations from the largely climate-focused ocean observing system often provides valuable information on the mechanisms and processes associated with these extreme weather conditions. Ocean data in support of extreme weather events need to focus on resolving upper ocean features such as barrier layers, spatial variability of warm currents, mesoscale OHC changes, and surface waves (Centurioni et al., 2019) prior to and during the season in each basin where TCs occur, with distribution of data in real-time. However, the scientific and operational requirements of observing platforms, such as profiling floats (Roemmich et al., 2019), moorings (Foltz et al., 2019; Masumoto et al., 2019; Smith et al., 2019), and expendable probes (Goni et al., 2019), do not explicitly target these needs. Sustained and targeted high-resolution ocean observations provide a means to better understand the processes responsible for the rapid evolution of the ocean and its feedback on the atmosphere during these extreme weather conditions. These concerns have been presented and discussed in workshops on TCs from a global perspective, as for example where WMO Recommendations focused on structure and intensity of TCs (Shay et al., 2014).

Pilot networks of sustained multi-platform observations and targeted observations in the tropical Atlantic during hurricane season have proven to provide key upper ocean observations to initialize numerical ocean-atmosphere coupled forecast models in areas where TC intensification and weakening may occur. The assimilation of ocean observations allows for a better representation of ocean conditions within coupled TC forecast models, which in turn provides a more realistic simulation of air-sea interactions and flux exchanges, generally resulting in an improved TC intensity forecast (e.g., Chen et al., 2017; Dong et al., 2017). OSEs (e.g., Dong et al., 2017) need to be extended to more storms in order to provide a more robust estimate of the benefit of various types of observations. These experiments should ideally be performed using operational models so as to quantify the benefit of ocean observations in operational conditions. Furthermore, the OSSE approach dedicated to hurricanes should continue to be followed in order to optimize the deployment of dedicated TC ocean observations, typically gliders and air-deployed profilers. Carrying out OSSEs and OSEs to design, implement, and assess the impact of new sustained components within the ocean observing system (e.g., underwater gliders, profiling floats, drifters, etc.) will be key to continued improvement of TC intensity forecasts, since significant errors still remain in data-assimilative ocean analyses due to existing

observations being scarce in space and time. Improvements in spatial and temporal coverage of ocean observations should improve the ocean representation within coupled TC forecast models, which in turn will allow for better forecasts. Targeted ocean sampling, when appropriate, also has the potential to help improve TC predictions (e.g., Chen et al., 2017). In addition, improvements in data availability for the forecast community are also essential for ensuring that ocean observations reach operational forecast centers in real-time. In one effort to help with this requirement, the EMC and the National Data Buoy Center (NDBC) within NOAA are working to increase the frequency of data transfer to the GTS.

For the next decade, coupled model systems will extend to multi-way dynamic coupling. In recent years, NOAA/EMC has demonstrated three-way dynamic coupling with HYCOM-WaveWatchIII-HWRF model. This would allow for revisiting air-sea interaction dynamics in greater detail, and also exploring observational measurements to support research and simulations. The importance of air-sea flux exchanges to TC development is widely known, yet simulations are still based on bulk parameterizations. To support evolving modeling efforts, observational efforts should accordingly extend to collecting data on waves, sea spray, roughness, turbulence, and relative humidity over the ocean. For example, measurements derived from turbulent microstructure sensors, such as those based on underwater gliders (e.g., St. Laurent and Merrifield, 2017) and moorings (e.g., Warner et al., 2016) will help obtain direct measurements of diapycnal heat flux and temperature diffusivity that can be used to develop, assess, and validate turbulent mixing schemes employed in coupled forecast models.

Expansion of sustained and targeted upper ocean observations in locations where TCs often intensify is one of the best strategies to support hurricane studies and forecasts. Underwater gliders and other autonomous vehicles offer one option for carrying out sustained surveillance in support of TCs studies and forecasts, given that these vehicles can be remotely operated along predetermined routes, they can provide observations in real-time continuously for several months, they withstand hurricane-force winds, and they can be refurbished and serviced for multi-year applications. Targeted and rapid-response observations also provide critical information that instruments surveying in sustained mode cannot. For instance, air-deployed instruments are particularly useful since they are deployed from aircraft already tasked with storm surveillance, and they are logistically easier to position along the forecast track ahead of a TC. Flexible deployments of *in situ* marine and airborne platforms also allows for co-located measurements with other air/ocean observing systems that are key for advancing our understanding air-sea fluxes across the oceanic surface.

Further advances in satellite remote sensing are also expected to improve the representation of features that impact storm development. For instance, the advent of wide-swath, high-resolution satellite altimetry (e.g., Fu and Ubelmann, 2014) will enable the evaluation of air-sea interaction processes during high-wind events in detail, such as, for example, the generation of internal waves in the wake of TCs that help drive upper-ocean

mixing. Satellite measurements of surface salinity also have potential for improving our understanding of the oceanic factors and processes that lead to TC intensification, especially in the western Atlantic and the Bay of Bengal, where there is persistent shallow salinity stratification. It is important that these measurements continue, along with satellite SST, sea level, and winds.

Considering the positive impacts of upper-ocean observations from pilot networks, and targeted deployments, the following key recommendations have been identified to continue and enhance ocean observations in support of TCs:

- Maintain the elements of the observing system that have proven valuable for Tropical Cyclone ocean research and operational intensity forecast.
- Utilize numerical Observing System Experiments to quantify the impact of the current ocean observing platforms in Tropical Cyclone forecasts.
- Evaluate optimal ocean observational strategies in support of Tropical Cyclone studies and forecasts using numerical Observing System Simulation Experiments.
- Implement sustained and targeted ocean observations (gliders, profiling floats, drifters, etc.) dedicated to improving Tropical Cyclone intensity forecasts; and foster co-incident, co-located air-deployed profile observations (AXBTs, AXCTDs, floats, thermistor chains, etc.) of ocean temperature, salinity, and currents.
- Foster additional sustained measurements of sea level pressure (e.g., from drifters and moorings), and of waves, sea spray, and mixed-layer turbulence (e.g., from gliders) to help develop, evaluate, and validate boundary layer parameterizations.
- Use upper ocean metrics (e.g., Tropical Cyclone Heat Potential, ocean mean temperature, barrier layer thickness, etc.) derived from profile and satellite ocean observations in the operational evaluation and validation of numerical forecast models.
- Continue with efforts focused on improving coupled ocean-atmospheric numerical weather models, especially those relating to enhancing ocean data assimilation techniques and mixed layer parametrizations.
- Create an ocean database easily accessible to the scientific community to facilitate research in support of assessments of the role of the ocean in Tropical Cyclones studies.
- Enhance data management efforts to transmit and QA/QC data in real-time for assimilation in operational forecast models.

Ocean Observations in Support of Extratropical Bomb Cyclones Studies

Recommendations to improve the understanding of ocean-atmosphere interactions during EC events are:

- Increase efforts to implement and improve coverage of high-frequency and high-resolution observations using profiling instruments and biologging to detect oceanic fronts associated with western boundary currents in winter.

- Enhance efforts dedicated to observing surface wind, and waves, using surface drifters, and floating seabirds equipped with weather, GNSS, and motion sensors, respectively, to estimate air-sea flux exchanges under Extratropical Bomb Cyclones.
- Foster additional efforts aimed at observing ocean turbulent mixing induced by Extratropical Bomb Cyclones using, profiling floats and other platforms (e.g., gliders, moorings, floats, etc.).
- Incorporate real-time meteo-ocean observations, including ocean bottom pressure, in moorings from the Tsunami monitoring network in support of Extratropical Bomb Cyclones studies and forecasts.

Air-sea interactions under ECs are poorly understood because of the sparseness of *in situ* observations and lack of satellite observations caused by thick clouds and heavy rain. Seabirds are often observed to fly and float under ECs to forage (Yoda et al., 2014; Yonehara et al., 2016; Goto et al., 2017), providing an additional potential source of environmental data. Estimation of surface winds and waves using biologging, GNSS and motion sensor can provide useful information about air-sea interaction processes under ECs as well as their temperature and pressure measurements. In addition, the development of profiling floats equipped with motion sensors can also help to provide metrics to evaluate ocean mixing near the sea surface.

To monitor Tsunami, several real-time observation networks of ocean bottom pressure have been established (Kaneda, 2010; Bernard and Meinig, 2011; Lawson et al., 2011; Mochizuki et al., 2017). Most of the sites in the networks are located under the area where ECs frequently develop. Recently, seismic stations on land can catch microseisms induced by ECs (Nishida and Takagi, 2016). The real-time monitoring networks will provide oceanic responses to ECs and informations of winds and waves which may contribute to forecast improvement of ECs.

SUMMARY

In this community white paper, we provide a summary of current ocean observing efforts, and recent research findings in support of studies and forecasts of TCs and ECs. Substantial progress has been made over the past decade in terms of ocean observations, improving our understanding of the role that the ocean plays in the evolution of TCs and ECs, and on transitioning state-of-the art coupled forecast models to operational mode. These advances have largely addressed recommendations made

- by the scientific community during OceanObs'09 (e.g., Goni et al., 2010) and emphasize the critical value of sustained and targeted ocean observations, real-time data transmission, and multi-platform efforts.
- With recent advances in ocean modeling and coupled atmosphere-ocean modeling, operational forecasts increasingly rely on assimilating real-time ocean measurements to produce accurate ocean, weather and extreme weather forecasts. For example, assimilation of ocean observations can dramatically improve hurricane intensity forecasts (e.g., Dong et al., 2017). OSEs can assist in quantifying the impact of upper ocean observations on TC and ECs forecasts. Similarly, OSSEs can also be applied to various regions to design optimal and cost-effective deployment strategies for both targeted and sustained observations in support of ECs and TCs.
- Given the large benefits provided by the ocean observing system in support of extreme weather studies and forecasts, it is critical that current components are maintained and possibly expanded over the next decade. In addition, new technologies, pilot networks, and targeted deployments are greatly expanding the observation capabilities; incorporating these components into the sustained observing system will likely greatly benefit studies and forecasts of TCs and ECs. Finally, considering the large number of countries whose coastal areas are often impacted by TCs and ECs, results and advances presented here emphasize the critical value of carrying out a coordinated international effort in the design, implementation, maintenance, and data management of key aspects of ocean observations that will ensure the feasibility of logistical, operational, and research activities.

AUTHOR CONTRIBUTIONS

RD, AK-Y, PC-M, and GG elaborated the initial outline, and wrote the first draft of the manuscript. All authors of this community white paper have provided input in the form of language, figures, and recommendations for the future of the ocean observing system in support of studies and forecasts of Tropical and Extratropical Cyclones.

This paper summarizes recent efforts on Observing System Evaluation (OS-Eval) by the Ocean Data Assimilation and Prediction (ODAP) communities such as GODAE OceanView and CLIVAR-GSOP. It provides some examples of existing OS-Eval methodologies, and attempts to discuss the potential and limitation of the existing approaches. Observing System Experiment (OSE) studies illustrate the impacts of the severe decrease in the number of TAO buoys during 2012–2014 and TRITON buoys since 2013 on ODAP system performance. Multi-system evaluation of the impacts of assimilating satellite sea surface salinity data based on OSEs has been performed to demonstrate the need to continue and enhance satellite salinity missions. Impacts of underwater gliders have been assessed using Observing System Simulation Experiments (OSSEs) to provide guidance on the effective coordination of the western North Atlantic observing system elements. OSSEs are also being performed under H2020 AtlantOS

project with the goal to enhance and optimize the Atlantic *in-situ* networks. Potential of future satellite missions of wide-swath altimetry and surface ocean currents monitoring is explored through OSSEs and evaluation of Degrees of Freedom for Signal (DFS). Forecast Sensitivity Observation Impacts (FSOI) are routinely evaluated for monitoring the ocean observation impacts in the US Navy's ODAP system. Perspectives on the extension of OS-Eval to coastal regions, the deep ocean, polar regions, coupled data assimilation, and biogeochemical applications are also presented. Based on the examples above, we identify the limitations of OS-Eval, indicating that the most significant limitation is reduction of robustness and reliability of the results due to their system-dependency. The difficulty of performing evaluation in near real time is also critical. A strategy to mitigate the limitation and to strengthen the impact of evaluations is discussed. In particular, we emphasize the importance of collaboration within the ODAP community for multi-system evaluation and of communication with ocean observational communities on the design of OS-Eval, required resources, and effective distribution of the results. Finally, we recommend further developing OS-Eval activities at international level with the support of the international ODAP (e.g., OceanPredict and CLIVAR-GSOP) and observational communities.

Keywords: observing system evaluation, ocean data assimilation, ocean prediction, OSSE (observing system simulation experiment), OSE (observing system experiment), GODAE OceanView, OceanPredict, CLIVAR-GSOP

INTRODUCTION

Ocean Data Assimilation and Prediction (ODAP; see **Table 1** for summary of essential acronyms) systems, which include ocean reanalysis systems for seasonal forecasting and long-term ocean state estimation systems, are used in a large range of oceanic applications and weather and climate forecasting services as an essential tool for integrating ocean observations and numerical forecasting models (e.g., Davidson et al., 2009; Brassington et al., 2015; Le Traon et al., 2017). The Global Ocean Observing System (GOOS) and Regional Ocean Observing Systems (ROOS) largely depend on ODAP systems for delivering analysis products used to promote safety (e.g., search and rescue or identifying periods of high risk to oil and gas operators) and efficiency (e.g., seasonal prediction to support agriculture or optimal ship-routing) at sea, and societal well-being (e.g., monitoring of our changing climate and protection of marine resources). Therefore, evaluating impacts of ocean observation networks on ODAP products in a scientific way provides important feedback to agencies responsible for maintaining and enhancing the GOOS/ROOS. Observing System Evaluation (OS-Eval) is invaluable to assess the effectiveness in ODAP systems of a novel observation type and to determine optimal network design when planning a new observing system or reorganizing existing observing networks (e.g., Fujii et al., 2015a; Oke et al., 2015a,b). In this context, several efforts of evaluating the GOOS/ROOS using ODAP systems have been made and some are ongoing under the support of ODAP communities such as GODAE OceanView (GOV; Bell et al., 2015) and CLIVAR Global Synthesis and Observations Panel (CLIVAR-GSOP, Caltabiano et al., 2015). In particular, GOV formed the OS-Eval Task Team (TT) in order to

promote international collaboration and information sharing on these efforts.

There are several methods of OS-Eval based on ODAP systems that are proposed or have been used before. In the Observing System Simulation Experiment (OSSE) framework, synthetic observation data, intended to mimic observations from the proposed observing system, are generated from a free-running simulation run of an ocean model that is intended to represent the “true” ocean (and is thus called the “Nature Run”), with observation errors added based on information from the observing community (e.g., Hoffman and Atlas, 2015). The synthetic data are assimilated into a different data-assimilative simulation run, called an OSSE, in which different initial/forcing conditions are used. It is also preferable to change the model sufficiently from the Nature Run, either due to reduced resolution or differences in physical parameterizations. The impact of the synthetic data on forecast improvement is assessed from the error reduction in OSSEs when assimilating the new data. In this framework, the errors on the full model space can be directly estimated by taking difference of variables between the Nature Run and OSSE fields. An important aspect of OSSEs is that they can be used for evaluating both existing and future observation data types (e.g., Halliwell et al., 2017).

To evaluate existing observations, Observing System Experiments (OSEs) may be performed. An OSE is a data assimilative run in which a certain observation-type is withheld from, or added to, the regularly assimilated data. The impact of these withheld/added data are assessed by comparing the OSE with the control simulation in which only the regular data are assimilated. Although the methodology of OSEs is simple, it is widely applied due to its applicability to any ODAP system including highly non-linear or stochastic systems, and ability to

3DVAR	Three-Dimensional Variational
4DVAR	Four-Dimensional Variational

directly give the differences caused by assimilation of targeted data (e.g., Oke and Schiller, 2007; Turpin et al., 2016; Xue et al., 2017b). In the OSE framework, reduction of errors cannot be estimated accurately because the true state is unknown. Instead, errors are evaluated using reference data, which are preferably independent from the data assimilation process performed in advance in the OSEs in order to perform fair evaluation (Fuji et al., 2015b).

Adjoint based sensitivity methods are also very applicable for OS-Eval. In particular, Langland and Baker (2004) proposed a technique to compute the variation in forecast error due to the assimilated data using an adjoint model, which is often called Forecast Sensitivity Observation Impact (FSOI) and widely used for monitoring observation impacts in weather centers. Meanwhile, Degrees of Freedom for Signal (DFS) are used to indicate how effectively signals which can potentially improve analysis accuracy are observed (e.g., Cardinali et al., 2004). In an Ensemble Kalman Filter (EnKF) system, FSOI, and DFS are evaluated based on statistical information of ensemble members. In addition, the analysis uncertainty (i.e., error variance) in an ODAP system can also be exploited for OS-Eval because the impact of assimilating specific observations can be measured by the uncertainty reduction. The uncertainty is estimated from the inverse Hessian matrix of the cost function in a

4-dimensional Variational (4DVAR) system (Thacker, 1989), while it is approximated by the variance among ensemble members in an EnKF system (Evensen, 2003). These methods are very powerful and allow the impact of all observations to be assessed at once. The main downside of the methods is that make the assumption of linearity. Effective application of these methodologies to oceanic OS-Eval is one of the on-going challenges in ODAP communities.

This paper introduces recent OS-Eval results shared in GOV OS-Eval TT and CLIVAR-GSOP. We then discuss the value of current OS-Eval methods and the future strategy toward more comprehensive and reliable evaluation. The effective use of OS-Eval in support of observing system review and design is also discussed.

OBSERVING SYSTEM EXPERIMENTS (OSEs)

In OSEs the impact of an existing observing system or observations is tested by adding or removing it from a data assimilating system. See section Introduction for more details.

OSE Studies for Evaluation of TAO/TRITON Array

The TAO/TRITON array provides subsurface temperature and salinity data in the equatorial Pacific, which was vital for an ocean data assimilation system to provide oceanic initial condition for coupled atmosphere-ocean models in ENSO forecasts before the Argo era (McPhaden et al., 1998). However, the rapid increase in the number of Argo floats in 2000s was presumed to reduce the importance of the TAO/TRITON array as the primary provider of tropical Pacific subsurface data, which in view of the costs of maintaining the array make it crucial to reassess the importance of TAO/TRITON data in seasonal predictions.

ECMWF¹ evaluated the impacts of TAO/TRITON, as well as Argo and satellite altimetry data, in their operational seasonal forecasting system through OSEs, and find complementarity among those data in late 2000s (Balmaseda et al., 2007; Balmaseda and Anderson, 2009). Fuji et al. (2011) carried out a similar OSE study to evaluate the impacts of TAO/TRITON data on the ENSO forecasts using the JMA²'s seasonal forecasting system at the request of JAMSTEC³, the agency deploying TRITON buoys as a part of the array west of 165°E. These results were shared in the GOV OS-Eval TT (Oke et al., 2009), and presented in OceanObs'09 (Balmaseda et al., 2010).

In spite of these efforts, the data received from the TAO buoys deployed by NOAA⁴ as a part of the TAO/TRITON array east of 165°E was severely reduced in the period of 2012–2014 (Tollefson, 2014). In addition, the number of the TRITON buoys has also started to reduce since 2013. The influence of the reduction of subsurface temperature and salinity data in the equatorial Pacific was discussed in the Tropical

Pacific Observing System (TPOS) workshop in 2014 [hereafter TPOS2014 workshop; Ocean Observations Panel for Climate (OOPC) (2014)]. OSE studies in ECMWF and JMA introduced above and new OSE studies in NCEP⁵ (Xue et al., 2017b) were summarized in order to highlight the importance of the array for seasonal forecasting (Fuji et al., 2015a). Consequently, the workshop recommended the scientists to make a proposal of reorganizing the TPOS, which includes buoys, Argo, other *in-situ* measurements and satellite data, in a more efficient and sustainable way by launching the TPOS2020 project (Smith G. C. et al., 2019).

During the TPOS2014 workshop, inconsistency among the impacts of the subsurface data was recognized in OSE results. For example, the results in JMA (Figure 1) indicates that removal of only near-equatorial buoys causes larger decrease of Anomaly Correlation Coefficients (ACCs) compared to the removal of all TAO/TRITON buoys in the forecast Sea Surface Temperature (SST) averaged in the NINO3 region for 9–12 months lead-time and in the NINO4 region for 5–12 months lead-time although Argo and TAO/TRITON data have positive impacts in all cases. The participants considered that these inconsistencies were mostly caused by large systematic errors, or biases, of coupled models, which prevented the systems from extracting the full potential impact of the observation data. The dependency on systematic errors is recognized as a general limitation of OSE studies.

Another problem found in the workshop was that OSEs do not fully evaluate the value of all observation data. It cannot evaluate the value of data which are not assimilated in the system. Therefore, near-surface atmospheric data observed by moorings are not evaluated although they are vital for an ODAP system for seasonal predictions because those data can effectively constrain the atmospheric forcing which is crucial to determine the oceanic interior state. Even the value of temperature and salinity data are not fully evaluated because these data are not only assimilated, but also used for the determination of prescribed error statistics and biases which are indispensable for data assimilation.

In addition, our inability to evaluate the impacts of temporal changes of the observing system in a timely way was also revealed in the workshop (see section Near-Real-Time Evaluation). This motivates work to start routine near real time intercomparison of operational ODAP products (section Use of Multi-system Ensemble Spread).

OSEs for Evaluating Satellite SSS Data Impacts During the El Niño 2015 Event

Monitoring Sea Surface Salinity (SSS) is crucial for understanding and forecasting the ocean circulation, water cycle and the changing of the climate. The recent satellite missions of ESA⁶'s SMOS, NASA⁷'s Aquarius, and SMAP missions have made it possible for the first time to measure SSS from space, and it is important to assess the impact of these measurements in order to justify follow-on missions. However, the assimilation

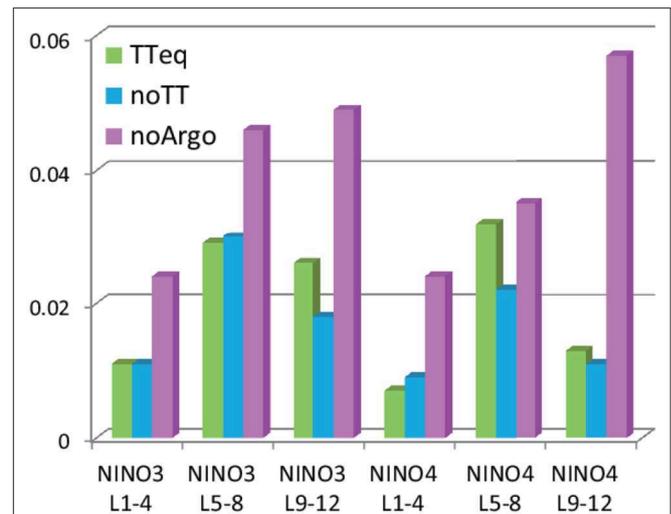

FIGURE 1 | Result of an OSE study evaluating the impacts of TAO/TRITON and Argo data in a seasonal forecasting system in JMA (Fuji et al., 2015a). Compared to a control run this shows a decrease of the ACCs of SST averaged in the NINO3 (5°S–5°N, 90°–150°W) and NINO4 (5°S–5°N, 150°W–160°E) regions in the hindcasts from OSEs with removal of TAO/TRITON data only within 2.5°S–2.5°N (TTeq), all TAO/TRITON data (noTT), and all Argo data (noArgo) for the lead-times of 1–4, 5–8, and 9–12 months (L1-4, L5-8, and L9-12, respectively). Hindcasts are started from the end of January, April, July, and October in 2004–2011 with 11 ensemble members. Forecast biases are estimated for each lead month and for each OSE separately, and removed from the forecasted values.

of satellite SSS observations is still challenging because of the various and complex biases that affect them. The difference between the forecast and the satellite SSS can be 5 times larger than the misfit between the forecast and near surface Argo salinity. Nevertheless, several studies (Lee et al., 2012; Reul et al., 2013; Toyoda et al., 2015) show that SSS measured from space can bring new information.

In the framework of the SMOS-Niño15 ESA project⁸, OSEs were designed to explore the potential impact of SMOS, Aquarius and SMAP SSS data assimilation using the ODAP systems of UKMO⁹ and Mercator Ocean. The project was expected to produce an Observation Impact Statement (OIS; see section Community Collaborations) based on the OSE activities for the GOV OS-Eval TT. The 2015/16 ENSO event has been chosen as a case study for this project. The ODAP systems are based on the same Ocean General Circulation Model (OGCM) (NEMO; Madec, 2016) but with different settings and atmospheric forcing fields. The data assimilation techniques are also quite different; Mercator Ocean uses a reduced order, localized Kalman Filter approach with a 1-week assimilation window and UKMO uses a 3-dimensional Variational (3DVAR) approach with a 1-day assimilation window. Assimilated data sets in the control simulation are along-track satellite Sea Surface Height (SSH), SST, and *in-situ* temperature and salinity profiles. The SSS data

⁹UK Met Office.

assimilation is restricted to the 40°S–40°N area, due to increasing uncertainty in the salinity observations at higher latitudes. For both systems, specific bias correction schemes have been adapted to estimate the bias for the different SSS datasets. Performing OSEs with different ODAP systems and data sources allow for more robust conclusions to be made on the sensitivity of ocean estimates to SSS data assimilation.

The success of assimilating SSS data was confirmed by the reduction seen of the Root Mean Square (RMS) differences between SSS observations and model forecast (**Figure 2**). In both systems, the differences are around or >0.2 PSU when assimilating SSS data (Martin et al., 2018; Tranchant et al., 2019). Changes due to SSS data assimilation are mainly confined to the first 50 m of the water column. Other variables, such as the temperature, velocity and sea level fields are also modified. Looking at the innovation (observation-minus-background differences) statistics for *in-situ* and altimetry confirms that information brought by the assimilation of SSS data is consistent with that from already assimilated data sets.

These results demonstrate that the ocean forecasting systems are ready to assimilate SSS data, without introducing incoherent information compared to the other assimilated observations. Note to achieve this result an observation bias correction scheme is still needed within the assimilation process, even if a “debiased” SSS data product is used. The RMS differences between model forecasts and observations are, in the Tropical Pacific region, around 0.2 PSU, which gives a quite stringent request on the accuracy of any new measurements.

OSE Studies for Ocean Reanalysis and Seasonal Forecasting

Adding new observation data in an ocean reanalysis should in principle never degrade the quality of analysis or forecast, assuming that the data are assimilated in a consistent way. However, in practice the exploitation of observations is challenging in ocean reanalysis and seasonal forecasts. The forecasts need balanced initial conditions consistent with the model dynamics and physics, so they are able to retain the observational information for longer than the typical assimilation window. In reanalysis, because it is important to retain temporal consistency, systems should be stable to changes in the observing system. OSEs are a practical way to validate consistency of a data assimilation system as well as a method for evaluating impacts of observation data.

For this reason, OSEs are routinely conducted at ECMWF. For example, Balmaseda et al. (2007) reported the impact of the Argo data in the climate of the ocean reanalysis simulated by a previous operational ocean reanalysis system (Balmaseda et al., 2008), showing the large impact in the estimation of salinity, especially in the Southern Ocean. An ensemble of OSEs withholding Argo data was exploited to verify that the increased heat uptake during the recent warming hiatus found in ocean reanalysis was robust to the changes in the observing system (Balmaseda et al., 2013b). OSEs were also conducted to assess the impact of XBT bias corrections and different SST products on the climate variability (Balmaseda et al., 2013a). Assessment of ocean

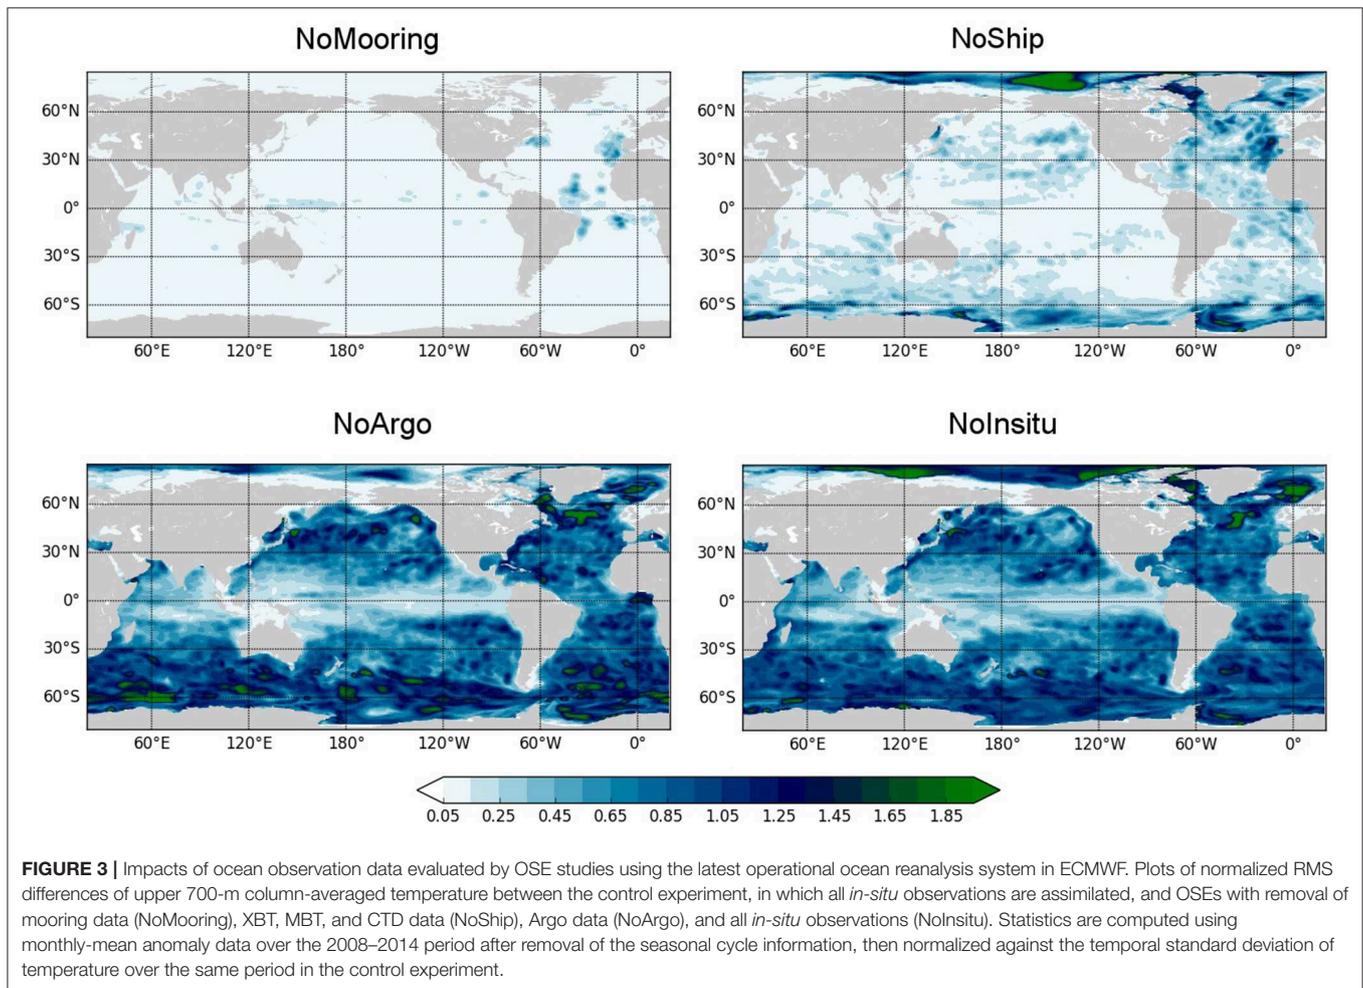

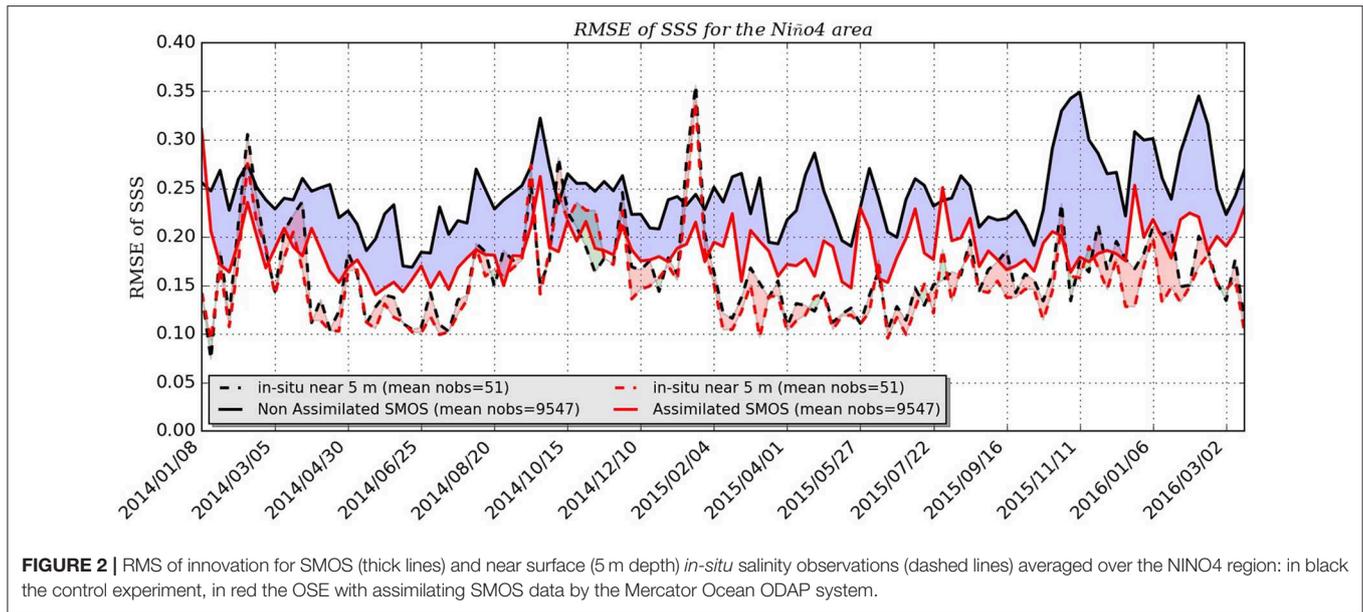

observation impacts on seasonal forecasts is firstly conducted by Alves et al. (2004), which showed that assimilating observations improved the skill of the first operational seasonal forecasting system in ECMWF. Balmaseda and Anderson (2009) reported the impact of different observing systems in a later seasonal forecasting system. They reported that the individual observing systems were shown to improve the seasonal forecasts in most ocean basins, except in the tropical Atlantic, probably because of problems with the data assimilation system in that area.

A series of OSEs has been carried out using a low-resolution version of the latest ECMWF operational ocean reanalysis system OCEAN5 (Zuo et al., 2018). Since sea-level anomaly data were also assimilated in these OSEs, they are different from the OSEs carried out by Zuo et al. (2019). Maps of temperature RMS difference for the upper 700 m between the OSEs and the control experiment (**Figure 3**) suggest that removal of mooring data from TAO/TRITON, PIRATA, and RAMA arrays (NoMooring) mostly affects the tropical regions alone. Ship-based observations (XBT/MBT and CTD) show important contributions especially in the high-latitude where Argo floats are not often available (e.g., in the Arctic basin). Removal of Argo floats (NoArgo) degrades the ocean state almost everywhere except for the tropical Pacific and Indian Oceans, where the ocean state is well constrained by the assimilation of satellite SSH data (Zuo et al., 2017). Removal of all ocean *in-situ* observations (NoInsitu) gives an estimation about the total impact of the global *in-situ* data, which is not a simple linear combination of individual observation types. Note that in the Southern Ocean the RMS difference is sometimes larger in NoArgo than in NoInsitu, which indicates some inadequacy of the data assimilation process. Overall, the weak impact of removal of observations in the Indian Ocean is possibly related to the comparatively sparse observing system in that region. And the tropical Atlantic seems to be generally more sensitive to the removal of *in-situ* observations than the other tropical ocean basins. It would be useful to assess the robustness of these results by doing the same experiment with different ODAP systems in a multi-system approach (see section Multi-system Evaluation).

OSEs for assessing ocean observation impacts in seasonal forecasts are now being carried out with the current operational ocean reanalysis and coupled prediction systems in ECMWF. This time, the OSEs are planned to be also used for assessing impacts in sub-seasonal predictions (see section Medium-Range and S2S Coupled Prediction and Coupled Data Assimilation).

OSE Study for Evaluation of Coastal Gliders in a High-Resolution Coastal Model

OSEs are also used to evaluate impacts of coastal observation data/platforms on a high-resolution ocean model (e.g., Oke and Schiller, 2007; Aydogdu et al., 2016). An example of the impact of the assimilation of ocean glider data is presented in **Figure 4**. The ocean model used is configured based on the Sparse Hydrodynamic Ocean Code (Herzfeld, 2006) for south-eastern Tasmania (**Figures 4D,E**), and run for a period during April 2009. The model grid spacing ranges from 250 m in the estuary to 2.5 km near the open boundaries (**Figure 4F**). In the control

run without data assimilation, the model mis-represents both the potential temperature (**Figures 4A,B,G**) and salinity (not shown) fields with temperature errors in excess of 2°C at depth and over 1.4°C at the surface. This error is mostly due to uncertainty in fluxes from the nearby rivers. Then, in the OSE run in this study, glider data are assimilated once a day using the ensemble optimal interpolation (Oke et al., 2002, 2010), with a 91-member ensemble of weekly anomalies. For a full description of the model, assimilation, and experiments performed, the reader is referred to Jones et al. (2012). For this example, the model-observation misfit is reduced by up to 90% with the OSE run reproducing mixing (e.g., 10 April) and re-stratification (e.g., 15 April) events.

The impact of glider data on this high-resolution coastal model is further demonstrated by comparison with unassimilated SST data (**Figures 4G,H**). The differences between simulated and observed SST are reduced from $0.4\text{--}1.4^{\circ}\text{C}$ (**Figure 4G**) when the model is run with no data assimilation (the control run) to $>0.3^{\circ}\text{C}$ in the OSE run with data assimilation (**Figure 4H**). For this example, Jones et al. (2012) report that assimilation of glider data not only helped reproduce the realistic variability of the properties in the coastal ocean, but it also reduced the bias of temperature from 1 to $>0.2^{\circ}\text{C}$.

OBSERVING SYSTEM SIMULATION EXPERIMENTS (OSSEs)

In OSSEs potential new observations or observing systems are tested by assimilating synthetic observations. See section Introduction for more details.

OSSEs for Evaluating an Underwater Glider Array in Western North Atlantic

A research ocean OSSE system has been developed through collaboration between the NOAA/AOML¹⁰ and the University of Miami. The system uses two substantially different configurations of the HYbrid Coordinate Ocean Model (HYCOM) for the free-running Nature Run and the data-assimilative OSSEs. The design and evaluation procedures follow strict guidelines developed for atmospheric OSSE systems to ensure that credible impact assessments are obtained (Atlas, 1997; Hoffman and Atlas, 2015). The system was initially set up and evaluated in the Gulf of Mexico (Halliwell et al., 2014), and then was expanded into a larger Atlantic domain (5°S to 45°N , extending east to 20°W). Rigorous validation of the Atlantic system is presented in Kourafalou et al. (2016), Androulidakis et al. (2016), and Halliwell et al. (2017).

OS-Eval with this OSSE system is used to assess the impact of deploying arrays of underwater gliders on initialization errors in ocean prediction models. Particular focus was given to document the additional positive impact that is realized by using moving platforms, such as gliders, compared to using stationary platforms, such as moorings. Maps of RMS errors with respect to the truth represented by the Nature Run calculated over the time interval July to October 2014 are presented for dynamic height

at the surface relative to 1,000 m (D1000, **Figure 5**). For profiles collected from stationary platforms, large error reduction is concentrated around each measurement location. Observations collected at fixed locations therefore have a limited radius of influence. By contrast, the ability of each moving glider to map a sub-region of the analysis domain extends the radius of influence and roughly equalizes error reduction across the domain.

Evaluation of the Observing System Network in the Atlantic

The H2020 AtlantOS project aims at building a multinational framework for a better-coordinated ocean observing system for the Atlantic by involving the main stakeholders from science and society (Visbeck et al., 2015), and leads coordinated efforts by European forecasting centers to provide quantitative information of potential impacts of further evolution of the *in-situ* networks on global ODAP systems. The main objectives are (i) to help defining and testing future observing systems from an integrated system perspective involving satellite and *in-situ* observations and numerical models, and (ii) to optimize the use of observation information in the analysis step and to improve the assimilation component. This initiative includes a set of physical OSSEs, using four global eddy-permitting ($1/4^{\circ}$) systems, i.e., three ODAP systems (Mercator Ocean, CMCC¹¹, UKMO) and one model-independent analysis system (CLS¹²). It is important to note that these experiments take fully into account the complementarity between satellite and *in-situ* observations. Impact of a given *in-situ* network is not analyzed in isolation and its value is assessed taking into account the information already provided by satellites.

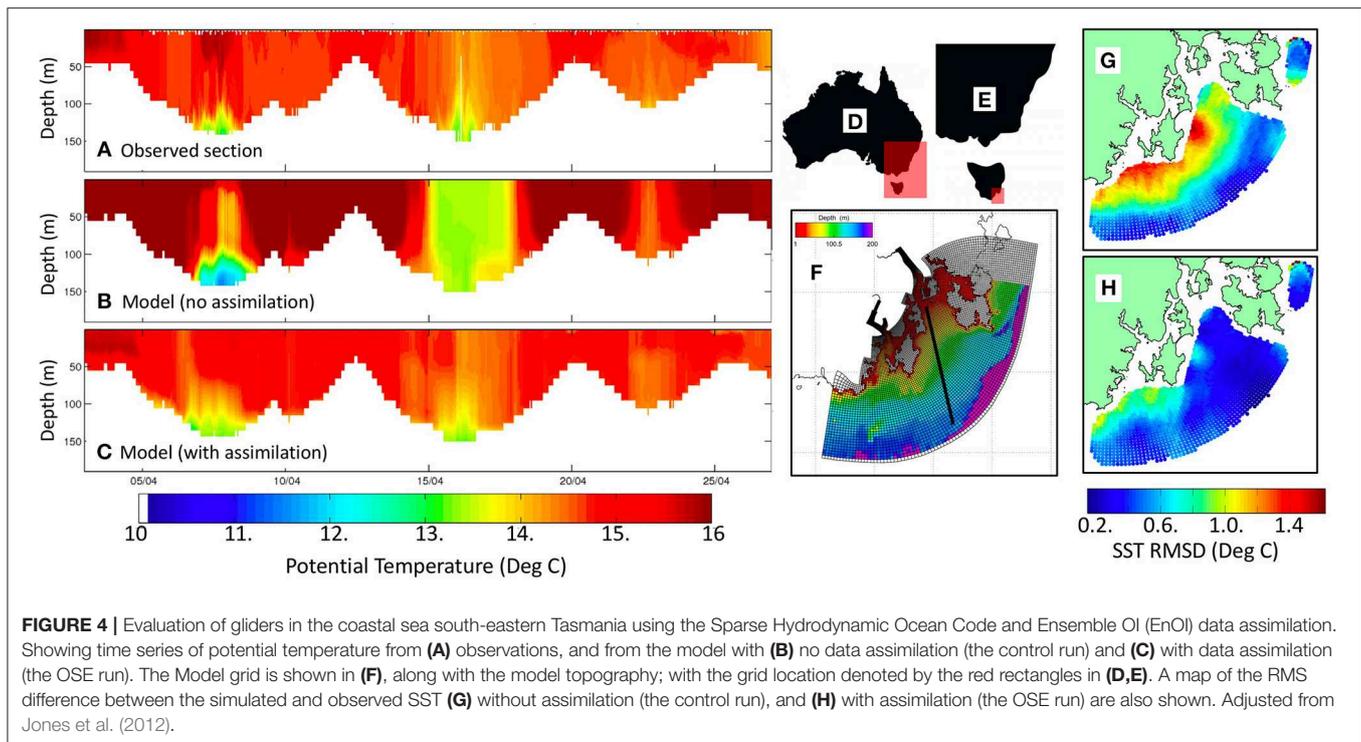

The originality of this study lies in the assimilation in the four global systems of exactly the same synthetic data sets, which are derived from the Nature Run produced with the Mercator Ocean global $1/12^{\circ}$ unconstrained model (Gasparin et al., 2018). Potential future evolutions of the *in-situ* observing system, including Argo floats, drifting buoys, and mooring arrays, are defined based on strong interactions between observation agencies and forecasting centers. To our knowledge, this is the first time that such a coordinated effort is made using OSSEs. The multi-model and multi-approach feature is a critical point to ensure the robustness of the results (see section Multi-System Evaluation).

OSSEs are conducted for five potential future observing system designs as well as for the reference design which includes the satellite component (three altimeters and SST), moorings, XBT, and Argo floats (1 float in every $3^{\circ} \times 3^{\circ}$ square). For each design, at least two groups conducted OSSEs and assessed the impacts of the integrated observing system. The doubling of Argo floats in the western boundary current regions and along the equator demonstrates an improvement of both temperature and salinity representation for the entire Atlantic of 5–10% compared with the reference design. Stronger improvements are found in the western boundary current regions and along the equator. These results are consistent with Oke et al. (2015b) and Turpin

¹⁰NOAA Atlantic Oceanographic and Meteorological Laboratory.

¹¹Centro Euro-Mediterraneo per i Cambiamenti Climatici.

¹²Collecte Localisation Satellites.

et al. (2016), who have investigated the impacts of removing half of the existing Argo floats. The implementation of a deep Argo array (1 float in every $5^\circ \times 5^\circ$ square, monthly), which samples to 4,000 m or to the bottom, shows a significant impact in reducing the bias in the temperature and salinity fields in the deep ocean. The ensemble mean of the four systems shows large error reduction of temperature and salinity up to 40%, but the associated standard deviation indicates that there is quantitative difference among the systems (Figure 6). The implementation of a global drifter array equipped with a thermistor chain to 150 m, which is an optimistic perspective on future evolution of the observing system, shows significant improvement of the temperature and salinity representation in the surface layer (10–20% of error reduction). The impact of removing the current mooring array is localized near the moorings, and does not affect significantly the large-scale structures, consistent with the findings of Fujii et al. (2015a).

Overall, this original study has demonstrated a positive impact of the different simulated observation networks, and is further detailed in a synthesis publication (Gasparin et al., 2019a).

Evaluation of Impact of Wide-Swath Altimetry Missions

The impact of forthcoming wide-swath altimetry missions was investigated at Mercator Ocean with OSSEs using a $1/12^\circ$ -resolution regional ODAP system of the Iberian-Biscay-Ireland (IBI) region (Lellouche et al., 2013). The synthetic observations are derived from the Nature Run simulated by the same OGCM at $1/36^\circ$ resolution over the same region (Bonaduce et al., 2018). All the experiments assimilated the same synthetic

observations of SST and temperature and salinity profiles. The synthetic data for conventional altimeters were derived from the sampling of the Nature Run over the theoretical tracks of the satellite missions Jason2, Jason1 on a geodetic orbit (Jason1g), and Envisat, with a sampling frequency of 1 Hz (~ 7 km). An observational white noise of 1 cm RMS was added to these pseudo-observations. The JPL simulator (Gaultier et al., 2016) was used to produce synthetic SWOT data. The wide-swath data were derived considering a 20.9-day repeat orbit at a spatial resolution of 7 km along and across the swath. Figure 7A shows examples of SSH fields in the Nature Run and the spatial coverage of simulated satellite altimetry data for conventional nadir and SWOT altimeter missions. Only the Ka-Band Radar Interferometer (Karin) noise in accordance with the error budget of SWOT mission concept (e.g., Durand et al., 2010; Rodriguez and Esteban-Fernandez, 2010). With 7×7 km spatial resolution, the noise ranges from 0.2 cm RMS in the inner part of the swath to about 0.35 cm on the outer edges of the swath.

Four experiments were run OSSE0, OSSE1, OSSE2, and OSSE3. A free run experiment without assimilation (OSSE0) is used as a reference to quantify the contribution of the various data sets. SST and *in-situ* profiles are assimilated in all other experiments. In addition, synthetic SSH data along the tracks of conventional altimeters were assimilated in OSSE1. Only the synthetic data of SWOT were assimilated in OSSE2. Note that they include the nadir altimeter in the middle of the swaths of the SWOT satellite. Synthetic SSH data of both the nadir altimeters and SWOT were assimilated in OSSE3. All experiments are performed with the same initial conditions and forcing for 1 year January to December 2009.

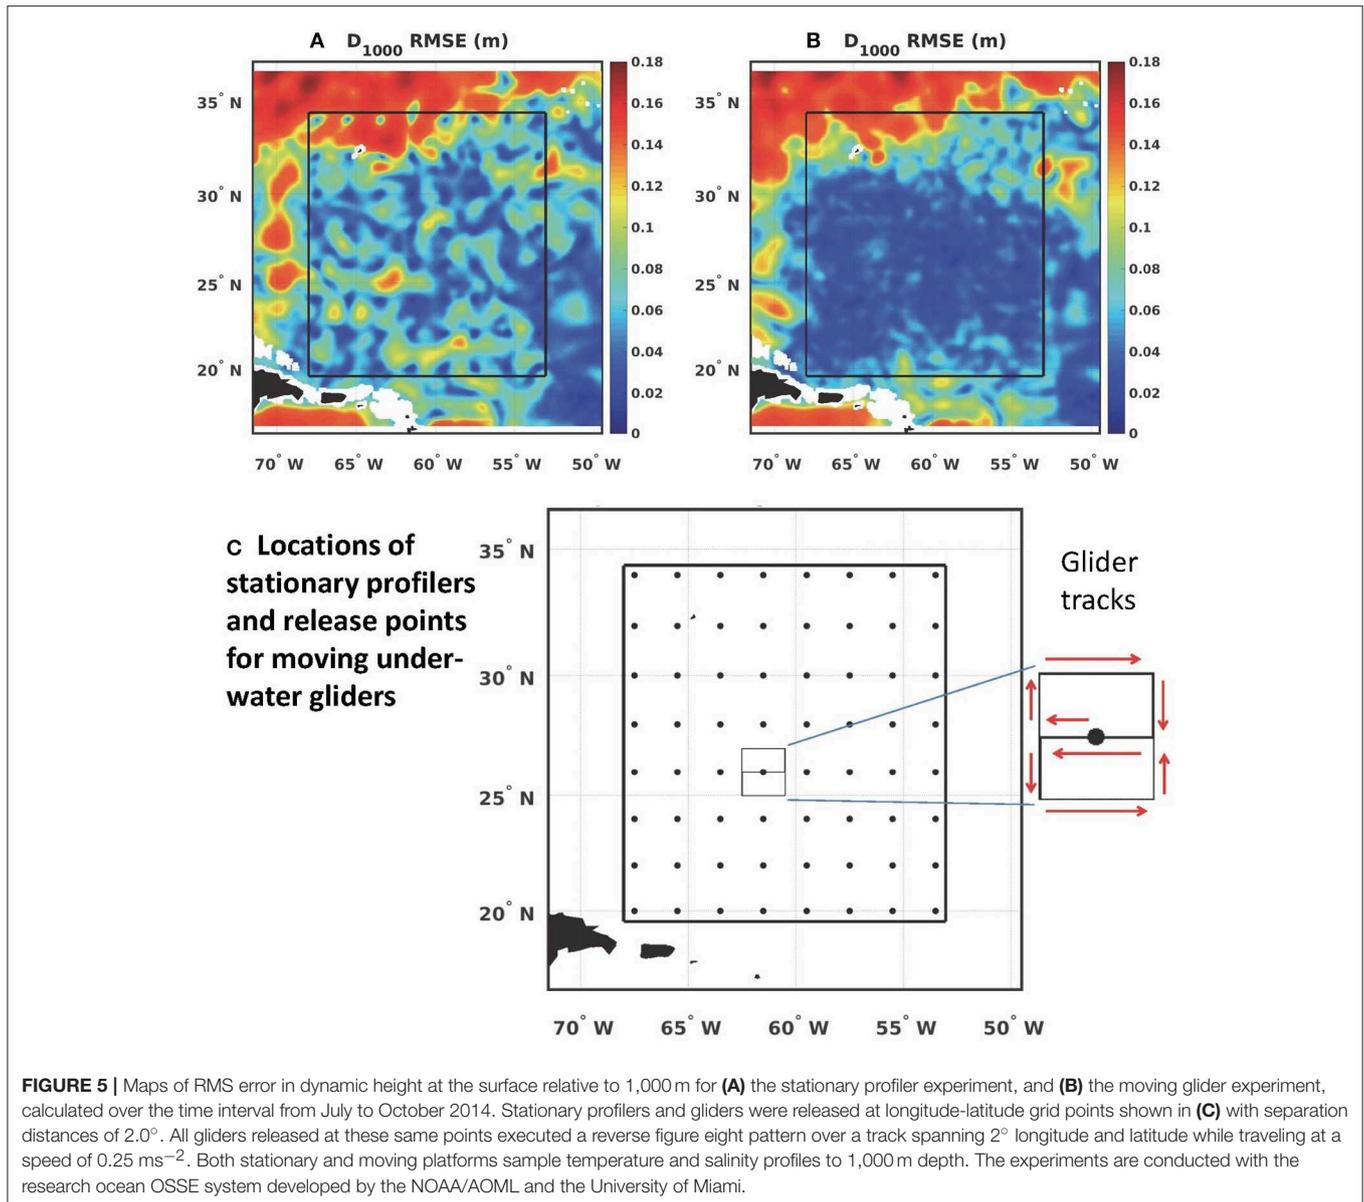

FIGURE 5 | Maps of RMS error in dynamic height at the surface relative to 1,000 m for (A) the stationary profiler experiment, and (B) the moving glider experiment, calculated over the time interval from July to October 2014. Stationary profilers and gliders were released at longitude-latitude grid points shown in (C) with separation distances of 2.0° . All gliders released at these same points executed a reverse figure eight pattern over a track spanning 2° longitude and latitude while traveling at a speed of 0.25 ms^{-2} . Both stationary and moving platforms sample temperature and salinity profiles to 1,000 m depth. The experiments are conducted with the research ocean OSSE system developed by the NOAA/AOML and the University of Miami.

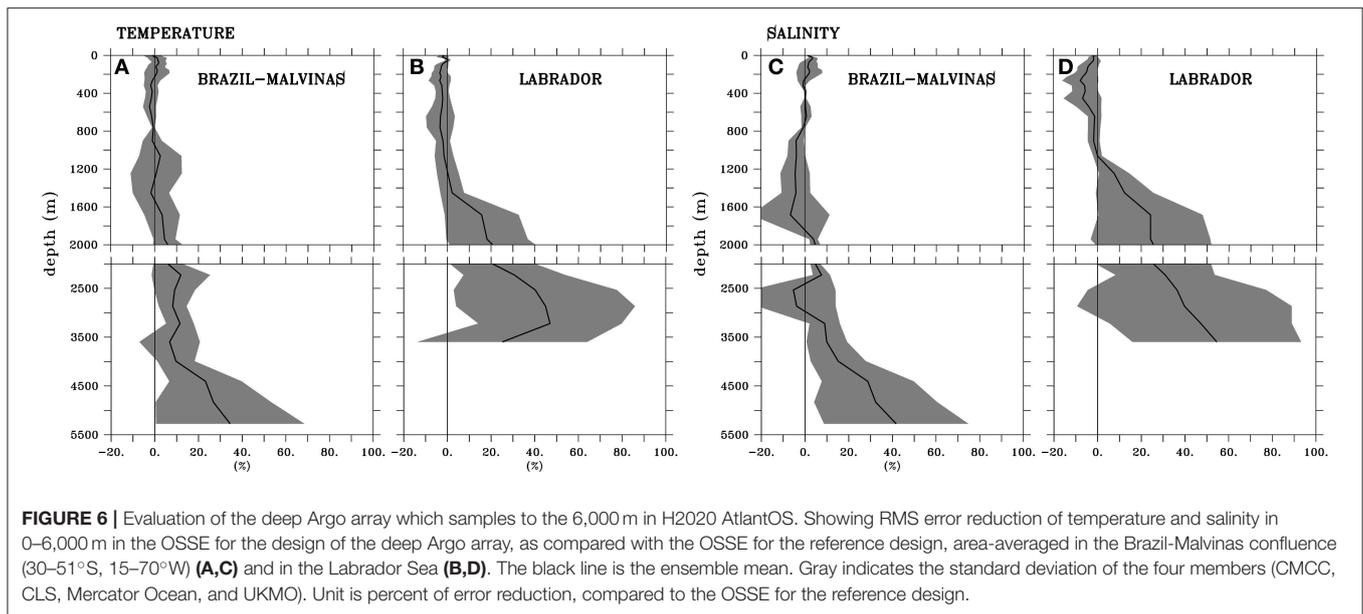

Figure 7B shows the impact of assimilating synthetic SSH data evaluated by comparing the SSH errors in each OSSE. OSSE1 shows a clear reduction of the error by the assimilation of the nadir altimeter data compared to the free model (OSSE0). The best solution is the OSSE3 with assimilating SWOT and nadir altimeter data together. A constellation of SWOT and nadir altimeters shows a significant reduction of the error over the entire domain. The error variance does not exceed 9 cm^2 except at the North Atlantic drift (between 50°N and 53°N) and close to the open boundaries which are unchanged in these experiments. A coherency analysis (Thomson and Emery, 2014) was done to investigate the reliability of the SSH signal in the OSSEs at the different spatial scales (**Figure 7C**). If 0.6 is chosen as a threshold for reasonable performance, the figure implies that assimilation of nadir and SWOT altimeter data performs well for wavelengths

down to 110 km in OSSE3, while OSSE1 performs well-down to 180 km. This indicates that smaller scale features in the SSH fields are better captured when assimilating wide-swath altimeter data compared to nadir altimeter data.

ADJOINT AND ENSEMBLE-BASED APPROACHES

Use of Adjoint Models and Uncertainty Quantification

An ODAP system based on a 4DVAR method employs the adjoint of a forecast model in order to minimize the cost function which, in part, represents the model-data misfit. An adjoint model calculates the sensitivity of a scalar function

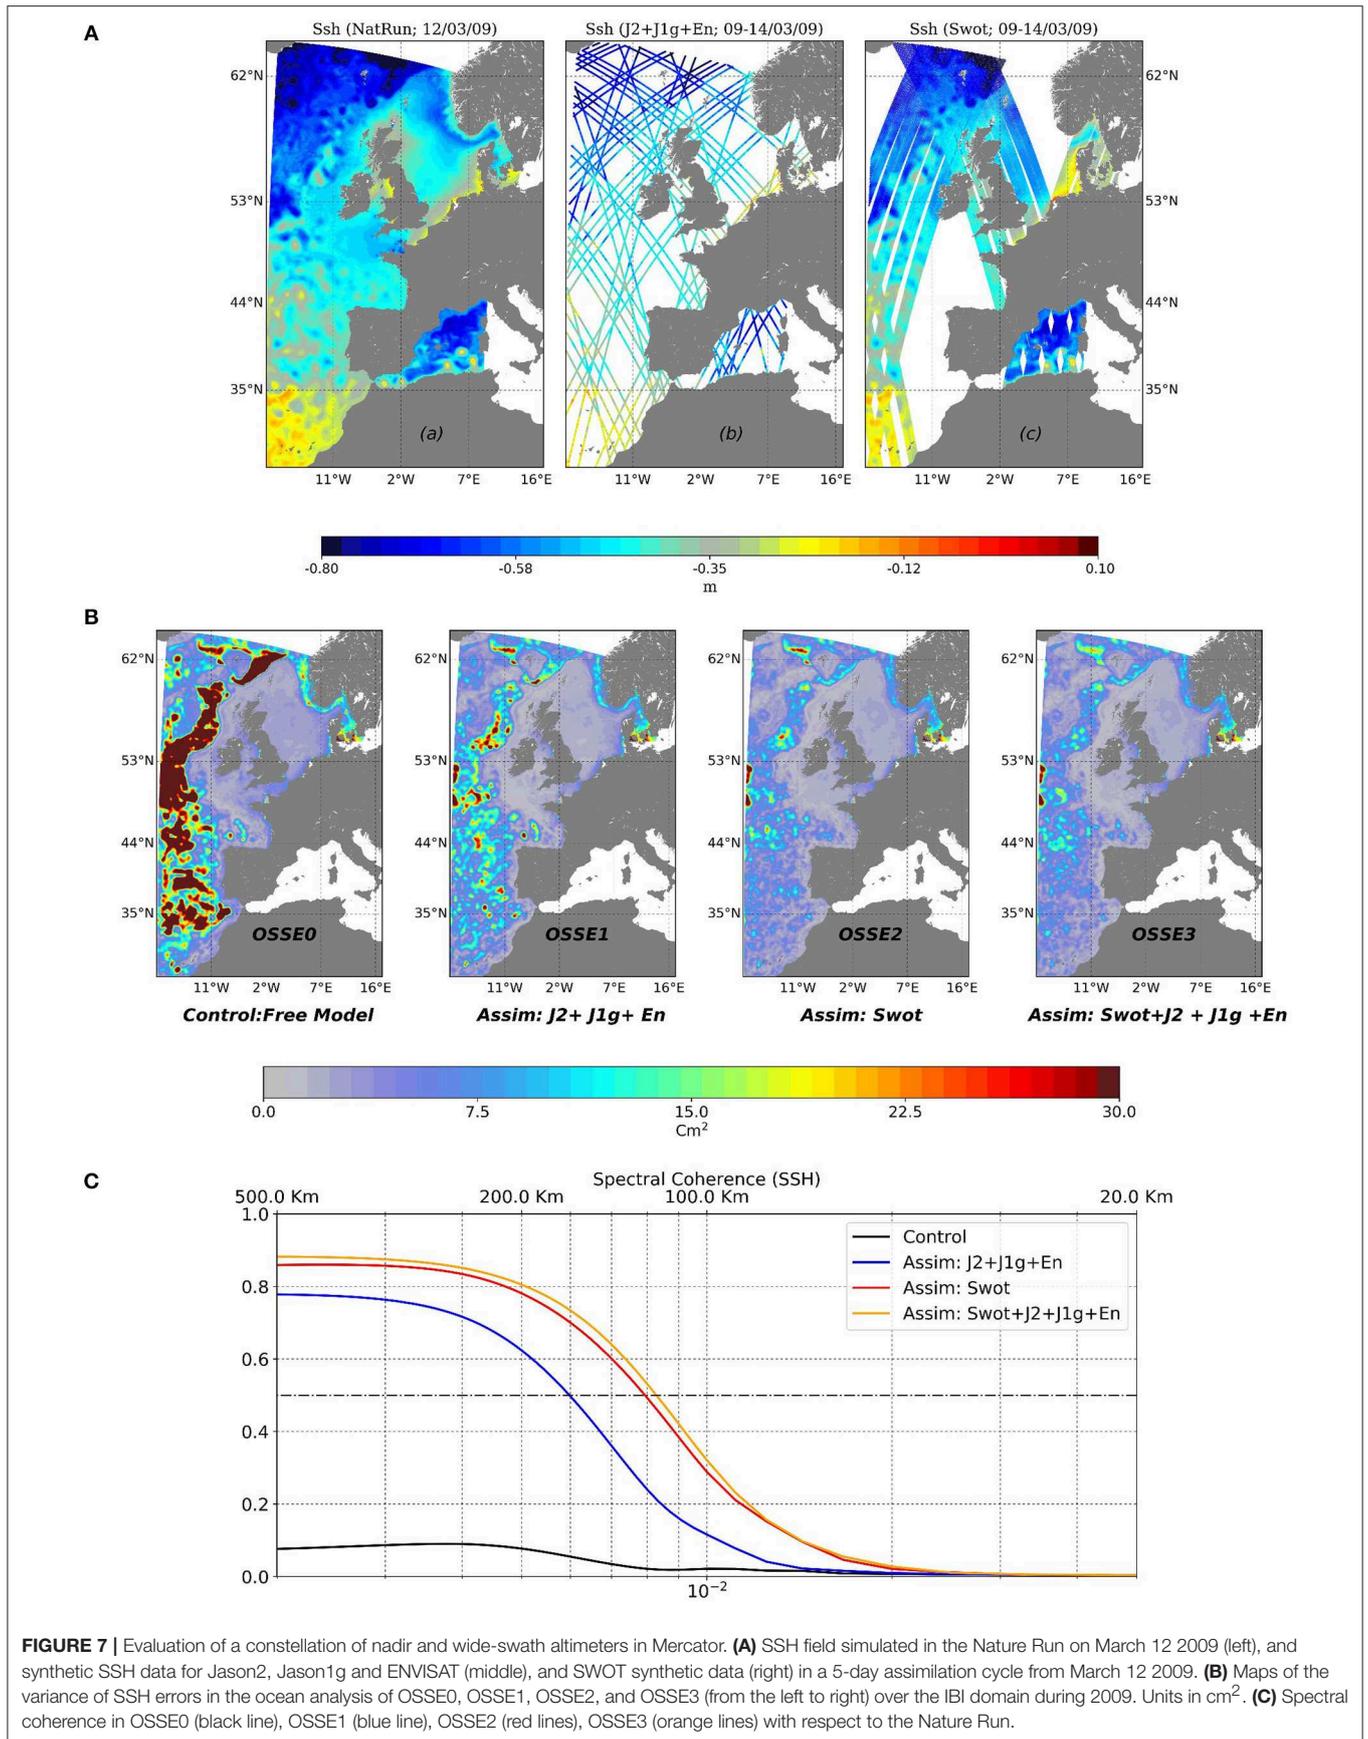

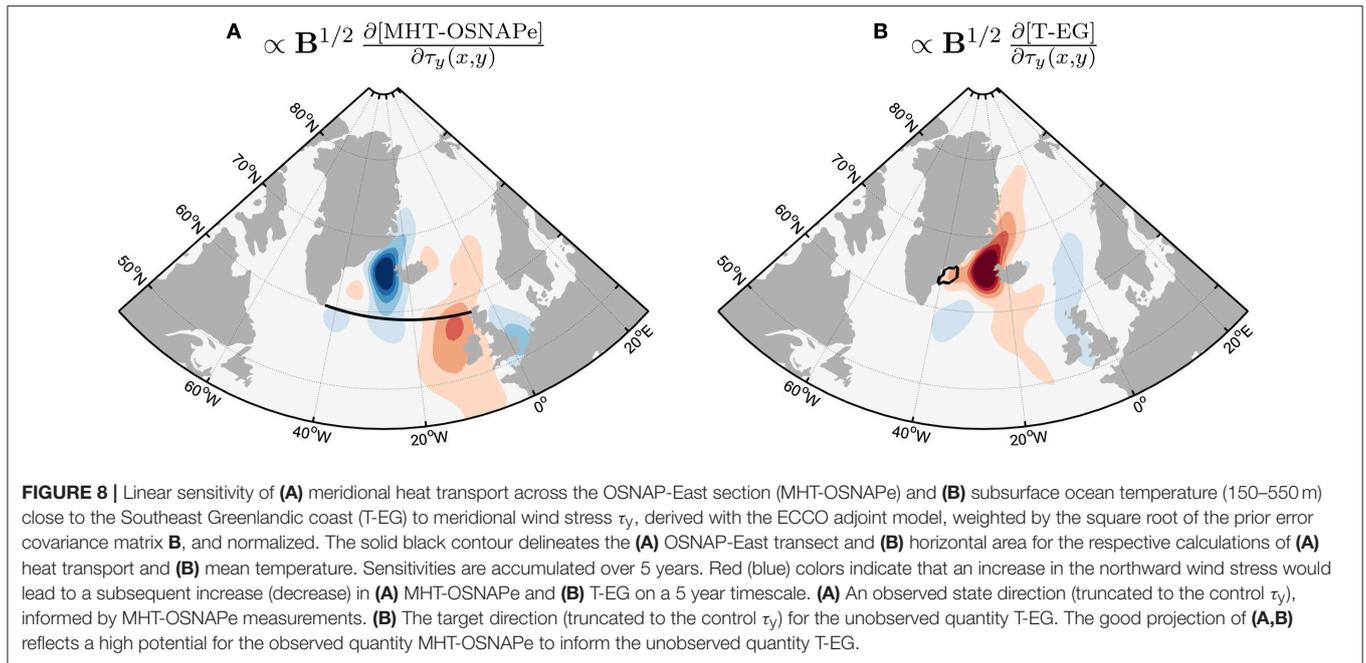

based on the model state at any time during a model integration (not limited to the 4DVAR cost function) to model state variables, boundary conditions, and parameters applied at previous times. Adjoint sensitivity experiments are, thus, applicable for OS-Eval studies. For example, an adjoint sensitivity study by Masuda et al. (2010) indicated that the temperature of the bottom water in the North Pacific is sensitive to the air-sea heat flux and temperature of the whole water column off the Adélie Coast of Antarctica multiple decades back in time. This result highlights the importance of temperature observations in that area, and motivated JAMSTEC to enhance ocean observation in that area through deep Argo floats. Meanwhile, singular vector analysis (e.g., Fujii et al., 2008; Zanna et al., 2011) and its non-linear extension, conditional non-linear optimal perturbation analysis (e.g., Wang et al., 2013) also employ adjoint models and provide insight into where observations are needed. Fujii et al. (2008) identified the rapidly developing perturbation which affects the Kuroshio large meandering, and indicated the importance of observations southeast of Kyushu in Japan where the perturbation is originated.

Hessian-based uncertainty quantification is an extension of adjoint sensitivity studies, and is performed within the framework of ocean state and parameter estimation. This framework uses the 4DVAR method, where the assimilation window is chosen equal to the entire estimation period, covering multiple years to decades. The long assimilation window guarantees a data-constrained solution for the time-evolving ocean state that is entirely dynamically and kinematically consistent, a desirable property for studying the ocean's climate and variability (e.g., Wunsch and Heimbach, 2013; Stammer et al., 2016). Uncertainty quantification is an appropriate tool to evaluate and design observing systems that are targeted at climate monitoring.

An example is measuring ocean connectivity via the mooring array deployed by the Overturning in the Subpolar North Atlantic Program (OSNAP; Lozier et al., 2016). The eigenvectors of the local Hessian of the cost function represent the state directions that are informed by the observations. They can be interpreted as prior-weighted adjoint sensitivities of the observed quantities to all control variables, as highlighted by Loose (2019). For instance, **Figure 8A** shows the state direction (truncated to the control variable meridional wind stress) that is informed by heat transport measurements across the OSNAP-East leg (MHT-OSNAPe), computed within the Estimating the Circulation and Climate of the Ocean (ECCO) framework. It is given by the prior-weighted adjoint sensitivity of MHT-OSNAPe to meridional wind stress. **Figure 8B** shows the prior-weighted meridional wind stress sensitivity of an unobserved quantity, namely subsurface temperature close to the Southeast Greenlandic coast (T-EG). Strong projection of the two patterns in **Figure 8** reflects a high potential for the observed quantity MHT-OSNAPe to inform the unobserved quantity T-EG. How much of this information potential can actually be extracted is determined by a signal-to-noise ratio, which incorporates magnitudes of prior and observation uncertainties.

Extracting the leading eigenvectors of the Hessian for large observing systems replaces performing thousands to millions of adjoint sensitivity experiments (where each observed quantity would be the objective function of a new experiment). Importantly, uncertainty quantification evaluates observation uncertainties and prior information. Moreover, the orthogonal Hessian eigenvectors represent data-informed state directions with data redundancy removed. Unlike conventional adjoint sensitivities, they inform about data redundancy and complementarity of new observing systems in the context of existing observations, e.g., Argo profiling floats. Although full Hessian-based uncertainty quantification has not yet been

realized for global state estimation, substantial progress has been made within ECCO (Kalmikov and Heimbach, 2014, 2018). The coming decade will bring to bear the full potential of uncertainty quantification and optimal design of observing systems.

Use of FSOI for Monitoring Ocean Observation Impacts in an ODAP System

FSOI measures the variation in forecast error due to the assimilated data, and its evaluation is another promising application of an adjoint model for OS-Eval. Evaluation of FSOI has recently been applied to the ODAP system in operation at the US Navy and NOAA centers (Cummings and Smedstad, 2014). The system uses the global HYCOM and 3DVAR schemes, and measures the impact of all observations assimilated on reducing 48-h forecast temperature and salinity forecast error every day. Calculation of FSOI is formulated such that a negative value indicates a beneficial observation in that assimilation of that observation reduced forecast error. A positive value indicates a non-beneficial observation in that forecast error actually increased from assimilation of the observation. Non-beneficial impacts are not expected but if they occur, and they are persistent, then that may indicate problems with data quality or model performance. Thus, FSOI can be used as an effective observation monitoring tool with feedback to data providers on potential issues with their data.

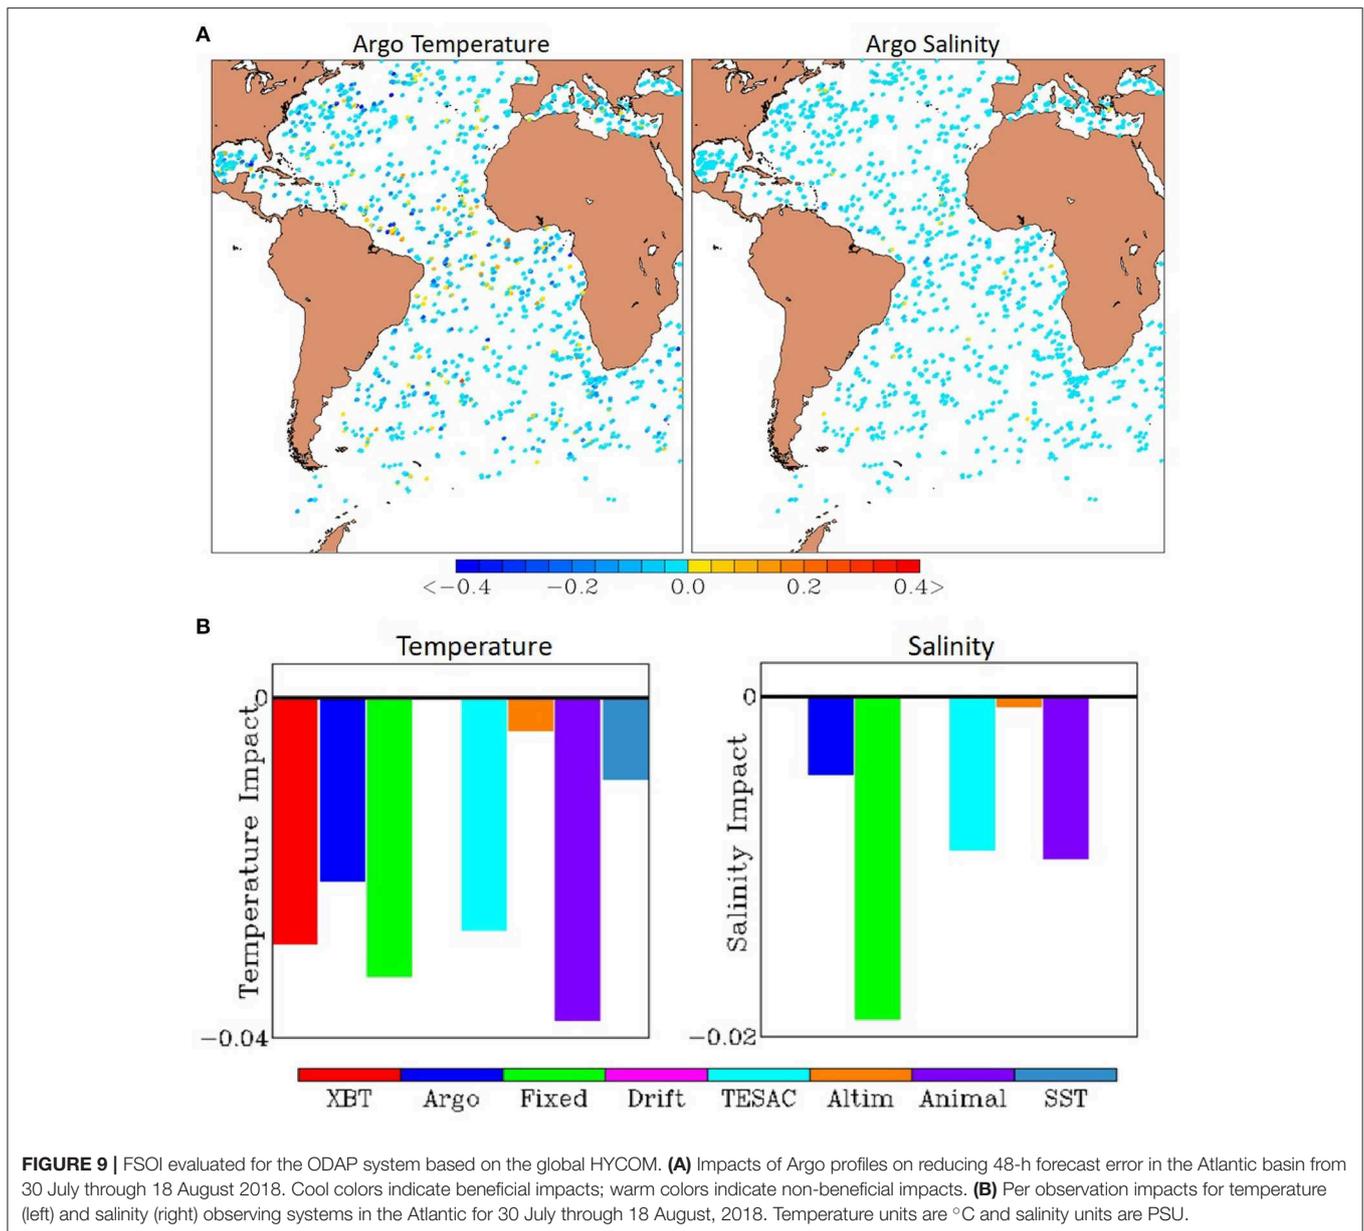

To illustrate the routine application of FSOI, **Figure 9A** shows the geographic variation of the impacts of assimilating Argo temperature and salinity profiles from July 30 through August 18, 2018 in the Atlantic basin. In general, assimilating Argo data has beneficial impacts on reducing forecast error across the basin, although slightly non-beneficial impacts can be seen in some Argo temperature profiles. FSOI can also be partitioned by observing system. **Figure 9B** shows histograms of FSOI averaged

within observing system in the Atlantic basin for the same time period. Here, impacts are normalized by the number of observations in an observing system such that the results are presented on a per observation basis. The results show that the most important temperature observing system is animal borne sensors, while for salinity the most important observing system is fixed moorings. When the per observation impacts are calculated without normalization, satellite altimeters, and satellite SST have the greatest impacts simply from the overwhelming number of observations generated by those observing systems. It is important to note that all ocean observing systems assimilated have beneficial impacts on reducing forecast error.

Evaluation of FSOI provides an all at once approach to estimating observation impacts. The method automatically adjusts to changes in the observation suite assimilated as new observing systems are introduced and to changes in the forecast model as model resolution increases or new physics are introduced. It is now possible to efficiently and routinely evaluate the entire global set of oceanographic observations assimilated in the HYCOM system, determining which data are most valuable and which data are redundant or do not add significant value. Like other OS-Eval methods, FSOI strongly depends on the ODAP system. Thus, the data impact results thorough evaluation of FSOI cannot be generalized to all ODAP systems.

Use of DFS for Evaluating the Impact of the SKIM Mission

In contrast to FSOI, DFS represent impacts of observations on the analysis fields. The DFS can be conveniently computed in an EnKF setting as a by-product of the calculation of the Kalman Gain without additional computing costs (Sakov et al., 2012). It is particularly relevant in the planning phase of a new observing system when the actual data are not yet available,

but some knowledge of the locations of observations and their uncertainties are sufficient to measure their potential impact on a given modeling system assimilating observations from a pre-existing network.

An initial evaluation of the impact of surface current data from ESA Earth Explorer 9 candidate mission SKIM¹³ (Ardhuin et al., 2018) has been performed using the TOPAZ ODAP system (Sakov et al., 2012) based on DFS. SKIM is designed with rotating altimeter and SAR Doppler technology at two incidence angles (6° and 12°). SKIM is the first satellite mission designed to measure the ocean surface current directly, and also designed to measure wave spectral parameters and sea ice drift.

¹³Sea surface Kinematic Multiscale monitoring.

In this study, the surface currents from both the 6° and 12° beam angles have been considered with observation errors of 0.23 and 0.19 ms⁻¹, respectively (Lucile Gaultier, personal communication). Considering that the TOPAZ system is only eddy-permitting and the SKIM currents are likely sensitive to submesoscale processes, high representativeness errors have been accounted, although very crudely, by applying a factor of 5 on the above standard deviations. Since the absolute values of DFS have little physical meaning on their own, the relative fraction of each observation type to the total DFS are presented.

The restart files from a TOPAZ ensemble have been extracted in the end of a 25-years reanalysis (Xie et al., 2017) in May 2017 which assimilated SST, along-track SSH, sea ice concentrations, *in-situ* temperature and salinity profiles. We compare the relative

impact of SKIM surface currents to that from the along-track SSH which also informs surface currents (**Figure 10**). In view of the above simplifying assumptions on the observation errors and the fact that the simulated SKIM data does not cover the TOPAZ area completely, the quantitative share of DFS (22.6% for SSH against 10.2% for SKIM) are only indications that the SKIM dataset is potentially valuable even in the presence of a good observing network as of May 2017. The patterns of the relative impacts in **Figure 10** show strong benefits in the equatorial band where the SSH data has no information content and the area close to the ice edge. These improvements are likely to carry over to other ODAP systems. The high impacts seen in the Gulf Stream area may on the contrary be system-dependent and may diminish if the observation representativeness errors are increased to account for the intensity of ocean submesoscale activity.

Use of Multi-System Ensemble Spread

The spread of a multi-system ensemble can be used for evaluating the uncertainty of ODAP products. The International Real-Time Ocean Reanalysis Intercomparison project (Xue et al., 2017a), provides beneficial information for OS-Eval as the ensemble spread can be monitored as the observing network changes in time. The project was started in 2014 following to the recommendation of the TPOS2014 workshop (see section OSE Studies for Evaluation of TAO/TRITON Array). In the project an ensemble of nine ODAP products has been routinely collected at NCEP, and the temporal and spatial variations of the ensemble spread of total temperature and anomalous temperature have been monitored and used to discern the influences of the TPOS data on the uncertainty of the ODAP products in near real time.

Figure 11 shows the temporal variations of the number of daily temperature profiles and the ensemble spread of temperature in the upper 300 m for the TAO and TRITON regions, respectively. For the TAO array region, the number of temperature profiles dropped rapidly in early 2012 and then recovered to the historical level after 2015. In responding to the TAO decline in 2012–2013, the international Argo community significantly increased the deployment of Argo floats in the equatorial Pacific in early 2014. The ensemble spread of total and anomalous temperature is closely related to the number of temperature profiles: it had decreased gradually since early 2000s due to the increase of the Argo data, increased rapidly in 2012–2013 due to the TAO decline, and then decreased in 2014–2015 due to the increase of temperature profiles. This clearly demonstrated that ocean observations played a critical role in reducing the uncertainties among the ODAP products.

Another urgent issue is the decline of the TRITON array since 2013. **Figure 11C** shows that the spread of both total and temperature anomaly increased rapidly since 2014 due to the TRITON decline. The spread of total and anomalous temperature became comparable after 2016. Therefore, we need to address the data decline in the region, and also be aware of the influences of the time evolution of ocean observations on model climatology and anomalies.

NEW CHALLENGES FOLLOWING EVOLUTION OF ODAP SYSTEMS

Coastal Regions

Many coastal applications based on ODAP systems have been developed, and are being used as essential tools for improving coastal predictions. Coastal observation data are indispensable to improve the performance of the systems and to ensure that socioeconomic benefits can be obtained. Therefore, needs of OS-Eval studies for designing, developing, and sustaining coastal observing systems are now increasing. Relevant OSE and OSSE studies have been conducted as introduced in sections OSE Study for Evaluation of Coastal Gliders in a High-Resolution Coastal Model, and OSSEs for Evaluating an Underwater Glider Array in Western North Atlantic. Adjoint-based evaluations have also been applied for coastal regions (e.g., Moore et al., 2011). These studies have showcased the importance of various observation platforms in different coastal regions (e.g., HF radar, ocean gliders, etc.). Coastal regions have diverse characteristics and it is challenging to conduct OS-Eval studies that can be compared and contrasted. Due to the unique nature of the coastal regions a coordinated effort is needed from the international community of coastal ODAP systems.

Deep Ocean

The deep ocean, in particular below 2,000 m depth, is a new frontier for ocean observations in contrast to the upper ocean which is now well-sampled by standard Argo floats. Several deep cast cruises have explored the changes in the deep ocean (e.g., Johnson et al., 2008; Purkey and Johnson, 2010; Kouketsu et al., 2011; Desbruyères et al., 2016) following Fukasawa et al. (2004)'s finding of bottom-water warming in the abyssal North Pacific Ocean. Due to the huge volume of ocean involved, subtle thermal changes in the deep ocean are known to be an important signal for the trends of world climate (e.g., Severinghaus et al., 1998; IPCC, 2014). Recently, the success of the monitoring network of Argo for the upper ocean (e.g., Riser et al., 2016) motivates the construction of a similar global monitoring network for the deep ocean (e.g., Roemmich et al., 2019). Within this background, a deep ocean state estimation and prediction is greatly anticipated. Studies on deep ocean state estimation is, however, at an early stage. Some examples of work on this are found in Kouketsu et al. (2011), Balmaseda et al. (2013b), and Osafune et al. (2015).

As mentioned in section Use of Adjoint Models and Uncertainty Quantification, the adjoint sensitivity experiments by Masuda et al. (2010) motivate deployment of deep floats. Masuda et al. (2018) try examine the impact of available deep float data on deep ocean state estimation by comparing two data sets from a set of comparative experiments with and without the deep-float data. The results demonstrate that the available float data enables corrections of the modeled ocean state locally for each float. The impact of the deep float data on a small basin (50° latitude and 10° longitude) deep ocean state estimation is quantitatively estimated to show its dependence on the float density. In addition, the H2020 AtlantOS project (section Evaluation of the Observing System Network in the Atlantic) and other recent studies (e.g., Chang et al., 2018; Gasparin et al.,

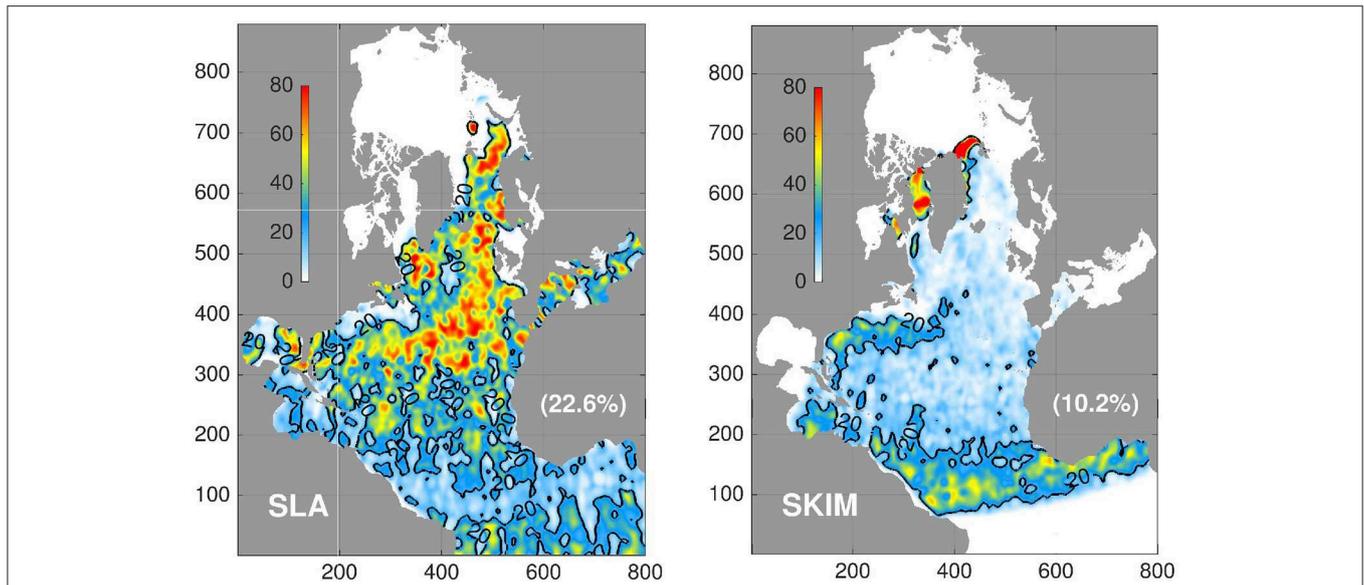

FIGURE 10 | Relative DFS impact factor projected in model coordinates in the TOPAZ system. The area-averaged impact fraction is indicated in parenthesis. The chart is presented in model native coordinates and shows the whole model domain.

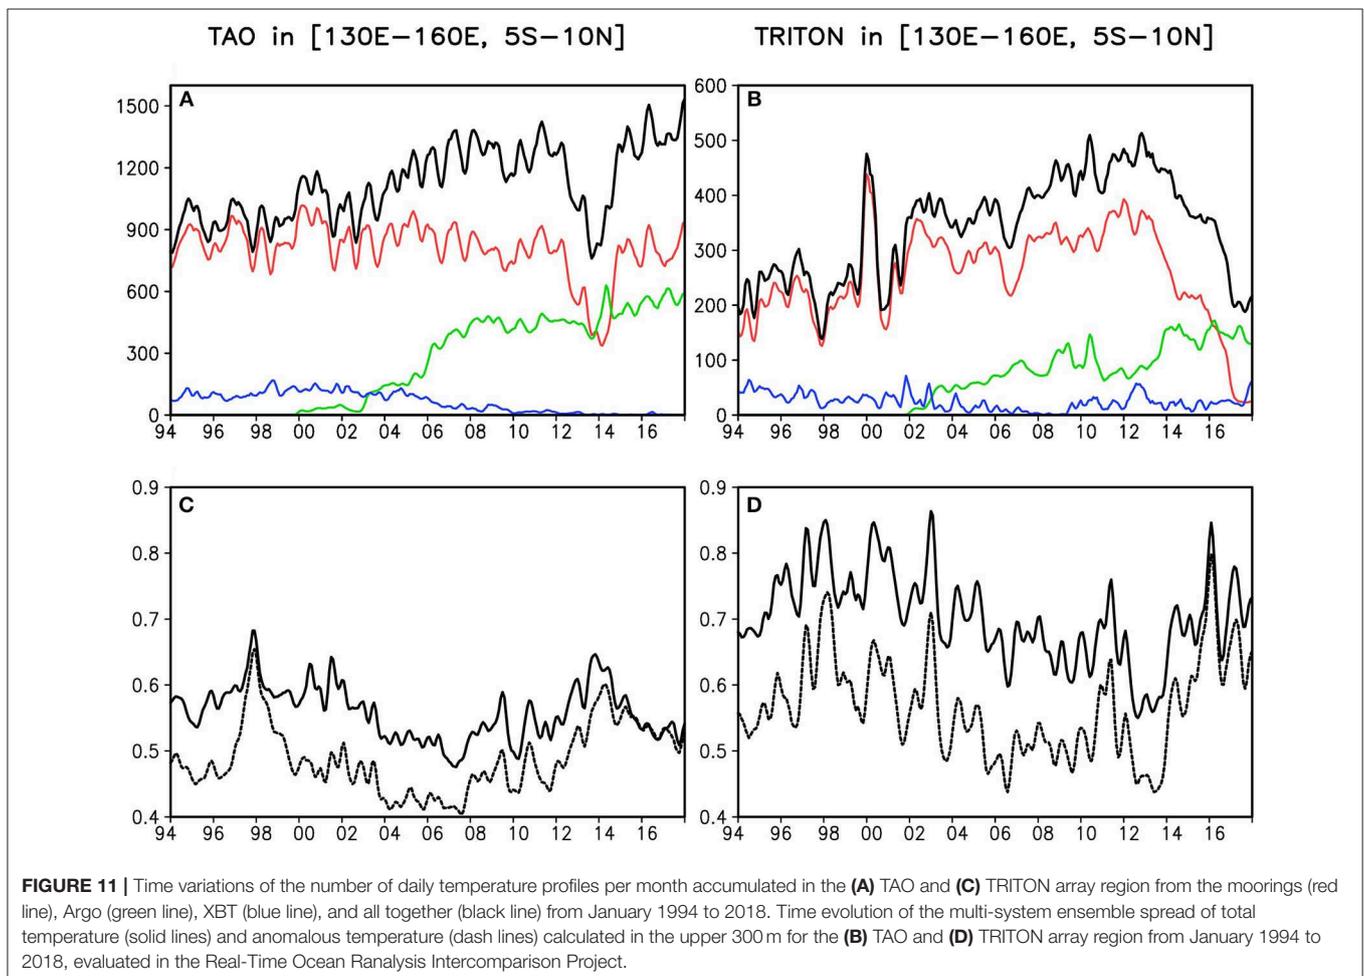

FIGURE 11 | Time variations of the number of daily temperature profiles per month accumulated in the (A) TAO and (C) TRITON array region from the moorings (red line), Argo (green line), XBT (blue line), and all together (black line) from January 1994 to 2018. Time evolution of the multi-system ensemble spread of total temperature (solid lines) and anomalous temperature (dash lines) calculated in the upper 300m for the (B) TAO and (D) TRITON array region from January 1994 to 2018, evaluated in the Real-Time Ocean Ranalysis Intercomparison Project.

2019b) have investigated the impact on assimilating a deep Argo array. However, the limited number of studies does not allow for firm statements to be made about the optimal spatial and temporal resolution of the deep Argo array. Further investigation is required to better understand the impact of the deep Argo array in the assimilation systems at long time scale.

Arctic Ocean

The relative remoteness and harsh environmental conditions over polar regions hinder efforts to provide adequate observations for ODAP systems. Improvements in observing technology and capabilities provide new avenues for sustained observations in polar regions suitable for ODAP systems (Smith N. et al., 2019). While these technologies make a more comprehensive polar ocean observing system, including sea-ice observations, feasible, the question remains, is it worth the cost?

A partial answer to the cost-benefit question may come from an ongoing international activity led by the World Weather Research Programme's Polar Prediction Project (PPP Steering Group, 2013, 2014). In particular, a Year of Polar Prediction (YOPP) for 2017–2019 aims to help address this question by coordinating international observing activities and fostering efforts to assess the impact of additional observations on environmental prediction skill, including impacts on downstream users and products (Jung et al., 2016). This effort will include OSEs to assess the benefit to forecast skill and product quality afforded by the additional observations, and evaluation of sea-ice observations will be an important target. The YOPP core period will be followed by a consolidation phase during which these experiments will be performed and results synthesized. This effort culminates in a YOPP summit, planned for 2022, which should provide an ideal opportunity for funding and implementation agencies to benefit from this community effort.

Medium-Range and S2S Coupled Prediction and Coupled Data Assimilation

The evaluation of the ocean observing system is gaining increasing importance in the context of medium-range and Subseasonal-to-Seasonal (S2S) coupled prediction and coupled data assimilation. Coupled atmosphere-ocean-land-sea-ice models are adopted in current operational medium-range weather forecasts at ECMWF (Buizza et al., 2018) and the CCMEP¹⁴ (Smith et al., 2018), and other several operational weather centers developed their systems in this direction. Operational centers also examine feasibility of sub-seasonal predictions with a coupled model, and started development of coupled data assimilation for further improvement of prediction skills (e.g., Lea et al., 2015; Laloyaux et al., 2016).

Although the impact of the ocean in medium-range and sub-seasonal predictions is not as dominant as in seasonal, those predictions are still sensitive to air-sea interaction in the tropics, mixed layer physics, and sharp SST fronts. For example, the impact of ocean heat content on tropical cyclones is well-demonstrated in previous studies (e.g., Mogenssen et al., 2017). The idea that ocean fields affect Madden-Julian Oscillation

(MJO) is also widely accepted. Therefore, ocean observations are considered to have potential to increase the skill of those predictions. Thus, it is expected we now assess what is an effective ocean observing network for coupled predictions. In particular, the assessment of the adequacy of the current ocean observing system for the sub-seasonal range will be a focus activity of the WWRP/WCRP S2S prediction project [World Weather Research Program (WWRP) (2017)] in the next few years. An example of such work is that of Subramanian et al. (2019) who found that prediction skill of tropical cyclones, in the operational coupled prediction system at ECMWF, is increased with the assimilation of SSH satellite data.

A coupled data assimilation system can propagate impact of observation data across the sea surface and thus exploit the data more effectively. In addition, it enables us to assimilate new-types of observation data around the sea surface in a more physically consistent manner. For example, Laloyaux et al. (2017) showed that satellite scatterometer sea surface wind data are more effectively assimilated giving improved oceanic mixed layer temperature in a coupled data assimilation system. Akella et al. (2017) reported on effective assimilation of satellite skin SST data in an atmospheric data assimilation system coupled with a skin SST model.

Applying regular OS-Eval techniques to a coupled data assimilation system usually requires some new developments. OSSEs with a coupled model requires a Nature Run based on a simulation of a coupled model (see section Nature Run and Calibration of OSSEs). Adjoint codes of a coupled model are required for calculating the FSOI of a coupled data assimilation system.

Evaluation of BGC Argos

Observing and forecasting systems for ocean biogeochemistry are not yet as mature as for the physical systems considered in the previous sections. Ocean color satellites routinely provide global observations of optical properties and chlorophyll concentration for over two decades. This has proved an invaluable tool for reanalysis and forecasting (Gehlen et al., 2015), but the coverage is restricted to the near-surface and cloud-free conditions, and limited information can be obtained about other variables such as nutrient concentrations. The *in-situ* observing network should develop significantly over the next few years with increase in the Biogeochemical (BGC) Argo network (Biogeochemical-Argo Planning Group, 2016). The deployment of a sustained global array of ~1,000 BGC Argo floats is foreseen, with a capacity to measure a variety of new variables (e.g., oxygen concentration, nitrate concentration, pH, etc.).

In addition to OSSE experiments reported in section Evaluation of the Observing System Network in the Atlantic, H2020 AtlantOS have conducted observation impact studies to help in the design of the future BGC Argo network in the Atlantic basin, and assess the complementarity with existing satellite ocean color observations. For monitoring and forecasting purposes, the effect of uncertainties due to various BGC model imperfections (e.g., simplified biology, unresolved biological diversity, and unresolved scales) has to be properly simulated as it should play a key role in estimating the dynamical behavior

¹⁴Canadian Centre for Meteorological and Environmental Prediction.

of ocean ecosystems. To better represent model uncertainties, Brankart et al. (2015) and Garnier et al. (2016) investigated the use of an ensemble Monte Carlo approach based on the inclusion of stochastic processes in the NEMO-PISCES modeling framework. This study showed the potential of such an approach by explicitly simulating the joint effects of uncertain biological parameters and unresolved scales using a stochastic model to simulate an ensemble of 60 members in a 1/4° resolution North Atlantic configuration.

Verification tools used in conventional OSSEs, such as RMS error metrics, need to be adapted for evaluating ensemble-based experiments, requiring a probabilistic approach. Thus, this BGC Argo OSSE study set up an integrated ensemble-based probability score methodology based on a set of probabilistic verification tools which have been mostly developed within the numerical weather prediction community to assess ensemble forecasts, and include a modified version of the entropy skill score introduced by Roulston and Smith (2002). For the sake of brevity, only the results associated with entropy are shown here.

This new methodology was applied to a single date, 15/04/2005 to compare four basic deployment scenarios while keeping numerical costs tractable. In the scenarios of BGC-Argo array deployment without satellite ocean color data (Figures 12A,B), the entropy of the updated ensemble related to chlorophyll distributions at 24 m depth shows a significant gain of information at the positions of the assimilated BGC floats, meaning that the prior uncertainty is only reduced locally. In the other two scenarios in which both BGC-Argo arrays and ocean color data are included (Figures 12C,D), the prior uncertainty is mostly reduced within a zonal band across the North Atlantic Basin at around 30°N, matching with the best coverage of satellite ocean color tracks assimilated at the surface, while BGC-Argo data (especially on nominal array) adds significant information gain in the equatorial region and at high latitudes in the northern basin. Thus, inclusion of BGC sensors on roughly one quarter of the current Argo array (around 1,000 floats) is expected to provide major improvements. There is also some evidence that a higher density network of BGC floats would add further value.

LIMITATIONS AND EFFORTS TOWARD IMPROVED OBSERVING SYSTEM EVALUATION

Limitations of OS-Eval and System Dependency

Although OS-Eval gives practical feedback to observation communities, it has several limitations which should be noted in interpreting the results. In order to use the OS-Eval results effectively, we should recognize the limitations, and interpret the results appropriately based on this knowledge. Here, the limitations are summarized as follows:

- (i) OS-Eval results inevitably depend on the properties of the ODAP system employed for the evaluation, including systematic errors, or biases, of the forecast model, and the

characteristics of the data assimilation scheme. They are thus “system dependent.”

- (ii) OS-Eval also depends on the forecast/monitoring target (e.g., ENSO, variation of the Kuroshio axis, coastal phenomena, rapid tides, etc.), forecast lead-time, and the period for the evaluation. They are thus “question dependent.”
- (iii) OS-Eval generally evaluates only the value of observation data as those to be assimilated, and the value for other purposes (e.g., as forcing data, as reference data in system validation or for the determination of prescribed error statistics and biases) is not accounted for.
- (iv) OS-Eval is usually unable to evaluate impacts of changes within observing networks in near real time.
- (v) OS-Eval often requires heavy computer and human resources.

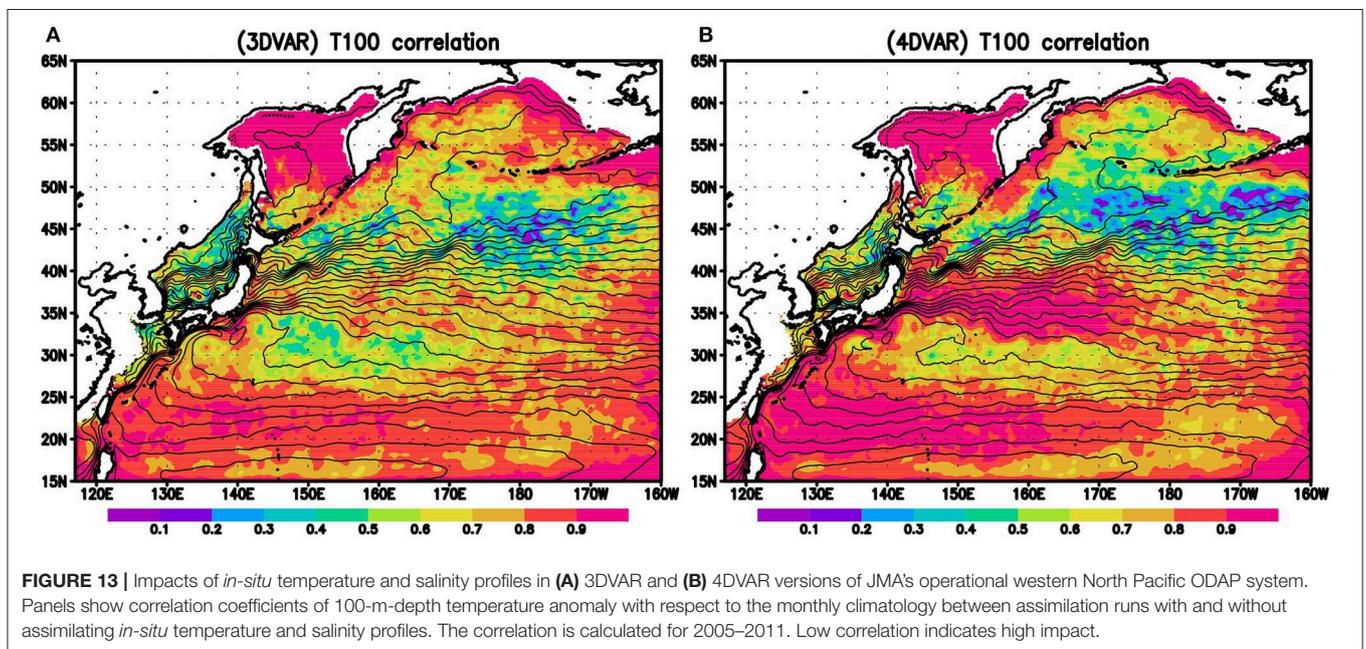

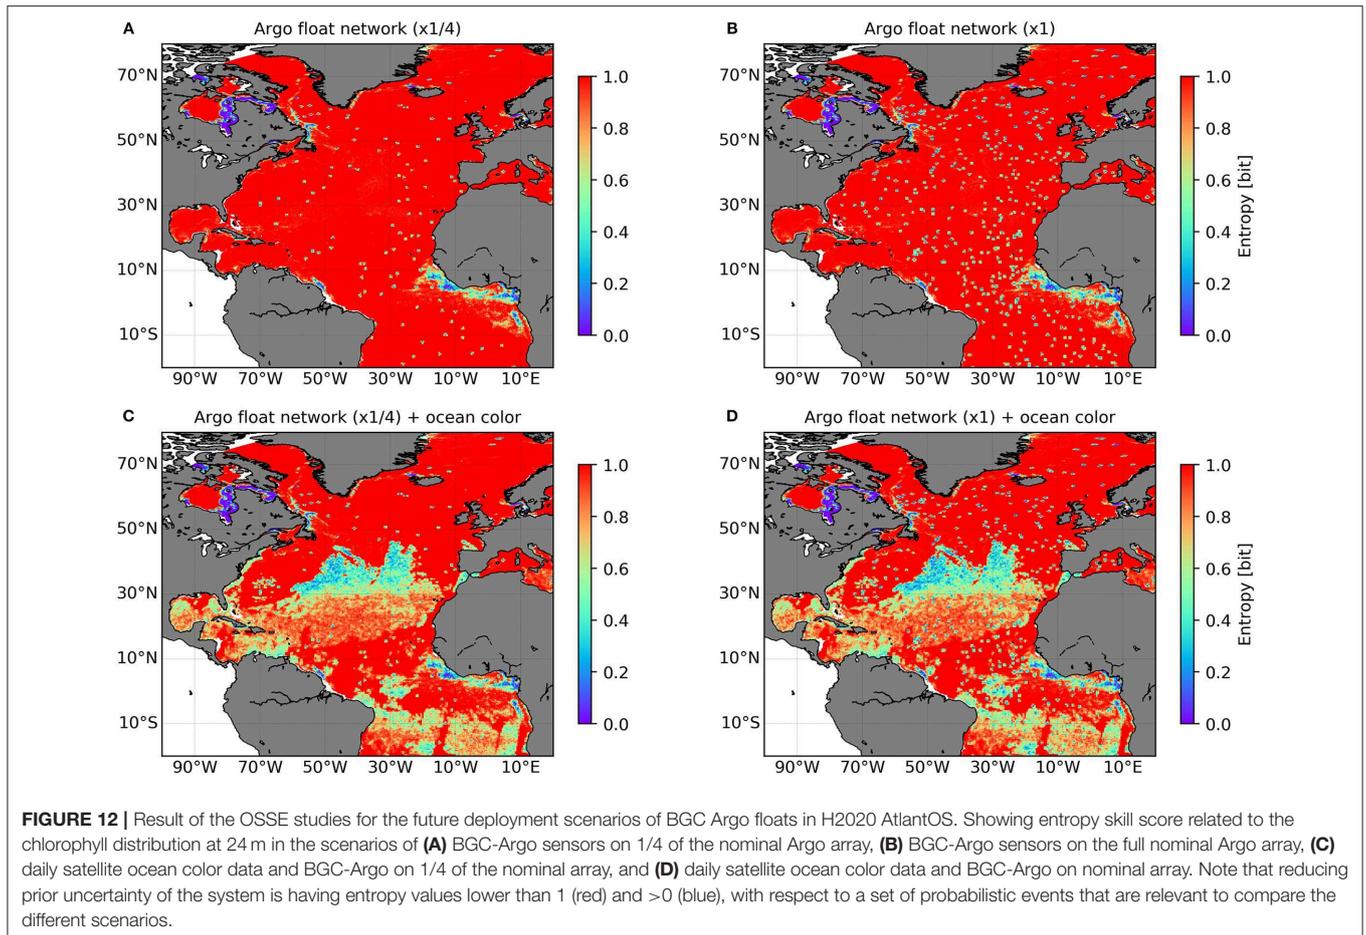

Among the limitation above, the most influential one is probably (i) the system dependency. In particular, this limitation was regarded as the main reason of the inconsistency among evaluations in the TPOS2014 workshop (section OSE Studies for Evaluation of TAO/TRITON Array). In this workshop it was concluded that large systematic errors of coupled atmosphere-ocean models severely reduce the reliability of the OS-Evals. Similarly, reasonable evaluation of coastal observing systems may be limited by insufficient representation of small-scale coastal features by the current generation of ocean models. An essential way to mitigate this limitation is by reducing the systematic errors by improving the forecast model.

The effectiveness of a data assimilation scheme in using observation information can vary which will affect OS-Eval results. Figure 13 clearly demonstrates this. This figure depicts impacts of *in-situ* temperature and salinity profiles, mainly profiles of Argo floats, on 100-m-depth temperature fields produced by 3DVAR and 4DVAR versions of the same ODAP system in JMA (Usui et al., 2015). Although a common large impact can be seen in the subarctic region and inside of the subtropical gyre, the large impacts around the Kuroshio Extension found in the evaluation with the 3DVAR system disappears in the 4DVAR evaluation due to high ability of 4DVAR to reproduce the thermal front from satellite altimetry data alone.

Because of the system-dependency, the impacts of observing systems in practical operation continuously change following to evolution of prediction models and data assimilation technologies. Meanwhile, we can only perform OS-Eval based on current ODAP systems. We thus need to consider future evolution of models and data assimilation in order to assess the true potential of an observing system. OS-Eval results also depend on how the system used for the evaluation is tuned. ODAP systems are usually tuned for the currently existing observation network. An OS-Eval study may, therefore, underestimate the impact of a future observing network as the system may need to be retuned to obtain the full benefit of it.

Multi-System Evaluation

In spite of continuous progress of model and data assimilation technologies, it is not likely to be feasible to reduce the influence

of the system-dependency to a negligible level. But using multiple systems in OS-Eval is a potential way to reduce influence of dependency on a single system because the systematic errors of each system may be independent, and will be canceled out, to some extent, when the results from several systems are averaged or summarized. An ideal way to use multiple systems for evaluation is to conduct OSEs/OSSEs simultaneously using several different systems based on a common protocol. However, this requires coordinating the common protocol among operational/research centers. In addition, OSE/OSSE requires large computer resources as pointed out above. A single-system OSE/OSSE study typically requires one OSE/OSSE by each observation type to be evaluated and one control run. The period of the OSEs/OSSEs must be sufficiently long in order to obtain statistically robust results. Forecasts from the results of OSEs/OSSEs and control experiments for sufficient cases are also required if impacts on the forecast skill are evaluated. Ensemble forecasts are required if the system is highly stochastic. Furthermore, single-OSEs/OSSEs must be conducted simultaneously in several centers for a multi-system OSE.

Actually, the GOV OS-Eval TT has investigated the possibility of conducting multi-system OSEs in order to assess the tropical arrays, and the TPOS2014 workshop recommended the proposal. Although it has not been fully implemented yet an initial intercomparison of OSE results is presented in Fuji et al. (2015a). A main reason of the effort did not fully succeed is probably the lack of financial support, needed to perform such a resource-consuming experiment at the same time in different groups. Nevertheless, multi-system OSEs for the evaluation of satellite salinity data have been successfully conducted using the UKMO and Mercator Ocean ODAP systems with financial support from ESA for the SMOS-Nino15 project (section OSEs for Evaluating Satellite SSS Data Impacts During the El Nino 2015 Event). In addition, a multi-system OSSEs are also conducted for evaluation and design of the Atlantic *in-situ* observation network within the H2020 AtlantOS project (section Evaluation of the Observing System Network in the Atlantic). This activity is feasible due to the close relationship among European countries and financial support from the European Union.

Although some European centers do successfully conduct multi-system activities, the number of the participating systems is still not sufficiently large (two for SMOS-Nino15, and four for H2020 AtlantOS). In order to perform more significant and more robust evaluation, it is desirable to conduct multi-system OSEs/OSSEs in a broader community. The growing understanding of the benefits of this work and the increasing requests to assess the merits of observing systems improves the chance of obtaining effective support for multi-system OS-Eval from operational and research centers and/or observational agencies. In fact, a common protocol on the method of OS-Eval may not be needed. It would still be beneficial to compare various evaluations of a specific observation types. This is more feasible, and may indeed offer more reliable and useful results because they do not depend on a single evaluation method. This type of collaboration is also ongoing in the community (see section Community Collaborations).

Nature Run and Calibration of OSSEs

OSSEs are widely used for the evaluation of future observing systems and network designs as introduced in section OSSEs. A clear advantage of OSSEs is that wide range of observation data, even data that do not exist in reality, can be evaluated by synthesizing the data from a simulated true state. Another advantage of OSSEs is that estimation errors in each experiment are easily calculated using the Nature Run as the true state. However, several limitations are identified through the H2020 AtlantOS project (see section Evaluation of the Observing System Network in the Atlantic). In particular, it should be noted that OSSEs operate under the following two limitations: the dependency on the performance of the Nature Run, and the difficulty in synthesizing observation data with realistic error properties.

In preliminary OSSE studies, the model used in the data assimilative experiment is also used as is, or with some changes of settings to generate the true state. However, the adequacy of OSSEs strongly depends on how appropriately the true state is simulated. The true state should favorably include a wide-range of phenomena that exist in the real world and are considered to affect the quality of data assimilation. Therefore, the true state is preferably simulated by a state-of-the-art model with an especially high resolution and no data assimilation. Such a very high performance free-running simulation generated for OSSE studies is often called the “Nature Run.” The community often collaborate to generate a Nature Run because it requires very large computer resources (e.g., Gasparin et al., 2018).

For an OSSE to give a realistic real world idea of the impact of the tested observing system the Nature Run needs to be sufficiently different from the forecast model (which is known to have systematic errors). Ideally the Nature run would be as close as possible to the real world. The OSSE studies introduced in section OSSEs all give special attention to the generation of good quality Nature Run. Thorough validation of the Nature Run is a critical part of this work (Kourafalou et al., 2016). Even so the Nature Run will still inevitably have systematic errors and will lack some real world physics processes which can degrade the applicability of the OSSEs.

It is also not straightforward to generate synthesis observations from the Nature Run because adequate observation errors must be added to the model equivalent values calculated from the Nature Run. Observation errors include measurement and representativeness errors, and the errors due to inaccuracies of the observation operator. It is quite difficult to estimate those errors appropriately. Thus, modern OSSEs require the calibration of the error setting such that the OSSEs can provide impact assessments similar to OSEs with the same ODAP systems, as for example conducted in Halliwell et al. (2014), in order to guarantee that a similar result will be obtained even if the real observations are assimilated. The requirements of modern OSSEs are summarized in Hoffman and Atlas (2015).

Evolution of observation technology and ODAP systems makes further requirements for OSSE preparation. For example, some new-type observations may reflect both the ocean

and atmospheric state. In order to evaluate the impacts of assimilating those data in a coupled data assimilation system, the true state must include both the atmosphere and ocean fields, and therefore the Nature Run must be generated by a coupled model. Considering the fact that state-of-the-art coupled models still have significant systematic errors, this may still be a big challenge. In addition, we need to design a new observation operator and its systematic errors carefully for the new-type observations, as well as its measurement and representativeness errors.

Near-Real-Time Evaluation

One of major limitation of current OS-Eval is inability to assess the effectiveness of the current observing network in near real time because the status of observing systems continuously change due to a break of an instrument for example. GOV OS-Eval TT recognized this limitation since the TT was formed, and had recommended to conduct routine OSEs in near real time in order to overcome this limitation.

According to the recommendation, a series of the Near-Real-Time OSEs (NRT-OSEs) with a period of a month were performed with FOAM, the UKMO operational ODAP system, in 2011 (Lea et al., 2014). The method was to run a parallel version of the operational system identical to it except that a particular observation type is excluded. The results of the NRT-OSEs demonstrated the importance of all the observation types excluded and showed a good amount of complementarity between observations. Particularly notable is that excluding Argo data results in an increase in surface height errors as well as temperature and salinity. Even though all the altimeter data were assimilated it is necessary to have a good T-S structure in the model in order to obtain the full benefit of altimeter data assimilation.

The trial in UKMO, thus, demonstrated the potential of NRT-OSEs to evaluate observing systems in near real time. However, it is important to note that these results may not be robust due to the system-dependency as discussed in section Limitations of OS-Eval and System Dependency. The hope was that NRT-OSEs would become routine and would be run by other operational centers which would have given a better picture of the benefits of the components of the observing system in near real time. As of yet this has not happened and this remains the only example of NRT-OSEs in the ocean. The main barrier to wider implementation is the expense in terms of computer and human resources of running an additional version of the operational suite.

The importance of near real time evaluation was also highlighted in the TPOS2014 preliminary workshop. Although the influence of the reduction of the number of TAO data on seasonal predictions and other operational ocean services had to be evaluated promptly, there were few ways to examine the impacts at that time. Finally, the spread of the equatorial Pacific temperature anomaly fields among ocean reanalyses of operational centers are examined (Fuji et al., 2015a). The spread increased after the reduction of TAO data, implying it caused the increased uncertainty. This experience demonstrates that near-real-time intercomparison of ODAP

products has a potential value for real time assessment of observing system status. Thus, the Real-Time Ocean Reanalysis Intercomparison project (Xue et al., 2017a) started after the workshop (section Use of Multi-system Ensemble Spread). We can quickly see the impact of changes in the observing system status by monitoring the spread among ocean reanalysis fields. For example, sudden break of observations by a specific platform may be identified from a spread increase in near real time. In contrast to the NRT-OSEs this uses existing runs and so does not require large computer resources in addition to operational calculation of ODAP systems. Thus, this strategy is very efficient and effective for monitoring observing system impacts.

The FSOI and DFS methods are also suitable for examining the impacts of observation data in near real time because these methods made evaluation in each analysis-prediction cycle, and are, therefore, widely used in operational weather forecasting systems. FSOI and DFS are also used in the US Navy's ODAP system (section Use of FSOI for Monitoring Ocean Observation Impacts in an ODAP System), and the TOPAZ ODAP system (section Use of DFS for Evaluating the Impact of the SKIM Mission). Since evaluation at each analysis-prediction cycle is not robust, averaging for a sufficiently long period is necessary to obtain a reliable conclusion. Additional developments are required to calculate FSOI and DFS. For example, FSOI requires an adjoint model or results of ensemble predictions. But computational cost is relatively small as these methods simultaneously estimate impacts of all observation data assimilated on a particular metric. The results can be partitioned for any subset of the observations (e.g., instrument type, geographic region, etc.). Therefore, use of these methods for routine evaluation of observing systems in operational centers is expected to be increased in the future. There is still a role for NRT-OSEs as although they requires more computational resources. They can provide fully non-linear sensitivity, which can be used for calibration of FSOI and DFS which relies on the linear assumption.

Community Collaborations

Close community collaboration within the ODAP community is indispensable to integrate OS-Eval results in order to mitigate influence of dependency on the systems and methodology and to increase the reliability as discussed in section Multi-system Evaluation. This collaboration can also provide a forum for the exchange of ideas on OS-Eval studies and to review the latest achievements and ongoing activities. Such forum is essential to share our experience with newcomers. Awareness of the importance of this collaboration, GOV established the OS-Eval TT, which is continued in its follow-on program, "OceanPredict." CLIVAR-GSOP has also made significant support to OS-Eval efforts. Effective collaboration with the ocean modeling community will also be essential to increase the reliability of OS-Eval by reducing the model systematic errors.

We also emphasize the importance of communication between the ODAP and the ocean observational communities. While ocean observations provide indispensable information for

ODAP systems, OS-Eval results can give valuable feedback to the observation community by providing scientific information on the value of ocean observations and their effective design, which supports development, maintenance, and improvement of the ocean observing system. For example, OS-Eval activities in near real time may help to target areas where Argo and drifting buoys need to be deployed for effective sampling at any given time. This is extremely useful for organizations such as the JCOMM Drifting Buoy Cooperation Panel tasked with overseeing the drifting buoy array. In order to perform a meaningful OS-Eval, requests of observational agencies/groups on the future observing networks and potential of emerging observation technologies should be considered in designing OS-Eval studies. The communication is necessary to build up the understanding on the potential of ODAP systems in the observational community to help in securing financial and human resources and to set up an adequate infrastructure in operational/research centers for OS-Eval activities. As a tool of the communication, the GOV/OceanPredict OS-Eval TT now plans to publish the Observing Impacts Statement (OIS; Lea, 2012) ideally once a year for a specific observing platform based on integration of OS-Eval results within the TT. The SMOS-Nino15 work (section OSEs for Evaluating Satellite SSS Data Impacts During the El Nino 2015 Event) highlights the interest of space agencies in developing OIS to justify follow-on missions for SSS. OISs, thus, support observational agencies to secure resources for sustaining and improving ocean observing systems.

The evolving nature of the ocean observing system (emerging technologies, possible obsolescence of existing approaches), as well as the ever changing societal needs (new applications and services, new science questions), implies that assessment of how fit-for-purpose of the ocean observing system requires continuous evaluation. Thus, the initiative on the OS-Eval by the GOV/OceanPredict OS-Eval TT and CLIVAR-GSOP should continue in the future. They are essential as an objective and authoritative source of advice on the relevance of the observing system design.

CONCLUSION

We have reviewed the methodologies of OS-Eval based on the ODAP systems, highlighting recent achievements and ongoing challenges in the evaluation of various ocean observation systems. We discussed the need to, and the strategy to, increase robustness and reliability of OS-Eval results. We showed the future vision of increasing the value of this work for designing and supporting ocean observing networks. Consequently, we make the following recommendations:

- Improvement of data assimilation methods in ODAP systems is required.
- Increased sophistication of OS-Eval methodology is needed.
- There should be clearer interpretation of the results, considering OS-Eval limitations to help the observational community.
- We should work toward performing OS-Eval in near real time.

- We should continue the efforts toward new frontiers of the ODAP systems, such as coastal regions, the deep ocean, polar regions, coupled data assimilation, and BGC applications, and to contribute the observing systems that underpin those frontiers.
- There should be closer collaboration between the ODAP and ocean modeling communities to reduce model systematic errors.
- Multi-system evaluation is needed under international coordination to improve the robustness of the results with moderating system-dependency.
- Enhanced communication is required between the ODAP and observational communities to better understand the respective needs and issues of each group. Specifically, the ODAP community must understand the key needs, opportunities, and issues of those managing the observing system; and the observational community should understand the potential of ODAP systems, as well as their strengths and weaknesses.
- Provision of human and financial resources and infrastructure is required for the OS-Eval activities under the collaboration between the ODAP and observational communities.
- Implementation of standard reporting in the form of OISs is needed to support decision-making and to provide quantitative demonstrations of data impacts that may strengthen the case for funding and improvements to ocean observing systems.

Finally, we recommend the continued development of OS-Eval activities at international level with the support of the international ODAP (e.g., OceanPredict and CLIVAR-GSOP) and observational communities. This is mandatory to guide the development of the observing system and to monitor its impact.

YF: OSE studies for evaluation of TAO/TRITON array. ER, BT, MM, and CD: OSEs for evaluating satellite SSS data impacts during the El Nino 2015 event. HZ and MBa: OSE studies for ocean reanalysis and seasonal forecasting. PO: OSE study for evaluation of coastal gliders in a high-resolution coastal model. GH and VK: OSSEs for evaluating an underwater glider array in Western North Atlantic. FG, P-YL, and ER: Evaluation of the observing system network in the Atlantic. MBe, AB, and ER: Evaluation of impact of wide-swath altimetry missions. NL, PH, YF, and SM: Use of adjoint models and uncertainty quantification. JC: Use of FSOI for monitoring ocean observation impacts in an ODAP system. JX and LB: Use of DFS for evaluating the impact of the SKIM mission. YX: Use of multi-system ensemble spread. YF and VK: Coastal regions. SM and FG: Deep ocean. GS: Arctic ocean. MBa and YF: Medium-range and S2S coupled prediction and coupled data assimilation. CG and PB: Evaluation of BGC Argos. YF

and NU: Limitations of OS-eval and system dependency. YF and ER: Multi-system evaluation. YF: Nature run and calibration of OSSEs. DL and YF: Near-real-time evaluation. GL, YF, and CD: Community collaborations. YF, P-YL, and PO: Conclusion. The manuscript is edited by YF with the support of YK, SP, CD, VK, MM, ER, PO, and DL.

FUNDING

SSS OSE studies at CLS, Mercator Ocean, and UKMO were funded through the ESA SMOS-Nino15 project. OSE studies in ECMWF have been partially funded by the EU-H2020 program through the AtlantOS project (633211). OSSE studies on *in-situ* observations in Mercator Ocean and CNRS/IGE have been funded by the EU-H2020 program through the

AtlantOS project (633211). YF and SM are supported by JSPS KAKENHI Grant Number JP15H03727. YF is also supported by JPS KAKENHI grant Number JP17H00728. GH and VK are supported by the NOAA Hurricane Sandy Disaster Relief Act [OAR-M8R2WHSP01 and NA13OAR4830224] and from the NOAA Quantitative Observing System Assessment Program [QOSAP; OARP8R2W02PQF and NA15OAR4320064]. The publication fee is provided by JMA/MRI.

ACKNOWLEDGMENTS

This synthesis work was conducted as a part of the OS-Eval TT activity and underpinned by a number of studies within GOV/OceanPredict. CLIVAR-GSOP also supports this work.

The ocean plays a vital role in the global climate system and biosphere, providing crucial resources for humanity including water, food, energy, and raw materials. There is a compelling need to develop an integrated basin-scale ocean observing system to support of ocean management. We articulate a vision for basin-scale ocean observing – *A comprehensive All-Atlantic Ocean Observing Systems that benefits all of us living, working and relying on the ocean.* Until now, basin-scale ocean observation has been conducted through loosely-aligned arrangements of national and international efforts. The All-Atlantic Ocean Observing System (AtlantOS) is an integrated concept for a forward-looking framework and basin-scale partnership to establish a comprehensive ocean observing system for the Atlantic Ocean as a whole. The system will be sustainable, multi-disciplinary, multi-thematic, efficient, and fit-for-purpose. Platforms, networks, and systems do already exist that operate at various maturity levels. AtlantOS will go beyond the status quo by bringing together the observing communities and countries of the Atlantic basin, providing the opportunity to join and support the system. AtlantOS will build upon the coordinated work of the Global Ocean Observing System (GOOS) and the Group on Earth Observations (GEO), two international bodies that support and coordinate global ocean observing. AtlantOS will complement those efforts and offers a new approach to organizing ocean observing at the basin-scale. AtlantOS will focus not only on the physics but also the biology, ecology and biogeochemistry of the ocean and seafloor and will enhance new partnerships among governments, science, civil society and the private sector.

VISION FOR AN ALL-ATLANTIC OCEAN OBSERVING SYSTEM IN 2030

A Comprehensive All-Atlantic Ocean Observing System That Benefits All of Us Living, Working and Relying on the Ocean

The All-Atlantic Ocean Observing System (AtlantOS) is a concept for a forward-looking framework and basin-scale partnership to establish a comprehensive ocean observing system for the Atlantic Ocean as a whole (**Figure 1**). The system will be sustainable, multi-disciplinary, efficient, and fit-for-purpose. AtlantOS recognizes that platforms, networks, and systems already exist that operate at various maturity levels. AtlantOS will go beyond the status quo by bringing together the countries of the Atlantic basin providing the opportunity to join and support the system. AtlantOS, the All-Atlantic Ocean Observing System, grows out of the European Union's (EU) Horizons 2020 project *AtlantOS* into a program that will build upon the coordinated work of the Global Ocean Observing System (GOOS) and the Group on Earth Observations (GEO), two international bodies that support and coordinate global ocean observing. AtlantOS will complement those efforts and offers a new approach to organize ocean observing. AtlantOS will focus not only on the physics but also the biology, ecology and biogeochemistry of the ocean and seafloor.

Ocean observations touch our lives every day from the food we eat, to the clothes we wear, to how we spend our leisure time. The ocean is estimated to be the seventh largest economy in the world. Goods and services from coastal and marine environments have been estimated at US\$2.5 trillion each year worldwide (Hoegh-Guldberg et al., 2015).

In building AtlantOS it is important that we define and follow clear and transparent principles. The implementation of this vision will lead to a sustainable comprehensive observing system in the Atlantic basin from which societies, governments, and industries around the Atlantic will benefit (**Figure 2**). To guide this development, this paper lays out the vision and shows why the community should work together toward and invest in ocean observing. It defines the principles of the system, how partners could contribute, and presents the benefits that will be derived from an effective ocean observing system. This vision then needs to be complemented by the development of an Implementation Plan, that offers a more detailed review that points to the operational challenges and approaches and offers guidance on implementation of the ocean observing system and the roles of different partners.

This high-level strategy and its vision were developed to provide a structural framework for guiding the development of the Atlantic Ocean Observing System. We will outline a baseline of core platforms, networks and systems that make up AtlantOS and a path: from initial capability at the beginning of the United Nations (UN) Decade of Ocean Science for Sustainable Development in 2021, to full operating capability at the end of the decade in 2030. The program will build upon past development of ocean observing. Ocean Observations are critical

to public services, facilitate commercial activity, support scientific research, foster well-being, and protect lives and property. While much has been accomplished, there remain gaps in fully meeting user needs at the basin-scale.

By 2030, we foresee that AtlantOS will have the following attributes:

- AtlantOS is the All-Atlantic part of the Global Ocean Observing System,
- All designated AtlantOS data providers are coordinated, integrated and cooperating to efficiently make accessible all relevant Essential Ocean Variables (EOVs) as part of the Global Ocean Observing System and the Group on Earth Observations Blue Planet programme,
- User needs are met by keeping connected with users and understanding their evolving requirements,
- A fully functioning governance framework is in place and provides a forum for coordination, resource mobilization, review and decision making, and
- Long-term sustainability has been achieved through national and stakeholder commitments with a goal of reaching 75% of sustained resources, in line with present meteorological observational support.

Full operating capability does not imply the end of development but an objective that defines the initial establishment of a fully functional AtlantOS. AtlantOS will be an agile system that will evolve as user needs change, new technologies are developed and new frontiers in ocean and earth system research are discovered.

AtlantOS will support many users including governmental and intergovernmental, commercial, non-governmental organizations, and scientific sectors to advance the use of ocean observations in the delivery of public services, sustained economic benefits and earth systems research. We envisage a basin-scale system that is compatible with global aspirations and serves as a model for other ocean basins, to realize the potential of well-integrated ocean information in support of a wide range of benefits including sustainable ocean economy with strong ocean stewardship. AtlantOS will serve a multi-dimensional range of interests relevant to the broader social and economic concerns of society.

Key examples of where AtlantOS ocean observing and information enables benefits:

- **Disaster Resilience:** Storm surge, hurricane and tsunami warnings are provided with enough advanced notice and precision to support successful emergency response.
- **Blue Economy:** Supporting sustainable prosperity from the ocean through advanced seafloor ecosystem mapping and habitat characterization, pollution tracking, identification of renewable energy options, carbon sequestration mechanisms, and other of ecosystem services.
- **Food Security:** Helping to achieve global food security, maximizing the sustainable food benefit that we can extract from the ocean now and in the future, by supporting sustainable fisheries and mariculture operations and management.

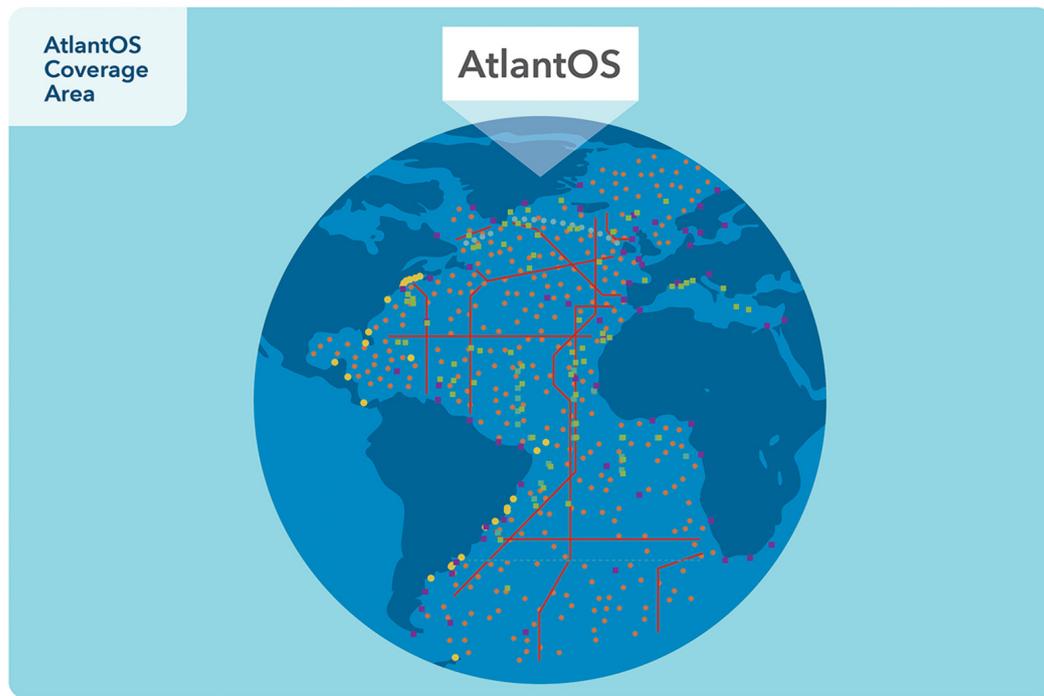

FIGURE 1 | AtlantOS coverage area. The Atlantic Ocean, depicting the focus area of ocean observing for AtlantOS. Dots and lines conceptually indicate current ocean observing activities by major networks, such as Argo, GO-SHIP, PIRATA, and OSNAP.

FIGURE 2 | Types of users. The data and data products provided by AtlantOS will support many user groups, ranging from industry to private citizens, from government to non-governmental organizations.

- Biodiversity and Ecosystem Sustainability:** Understanding changes in biodiversity and ecosystems to determine impacts on natural capital and ecosystem services and ensure our ocean resources can support human nutritional, recreational, and health needs. This includes monitoring the present abundance and distribution of organisms and improved forecasting of events such as harmful algal blooms (HABs), marine life mortality, or coral bleaching, which impact recreational and commercial use of the ocean.
- Marine Transportation:** Forecasts of extreme wave events, hurricanes and tropical storm tracks, forecasts of ocean currents, sea-ice monitoring and iceberg tracking, oil spill and pollutant dispersals, and the locations of whales and other protected species, with advisories to modify ship routes or decrease speeds to avoid collisions in the North Atlantic with the busiest shipping lanes on the planet.
- Climate Change:** Research that includes climate change indicators, such as the Atlantic Meridional Overturning Circulation, including measurements of ocean heat and circulation providing regional sea level monitoring, ocean circulation changes and climate feedbacks, and changes that affect ocean life, such as regional pH and oxygen levels.
- Ocean System Science:** Research that allows discovery of new processes and phenomena of the ocean system, supports embedded process observations, enables the development and validation of ocean system models and supports innovation in ocean state assessment and prediction.

As an example of the type of service that could be offered at the basin-scale, the operational ecosystem model SEAPODYM (Spatial Ecosystem And Population Dynamics Model) is used to simulate the mid-trophic levels of the ocean, i.e., the micronekton, and then the spatial dynamics of tuna and their fisheries. The optimal sampling conditions of epipelagic and mesopelagic biomass have been identified with modeling to support the calibration of this ecosystem variables now included in the CMEMS catalog. Then, a new management and monitoring system is proposed for tuna fisheries (Dragon et al., 2015) and illustrated with the Atlantic Albacore tuna. This pre-operational forecast system (**Figure 3**) can bring value by providing increased information about changes in catch rates due to environmental variability, e.g., changes in abundance over time and space by age class from larvae to adults. It also permits distinction between fishing impact and natural variability of the stock and supports real-time monitoring of fishing activity and stock assessment analyses.

We must see ocean observation as a fundamental requirement for a global society. Over the past century, humanity has come to see roads, electricity, policing and many other services as fundamental requirements of today's society. So too must we shift our perspective about ocean observation in the twenty-first century. We have a responsibility to act as stewards of our ocean – in our regions and globally, the international community has identified a range of goals and drivers that require

systematic ocean observations (e.g., Miloslavich et al., 2018; Tanhua et al., 2019).

The ocean provides crucial resources for humanity and plays a vital role in the global biosphere and climate system. Ocean resources include food, energy, raw materials, recreational use, global trade and cultural services. According to a study by the Organization for Economic Cooperation and Development (OECD), by 2030 the ocean could more than double its contribution to the global economy, reaching over US\$ 3 trillion. To conserve and protect our ocean and the vast resources it provides, we must observe and understand ocean regions and how they interact – through transfer of heat, freshwater, nutrients, oxygen, carbon dioxide and marine life.

Improved and sustained observation of our ocean is necessary for informed decision-making to ensure human-ocean interactions are sustainable (Weller et al., 2019). We need coordination of observations, bringing together the data from many sources and countries: surface buoys measuring wind and waves; robots documenting the ocean's interior, ships and other methods for surveying fish stocks; and satellites providing the view from above. We should share information widely, opening data to many uses and the greatest value. We will save time, money, and energy by working together.

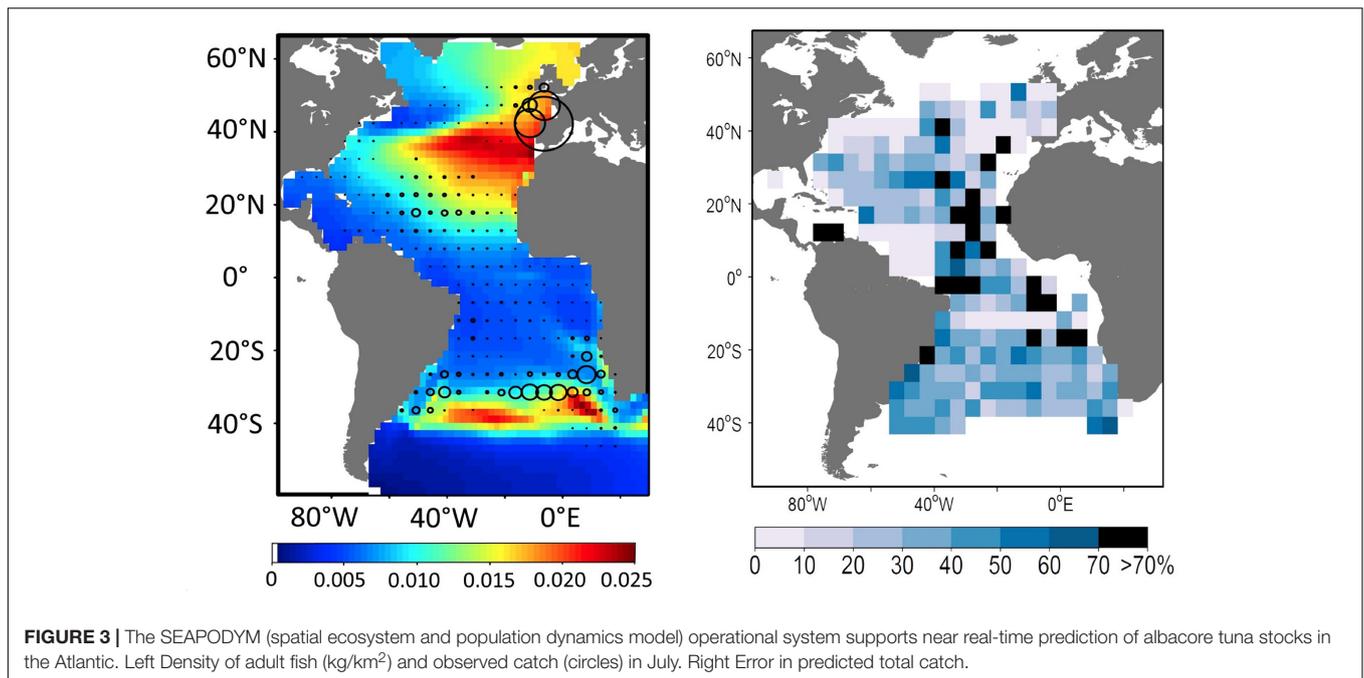

The ocean observing community has produced a Framework for Ocean Observing (Task Team for an Integrated Framework for Sustained Ocean Observing, 2012 – FOO), a guide to help us decide what to measure in our ocean and why. The FOO has been a useful guide in the writing this visionary strategy and will be helpful as we shift focus to the Implementation Plan.

Why Now?

Coordinated ocean observations have been in practice since the creation of GOOS in 1991. GOOS initially focussed on physics and climate issues. As a result of the OceanObs series of conferences (1999, 2009), GOOS was expanded to include ocean chemistry and biology as well as a focus on coastal observing. Indeed, these two meetings laid the foundations for the ocean observing systems that have developed since and documents such as the FOO, which arose from the OceanObs'09 meeting, guide much of the ocean observing community. New demands and expectations, and the upcoming OceanObs'19 meeting, offer opportunities to assess how we are conducting ocean observing and consider fresh approaches.

Our capabilities to observe the ocean, and our understanding of it, have been arisen from key collaborative science programs such as the World Ocean Circulation Experiment (WOCE), the Climate Variability and Predictability Programme (CLIVAR), the Joint Global Ocean Flux Study (JGOFS) and the Global Ocean Ecosystem Dynamics (GLOBEC) programs. These multi-disciplinary, large scale programs stimulated multinational collaborations and stimulated technological developments critical to our present ocean observing systems.

In 2015, the United Nations agreed to the 2030 Agenda for Sustainable Development and its 17 Goals (SDGs), and 195 countries agreed on the Paris Accord. In 2017, a call for action was adopted by member states at the high-level UN Ocean Conference supporting the implementation of SDG 14

to “conserve and sustainably use the oceans, seas and marine resources for sustainable development.” G7 leaders have also shown an interest in the importance of ocean science since 2016, most recently with the 2018 publication, Charlevoix Blueprint for Healthy Oceans, Seas and Resilient Communities.

Two international Atlantic cooperative agreements for marine science provide an incentive and context for a focus on ocean observing with a particular emphasis on the Atlantic. These are: the Galway Statement on Atlantic Ocean Cooperation, signed by the European Union, Canada and the United States of America (U.S.) in 2013; and the Belém Statement on Atlantic Research and Innovation Cooperation, signed by the European Union, South Africa and Brazil in 2017 with additional EU-Argentina and EU-Cabo Verde agreements and the ambition to include other countries around the Atlantic Basin.

Another opportunity for working together and growing ocean observing and information systems is the United Nations Decade of Ocean Science for Sustainable Development (2021–2030) which was declared in late 2017. We must seize these opportunities, to focus our efforts on developing an ocean observing system that fulfills our Atlantic and global stewardship responsibilities.

MEETING USER NEEDS

Meeting user needs begins with assessing the societal benefits of sustained ocean observations, and then understanding how an observing system can provide those benefits (Weller et al., 2019). Growing coastal populations and use of the ocean’s resources are creating increased demand for ocean information. Limited funds mean the observing system must be efficient, cost-effective,

and responsive to user needs. We must make the best use of the diverse range of ocean observations available. Much of the work in designing an integrated ocean observing system for the Atlantic Ocean involves ensuring that existing programs are integrated coherently into a system that is fit-for-purpose, i.e., responsive to the needs of stakeholders.

The process of identifying and refining components of the value chain, as discussed in the FOO, from instruments measuring the ocean to information in users’ hands, should be ongoing and iterative. We must pay attention to evolving technologies, changes in the ocean, societal needs, political alignment and leverage, and our ability to use observations to benefit society. Activities at each step in the value chain should be justified by the needs of one or more user communities. Different approaches are possible and all should be employed – bottom up, working from the data, or top-down working from users’ needs. Reviews of the system should be conducted on a regular basis.

GOOS has developed an open-access tool we can use to follow the links in the value chain. We can trace scientific questions, phenomena, Essential Ocean Variables, and the observing networks required to satisfy a societal benefit. Alternatively, we can determine the phenomena and societal benefits that rely on an EOVS or on observing networks.

A key challenge is to distinguish what ocean variables are essential (and feasible) from those that are only desirable. The ocean is vast and there are many possible variables to measure, and at many scales. We must focus to ensure that our observations create the greatest benefit. The needs of the users, which are diverse and complex, should be the main consideration for the development of products and services.

The aim of a multiplatform, multidisciplinary, multisector basin-wide system is to optimize observations at basin-scale

and maximize the benefits of the data collected. Data from observing platforms should be used for many different observing objectives in real-time and over and over again in delayed mode. The capacity and gap analysis should be done on the full value chain, for both societal benefit and improved scientific understanding.

Challenges in Meeting User Needs

An effective observing network or system needs clear standards for components and careful consideration of the societal benefits. The FOO document identifies lessons learned from the successes of existing observing efforts, and provides an internationally accepted common language and guidance for expanded collaboration in sustained ocean observations. The FOO uses EOVs as a framework to determine the key observations that are required to achieve the goals of the observing system. EOVs are negotiated based on feasibility and impact. Essential means that these observations are the minimum subset required; they are not replaceable by other variables. This framework, while challenging to implement, has been accepted by the user community as a guide to determine the key or essential measurements that should be made.

The review process should involve formal and analytical physical, biogeochemical, biological/ecological, and socio-economic metrics, as well as qualitative approaches. Many aspects of our present observing system, such as some historical coastal stations, were selected based on pragmatic considerations. Expert panels have often played a key role. For example, the observing system for climate was originally developed through international panels such as the Ocean Observing System Development Panel (OOSDP, 1995) and the following Ocean Observing Panel on Climate (OOPC) which supported early developments of sustained ocean observing systems. Today, the advancement of computer models, data assimilation systems and prediction systems have enabled more quantitative, purposeful specifications for ocean observing (Moore et al., 2019). Computer model-based experiments, or Observing System Experiments (OSEs), enable testing of existing observation networks and systems, and Observing System Simulation Experiments (OSSEs), “simulate” testing of future observing networks and systems.

Several international efforts are working to coordinate systematic observing system and modeling system evaluations through programs, e.g., CLIVAR – Global Synthesis and Observations Panel (CLIVAR-GSOP) and the Global Ocean Data Assimilation Experiment (GODAE) Ocean View (now OceanPredict) are two such programs, with a focus on physical oceanography. OceanPredict is also dealing with biogeochemical modeling and data assimilation. The EU Horizon 2020 project *AtlantOS* includes a focus on the Atlantic Ocean, using state-of-the-art models to refine methods used in computer models (OSSEs, OSEs) to provide consistent, calibrated results. The improvement of observing system technologies must develop hand-in-hand with improvements in modeling and data assimilation systems (see Smith et al., 2019, for some thoughts on approaches to consider). Given our capabilities, we should rely on evidence-based approaches for the

design of AtlantOS, the All-Atlantic Ocean Observing System (Ostrander et al., 2019).

PRESENT OCEAN OBSERVING IN THE ATLANTIC

AtlantOS is not a new system but rather a new approach to provide a comprehensive, state of the art observing system for the Atlantic Basin that can be fully realized and sustained for the long term. AtlantOS will build upon existing observing assets. Like other ocean observing systems, AtlantOS proposes to take measurements of ocean properties and use those measurements to understand how the ocean system functions, how it affects us, and how we affect the ocean. The system must encompass many types of platforms and sensors and needs to fully take into account the synergies and complementarities with present and future satellite observations. We learn a lot about the ocean from satellites including sea level and geostrophic ocean currents, water temperature, ocean color, sea ice, sea surface salinity, waves and winds (Le Traon et al., 2015). Satellites play a critical role in providing real time, global high space and time resolution observations of key ocean variables that are essential to constraining ocean models and for operational use (Le Traon et al., 2019). New capabilities (SWOT, SKIM) are also developed to observe the ocean dynamics at very high resolution (Morrow et al., 2019) or to directly observe surface ocean currents from space. Satellite observations are, however, largely restricted to the ocean surface. To fully understand, describe and forecast the 3D ocean, *in situ* observations (measurements taken in and out of the water) are mandatory. *In situ* observations are also essential to calibrate and validate satellite observations.

We still need direct measurements in the ocean – which can be from instruments left at a fixed spot in the ocean, from a ship or from drifting or mobile platforms (e.g., gliders or tagged animals). When we put these different data streams together, plus measurements of the atmosphere, we can see how the ocean and atmosphere work together, giving us a powerful tool to predict what is happening in our ocean and how this supports many societal benefit areas. Using evidence derived from ocean observations, we can keep people safe, support robust communities, and foster sustainable use while enabling the stewardship required to adapt and manage human-ocean interactions in changing ocean ecosystems.

Figure 4 would suggest that the whole ocean is fully covered and begs the question as to why there is concern about the state of ocean observation. Our response is that our observations are constantly improving, but still inadequate to respond to rapidly growing societal needs, and that the coordination and integration of the existing observations is less than it should be. We can get more value out of the effort we presently put into ocean observation. To do this, we need to understand what observing is happening and what user needs those activities meet.

To begin to realize a fully operational AtlantOS, we have proposed a methodology for determining what elements

JCOMMOPS AtlantOS Status Map

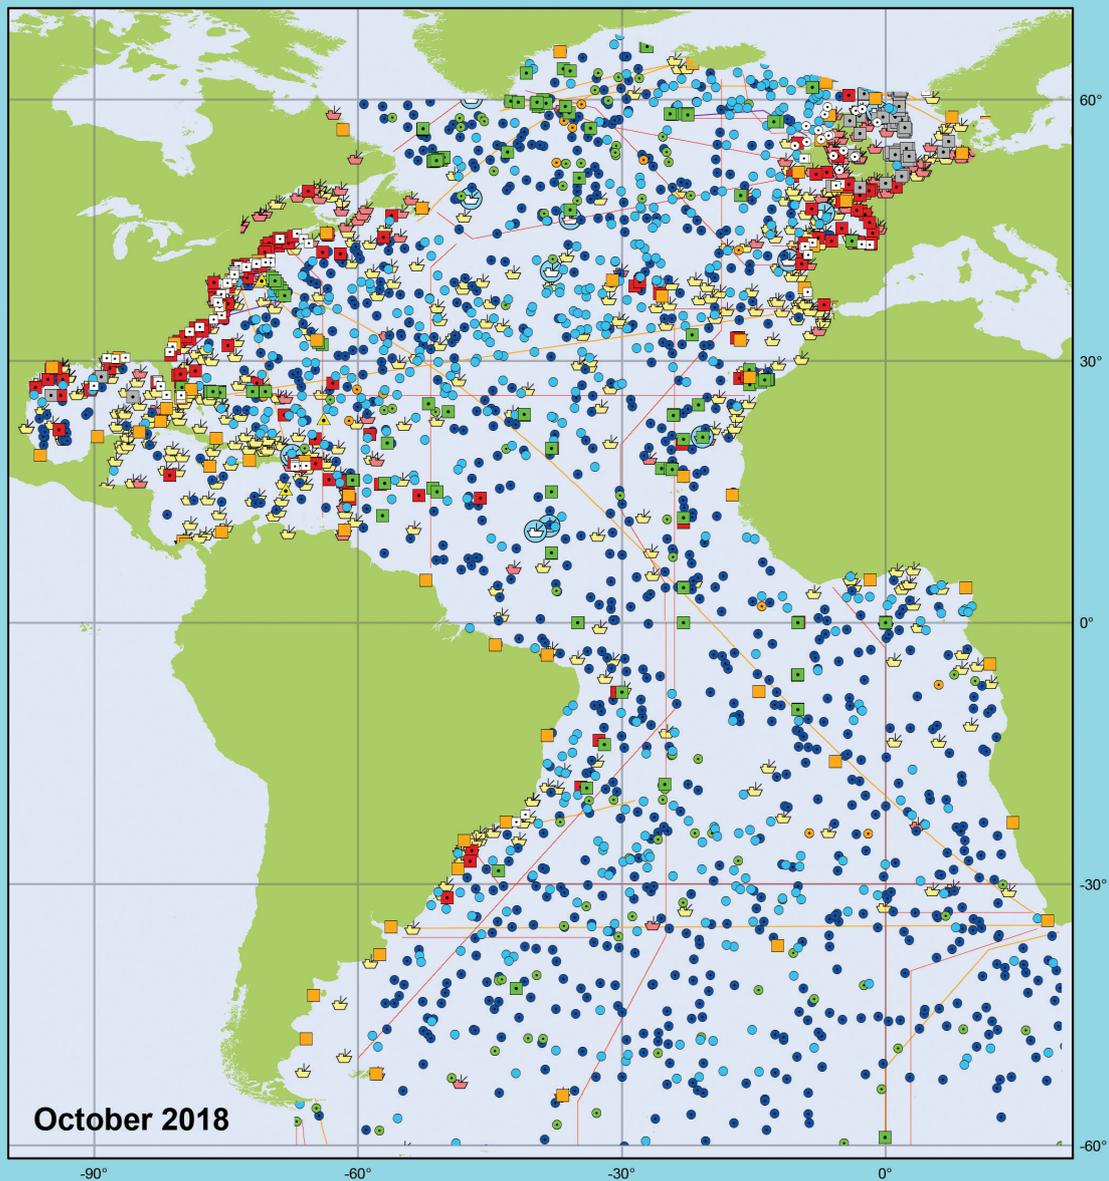

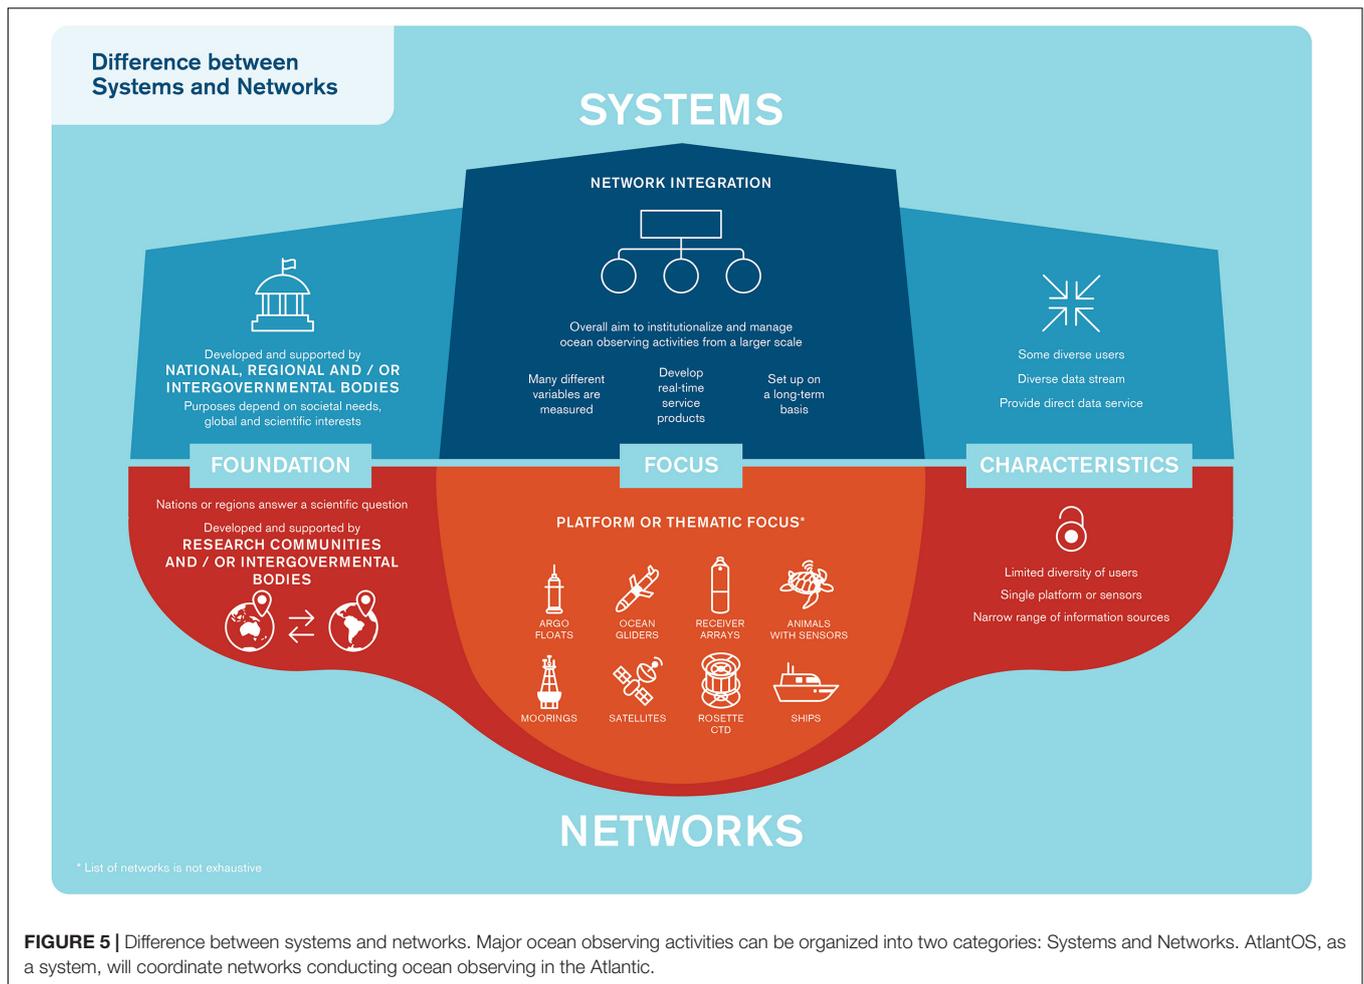

FIGURE 4 | Global ocean observing system (GOOS) status map for September 2018 (Source: JCOMMOPS). Map of the Atlantic Ocean showing the location of ocean platforms (drifters, moorings, buoys, etc.) with onboard instruments collecting ocean observations. Coverage map is of observing activities by GOOS network members.

represent the initial core network and which systems would be included. Existing observing activities can be described in two main forms (Figure 5). Often the terms *network* and *system* are used interchangeably, however, networks and systems are different:

- *Ocean observing networks* are typically platform- or theme-focused activities – where platforms can be ships, moorings, drifters, ocean wave gliders and more, to which instruments can be mounted – based on common technology and data types, and often cater to focused ocean issues; themes include topics such as biodiversity and acidification. Networks are typically founded via international collaborations between research institutes and countries (like GO-SHIP, MBON, OceanSITES, SOOP, and Argo) with the aim to observe the ocean together (Duffy et al., 2013). They have common practices and standards, shared scientific infrastructure within their own network but with policies to share data openly. Global networks, such as Argo, are often built around a particular instrument platform. As an example, the growing High Frequency (HF) Radar network is built around coastal radar networks that provide measurements of coastal current

and waves. The focus of networks is generally narrower, technology focussed and more specific than is true for observing systems.

- *Ocean observing systems* are large-scale national, regional or international programs founded and funded by governments and stakeholders that build on networks within a region. Three clear examples (presented later) are GOOS, EuroGOOS/EOOS and the U.S. Integrated Ocean Observing System (U.S. IOOS®). Many different variables are measured in an ocean observing system, such as temperature, sea state, ocean currents, salinity, ocean acidity, dissolved gas concentration, biodiversity or seafloor properties. The motivation is to coordinate ocean observing activities carried out by research institutes within a geographic region. Their purposes depend on societal needs and governmental interests, as well as scientific interests. Observing systems typically have some forms of legal bases. In general, the aim is to institutionalize and manage ocean observing activities on a larger scale. Ocean observing systems promote open access to data and cooperate with their members to develop products for users. Observing systems are set up on a long-term basis. Ocean observing *networks* are members of ocean

observing *systems* and are supported by them, e.g., via financial contributions.

For the All-Atlantic Ocean Observing System to succeed and provide benefit, ocean observing governance needs to evolve and recognize the basin scale as governing scale. There are key challenges with the coordination and governance of ongoing observation of the Atlantic Ocean:

- Today, not all of the networks and systems needed for AtlantOS are affiliated with GOOS and adequately governed or coordinated. Some systems, such as U.S. IOOS and EuroGOOS do identify as GOOS Regional Alliances (GRAs) and parts of the global system. Other networks, such as the Marine Biodiversity Observation Network (MBON), reside under the Group on Earth Observations Biodiversity Observation Network (GEO BON) and operate in explicit partnership with GOOS and the IOC. Others are national or regional in scope and governance – often established by treaty or other agreements or to satisfy national reporting requirements; these often exist and operate outside of GOOS or any other global body.
- There are differences in how systems are defined. For example, US IOOS is an adaptive, federated network of ocean observation, data management and communications, and modeling and analysis capabilities. EuroGOOS is a non-governmental organization (NGO) that coordinates national observing systems and funds coordinating activities.

These diverse groups, with different structures and responsibilities, present coordination challenges and gaps and there is widespread recognition that those gaps must be addressed if we are to embrace a true basin-scale observing approach.

Ocean observing systems exist also at the sub-basin scale. Two examples are presented here: EuroGOOS is a regional observing system with 42 members from 20 European countries. Members join EuroGOOS to have a single common voice, e.g., at the European Commission level. Since February 2013, EuroGOOS has been established as an international non-profit organization – it can enter into contracts and have direct managerial control over the secretariat. The system promotes an open data policy and funding includes membership contributions, external funding via research projects and tender contracts. At present an European Ocean Observation System (EOOS) is being developed that would integrate EuroGOOS and increase the range of activities from the European system. US IOOS is a nationally-funded program that aims to gather observing data and develop tracking and predictive tools to benefit the economy, the environment, and public safety across their nations and around the globe.

A few key examples of current Atlantic and global ocean observing networks and systems are:

- *Argo* is an international ocean observing network of nearly 4,000 freely profiling floats that measure temperature and salinity in the upper 2,000 meters of the global ocean and are also extending to deeper ocean and bio-geochemistry EOVS. Since 2000, when the network formed, *Argo* has

revolutionized oceanography, providing publicly-accessible data in near real-time. *Argo* data are vital for understanding ocean temperature, salinity, and current variations and their effects on weather, climate and ecosystems. *Argo* is a voluntary network, with the implication that long-term funding is not guaranteed. *Argo*'s primary users are the World Meteorological Organization (WMO), the operational oceanographic services and the research community – easily identified groups with which *Argo* has close connections. The tight link between users and networks suggests that support from users in systems, such as AtlantOS, may be more challenging as the path from the data collection to the users is harder to identify.

- In the Atlantic there are three regional scale observing networks (OSNAP, RAPID, and SAMOC) all measuring the Atlantic Meridional Overturning Circulation (AMOC) that is a major process for moderating climate change, transferring heat and carbon dioxide from the surface to the deep ocean and from the tropics to the subpolar regions. These three networks have simple governance models, taking the governance approach of major international scientific programs, mainly because they have voluntary contribution models and indeed most of the funding comes from scientific funding councils of the contributing nation states.
- The *Marine Biodiversity Observation Network* works in partnership with GOOS, the Ocean Biogeographic Information System (OBIS), and a broad range of global partners to coordinate and make available the marine biological and ecosystem observations needed to ensure living marine resources are sustainably conserved and managed and can support essential human needs. MBON is refining methods for environmental DNA applications in an operational ocean observing context and has developed advanced methods to evaluate marine biogeographic provinces (seascapes) using multidisciplinary satellite remote sensing data. The MBON Pole to Pole initiative is building a community of practice that helps nations to improve conservation planning and environmental impact mitigation, serves the scientific community, and satisfies commitments to the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES), Aichi Targets of the Convention of Biological Diversity (CBD), and the UN 2030 Agenda for Sustainable Development Goals, as well as supporting efforts to produce and international, legally binding instrument under UNCLOS (United Nation Convention on the Law of the Sea) on the conservation and sustainable use of marine biological diversity of areas beyond national jurisdiction. MBON Pole to Pole is achieving this goal through: (1) Enhanced coordination of coastal and ocean observations and data collection among nations, (2) improved collection of harmonized data, and furthering data standards and methodologies, (3) integration of physical and biogeochemical observations with biodiversity information to characterize status and trends, and (4) generation of products needed for informed management of the ocean.

- *PIRATA* is a regional-scale ocean observing system in the Tropical Atlantic founded in 1995 and has recently been renamed to “Prediction and Research Moored Array in the Tropical Atlantic.” It is recognized as the reference network of oceanic and atmospheric observations in the Tropical Atlantic, as well as for climate-dedicated research and for operational climate and ocean prediction. The network was designed for studying ocean-atmosphere interactions in the tropical Atlantic that affect regional weather and climate variability on seasonal, interannual and longer time scales. Ocean-atmosphere interactions in this region influence the development of droughts, floods, severe tropical storms and hurricanes, with impacts felt by millions of people in America and Africa. This system is supported mainly by three member countries – the U.S., France and Brazil and collaborates with others such as Germany. The governance structure is more “formal” because the member countries work through a Memorandum of Understanding that is renewed every four to five years.
- The IOC-WMO *Joint Technical Commission for Oceanography and Marine Meteorology* (JCOMMOPS, 2017) provides organizational support through the JCOMM Ocean Coordination Group (OCG) and status reviews and metrics through the JCOMM Operational Program Support (OPS). Most of the programs supported by JCOMM operate as networks and not as systems. Many global networks supported by JCOMM are well-established (e.g., ARGO, GO-SHIP, OceanSITES) but there are new emerging networks such as HF Radar and Ocean Gliders, which are also JCOMM networks. All JCOMM networks support free access to open data and quality control processes.

Challenges for Existing Ocean Observation Networks and Systems

Ideally these existing networks would be integrated into coordinated systems at the global level. That is true for example of the AtlantOS components of Argo, OceanSITES and GO-SHIP. But overall there is a lack of coordination linking the national/regional to the basin-scale (i.e., AtlantOS) and from the basin scale to the global scale. It is therefore the right time to articulate how we can adjust or integrate these component networks to form a desired fit-for-purpose, basin-scale system. While many may agree on the goal for a clearer more integrated system, the steps to reach or achieve this goal are actively debated by the ocean observing community.

Several key issues, or challenges can be identified:

Multiple Sensors and Platforms

First, the existing observing landscape includes many sensors and platforms. Many states conduct monitoring activities within their Exclusive Economic Zone (EEZ) that do not link systematically with the GOOS networks [e.g., Continuous Plankton Recorder (CPR) or fish stock monitoring that respond to EU habitat requirements]. Such activities use platforms and methodologies that meet local/national needs and are managed and archived at the national level. For a sustainable ocean

observation system, it will be important to incorporate all these networks into a more connected governance structure. This might be more effectively coordinated at the basin-scale level. The coastal networks should be aligned so that vital ocean information products like storm surge, hurricane, oil spills or harmful algal bloom forecasts as well as changes in distributions of fish or other organisms could be predicted earlier and more reliably.

Focus Too Narrow

Many existing observing networks are too focussed on the physical Essential Ocean Variables articulated by the GOOS physics panel, e.g., ocean temperature, salinity, currents, waves, and sea level. There is increasing interest from users, and the scientific community to incorporate biogeochemistry, biology and ecosystem EOVS; GOOS panels are developing specification sheets and implementation plans to guide that effort, which includes newer activities such as animal tracking. One challenge as we widen the scope of our interest is how to provide guidance (e.g., using the FOO) for practitioners to select from an ever growing set of measurement expectations and requirements.

Independent Operation

Ocean observing networks and systems tend to work and be comfortable within their own structures. Collaborations between the different networks and systems, like the Argo-GO-SHIP cooperation, where the two networks collect overlapping data types and can validate and build on one another, hold valuable potential and are only partly exploited. Increased collaborations will lead to a faster-evolving, more integrated and effective observing in the Atlantic Ocean where time, money, and knowledge would be used in an optimized and sustainable way.

System Evaluation and User Feedback

Ocean observing networks and systems are largely thematically or issue focussed and often started with a scientific need for information. AtlantOS has the ambition to connect existing systems, facilitate platform and information sharing and improve overall system efficiency. However, a system evaluation and feedback mechanism needs to be established to ensure the AtlantOS system is meeting multiple user needs. Thematic reviews, user consultations and discussions and agreements between resource providers are essential.

Lack of Long-Term Funding

Most observing networks lack long-term, sustainable funding. They depend on voluntary contributions from members or national governments, which often change from year to year. Much of the present funding structure is based on research funding and may not be sustainable. Without adequate and reliable sustainable funding, user needs cannot be met and innovation and capacity building will weaken. Governments must recognize the societal and economic benefits of open data policies and equipment and resource sharing. The governance structures of ocean observing systems should be oriented toward reliable, long-term strategies, akin to what we have for weather

observations. The funding structures should be similarly aligned. With the development of AtlantOS, we can grow and coordinate collaborations between ocean observing systems, to improve data sharing and build a common data policy, and promote an effective voluntary funding structure and support capacity building activities.

MOVING FROM THE PRESENT TO ATLANTOS

In considering how to develop AtlantOS, it is clear that we will not start from nothing. There is a wide array of infrastructure in place. Many global networks presently operate well as do many coastal and regional systems. How do we move forward from this present patchwork of activity to the more coordinated and comprehensive system that we envisage?

A first step is to determine which present networks and systems could form the core of the developing AtlantOS system, which could be emerging networks, and which might best be partners to AtlantOS. In considering the wide array of existing networks and systems, the first step is to define the criteria by which to assess the state and status of a network and system. We suggest following: The general approach to this problem has been addressed practically by the JCOMM OCG (Legler et al., 2016) and as considered in the FOO. Adapting this approach, we suggest four key criteria to consider in determining how to organize existing activities into the basin-scale AtlantOS system:

1. Location and scale – it must take place in the Atlantic. This includes both coastal and open ocean areas but likely not the regional seas such as the Baltic and Mediterranean and the northern and southern boundaries are purposely vague.
2. There should be an intention for operation over multiple years. There is no expectation that funding is guaranteed but there should be a plan for ongoing operations.
3. There must be some formal governance structure including a management team, defined standards and plans and a multi-year strategy for operations.
4. There should be a policy for free and open data that is available in a timely manner.

We reviewed key existing networks and systems in the Atlantic, North and South, and present the following as examples (see Bourlès et al., 2008; Rayner, 2010; Roemmich et al., 2010; Cooke et al., 2011; Duffy et al., 2013; Legler et al., 2015, 2016; McQuatters-Gollop et al., 2015; Talley et al., 2016; Mayer et al., 2018) to demonstrate the types of networks and systems that could be included and to demonstrate that there are many existing activities that could contribute to the developing core of AtlantOS:

Persistent Core Components Networks

- *Argo*
- *GO-SHIP*

- *Ocean Tracking Network (OTN)*
- *OceanSITES (including OSNAP, RAPID, SAMOC)*
- *PIRATA*
- *Ship Observations Team (SOT)/Ship-of-Opportunity Programme (SOOP)*
- *Global Ocean Acidification Observing Network (GOA-ON)*
- *Continuous Plankton Recorder*
- *Global Sea Level Observing System (GLOSS)*
- *Marine Biodiversity Observation Network*
- *SeaBed 2030 (GEBCO)*

Systems

- *U.S. Integrated Ocean Observing System*
- *EuroGOOS*
- *South African Environmental Observation Network (SAEON)*
- *Sistema de Monitoramento da Costa Brasileira (SiMCosta) – Brazilian Coastal Monitoring System*

Partners

- *Voluntary Observing Ship (VOS)*
- *Satellite remote sensing (e.g., CEOS)*
- *Tsunami Networks*
- *Private Sector Installations (Oil-Riggs, Wind Farms, Offshore Mariculture)*
- *NGOs and Civil Society observing*

Examples of Emerging Components

- *OceanGliders*
- *HF Radar*
- *Surface Ocean CO₂ Observing Network (SOCOINET)*
- *Atlantic Seabed Mapping International Working Group (ASMIWG)*
- *Global Omics Observatory Network (GLOMICON)*
- *Canadian Integrated Ocean Observing System (C-IOOS)*
- *IOCARIBE*
- *OCEATLAN*
- *Global Coral Reef Monitoring Network*

The first steps in developing AtlantOS could begin with coordination and integration of those well-established networks that see the benefit of collaboration with an Atlantic focus. The demonstrated benefits of coordination would encourage other groups to join and stimulate further developed of ocean observing in the Atlantic. These benefits should be defined by AtlantOS and their assessment would further support sustainability of these networks and systems and expansion of new ocean observing activity. The two immediate benefits to existing networks and systems would be expanded access and use of data being collected, by reaching wider communities of users, and improved demonstration of the societal benefit derived from the observational activity stimulating improved financial support and long-term sustainability.

AtlantOS will adopt an inclusive operating environment with well established and transparent ways by which new networks and systems can be developed, accelerated and adopted as part of the basin-scale system.

GETTING DATA AND INFORMATION TO USERS

Observations have no meaning without open data policies and effective data management. They ensure observations are retained and accessible for current and future users. Data management that enables access, use and interpretation of data and products is essential and must be based on collaboration across activities, such as quality assurance and control (QA/QC), which enable local and interoperable discovery and access, and secure archiving.

The present data management landscape is complex and hard to navigate. There are many specific data management infrastructures for specific data types, which can cause delayed and duplicate data receipts, missing data and metadata, and undocumented data processing procedures. There are also missing data management structures making it hard to retrieve some specific data types. Streamlined, modern data management structures are required: they can simplify, automate, and make more efficient the flow of data. *New data systems should be interoperable.* This would support routine data exchanges within and between observation networks, and user-friendly tools for data/products discovery, viewing and access. Community standards are the foundation for interoperability (Figure 6).

We need better coordination of the national and international efforts for data management and communication. *Our goal: to harmonize data processing and distribution.* It is also important to set up internet portals to make it easy to access a network's data. Such data portals and access are particularly well-developed in the meteorological community: for example, they support operational meteorology through the World Meteorological Organization. Using and expanding the system of portals that are either EOV-based (primarily for delayed mode data) or platform based (for near real-time data but also scientifically assessed data) supports a rigorous and effective quality assessment service for data providers.

Ocean observations must be available to users on a free and unrestricted basis. There is global recognition that open access encourages wide use of data, and the development of new data products. A key component of data management is close monitoring and quality control of data streams. Communication between the observing system operators and data managers is important. Data centers should give priority to using modern information and communication technology. Data and associated metadata have to be discoverable through portals, catalogs and search engines (Figure 7). To assist discoverability and to ensure correct citation of all data, each dataset requires a unique permanent reference for identification.

Principles and Approaches to Data

The FAIR principles must guide the Atlantic Ocean data management system and should be central to the AtlantOS approach (e.g., Tanhua et al., 2019). There are four FAIR

principles. First, data should be *Findable* – this goal requires globally unique and eternally persistent identifiers for each dataset, rich standardized metadata attached to each dataset, and that data be searchable through standardized discovery services. Second, data should be *Accessible* – this goal will be achieved by establishing free and unrestricted access to data, ensuring full and open exchange of data, metadata and products, all with minimum delays. Third, data should be *Interoperable* and understandable – observations should always be provided with at least a minimum set of metadata, to enable traceability. Fourth, data should be *Re-usable* – there should be comparability built from agreement on quality control procedures, there should be clear recognition and citation to assist discoverability and data should be preserved so that there accessibility will remain indefinitely (Wilkinson et al., 2016).

The study of the many interrelationships that exist in the ocean requires the integration of multidisciplinary approaches and different investigative skills and methods. The ocean observing community therefore has a responsibility to provide the best scientific knowledge, based on international collaboration, to enable wise global strategic decisions. We need to adopt ethical behaviors such as highlighted in the Cape Town Statement on Geoethics: (a) ethical values regarding behavior, honesty, integrity, courtesy and equity; (b) social values calling for sustainability, prevention and education; and (c) cultural values to strengthen community relations (Peppoloni and Di Capua, 2017). The basis and criterion of geo-(marine)ethics is responsibility. Ethics is a sum of all elements that will enable a sustainable research/monitoring endeavor, and we include elements drawn from the philosophical, social, and natural scientific dimensions.

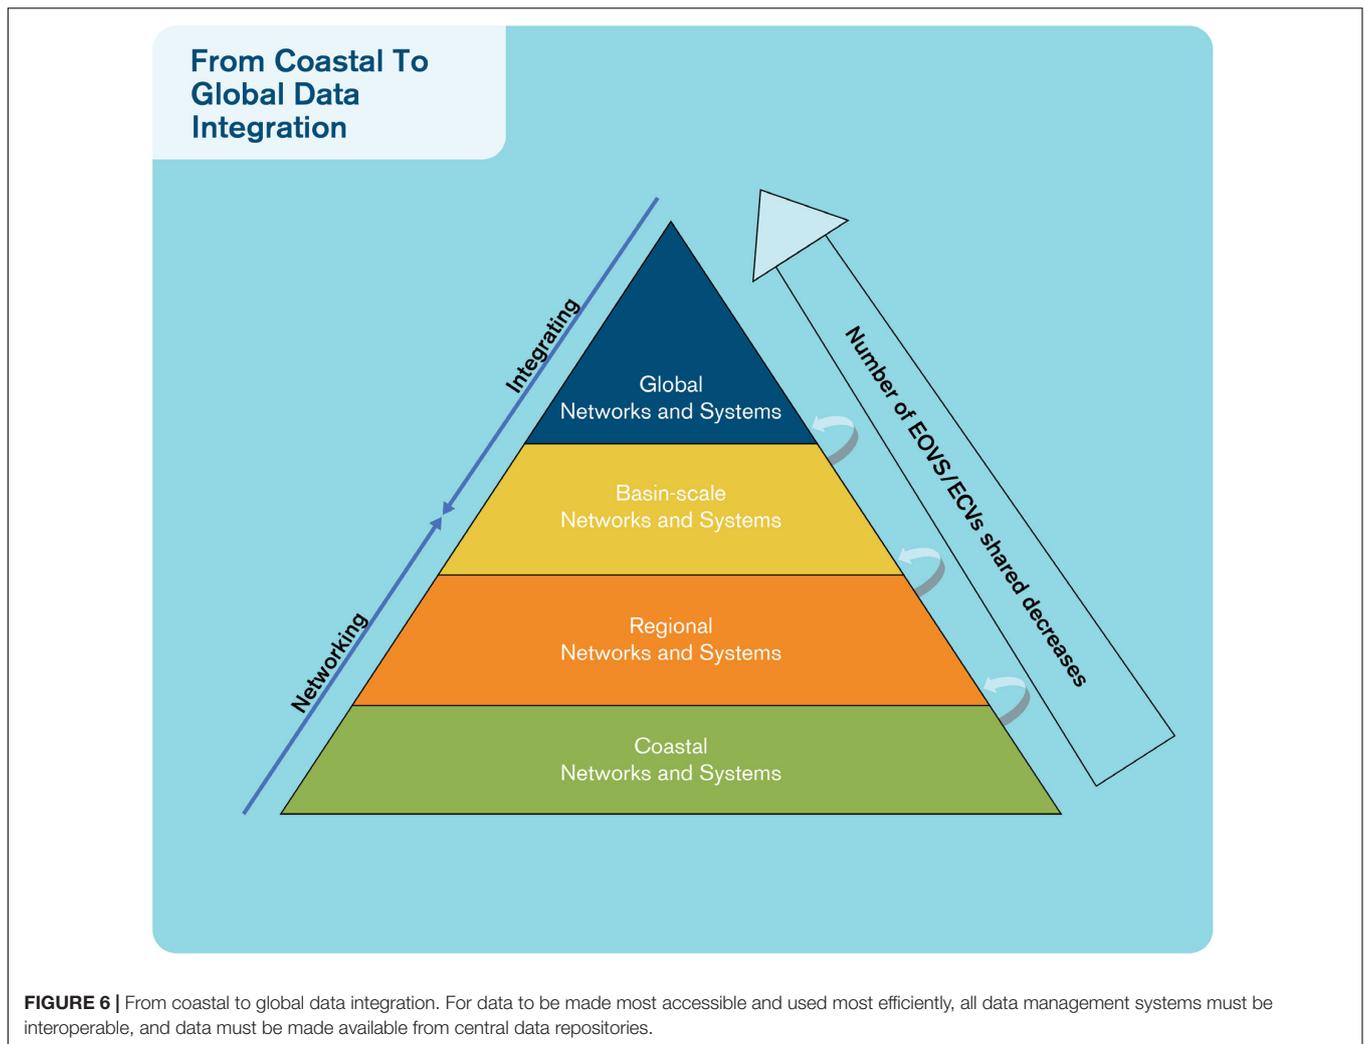

The ocean observation community is responsible to respect for and minimize impacts from research and monitoring on ocean ecosystems, to respect and engage local people in research activities from multiple culture and diverse sector, to work with the goal of global benefit based on reciprocal relation, transparency and responsibility, to maximize efficiency and quality of observations in research activities, engage the society, communicate to and advise policymakers, encourage learning, and share data – acquire once, use multiple times (Buck et al., 2019).

Basin-Scale Computer Models

Coordinated basin-scale modeling will:

- inform the blue economy and infrastructure planning,
- support ecosystem-based management, and
- predict and help mitigate the impacts of human actions and climate change.

Cyberinfrastructure requirements for a coordinated approach to developing basin-scale models will include both high-performance and cloud-based computing. A basin-scale approach requires seamless tools for integrating models, remote sensing observations (e.g., from satellites) and *in situ* observations, all at the basin and large regional scales. Computer models should be developed using a sequenced approach,

building on existing models. A framework for the seamless integration of models, remote sensing and *in situ* observations (**Figure 8**) will take time to develop and should address how basin-scale modeling can be seamless. Basin-scale models should be seamless:

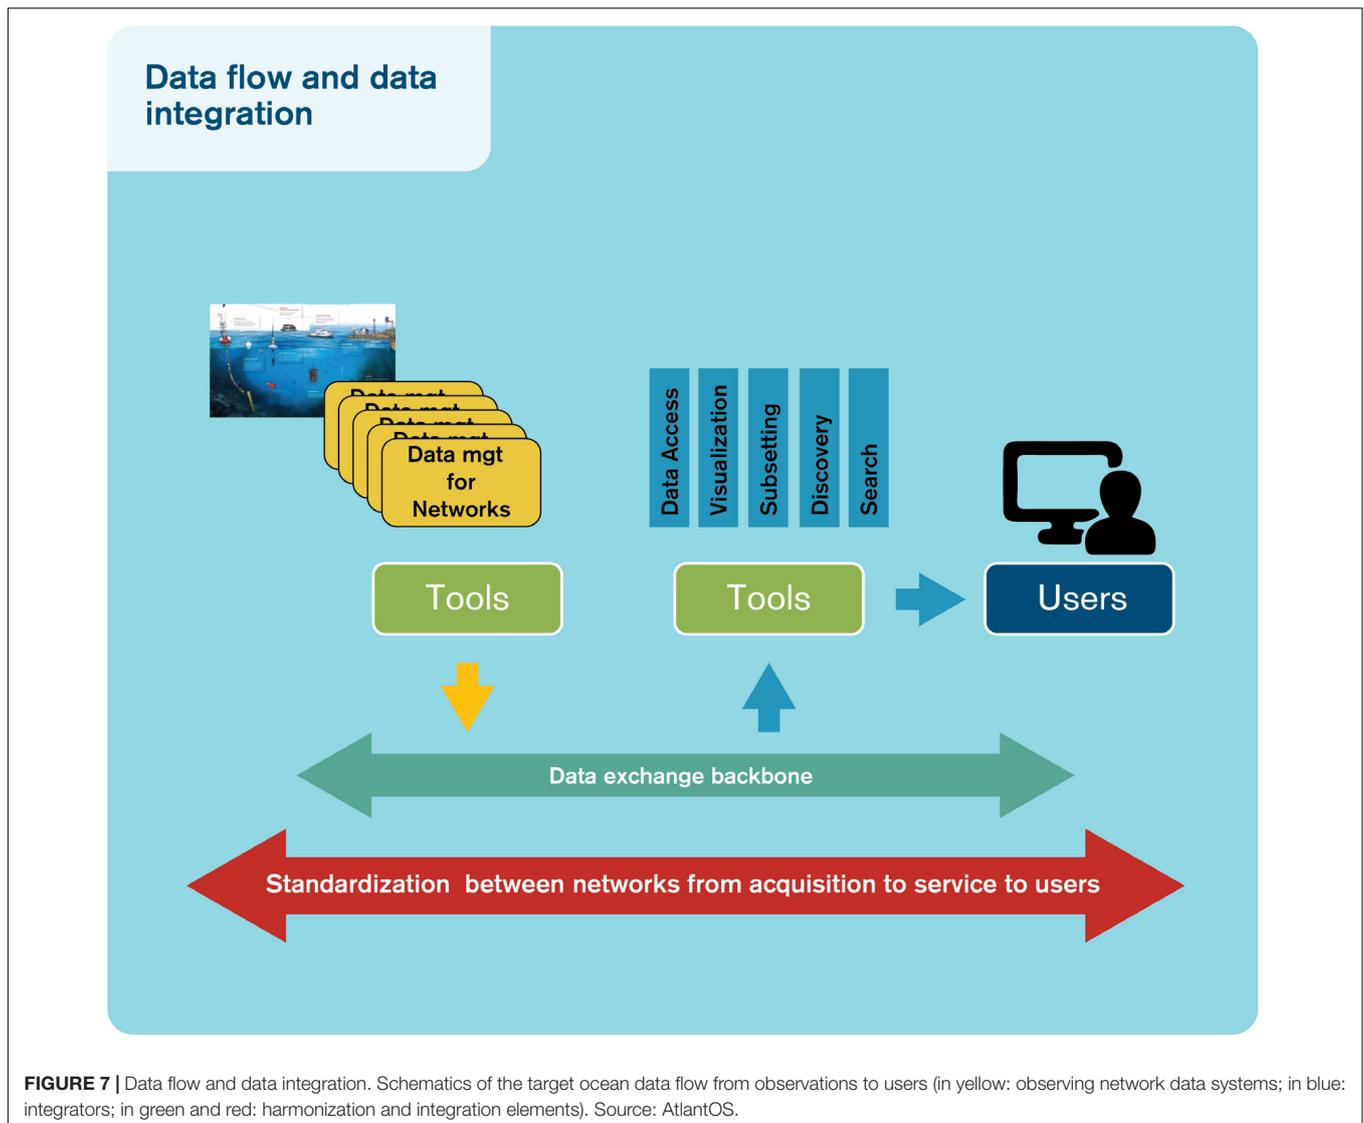

- In space: basin – continental shelf – coastal – estuary;
- With regard to processes: land – coastal – ocean – atmosphere;
- In time: from seconds (e.g., waves) to hundreds of years (e.g., meridional overturning circulation); and
- In variables: referring back to Essential Ocean Variables for physics, biogeochemistry, biology and ecosystems.

INNOVATION, GOOD PRACTICE AND CAPACITY BUILDING IN OCEAN OBSERVING

Innovation is key to ocean observing – it means creating developments or ideas that substantially enhance how we operate.

Many different areas of ocean observing have been enhanced by innovation including data communication, integration and sharing; the development and deployment of new sensors and platforms; ocean model guided observing system design, and new cooperative models for observing system governance. Innovation benefits all aspects of ocean observing (**Figure 9**).

A key innovation with big impact on ocean observing is *citizen science*. Citizen science programs are taking off. More and more people are getting involved in science – they’re getting their hands wet! The development and expansion of citizen science programs is well timed. Consumer electronics are becoming part of the scientific arsenal and scientific instruments are increasingly user-friendly. Citizen scientists can now easily and quickly share their data, and the results of their efforts are just as easily shared with the wider community. Advances such as smart sensors, autonomous vehicles, and web-based data systems will enable important roles for citizens in ocean observation. In addition, citizen scientists often have access to areas that are not as often reached by scientists, such as school groups heading to rocky shores, and divers collecting data in shallow ecosystems like kelp forests and seagrass beds.

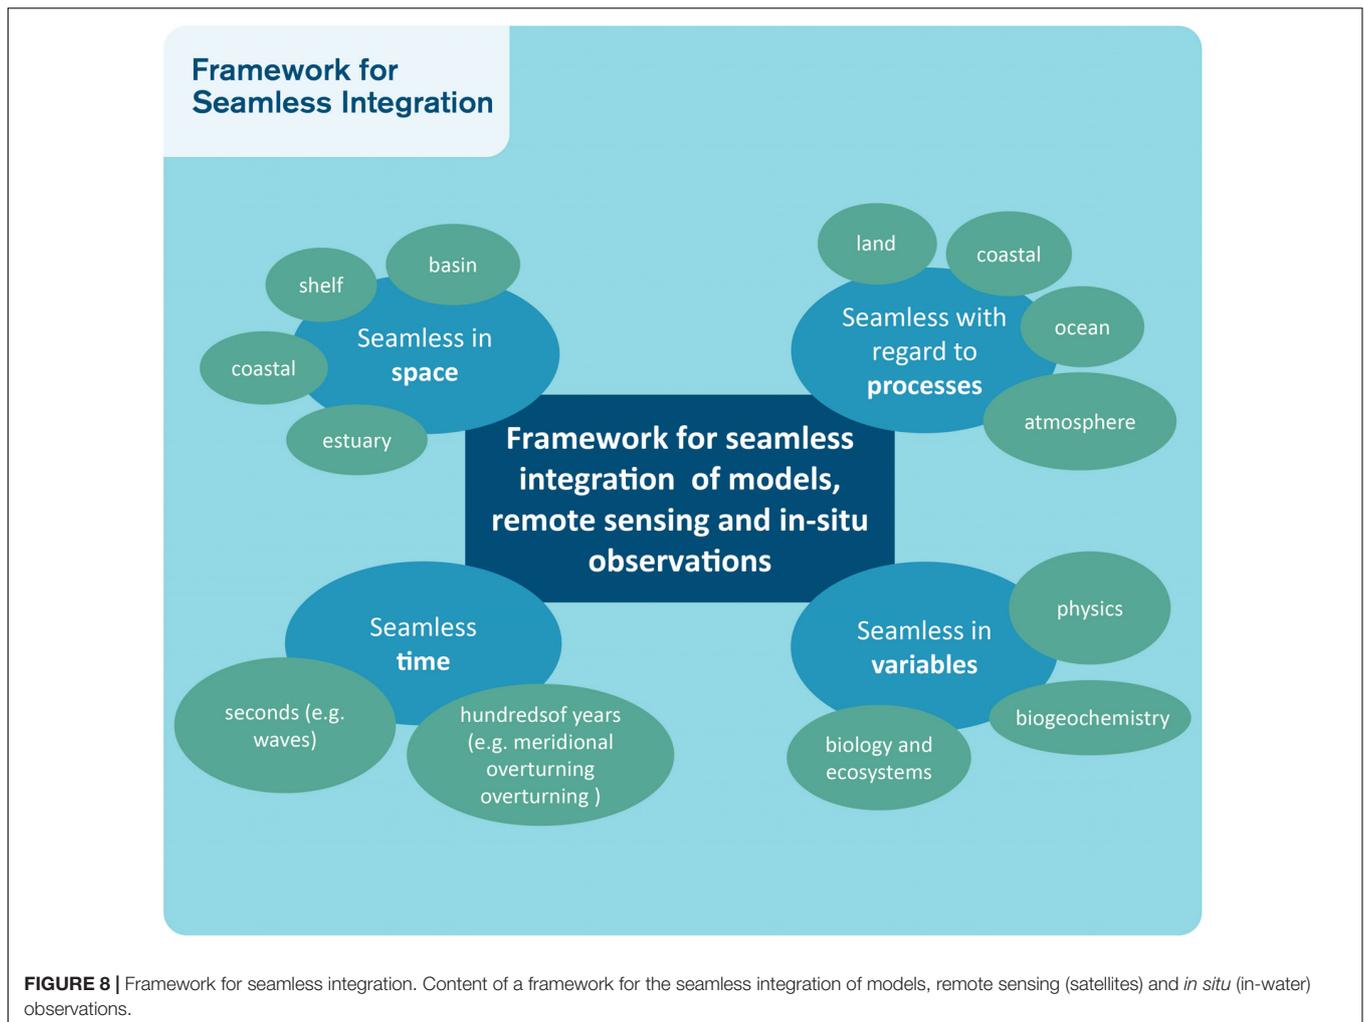

Even in more extreme and inaccessible environments, citizen scientists are collecting data – from images taken by Remotely Operated Vehicles (ROVs) and Autonomous Underwater Vehicles (AUVs), they are identifying species from the deep sea ecosystems or kelp patches in collections of satellite pictures that span decades. This work is time consuming and would not be possible solely with professional scientists. Citizen scientists are more than ever critical to science, and they offer an opportunity to extend our reach into the ocean and to expand on the partners who will contribute to ocean observing systems. We should encourage further development of citizen science activities and share in the development of best practices for their creation and innovation.

One important aspect of improving ocean observation methods and technology is through sharing technology (Figure 10) and best practices. Partnerships between countries and across ocean sectors permit new opportunities for collaboration and innovation that result in improved ocean

observing and downstream information for a large range of societal benefits. The ocean observing community can innovate by developing strategies for the use of new technology.

Capacity building activities benefit the ocean observation community. The biggest challenges to better education and technical skills lie in the disparate opportunities between countries – geographical, political, financial, economic and technical. AtlantOS should include formal structures to support capacity building and innovation, and to share best practices (Figure 11). We must do better to address issues of gender equity and diversity. The voices of those who are poorly represented must be better heard. We must raise our expectations and encourage wider participation in ocean observing to achieve greater participation and inclusion.

Each actor has particular skills and capabilities that should be shared widely across the community. Getting all Atlantic rim countries involved will enable a sense of community and ownership in each. It will also support synergies between

infrastructure investments and reduce barriers to multi-national efforts. Capacity building should include fostering cooperation between Atlantic rim countries. Cooperation can be fostered by exchanges of capacity, shared platform deployment opportunities, joint scientific expert teams to ensure high quality and diffusion of data, and focus on new measurements, including biological and bio-geo-chemical and seafloor variables (Barth et al., 2019).

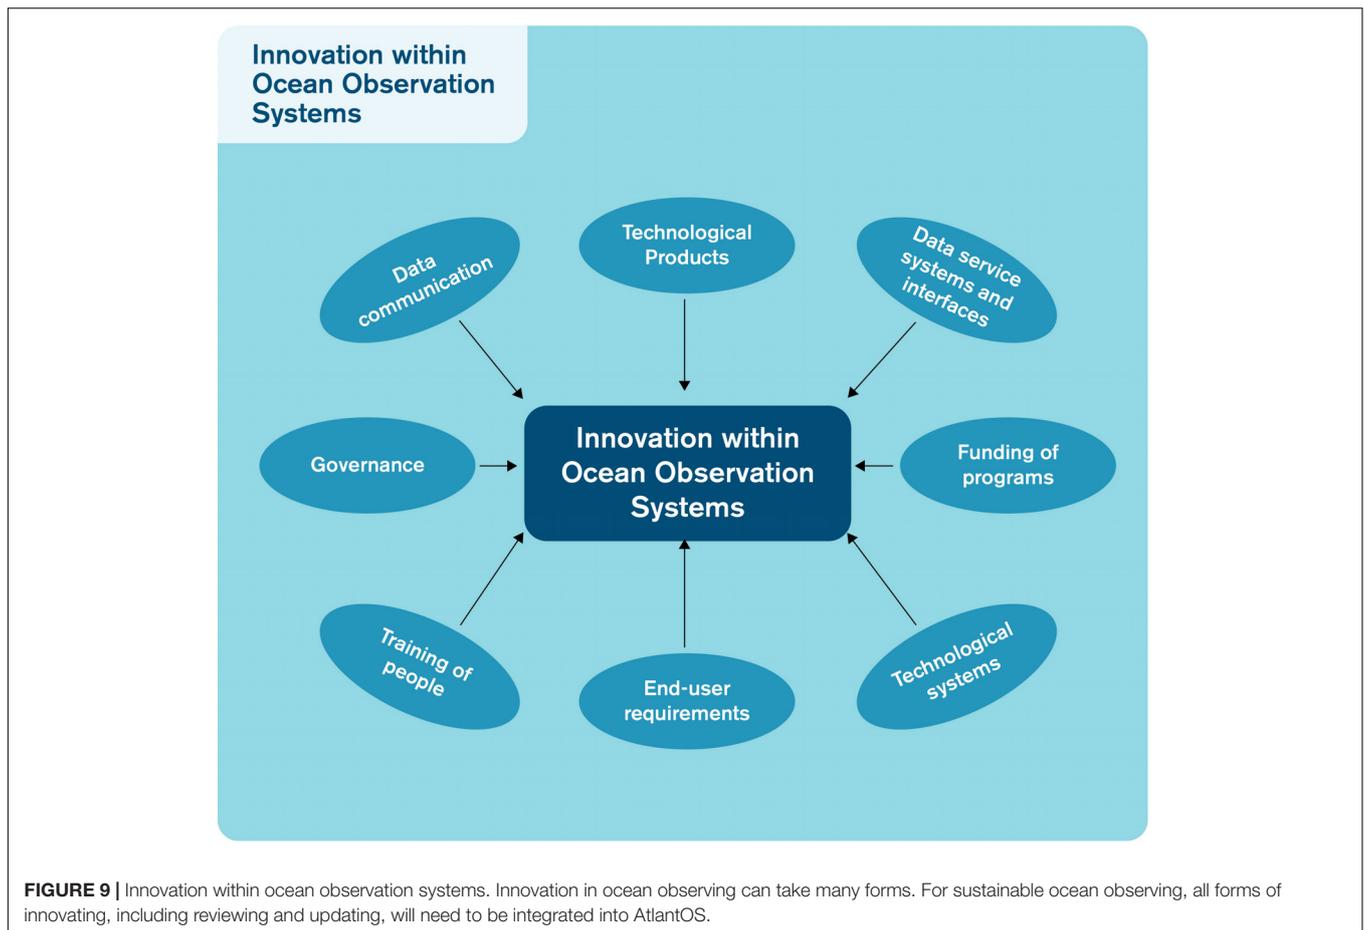

GOVERNANCE AND PARTNERSHIPS AT THE ATLANTIC BASIN-SCALE

Existing regional and national observation systems have both strengths and weaknesses. Their strengths lie in the transparency of the approaches used by different networks. Their key weakness is a lack of or loose coordination. A clear governance structure requires defined responsibilities and tasks for different actors. In general terms, a governance structure is a collection of functions and activities that support AtlantOS' development and management of policy, plans, guidance, resources, processes, tools and infrastructure. The degree of governance control varies

from the local to the basin-scale systems like AtlantOS. At a local level, governance is straightforward, and funding is often from a single source and is sustained as long as there is a user demand. At the national level, the governance structure becomes more complicated because it often involves more than one agency. For a national level system such as U.S. IOOS, the funding is complicated because different sectors (public, private, and academia) are involved and the governance model is more one of consensus, so funding has become more complex but is still within a single nation. For AtlantOS, governance will be based on the willingness and sense of purpose of individuals, governments and entities. International funding is often complex and tied to the political climate. For AtlantOS to be successful, the management framework must be built upon clearly expressed and transparent principles.

AtlantOS proposes six guiding principles of governance to be adopted and reviewed as the system evolves (**Figure 12**):

- **Engaging Stakeholders:** The diverse range of stakeholders must be identified, to address user needs for new and review existing ocean information products.

- *Collaborative and coordinated:* The stakeholder groups should form partnerships to define the roles and responsibilities of the partners and to extend and enhance the observational capability of the network or system.
- *Integrated and transparent:* The network or system should bring together all the observing components, partners and users to ensure that all of their interests are best met and that the maximum value is derived from each component. All partners must recognize and agree to their participation, and understand their expected contributions to and benefits from the observing network or system.
- *Flexible and responsive:* The observation network or system should be adaptive and responsive and have the ability to change in response to a shifting ocean environment and to changes in societal needs and structures.
- *Open with free access to data and information:* The ocean observation network or system should support and promote the open exchange of data to ensure that the maximum benefit is derived from the data collected.
- *Reliably resourced:* An effective ocean observation network or system requires reliable funding to ensure that it is sustainable.

Ocean observing is largely publicly-funded, and therefore public support is required. Present and future networks

and systems should build on voluntary participation from governments, research communities, and other stakeholders. Voluntary participation helps to ensure that the partners are actively engaged in supporting and sharing the success of the system and its sustainable nature.

Recommendations for Effective Governance of AtlantOS

Coordination Mechanisms That Span Three Dimensions: The Observing System, Resource Engagement, and Ocean Information Delivery

A single supervisory body is needed to coordinate the three dimensions with their respective tasks and responsibilities. A clear coordination structure of the different subgroups covering the three dimensions should exist, where tasks and responsibilities are distributed between all observation system contributors. As a result, overlapping and loosely coordinated structures that exist now could be streamlined.

An AtlantOS Executive Board

Governance and coordination of the AtlantOS system is important to better connect to the observing systems and networks operating in the Atlantic, and to the global system (GOOS).

Technological Ocean Observation Options / Development

Technological Ocean Observation Options	Technological Development
Platforms	Have developed aircraft and satellites that can make measurements at sea and now autonomous vehicles of many different types are capable of operating at sea and making useful measurements.
Sensors	New sensor development in the ocean sector has been stimulated by miniaturisation, automation and new manufacturing techniques such as Additive Manufacturing leveraging the large-scale use of low-power systems for consumer applications.
Satellites	Major developments in technology and new launches have greatly expanded the capability of satellite observing systems. The development of small, relatively inexpensive satellites, weighing just a few kilograms, has the potential to greatly expand the capabilities and range of users. It is expected that as many as a thousand such satellites could be launched in the next few years.

FIGURE 10 | Technological ocean observation options/development. Aspects of technological development leading to innovations in ocean observing.

A Resource Board to Promote Long-Term Funding

To promote long-term funding, the AtlantOS community should establish a Resource Board on a voluntary basis within this governance system. It should be arranged in a “resource engagement” dimension.

Implementation of a Formalized, Dynamic, and Flexible Ocean Partnership Panel (OPP)

A mechanism to inform the ocean observing community about the role of ocean data and products as well as their societal benefits, with representatives from within each stakeholder group.

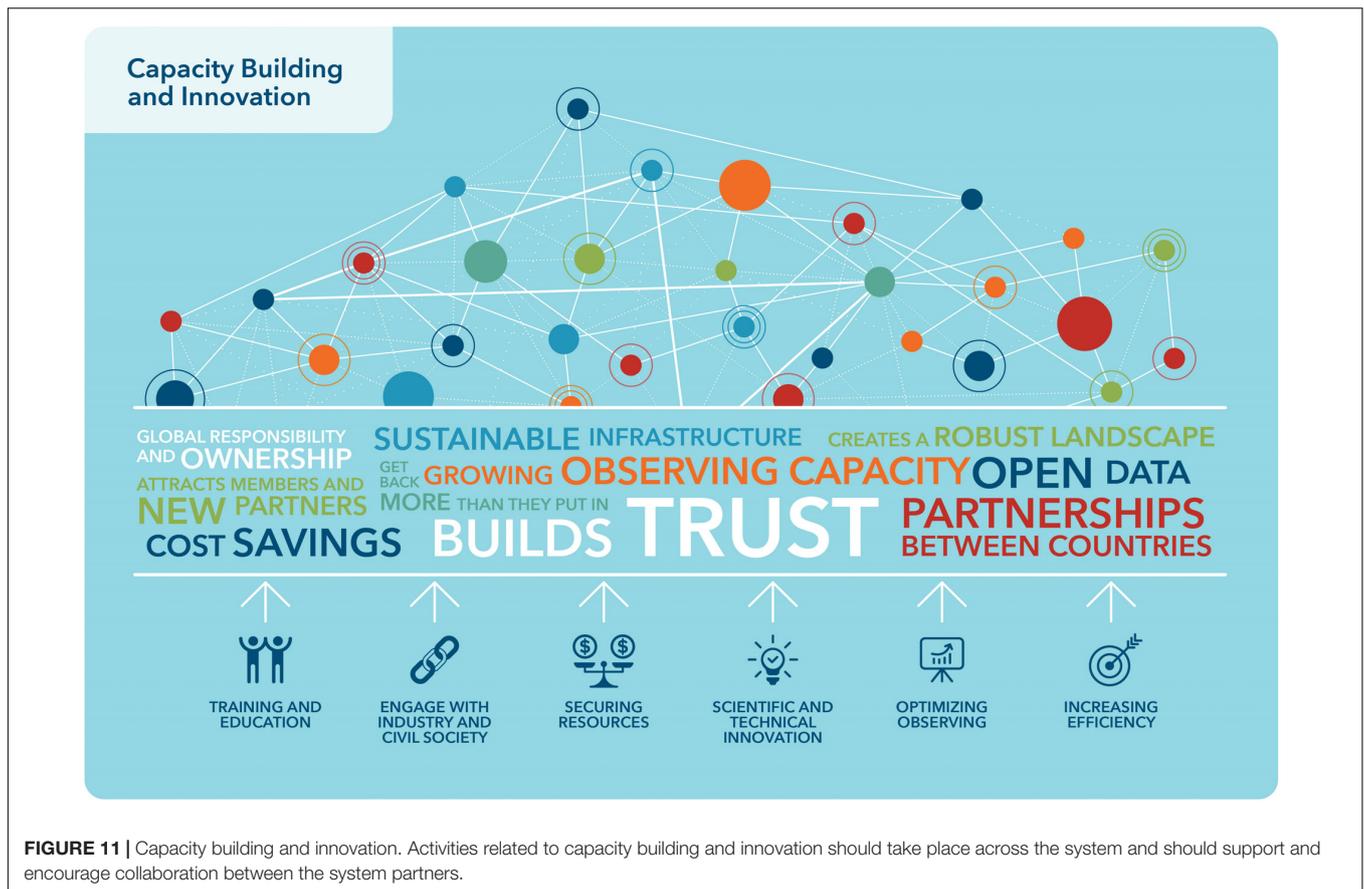

A Review Process

Regularly held to determine the adequacy of ocean observing activities and programs, as well as the system’s requirements. A review process would ensure long-term support and sustainability of the system. For this process, countries should be asked for information regarding the adequacy of the system, as well as ways to gain more resources and plans for future activities. The proposed timeline is every 5 years.

Countries Should Establish an Ocean Focal Point or Ocean Ministry

At the national level, responsibilities for ocean activities are often distributed across multiple sectorial actors, such as ministries or agencies (like transportation, finance, or environment). Several nations have already started an internal process to connect its actors and identified an Ocean Observing focal point. This mechanism can develop engagement opportunities, capabilities and national knowledge to more effectively contribute to govern their contributions and engagement with ocean observing and information generation. At the highest level of ambition, it could be beneficial if nations or regions create an Ocean Ministry or Ocean Focal Point Mechanism to combine and coordinate ocean information gathering and to provide advice to their governments and stakeholders on ocean issues (Degnarian and Stone, 2017).

In approaching governance at the basin-scale, spanning the Atlantic, there are already many programs with some form of governance. Many of these existing systems and networks exhibit one or more of the principles outlined, but few of them fully realize these principles. It is therefore a pragmatic challenge as to how to move forward building

upon existing structures so that we do not waste effort by working to “reinvent the wheel” but at the same time ensure that we follow the key principles needed to ensure sustainability.

It may be too late to develop a fully new governance structure, as there are too many already in place, from the local to the regional to the global scale. It is also important to recognize that funding for the existing systems and networks has been allocated based upon previous agreements with particular expectations, all of which may be difficult to change. We should avoid harming good governance systems in search of a new perfect governance model. Therefore, care must be taken to build a basin-scale system that can integrate all the relevant existing structures but may evolve to attain a fully integrated governance structure following the principles we laid out.

2030 – REALIZING THE VISION

In the coming decade, we will likely see many new changes in the ocean. A recent report stated that in the future:

scientific and technological advances are expected to play a crucial role both in addressing many of the ocean-related environmental challenges...and in the further development of ocean-based economic activities (OECD, 2016, p. 13).

Ocean observatories are expected to contribute data and information to these environmental and economic developments. We must shift our perspective as to why we make ocean observations and why we invest in ocean observing systems. Such activities should be seen as fundamental to a global society.

Ocean observing is a necessary service to fulfill our collective stewardship responsibility. To fully realize this service, we must change our view of the value of environmental data. Environmental data should be seen as contributing to the global public good and should be freely available to all. Thus, environmental data collected by fishermen should be openly shared, as too should data on seabed features collected in support of deep-sea mining, alongside scientific data. Commercial interests can be protected while at the same time ensuring that the environmental value of these data is not lost. Providing environmental data for the societal good must be seen as fundamental to a twenty-first century society.

When looking at existing sustainable observing infrastructures and systems that have been funded and implemented over the longer-term, e.g., U.S. IOOS and EuroGOOS, most share the following four characteristics:

- Meeting defined user needs;
- Inclusiveness such that partners or clients find their interests are served;

- Promoting open sharing and exchange of information; and
- Promoting partnerships between the private and public sectors, the academic community and users.

For a sustainable AtlantOS to benefit us in the long term, the system needs three key elements (discussed in more detail in the previous sections):

Governance Sustainability

Given that ocean observing is largely publicly-funded, basin-scale, *ocean observing must have state support*. At the international level, such support should be expressed through a governance framework that provides political and legal guidance, within a functional institutional setting. The governance framework encompasses the policies and rules that give any initiative a legal and political *raison d'être*. A governance framework also lays down the principles by which the observing system should function. Open data entails that data and information collected within the framework of an observing system should be freely available to all collaborators and of course the general public. Free

and open exchange of data and information are essential to support collaboration and encourage cooperation and capacity building. To date, ocean observing has been seen as a scientific-technical rather than socio-political challenge. In the future, an intergovernmental ocean observing system should play a special role in communicating the condition of the ocean to the world (Fritz, 2016). Ocean data governance must ensure that the principle of “*measure once, use multiple times*” is realized.

Institutional and Operational Sustainability

A coordinating body should be identified to provide a forum for coordinating *in situ* ocean observing networks. GOOS provides a good example for such a body but must be reviewed and strengthened to balance top-down strategy development amongst the owners/operators/funders of observing stations and intergovernmental bodies with the bottom-up inclusion of the scientific, commercial and societal communities. To date, strategies tend to be priority lists and supply-sided plans for the future. In future, more detailed analyses and interactive foresight

processes should be initiated to promote critical and reflective assessments of the current state and future of ocean observing.

Financial Sustainability

The diversity and number of ocean observing initiatives means that financial sustainability will not be equal in all initiatives. At best, financial sustainability of an observing system composed of ocean observing networks will require that, while each effort remains financially independent, together they be embedded in long value chains. From data collection to end use, ocean observing should be driven by providing societal or commercial benefits. To this end, efforts to secure more funding must consider capital vs. operational expenditures, so that technology is acquired and operated over the longer-term. A rigorous and continuous economic assessment of ocean observing is necessary, beginning with an assessment of the value added by investing in ocean observing for funders and stakeholders of an Atlantic Ocean observing system.

CONCLUSION

Looking forward, we see AtlantOS delivering comprehensive ocean observations that truly address existing and emerging needs of all those living by, working on and impacted by our Atlantic Ocean. We do not need to start from scratch –several successful networks and systems are effective in meeting user needs and can be integrated into this newly formed system. However, several key developments are required to enable the creation of a basin-scale system. New technologies present a wealth of opportunity – for making ocean observations, particularly in biology and biogeochemistry, and for facilitating the open and free access to ocean data to make sure the data we are already collecting can be used by all.

While some new funding is likely necessary to meet our needs, it is not just about spending more money. It is about working together more effectively, being driven by user needs, transparent sharing of data, and minimizing duplication of activities. Most importantly, it is about working together, coordinating our activities, and learning from each other so we can address some of our greatest challenges.

The AtlantOS All-Atlantic Ocean Observing System must be sustainable, offering the best value for the collective community investment. Only through such a basin-scale system can we truly understand our shared ocean, for the benefit of all.

ABBREVIATIONS

AMOC, Atlantic Meridional Overturning Circulation (Argo Broad-scale global array of temperature/salinity profiling floats that is a major component of the ocean observing system and exemplifies international collaboration, with 31 nations contributing floats (2017) and a data management system that delivers consistent quality controlled data streams.); ASMIWG, Atlantic Seabed Mapping International Working Group (AtlantOS Atlantic Ocean Observing System [and

Acoustics play a central role in humankind's interactions with the ocean and the life within. Passive listening to ocean "soundscapes" informs us about the physical and bio-acoustic environment from earthquakes to communication between fish. Active acoustic probing of the environment informs us about ocean topography, currents and temperature, and abundance and type of marine life vital to fisheries and biodiversity related interests. The two together in a multi-purpose network can lead to discovery and improve understanding of ocean ecosystem health and biodiversity, climate variability and change, and marine hazards and maritime safety. Passive acoustic monitoring (PAM) of sound generated and utilized by marine life as well as other natural (wind, rain, ice, seismics) and anthropogenic (shipping, surveys) sources, has dramatically increased worldwide to enhance understanding of ecological processes. Characterizing ocean soundscapes (the levels and frequency of sound over time and space, and the sources contributing to the sound field), temporal trends in ocean sound at different frequencies, distribution and abundance of marine species that vocalize, and distribution and amount of human activities that generate sound in the sea, all require passive acoustic systems. Acoustic receivers are now routinely acquiring data on a global scale, e.g., Comprehensive Nuclear-Test-Ban Treaty Organization International Monitoring System hydroacoustic arrays, various regional integrated ocean observing systems, and some profiling floats. Judiciously placed low-frequency acoustic sources transmitting to globally distributed PAM and other systems provide: (1) high temporal resolution measurements of large-scale ocean temperature/heat content variability, taking advantage of the inherent integrating nature of acoustic travel-time data using tomography; and (2) acoustic positioning ("underwater GPS") and communication services enabling basin-scale undersea navigation and management of floats, gliders, and AUVs. This will be especially valuable in polar regions with ice cover. Routine deployment of sources during repeat global-scale hydrographic ship surveys would provide high spatial coverage snapshots of ocean temperatures. To fully exploit the PAM systems, precise timing and positioning need to be broadly implemented. Ocean sound is now a mature Global Ocean Observing System (GOOS) "essential ocean variable," which is one crucial step toward providing a fully integrated global multi-purpose ocean acoustic observing system.

INTRODUCTION

The mesoscale revolution in oceanography was enabled by the acoustic tracking of floats. In the late 1950s, John Swallow and his colleagues deployed floats off Bermuda, returning a few weeks later to locate them acoustically. They expected them to have drifted only kilometers—but the floats had disappeared. When deploying the next set, they stayed and tracked them. Rather than moving slowly in one direction, as originally expected, they moved at relatively high speeds in random directions. It was from this study that mesoscale eddies were discovered (Crease, 1962; Swallow, 1971).

Marine mammals depend on acoustics in very fundamental ways, but this was not known early on. In the 1950s, classified navy surveillance systems heard many signals of unknown origin, including 20 Hz pulses or BLIPs (from the paper strip chart recorders) that were observed to be highly repetitive, point sources traveling at 1–4 knots. Various interpretations ranged from mechanical and geophysical sources to the breathing or heartbeat of a whale. Finally, in 1963, they were attributed to finback whale courtship displays (Schevill et al., 1964; Tavolga, 2012). This was but one step in revealing the rich babel of life in the ocean.

Since then float tracking and marine mammal studies have been major applications of acoustics in oceanography, with improvements along the way. As Watkins (1981) said, “The sounds from finback whales (Schevill et al., 1964) provided the stimulus for much of the early progress in design of equipment and techniques for the acoustic observations at sea.” Ever more acoustic tools were developed, including long-baseline positioning (~10 km, originally to support drillship dynamic positioning), inverted and bio-acoustic echosounders, and acoustic doppler profilers. Early autonomous underwater vehicles (AUVs), and mobile platforms in general in the 1990s, motivated more work on combined positioning and communication and miniaturized sensors. A mix of acoustic and non-acoustic tools were developed to directly measure the ocean and also to provide necessary support infrastructure.

Ocean acoustic tomography as proposed by Munk and Wunsch (1982) catalyzed new directions. Many process experiments have amply demonstrated the concepts [measuring sound speed (temperature) and currents, N^2 growth of information with number of instruments], technology (broadband low frequency sources, precise timing and positioning, and coherent signal processing enabling precise travel time determination), and utility for measuring coastal, meso- and larger scale ocean variability (heat content changes, vorticity, baroclinic tides, deep ocean convection, to name a few). A defining event was the Acoustic Thermometry of Ocean Climate (ATOC) project (1996–2006), that demonstrated and served as a pilot for a basin scale ocean heat content observing system (with cabled instrumentation), and catalyzed new efforts in ocean bio-acoustics and passive acoustic monitoring (PAM). The latter includes more than bio-acoustics, with wind, rain, ice, earthquakes, volcanoes, and anthropogenic sound. Throughout, ocean data assimilation techniques struggle to accommodate the new data types and large amount of data generated.

The hydroacoustic monitoring component of the global Comprehensive Nuclear-Test-Ban Treaty Organization International Monitoring System (CTBTO IMS) has been in operation in the Indian Ocean since 2000. The original and primary purpose of the CTBTO IMS is to monitor for signals related to unsanctioned nuclear activity, but the scientific value of the recordings has been demonstrated in numerous studies related to ocean ambient sound, marine mammal behavior, glacial/iceberg noise, human ocean use, tsunami warning, and search and rescue.

These developments—ocean tomography and attendant technology, PAM, mobile platforms, and data assimilation—motivated ideas about regional (and together global) tomography systems (for the OceanObs99 conference; Dushaw et al., 2001), integrated acoustic systems for ocean observing (Howe and Miller, 2004), global ocean acoustic observing network (for OceanObs09 conference; Dushaw et al., 2009), and multipurpose acoustic networks in the integrated Arctic Ocean observing system (Mikhalevsky et al., 2015).

The vision we present in this paper is of a multi-purpose acoustic ocean observing system where the sum is greater than the individual parts. It is the network formed by the parts that yield the gains, both in terms of raw number of data but also the ocean information gain. The individual parts or components—sources, receivers, platforms—can all be shared among the various applications, including PAM, undersea and under-ice mobile platform positioning, navigation and communication, tomography, and more, including cost (Figures 1, 2). Each individual dataset then increases in value within a global context. Because acoustic instrumentation is in general robust and scalable, it is well suited for sustained, long term, multi-scale deployment as part of the Global Ocean Observing System (GOOS).

The goal of this OceanObs19 community white paper is to provide evidence to the readers and conference attendees that such a multi-purpose acoustic ocean observing system is an achievable component of GOOS that will bring many benefits.

A major outcome of the OceanObs09 conference was the Framework for Ocean Observing (Lindstrom et al., 2014). This document outlined the overall goals, objectives, structures, and processes of the GOOS. These include requirements that GOOS must: (1) serve multiple users/requirements with the same observing system; (2) make sustained observations over time with global-scale coverage; (3) be driven by end-user requirements; (4) incorporate continual evaluation, feedback and re-evaluation of system; (5) execute a phased implementation of components (concept/pilot/mature) based on technical readiness levels, and essential ocean variables with high feasibility and impact.

“Ocean Sound” has just been accepted by the Biology and Ecosystem Panel of GOOS as a mature Essential Ocean Variable (EOV; see Ocean Sound EOV, 2018). This is an important milestone primarily addressing PAM. This recognizes the technical readiness, feasibility, high impacts, and operational status of systems already in place. The latter is especially important and is reflected in the long-established operational global array of hydroacoustic stations as part of the CTBTO IMS (Figure 3). Further, there

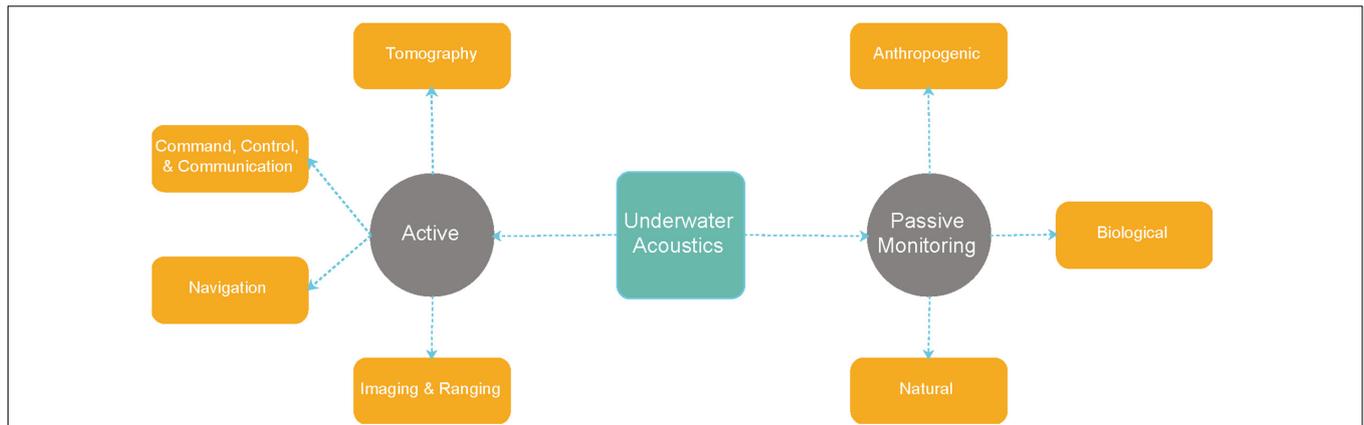

FIGURE 1 | Key core elements of a multipurpose acoustic system for ocean observing (Figure provided by E. Rehm, used with permission).

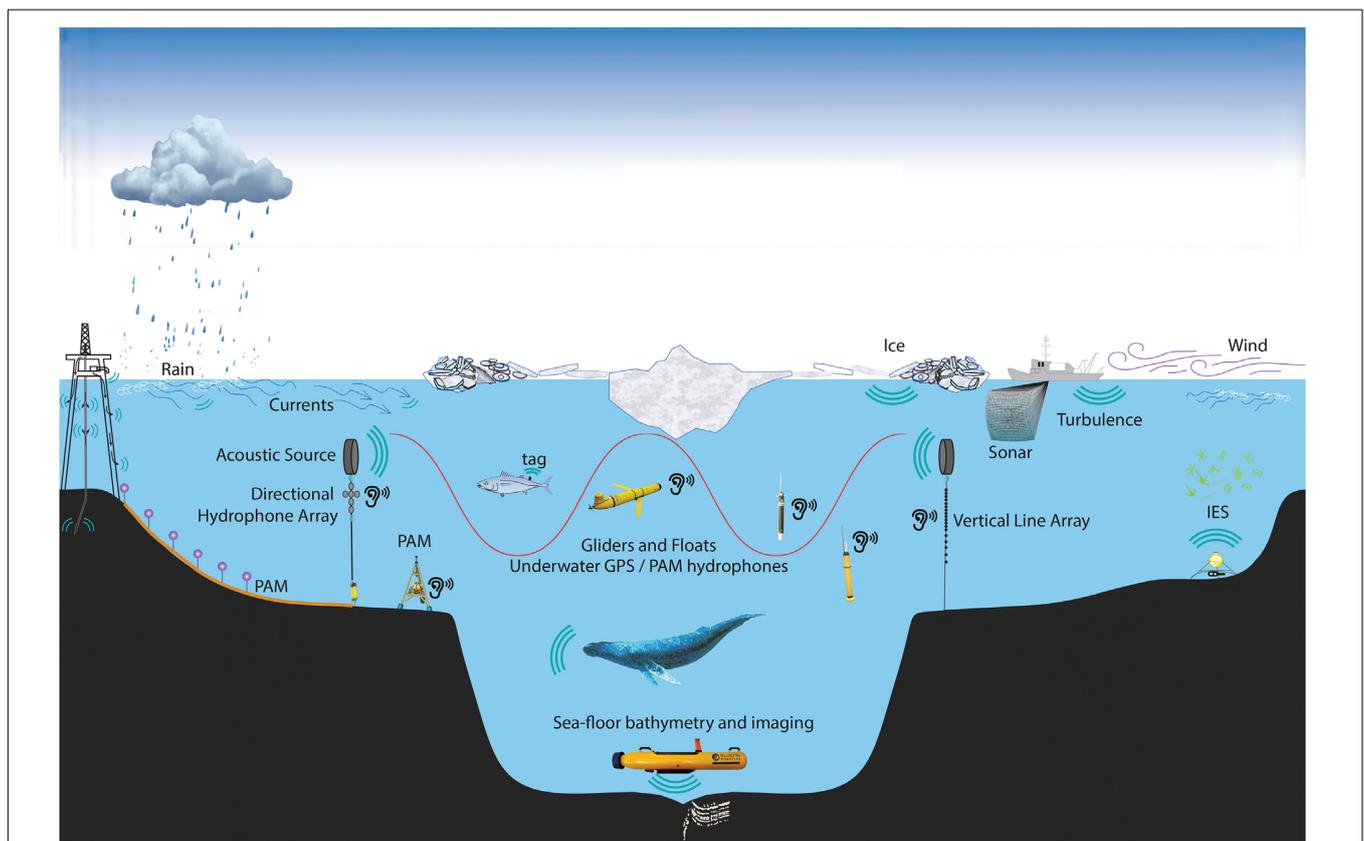

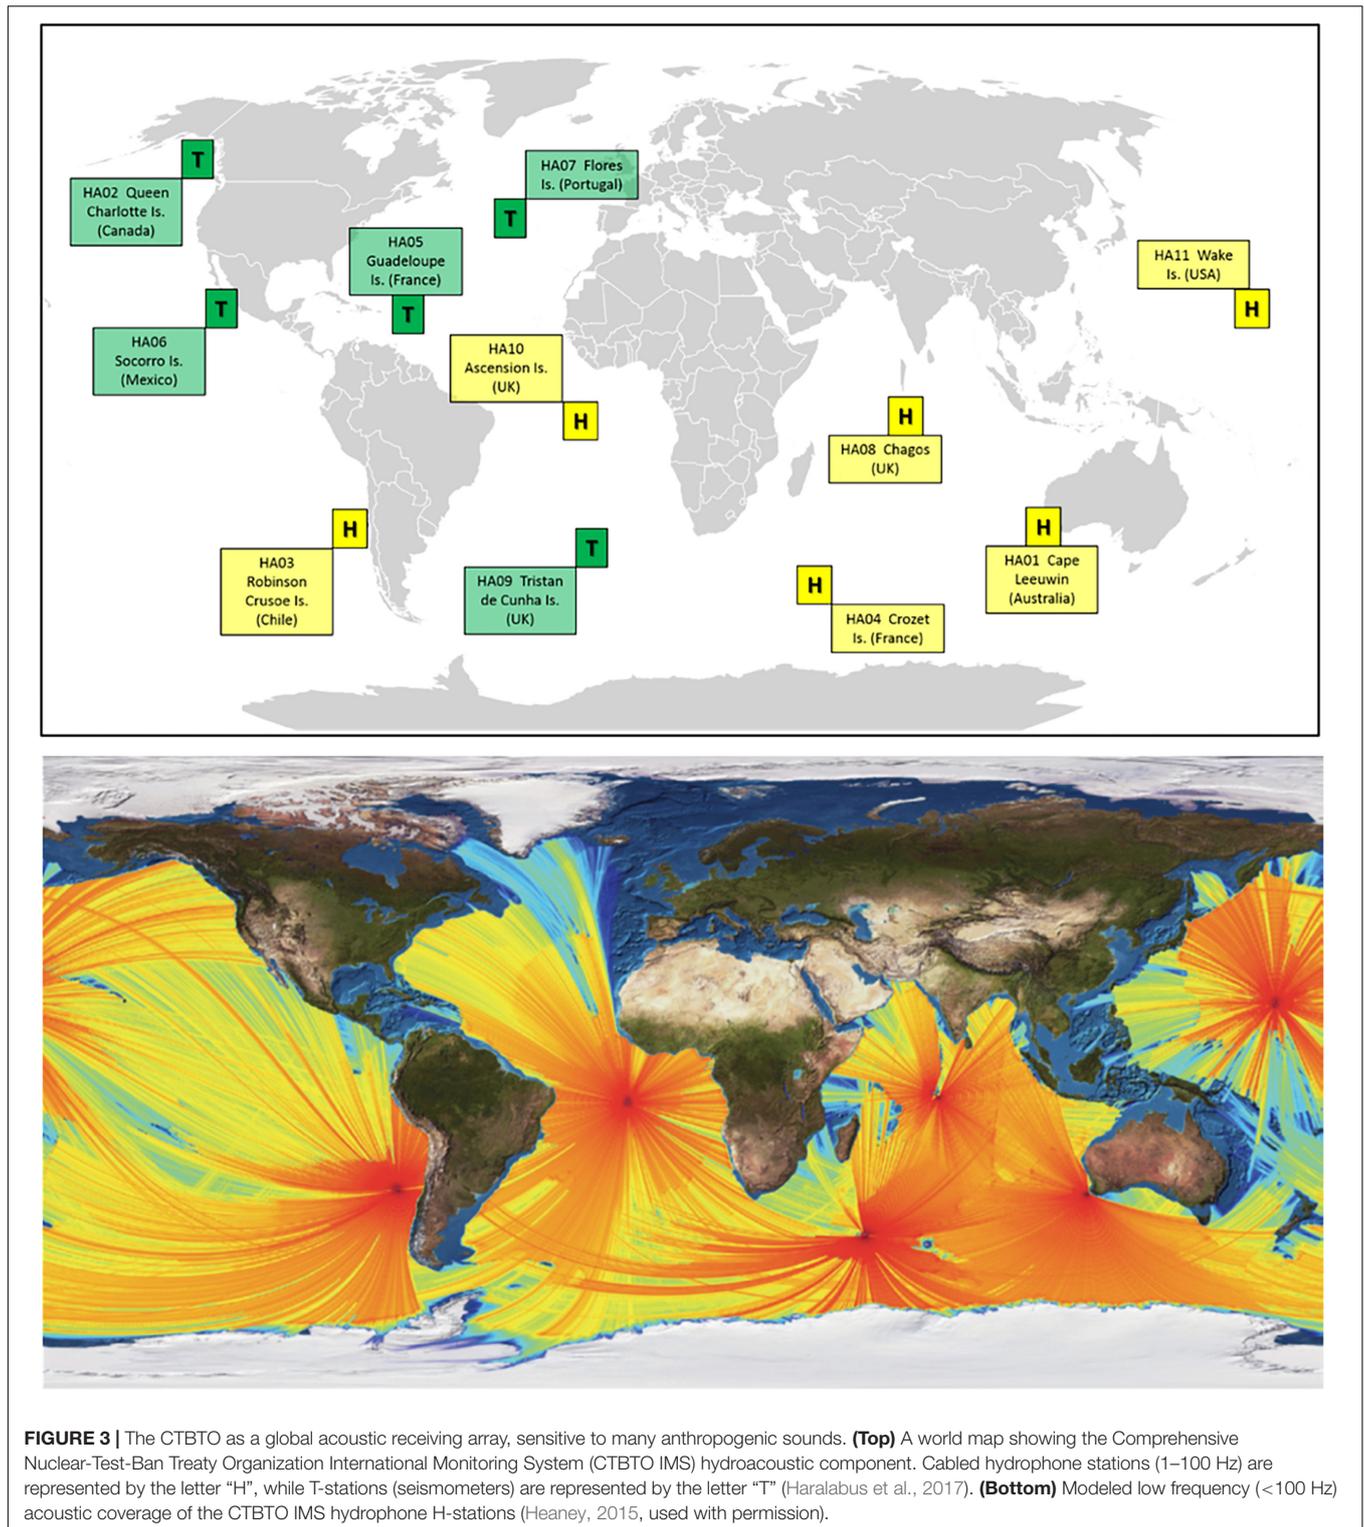

FIGURE 2 | A multipurpose acoustic observing system provides a range of capabilities: two-way transceivers provide support for low-frequency acoustic tomography (heat content, averaged currents), navigation, and communications as well as broadband passive acoustic listening posts. Bottom-mounted passive acoustic monitoring (PAM) stations provide additional coverage for observing soundscapes of natural (wind, rain, ice), biological (plankton, fish, marine mammals), and anthropogenic (ships, sonar, drilling platform) sources. The shifting paths of ocean currents and zooplankton populations can be detected using inverted echo sounders (IES). Autonomous platforms (floats, glides) take advantage of acoustic sources providing “underwater GPS” services and can also provide PAM services. (Figure provided by E. Rehm, used with permission).

are many additional ongoing regional programs, including the ALOHA Cabled Observatory (ACO), NEPTUNE in the northeast Pacific, Perennial Acoustic Observatory in the Antarctic Ocean (PALAOA), and NOAA Ocean Noise Reference

Station Network. There are a number of challenges, though, including: sustained funding for acoustic data management and network or system components; making ocean sound measurement ubiquitous on “integrated instrument packages”

meant for broad deployment; integrated data management (easy access to any and all data—a “big data” problem); and broadening the scope to more explicitly include geophysical variables such as wind, rain, T-phase/earthquake/tsunami detections. For the purposes of a multi-purpose acoustic observing system,

with positioning/tomography integral components thereof, it is important to require that receivers have adequate timing and positioning accuracy (1 ms and 1 m).

Other existing EOVs will directly benefit from measurements from multi-purpose acoustic systems. These include: EOV

Subsurface Temperature from acoustic tomography; EOVS Subsurface Velocity from acoustic tomography and mobile platform tracking; EOVS Sea State from ocean sound/wind; EOVS Marine Turtles, Birds, Mammals Abundance and Distribution from fixed and autonomous PAM sensors; EOVS Zooplankton Biomass and Diversity in high-latitude marginal ice zones from mobile platform (float, glider) tracking.

In the balance of the paper, we begin with a review of acoustic technology and its capabilities, emphasizing the aspects that are important to the multipurpose nature of the acoustic observing system. To address the OceanObs19 Observing Needs themes, we have sections on discovery, ecosystems, climate and variability, and hazards and maritime safety. This is followed by a discussion that synthesizes the preceding sections. Concluding remarks and recommendations are given in the final section.

OBSERVING TECHNOLOGY AND NETWORK

Multipurpose Acoustic Systems

Multipurpose acoustic networks directly provide unique observations while supporting and complementing other *in situ* observations – all are needed for a complete GOOS. Acoustic tomography provides observations of large-scale temperature and current. PAM records sounds generated by marine life, ice, earthquakes, volcanoes, wind (e.g., Vagle et al., 1990), rain (e.g., Nystuen, 2001), and other natural sources, as well as by anthropogenic sources such as ships and seismic air gun arrays. In a multipurpose acoustic system, PAM instruments will also record the signals from acoustic sources used for acoustic tomography and undersea positioning and navigation. Acoustic networks facilitate underwater and under-ice geo-positioning of floats, gliders, and other autonomous vehicles. **Figure 4** illustrates the various applications (an elaboration of **Figure 2**).

It is important to appreciate the network aspects that typically are involved in acoustics systems. In many cases, multiple receivers will record multiple sources, both natural and anthropogenic. As an example, data from a number of widely spaced PAM receivers could be used to simultaneously track a pod of blue whales, monitor volcanic activity along a mid-ocean ridge, and record transmissions from several acoustic sources to measure the temperature field. If desired, AUVs from a cabled docking station could be diverted from their routine mapping to monitor the ridge activity, using the acoustic positioning signals for locating themselves and navigating in real time (**Figure 2**).

Receiver and source technologies are mature, available, and ready for integration into an ocean observing system (e.g., Worcester et al., 2009; Morozov et al., 2016). The technology provides the required accuracy for tomography and underwater geo-positioning systems, as well as recordings of ambient sound and acoustic backscatter from the water column. Passive and active acoustic sensors are available for different frequency bands and different observing platforms, e.g., moorings, floats, bottom landers, and cabled systems. Passive systems can be quite broadband. The High-frequency Acoustic Recording Package (HARP), for example, has a bandwidth of 10–100,000 Hz

(Wiggins and Hildebrand, 2007). Acoustic sources with center frequencies ranging from 20 Hz (Mikhalevsky and Gavrilov, 2001) to several kHz (e.g., Send et al., 2002) have been used in acoustic tomography experiments, depending on the range and application.

Tomographic Instrumentation and Signal Processing

The low-frequency acoustic source technology used to make large-scale tomographic measurements has advanced significantly in recent years. The bottom-mounted, cable-connected, 75-Hz ATOC sources deployed during the 1990s in the mid-latitude North Pacific Ocean were large and heavy (~5000 kg) (ATOC Instrumentation Group, 1994). The autonomous acoustic sources used to generate the ~20 Hz signals needed to propagate for long ranges under the ice in the Arctic Ocean for the Trans-Arctic Propagation (TAP) experiment in 1994 and the Acoustic Climate Observations using Underwater Sound (ACOUS) project beginning in 1999 were one-of-a-kind, large devices (Mikhalevsky and Gavrilov, 2001). With the dramatic decrease in multiyear ice (e.g., Meier et al., 2014) and the associated deep ice keels, it is now feasible to effectively transmit higher acoustic frequencies over long ranges in the Arctic. Sources that operate at 32 Hz and are of manageable size and weight have recently become commercially available (**Figure 5**). These require pressure compensation to keep the inner gas pressure equal to the external water pressure, using a (largely) passive bladder system with 20 m dynamic range for operation at 100 m depth on a mooring in under-ice Arctic conditions. Slightly modified versions of the same source and pressure compensation technologies can be used at sound channel depths in mid-latitudes (~1000 m) at the ATOC frequency of 75 Hz. In this case, the same pressure compensation unit would have a dynamic range of 200 m to accommodate stronger currents and mooring pull down. Furthermore, these sources can be coupled together in small arrays that broaden the bandwidth and provide more power and some vertical directionality. (A vertical array would reduce vertically propagating energy in favor of more horizontal energy in the sound channel).

Acoustic receiver technology has also improved. Sub-basin-scale ocean acoustic tomography experiments have taken advantage of the flexibility of autonomous, moored systems. The expected magnitude of travel-time perturbations associated with the ocean mesoscale is roughly 100 ms. The differential travel-time signal from reciprocal transmissions is an order of magnitude smaller. The requirements to keep time with millisecond accuracy in submerged instruments for a period of a year or more, measure the motion of the moored sources and receivers to within a meter or so in order to correct for travel-time perturbations due to changes in range, and record the large amounts of data generated by the acoustic receptions made for early instruments that were sufficiently complex to be accessible only to highly specialized research groups. [Munk et al. (1995) provides a detailed discussion of the observational methods used in acoustic tomography]. Modern developments

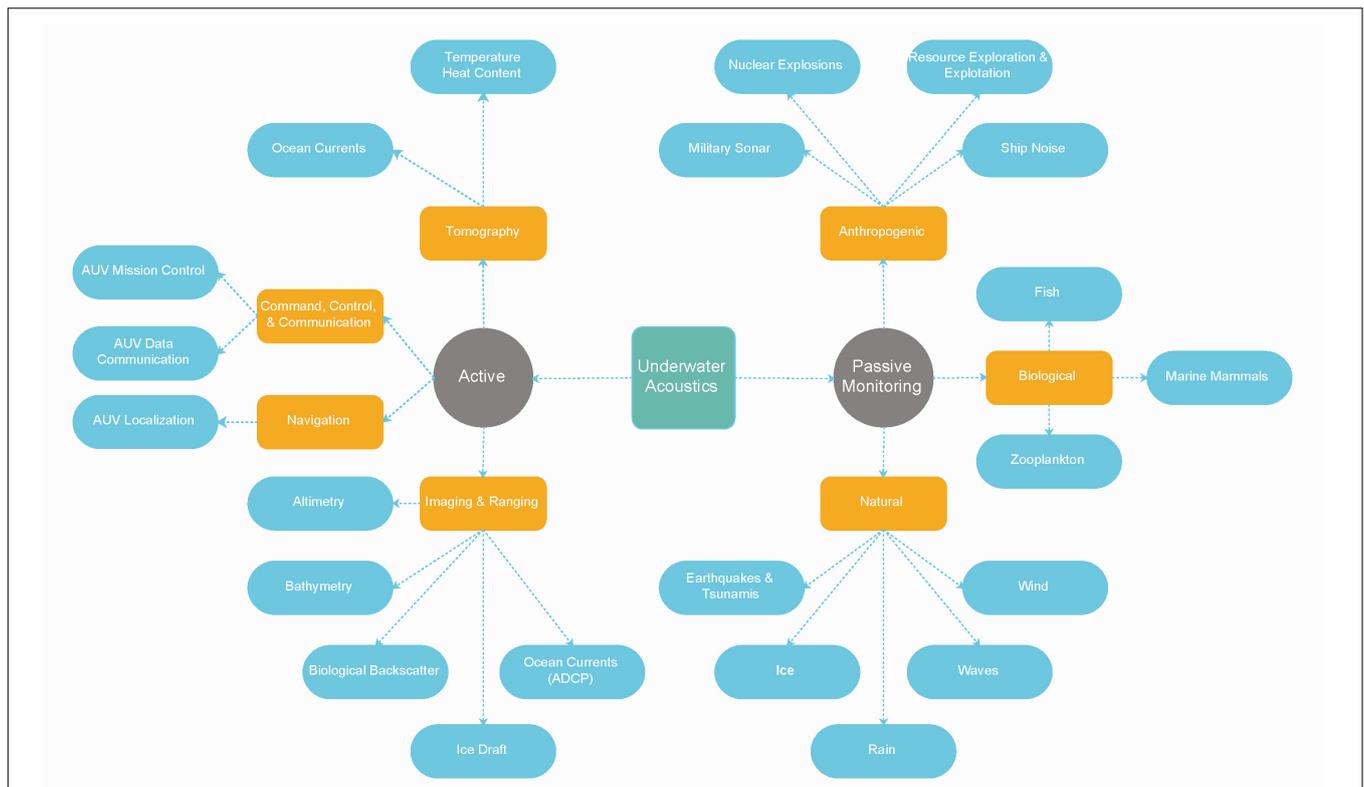

FIGURE 4 | Ocean observing applications of a multipurpose acoustic system, building on the core elements. (Figure provided by E. Rehm, used with permission).

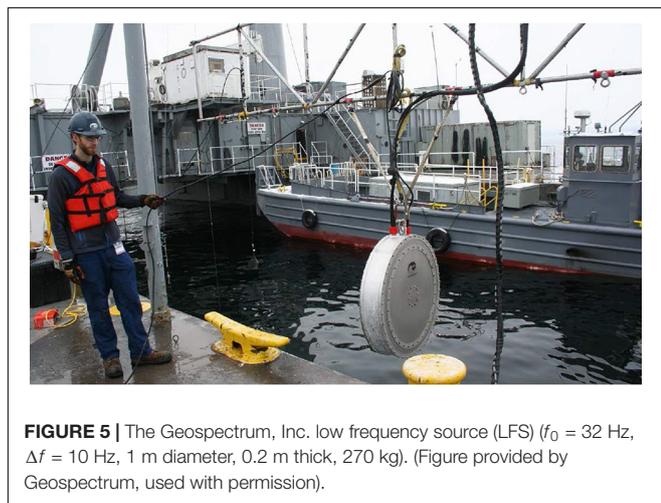

FIGURE 5 | The Geospectrum, Inc. low frequency source (LFS) ($f_0 = 32$ Hz, $\Delta f = 10$ Hz, 1 m diameter, 0.2 m thick, 270 kg). (Figure provided by Geospectrum, used with permission).

in data acquisition systems and data storage have now made the required instrumentation much more user-friendly. For climate-oriented, basin-scale experiments with requirements for high power and long duration, however, cabled systems are preferred. (Hybrid systems are of course possible). Mooring motion and accurate timing are not problems in systems mounted on the seafloor and cable-connected to shore. The ATOC project relied on cabled systems, for example, augmented by a few autonomous vertical receiving arrays deployed for

year-long periods to better characterize the propagation (ATOC Instrumentation Group, 1994).

The processing of tomographic data to obtain time series of travel times has become much more routine in recent years. For both moored and cabled systems, the signal processing and generation of time series of travel times for resolved acoustic ray paths has been labor intensive and subjective. After matched filtering and beamforming of the received signals, the procedure is to pick the peaks in the processed receptions. The peaks must then be associated with predicted ray arrivals. This procedure must be repeated for each reception for every source-receiver pair. However, internal-wave-induced scattering of the received signals impairs the ability to associate a measured peak with a computed ray path. Two procedures were developed to address these issues (Dzieciuch, 2014). First, an estimator-correlator that explicitly accounts for scattering is used to smooth the arrival pulse and improve the signal-to-noise ratio. Second, after defining an error metric that accounts for peak amplitude, travel time, and vertical arrival angle, the Viterbi algorithm has been successfully adapted to the task of automated peak tracking, eliminating the need to manually select appropriate peaks in each reception.

In the past, stochastic inverse methods have most commonly been used to interpret acoustic travel times to obtain ocean temperatures and currents (e.g., Munk et al., 1995). With recent improvements in the vertical resolution and realism of ocean

circulation models, acoustic travel times are now being used to directly constrain the models, taking advantage of the models to combine acoustic (and other data) from different times and locations in a way that is consistent with ocean dynamics (e.g., Lebedev et al., 2003). Time-evolving ocean circulation models implicitly supply a large amount of information about the ocean by enforcing the conservation of mass, momentum, and other properties. The practice of combining data with models, referred to as state estimation or assimilation, simultaneously tests and constrains the models. A variety of approaches are available to solve this problem, e.g., variational data assimilation (4DVAR) and ensemble Kalman filtering (EnKF) (e.g., Munk et al., 1995; Gopalakrishnan et al., 2019).

Combining integral tomographic data with time-evolving models does not differ in any fundamental way from using other data types, but tomographic data do differ from most other oceanographic data because their path-integral sampling and information content tend to be localized in spectral space rather than in physical space. It is therefore important to use methods that preserve the integral information contained in the acoustic travel times. Approximate data assimilation methods optimized for measurements localized in physical space are generally inappropriate because they do not preserve the non-local tomographic information (Cornuelle and Worcester, 1996). The data types used to constrain the models are largely transparent to the user of the resulting ocean state estimates, placing the rather unfamiliar acoustic data on the same footing as more familiar data types.

Although state estimation employing general ocean circulation models in ice-free regions has received the most attention, state estimation employing coupled ocean-sea ice models has received increased attention in the past decade (Fenty and Heimbach, 2013; Stammer et al., 2016; Nguyen et al., 2017). Present ice-ocean coupled models can assimilate sea ice parameters from remote sensing and profiles from floats and drifting ice buoys. The sea ice forecasts are improved through the assimilation of sea ice parameters. However, there is a significant gap in under-ice observations to evaluate or constrain the ice-ocean models. The ice-ocean models are therefore unconstrained and their performance is more or less unknown. The effect of repeating assimilation only on the surface and keeping the ocean under the ice unconstrained with data is unknown. Acoustic methods can be used to provide data to test the large-scale behavior of the ocean-sea ice models and, eventually, to constrain them.

Underwater Acoustic Positioning and Navigation

Positioning, Navigation and Timing (PNT) are vital infrastructure services of our modern technical society. PNT needs to be extended throughout the subsea environment. PNT is a combination of three distinct, constituent capabilities:

1. Positioning is the ability to accurately and precisely determine one's location referenced to a standard geodetic system;
2. Navigation is the ability to determine current and desired position (relative or absolute) and apply corrections to course, orientation, and speed to attain a desired position anywhere in the domain of concern; and
3. Timing is the ability to acquire and maintain accurate and precise time anywhere in the domain of interest within user-defined timeliness parameters; it also includes time transfer.

Navigation is real time and necessarily depends on positioning, and positioning depends on timing.

A key aspect of the multi-purpose concept is to transfer the precise measurement of travel time between a source and receiver, as done in tomography, to the long-range underwater positioning and navigation community as exemplified by RAFOS float positioning and AUV navigation. Providing an underwater navigation capability is particularly important in ice-covered regions, where floats, gliders, and AUVs have difficulty surfacing to obtain their positions. Multipurpose acoustic networks allow economy in source signaling: the same acoustic signals are used for both tomography and positioning. The Global Navigation Satellite System (GNSS), of which the US Global Positioning System (GPS) is part, has enabled ionospheric (electron density) and atmospheric (temperature, precipitable water vapor) tomography, while providing its core PNT service. The relatively expensive satellites provide signals to 10–100s of low earth orbiting satellites (radio occultation) and 1000s of ground stations to obtain dense, global coverage over land and ocean. For the ocean case, acoustic sources can transmit to both mobile vehicles and fixed receivers, solving for position and sound speed (temperature) in a joint estimation problem.

The difference between RAFOS and what has been called RAFOS-2 is comparable to the difference between old long-range navigation (LORAN) and Transit positioning and GPS today. The increased bandwidth of RAFOS-2/tomographic signals yields better positioning accuracy (Duda et al., 2006; Van Uffelen et al., 2016). **Figure 6** shows simulated arrival patterns for a narrow band 1.6-Hz RAFOS signal, which is about 1 s in duration, equivalent to 1600 m position uncertainty, and for a RAFOS-2/tomography signal with a 50-Hz bandwidth, where individual arrival peaks are 20 ms wide, giving roughly 30 m range uncertainty (assuming 1500 m/s sound speed).

Precision glider positioning was in fact demonstrated in the 2010–2011 North Pacific Acoustic Laboratory (NPAL) Philippine Sea Experiment (PhiiSea10) (Van Uffelen et al., 2016). Six broadband, 250-Hz tomography sources were deployed in a pentagonal array 660 km in diameter. Four Seagliders, each equipped with an acoustic receiver and the ability to keep precise time (syncing to GPS time while the Seagliders were at the surface), recorded receptions. Subsequent analysis showed that estimated underwater position errors were reduced from 900 m RMS using standard glider positioning to about 80 m RMS when incorporating measured travel times, over 700 km ranges (**Figure 7**).

In ice-covered regions, work has been progressing along several lines. Using conventional narrow bandwidth RAFOS sources, Argo floats have been positioned (after the fact) to

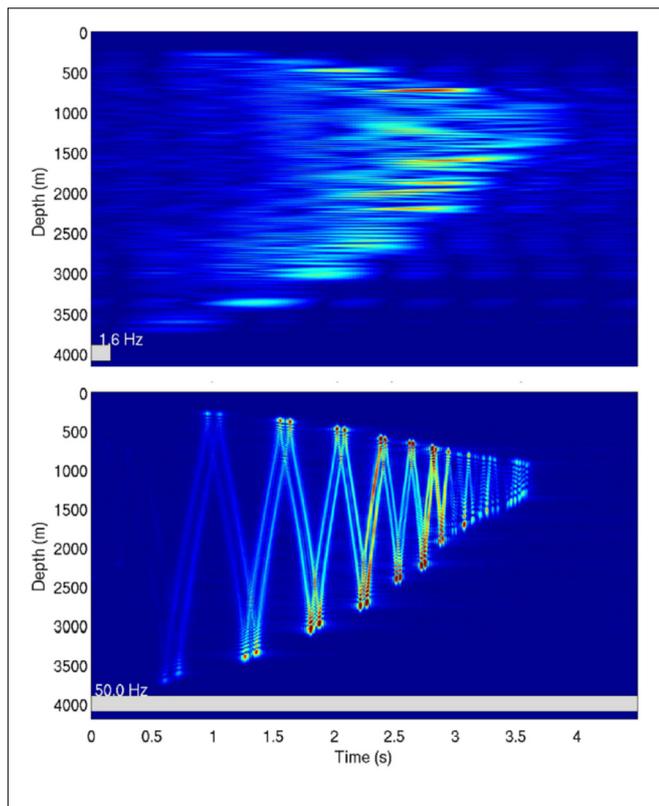

FIGURE 6 | Arrival patterns for a 1145-km transmission path in the North Atlantic Ocean for systems with 80-s linear FM signals of 1.6-Hz (**upper**, RAFOS) and 50-Hz bandwidth (**lower**, RAFOS-2/tomography) and 260-Hz center frequency (source at 700 m depth, receiver at 2000 m depth). The time scale is reduced time, which removes the gross transmission delay between the source and receiver. Positioning uncertainty for the first case is (sound speed/bandwidth) \sim 1000 m, while for the second it is 30 m (Duda et al., 2006, used with permission).

400 km range (Klatt et al., 2007). Gliders have navigated under ice in Davis Strait (Webster et al., 2014) and Fram Strait (Sandven et al., 2011) with position uncertainties on the order of kilometers or more. More recently in the Arctic, higher frequency (900 Hz) instrumentation has been used in an integrated system with ice-tethered GPS synchronized navigation transceivers (i.e., the “satellites”) talking to gliders. As with GPS, low data rate source position information is transmitted to enable the gliders to perform absolute geo-positioning and navigation. Additional information can also be transmitted, in this case new surfacing target waypoints. This system has been tested; performance is a function of range, the particular acoustic conditions present and the vertical position of the glider relative to structure in the sound channel (Freitag et al., 2015; Webster et al., 2015; Lee et al., 2017). These examples show that no one solution fits all, but that significant progress is being made toward multipurpose acoustic systems; especially in the last case all the elements are there.

The incremental cost of using a broadband tomography source relative to a narrowband RAFOS source is small compared to mooring and ship time costs. This simultaneous improvement in positioning and associated navigation accuracy coupled with obtaining tomographic temperature is a major motivator for the

multi-purpose concept. To obtain subsea positioning accuracy of 10 s of meters, one will need to account for the 4-D variation in sound-speed (e.g., mesoscale variability). For real-time subsea navigation this is clearly challenging; for delayed mode positioning, this would likely be done in the context of a large joint ocean-position estimation procedure.

Passive Acoustic Monitoring

Passive acoustic monitoring recording devices are now key to regional strategic plans for the successful monitoring of natural, anthropogenic, and animal sound. Audio data receivers support multiple hydrophones and associated recording channels and contain massive amounts of data storage, thanks to advances in non-volatile memory storage capacity and low-power digital signal processors. An autonomous directional PAM acoustic receiver array on a bottom lander is shown in **Figure 8**. Some acoustic recording systems contain sufficient on-board processing power to support real-time data reduction in the form of spectrogram generation, detection and classification of specific sounds, and localization of sounds from hydrophone arrays. For example, for ocean gliders equipped with acoustic receivers with on-board whale call classification software, only short data packets need be transmitted via Iridium satellite data connections to then allow real-time whale positions to be added to the automated identification system (AIS) used on ships and by vessel traffic services (Davis et al., 2016) to track vessel locations.

Passive acoustic monitoring receivers that are part of multipurpose acoustic observing systems need to have accurate and synchronized time bases. Timing is absolutely fundamental to undersea positioning, navigation and tomography, which use precision travel-time data, necessitating synchronized time bases across all platforms. Clock drift between acoustic sources and a receiver on an autonomous platform is the primary source of positioning uncertainty (Webster et al., 2015). Achieving synchronous time is straightforward for systems that have regular access to GPS signals. It is more difficult for autonomous subsea systems, but the technology to do so has been demonstrated, both via use of chip-scale atomic clocks and using time transfer methods, via acoustic communications.

Network Technology

One of the technologies that will be key to the vision of a multipurpose acoustic network as part of ocean observing systems is flexible low-power software-defined underwater signal processing systems. To support underwater sensor networks, next-generation Underwater Acoustic Networks (UANs) must be able to adapt their communication and networking protocols in real-time based on the environmental and application conditions. UAN developers initially found that commercially available acoustic modems, their embedded software systems being largely closed and proprietary, were not flexible enough to satisfy the requirements. This has led to a modular, evolving software-defined radio (SDR) framework for both research and commercial UAN devices supporting all layers of a network protocol stack, including the ability to flexibly encode/decode, in software, acoustic signal modulation at the physical layer (Dol et al., 2017). Such SDR technology enables, for example,

an AUV to flexibly decode and process a multiplicity of source signal types: narrow-band RAFOS signals; wide-band frequency-modulated (FM) or phase-shift-keyed tomography/navigation (RAFOS-2) signals; or simple phase-shift keyed data packets. This allows a variety of acoustic source types to co-exist and evolve on multipurpose acoustic networks. Similarly, software algorithms for specific signal classification (e.g., commands, whale call identification, ship noise, estimates of rainfall, wind, or specific ice deformation events) can co-exist on board such an AUV or tomography SDR. Eventually, these decoded characteristics can be relayed to shore as compact metadata rather than voluminous raw acoustic data. An example of such SDR flexibility was demonstrated by the WHOI Micro-Modem 2 (Gallimore et al., 2010), deployed in 2014 on Seagliders in the marginal ice zone of the Chukchi Sea, which decoded RAFOS-like signals for travel-time estimates (linear FM sweep, 900-Hz center frequency, 25-Hz bandwidth, per above), as well as a phase-modulated signal that encoded a 72-bit data packet containing an ice-tethered (moving) acoustic source location (high resolution latitude and longitude) and a new target glider waypoint (low resolution latitude and longitude) (Freitag et al., 2015; Webster et al., 2015).

ACOUSTICS ADDRESSING OCEAN OBSERVING NEEDS

Discovery

Innovative tools that lead to new discoveries, which ultimately lead to hypothesis-driven science and finally sustained application, enable forward momentum in science. Because sound travels farther and faster than any other signal underwater, acoustics is the primary mode of probing the ocean volume, a form of remote sensing, whether it be fish navigating by the sound of surf or AUVs mapping the mid-ocean ridges, whales communicating and socializing, or measuring ocean basin heat content and currents.

Using the new tools to pick the “low-hanging fruit” catalyzes discovery. New tools or techniques in one field can be repurposed for ocean use, or a simple upgrade to an existing tool can make it much more versatile. Here we briefly explore the vision of what acoustics might bring to ocean observing on time scales of decades and longer, based on the technologies and networking described above.

There are direct analogies between acoustic underwater positioning and the global navigation system of systems (GNSS) that provide precise and accurate time and positioning. Our science and our society are now totally dependent on the latter and take it as an essential critical infrastructure service. We envision that multi-scale acoustic navigation systems will enable the same incredible development of applications that GNSS has created. It will be a major tool in helping us transition from a rather incoherent and chaotic view of the ocean, to a focused, evolving, coherent image. It will enable humankind (using mostly robotic avatars) to “see” the ocean volume.

With precise navigation one can envision using long-range/endurance AUVs to map the ocean floor (Woelfl et al., 2019). They will transit between a rather sparse network of

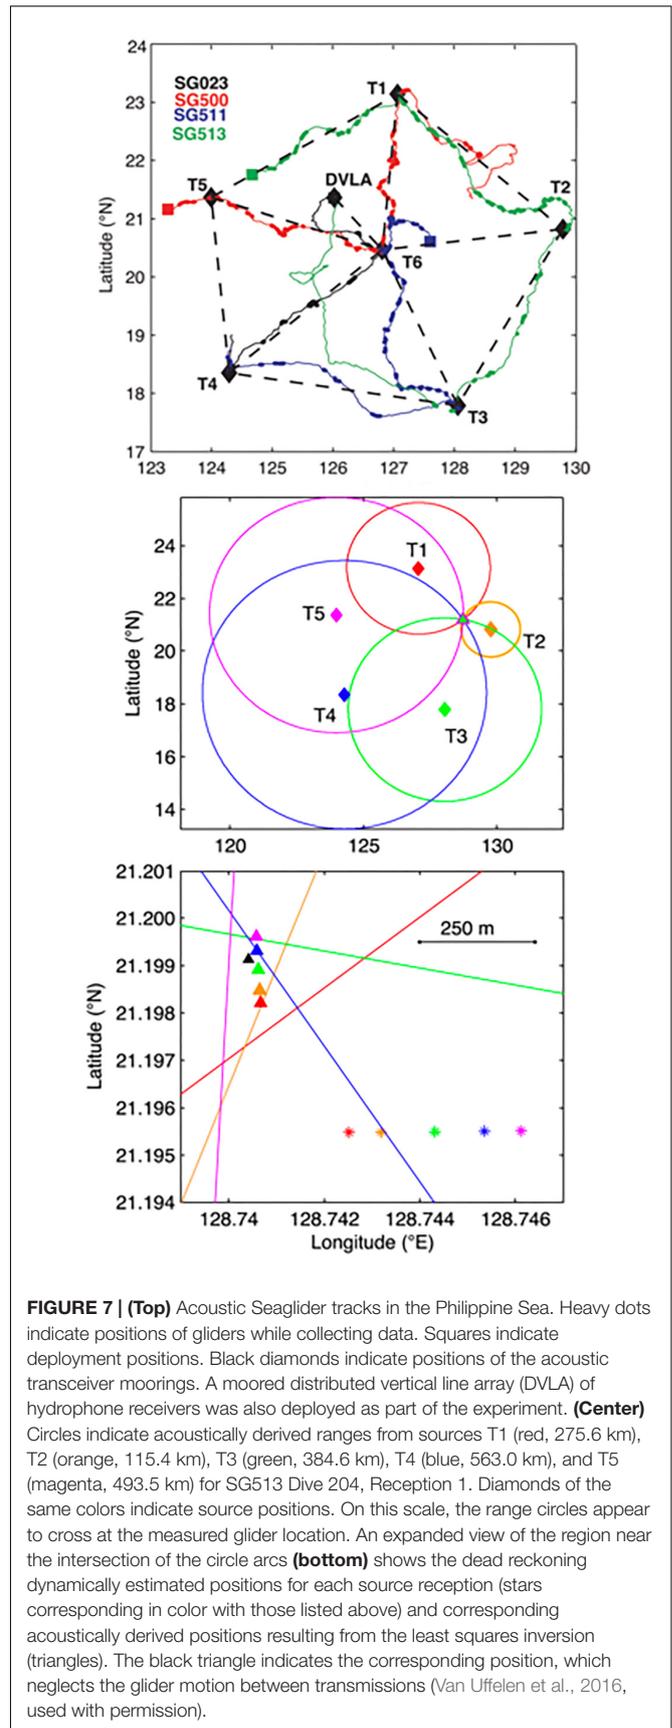

FIGURE 7 | (Top) Acoustic Seaglider tracks in the Philippine Sea. Heavy dots indicate positions of gliders while collecting data. Squares indicate deployment positions. Black diamonds indicate positions of the acoustic transceiver moorings. A moored distributed vertical line array (DVLA) of hydrophone receivers was also deployed as part of the experiment. **(Center)** Circles indicate acoustically derived ranges from sources T1 (red, 275.6 km), T2 (orange, 115.4 km), T3 (green, 384.6 km), T4 (blue, 563.0 km), and T5 (magenta, 493.5 km) for SG513 Dive 204, Reception 1. Diamonds of the same colors indicate source positions. On this scale, the range circles appear to cross at the measured glider location. An expanded view of the region near the intersection of the circle arcs **(bottom)** shows the dead reckoning dynamically estimated positions for each source reception (stars corresponding in color with those listed above) and corresponding acoustically derived positions resulting from the least squares inversion (triangles). The black triangle indicates the corresponding position, which neglects the glider motion between transmissions (Van Uffelen et al., 2016, used with permission).

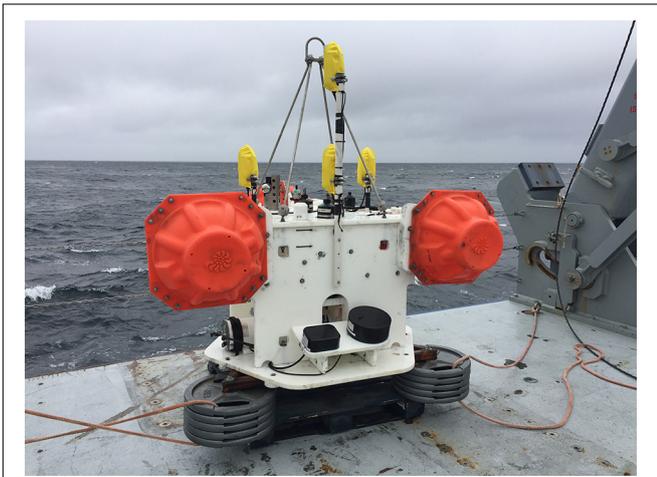

FIGURE 8 | Atlantic Deepwater Ecosystem Observatory Network (<https://adeon.unh.edu>) acoustic lander. A tetrahedral hydrophone array comprising four M36 hydrophones within an Autonomous Multichannel Acoustic Recorder (AMAR; JASCO Applied Sciences) located under the yellow protection covers. Two sets of transducers are shown mounted on the bottom of the lander looking upwards as part of a 4-frequency Acoustic Zooplankton-Fish Profiler (AZFP, ASL Environmental Sciences) echosounder system for capturing water column backscatter. (Photo by J. Miksis-Olds, used with permission).

cabled docking stations, which will also host the acoustic sources of the multipurpose system. There is no question that they will discover numerous volcanoes, hot and cold vent systems, mineral resources, and new life forms within these extreme environments. The latter is directly relevant to the conservation and sustainable use of marine biological diversity of areas beyond national jurisdiction (BBNJ). With precise navigation, AUVs can fly over repeat paths to absolute locations with certainty to observe changes, enabling and servicing autonomous platforms, and serving as energy “tankers” and communications gateways. These platforms (as well as the AUVs) will be sampling a myriad of ocean and geophysical variables, including, for instance, heat and material fluxes from the seafloor (Deep Ocean Observing Strategy [DOOS], 2016, 2018; Levin et al., 2019).

Very importantly, such navigation is essential to sampling under ice in polar regions (Arctic and Antarctic), both for the physics as well as the ecosystems in such an extreme and ephemeral environment, e.g., massive springtime plankton blooms under Arctic sea ice that control the timing of water column primary production (Arrigo et al., 2012). While summer ice may disappear in the near future, ice during the rest of the year will likely persist for decades. Support for under-ice navigation would apply to AUVs as well as gliders and floats (ANCHOR Working Group, 2008; Mikhalevsky et al., 2015; Smith et al., 2019). In this case, not only would basic navigation be enabled, precise geolocation would allow results between the various disparate sampling platforms to be combined coherently within the framework of ocean data assimilation models (running the joint positioning/ocean state estimation). This applies equally to non-polar regions as well. High resolution in time and space tracking will open up a

new domain of sampling space that includes smaller and faster ocean processes that are lost in crude RAFOS tracking (2 km, a few times per day).

We know there are sharp fronts in the ocean, but they are often difficult to sample. If they are sampled with mobile platforms, accurate georeferencing is important so that multiple sources of data can be coherently combined. Long-range acoustic propagation paths used in tomography are also sensitive to such features. One-second changes in travel time are observed as a result of Gulf Stream or Kuroshio meanders, for example (Spiesberger et al., 1983; Lebedev et al., 2003).

The use of “noise” sources of opportunity in a tomographic context is tantalizing, with sources being diffuse (wind, waves) to near points (ships, whales, earthquakes, glaciers). By cross-correlating noise signals received by spatially separated receivers, one can, in principle, infer acoustic arrival patterns for the intervening medium as if they were transceivers. This is well proven and utilized in seismology and many other fields. The critical factor in the ever-changing ocean, however, is the duration over which one can compute the cross-correlation before changes in the ocean medium cause the time delays between the receivers to vary (Kuperman, 2018). Some results have been obtained, for example using Antarctic ice noise as received on distant CTBTO arrays, and using vertical arrays listening to ships over short range. It may be that with the ever-increasing number of receivers being deployed with coherent signal processing, “passive tomography” will come to fruition (see Kuperman, 2018, for a recent review).

Extending this further, acoustic tagging of pelagic marine life is well underway (e.g., marine mammals, sharks) to address questions related to communication, foraging ecology, and impacts related to sound exposure (Johnson et al., 2009). With tags that include acoustic positioning capability, one can envision coherently processing the acoustic data in the context of other environmental data collected on other platforms (assuming the tag is eventually recovered). Information from animal tags have already been integrated into the Australian Ocean Data Network (AODN) (Hidas et al., 2018) and serve as a model for what is possible on a global scale.

Using acoustics to listen to marine life, from very small to very large, whether remotely or with a tag on an animal, will improve our understanding of communication and behavior. With accurate positioning, we can obtain finer and finer views of what the animals are doing, and why. With the improved ocean state estimates obtained by including acoustic tomography data, we will be able to more directly link animal behavior with ocean physics and determine how marine mammals function and adapt to the constantly changing conditions of a dynamic ocean.

Finally, the combined use of active and passive acoustics, as appropriate, to simultaneously observe the physics and biology will greatly aid the interpretation of the data. New insights will result when multi-frequency sonars and “acoustic vision” are coupled with observations of the physical flow throughout the water column, from the photic zone with the deep scattering layer, to the deepest hadal reaches.

Ecosystem Health and Biodiversity

Following closely on the heels of initial discovery is the quest to gain a full understanding of the environment surrounding targeted findings. The combination of active and passive acoustic technology is a powerful tool in building a comprehensive concept of ocean dynamics shaping the local or regional ecosystem. Ocean processes, marine life dynamics, and human ocean use are each inherently three-dimensional and time-dependent, and each occurs at many spatial and temporal scales. The versatility of acoustic observations provides the opportunity to obtain information over wide temporal and spatial scales. The value of ocean acoustic observations for understanding biology and ecosystems has been internationally recognized through the acceptance of the proposal by the International Quiet Ocean Experiment program to the GOOS Biology and Ecosystems Panel for the consideration of Ocean Sound as an Essential Ocean Variable (Miksis-Olds et al., 2018) and by the convening body of the Deep Ocean Observing Strategy (Deep Ocean Observing Strategy [DOOS], 2016, 2018). Additionally, the application of passive acoustic recordings in constructing underwater soundscapes to better understand ocean ecosystem dynamics has gained community traction. Clear evidence of the value and application of underwater soundscapes is demonstrated by the effort of the International Organization for Standardization (ISO) in developing ISO standard 18405 on Underwater Acoustics-Terminology to help ensure research measurements are repeatable and comparable across projects (International Organization for Standardization [IOS], 2017). ISO 18405 defines the underwater soundscape for the first time and illustrates the growing maturity of this ocean variable.

Ocean sound is a national and international focus because it crosses borders unimpeded. Acoustic signals, as opposed to visual and chemical signals, can propagate long distances in the ocean and provide a means for marine life and humans to gain information about the environment and for marine animals to exchange critical information. Passive acoustic technology allows us to eavesdrop on marine life interactions and physical processes that create the local soundscape. A soundscape is the characterization of the ambient sound in terms of its spatial, temporal and frequency attributes, and the types of sources contributing to the sound field (International Organization for Standardization [IOS], 2017). Passive acoustic recordings are used non-invasively to assess environmental sound levels, surface conditions, human activity, and the distribution and biodiversity of vocalizing marine life. Active acoustic technology provides a high-resolution (in both time and space) measure of biological (zooplankton and fish abundance and distribution) and physical oceanographic processes (internal waves, micro-turbulence, and frontal systems) through time series of acoustic backscatter measurements (Lavery et al., 2009).

A great deal of information related to ocean ecosystems can be gained simply by assessing the ambient sound. The concept of using information in ambient sound as cues to direct movement or identify appropriate habitats has recently been identified as a new field of study referred to as *soundscape orientation*, and the

concept is also included within the broader field of *soundscape ecology* in the scientific literature (Slabbekoorn and Bouton, 2008; Pijanowski et al., 2011). A large number of aquatic species use sound cues contained in local soundscapes to navigate, forage, select habitat, detect predators, and communicate information related to critical life functions (e.g., migration, breeding, etc.). Consequently, marine animals ranging from the smallest larvae to the largest whales have evolved mechanisms for both producing and receiving acoustic signals. Information contained in underwater soundscapes provide a means to better understand the influence of environmental parameters on local acoustic processes (McWilliam and Hawkins, 2013; Miksis-Olds et al., 2013; Staaterman et al., 2014), assess habitat quality and health (Parks et al., 2014; Staaterman et al., 2014), and better understand the impacts and risks of human contributions to the soundscape on marine life.

Underwater soundscapes are dynamic, varying in space and time within and between habitats. Underwater soundscapes are highly influenced by local and regional conditions but, unlike most terrestrial soundscapes, distant sources are also significant contributors because sound propagates such great distances underwater. The underwater soundscape may be composed of contributions from human activity (e.g., shipping, seismic air gun surveys), natural abiotic processes (e.g., wind, rain, ice), non-acoustic biotic factors (e.g., animal movement), and acoustic contributions from sound producing, biological sources (e.g., marine mammals, fish, and crustaceans). The soundscape can be selectively decomposed and visualized to gain a greater understanding of the sources and environmental dynamics contributing to and shaping the temporal, spatial, and spectral patterns of the acoustic environment. In the early 1990s, the ATOC program began collecting ambient sound in order to begin to better understand soundscapes and answer such basic questions such as how often does the sound level exceed a certain value, and can the constituents of ambient sound be discriminated (Curtis et al., 1999). **Figure 9** shows recent examples addressing these two questions.

Indicators of habitat quality and biodiversity that were developed for terrestrial applications are now being applied to marine habitats and soundscapes (Denes et al., 2014; Parks et al., 2014; Staaterman et al., 2014). Acoustic analysis of a habitat's soundscape using high level indicators such as the acoustic complexity index (ACI), acoustic entropy index, or acoustic similarity/dissimilarity indices provide a quantitative way to assess biodiversity and compare/contrast soundscapes of different habitats (Parks et al., 2014). Compared to *in situ* measurements of marine habitats by human divers, acoustic biodiversity indicators are less costly and less labor intensive. Acoustic systems also provide the added benefit of high temporal resolution resulting from long-term deployments of remote passive acoustic sensors. Acoustic diversity indicators are estimated by mathematically assessing the ratio of energy at different spectrum frequencies to make inferences about local community biodiversity. The larger the frequency bandwidth of recordings, the more information is available to accurately capture species and habitat diversity (Parks et al., 2014).

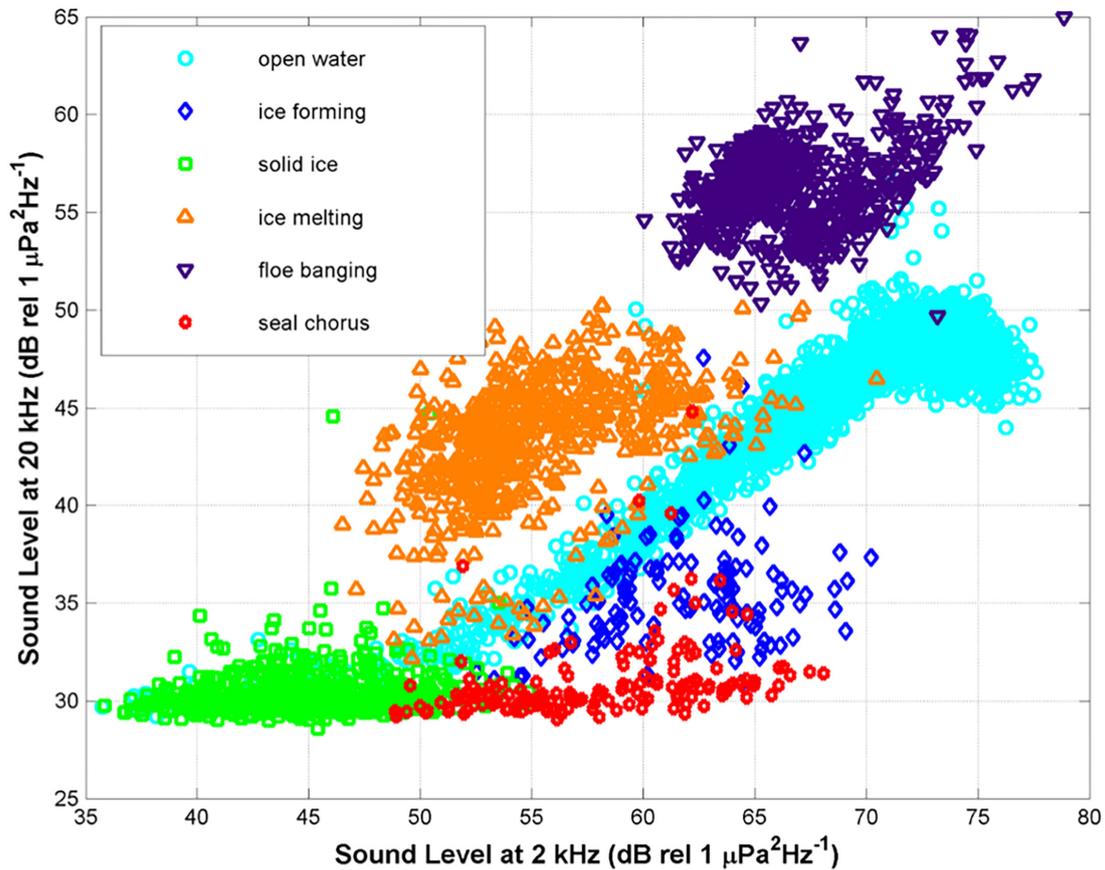

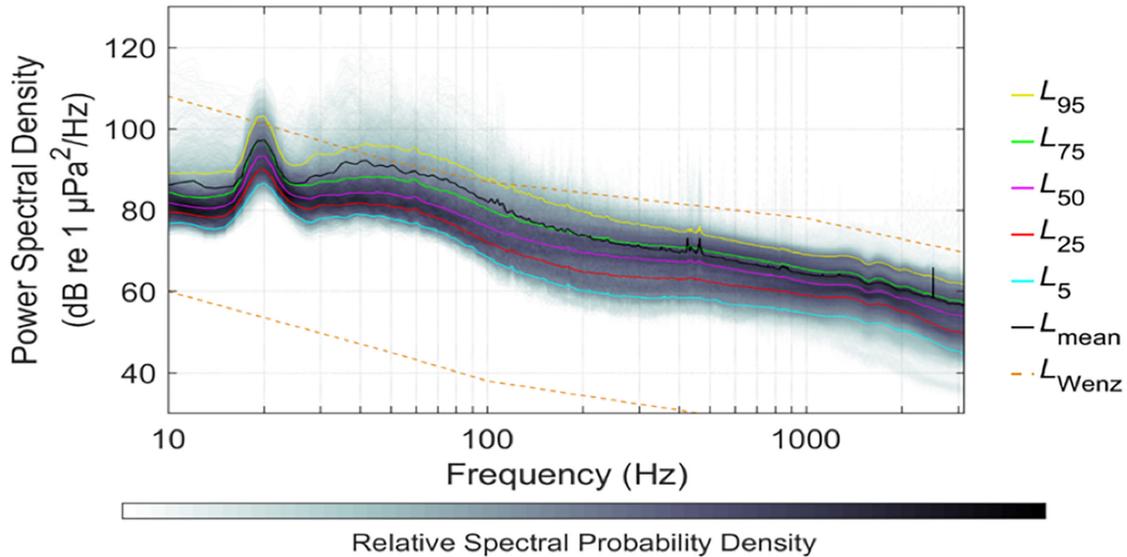

FIGURE 9 | Two examples of how soundscape data is visualized. **(Top)** Summary of sound levels by an ADEON lander (**Figure 8**) along the Outer Continental Shelf east of Virginia based on 1-min, 1 Hz resolution analysis of data sampled at 375 kHz. Percentiles and relative spectral probability density for the 1 Hz spectra (Figure provided by Bruce Martin, JASCO Applied Science, used with permission). **(Bottom)** Soundscape recorded in the winter/spring of 2009 in the central region of the Bering Sea Shelf. Each point on the image represents the ratio of sound pressure level between 2 and 20 kHz at a specific point in time. The acoustic environment changed based on the presence of vocalizing ice seals and state of sea ice at the surface. Sources are color-coded based on their stereotyped source characteristics. [Figure was produced by Jeffrey Nystuen (APL-UW) and is a reproduction from Figure 5 in Van Opzeeland and Miksis-Olds, 2012, used with permission].

Successful examples of linking biodiversity and ocean sound come from studies on coral reefs and kelp beds. Healthy coral reefs and kelp habitats support high levels of biodiversity and produce an overall soundscape rich in temporal and spectral signatures created by the cacophony of vocalizing animals ranging from low-frequency fish calls to high-frequency, broadband sounds of snapping shrimp (Radford et al., 2008a; Staaterman et al., 2013). Kelp forests of New Zealand have shown diel, lunar, and seasonal trends in sound production with the most intense sounds occurring at dawn, dusk, and during the summer months when the abundance of sea urchins, snapping shrimp, and noise-emitting fish are highest (Radford et al., 2008b, 2010). In this system, there was good agreement between measures of acoustic and *in situ* diver collected biodiversity, illustrating the potential value of acoustic metrics for monitoring and assessing biodiversity of kelp habitats (Harris et al., 2016).

As powerful as passive acoustics can be in detecting, localizing, and providing information about local soundscape sources, passive acoustic technology fails when objects or phenomena are not producing sound. Active echosounder technology provides a time series of acoustic backscatter information that not only provides critical information on biology but also physical components of the water column (Lavery et al., 2009; Benoit-Bird and Lawson, 2016). The integration of multi-frequency echosounders in cabled and remotely deployed observation systems have contributed invaluable knowledge on marine life community structure, distribution and size of marine organisms, oceanic microstructure, and suspended sediments. By recording acoustic backscatter from at least two frequencies, the differences in backscatter between the two frequencies can be used to distinguish between different scatterers in the water column (Watkins and Brierley, 2002; Warren et al., 2003). Successful incorporation of upward looking, single beam echosounders in moorings at Ocean Station Papa (Trevorrow et al., 2005) and in the Bering Sea (Miksis-Olds et al., 2013; Miksis-Olds and Madden, 2014; Stauffer et al., 2015) demonstrate the maturity of this technology in providing time series of acoustic backscatter used to investigate the abundance and behavior of zooplankton and fish, predator-prey relationships, and community structure.

Successful use of multiple single-frequency echosounders to study ecosystem dynamics has led to the evolution of broadband systems (e.g., Lavery et al., 2010; Stanton et al., 2010; Benoit-Bird and Lawson, 2016), which are now being used in both cabled and moored configurations for inferring species composition. Broadband data have the advantage of improved spatial resolution, allowing better target isolation and noise suppression through the use of pulse compression techniques (Chu and Stanton, 1998; Ross et al., 2013). Broadband measurements and theoretical physics-based approaches for classifying zooplankton were successfully combined to classify biological scattering layers from the Victoria Experimental Network Under the Sea (VENUS) mooring in Saanich Inlet, British Columbia (Ross et al., 2013). Two years of broadband data (85–155 kHz) were collected from the VENUS system. Data processing classified scattering layers based on their assemblages into four animal groups: (1) diel migrating euphausiids; (2) chaetognaths; (3) fish;

and (4) a mix of pteropods and bottom-to-oxycline migrating amphipods. Data generated from active acoustic systems provide biological information on trophic levels containing fish and zooplankton. When combined with the information obtained from passive acoustic systems related to physical conditions (e.g., surface conditions, ice cover, etc.), upper trophic level dynamics of marine mammals and other top predators, and even human use factors, underwater acoustics becomes a valuable tool in monitoring ecosystems in terms of overall function, biodiversity, and health.

Climate Variability and Change

Nearly four decades ago Munk and Wunsch (1982) proposed the establishment of a system for “Observing the ocean in the 1990s.” The hypothetical system that they described had two major observational components: ocean acoustic tomography and satellite measurements of sea surface topography (altimetry) and wind stress (scatterometry). (They also mentioned drifting floats but floats capable of profiling the upper 1000 m or so of the ocean did not exist at that time.) They expected that these complementary observations would “be assimilated into numerical modeling of the ocean circulation.” They listed the

“advantages and disadvantages of tomography as a tool for providing large-scale (and hence climatological) data. . .

Advantages

Large-scale spatial integration; information increases geometrically with the number of moorings; unattended recording over a year or more (1/3 year demonstrated so far); submerged instrumentation (of especial interest in regions of seasonal ice formation); remote sensing (of potential use in regions of strong currents); good vertical resolution.

Disadvantages

Sound speed is not a unique measure of temperature or density. However, in regions with stable temperature-salinity relations the separate temperature and salinity fields (and hence the density field) can be inferred to adequate precision. . .”

The notion of “unattended recording over a year or more” is now so routine that it seems quaint. Nonetheless, the basic advantages and disadvantages of the application of acoustic methods for studying climate variability are unchanged. The key advantage of measurements of climatological variability is that the spatial integration inherently provided by long-range acoustic transmissions suppresses the effects of mesoscale and smaller scale variability. The advantages of acoustic remote sensing for observing ocean climate variability were reiterated at the OceanObs’99 (Dushaw et al., 2001) and OceanObs’09 (Dushaw et al., 2010) conferences. These advantages still exist today. Obtaining the large-scale spatial averages needed for measuring climate change from profiles in which the majority of the variance is due to mesoscale and smaller scale variability is still very much a challenge. Satellite measurements of sea-surface properties, high-resolution vertical profiles of temperature and salinity (e.g., Argo), and large-scale average temperature and heat content from acoustic tomography are complementary for adequately sampling an ocean that varies on all time and space scales. As

Munk and Wunsch (1982) noted, “A condition underlying any ocean observing system is that the ocean is transparent to sound, but opaque to electromagnetic radiation.”

What makes the case for the application of acoustic methods for measuring ocean climate variability more compelling now than in past decades? Munk and Wunsch (1982) were clearly ahead of their time. The first three-dimensional test of ocean acoustic tomography, the 1981 Tomography Demonstration Experiment, which lasted only 4 months, had just been completed (Behringer et al., 1982). The numerical ocean models available at the time (and in the 1990s, for that matter) did not have the vertical resolution needed for acoustic calculations. The situation is now dramatically different.

Long-Range Ocean Acoustic Thermometry

Transmissions over ranges of 1000 km or more have been used to measure large-scale ocean temperature and heat content, beginning with recording of the transmissions during the 1981 Tomography Demonstration Experiment in the Northwest Atlantic Ocean on bottom-mounted receivers at ranges of 1000–2000 km (Spiesberger et al., 1983). The application of long-range transmissions to measure temperature is often referred to as “acoustic thermometry,” usually in the context of transmissions for which there are few or no crossing acoustic paths. (Thermometry is a subset of acoustic tomography). Long-range measurements have also been made in the North Pacific Ocean, Mediterranean Sea, and Arctic Ocean. Transmissions over global scales were made during the 1991 Heard Island Feasibility Test (HIFT), but these very long ranges are not optimal from the perspective of measuring climate variability because the transmissions average across distinct climatic provinces (Munk et al., 1994).

Acoustic transmissions from sources located near the sound-channel axis to vertical receiving arrays over gyre scales (1000 km) (Worcester et al., 1994) and basin scales (3250 km) (Worcester et al., 1999) established conclusively that acoustic methods can measure range- and depth-averaged temperatures at gyre- and basin-scale ranges with a precision of a few millidegrees C (**Figure 10**). The early portions of the acoustic arrival patterns at long ranges consist of ray-like wave fronts that are resolvable, identifiable, and stable. The later parts of the arrival patterns (finale) do not contain identifiable ray-like arrivals due to scattering from internal-wave-induced sound-speed fluctuations. Nonetheless, the time at which the near-axial acoustic reception ends can be used as a surrogate for the group delay of the lowest acoustic normal mode, providing information on near-axial temperatures. These experiments were unique in combining long vertical receiving arrays, extensive concurrent environmental measurements, and broadband signals designed to measure acoustic travel times with millisecond precision.

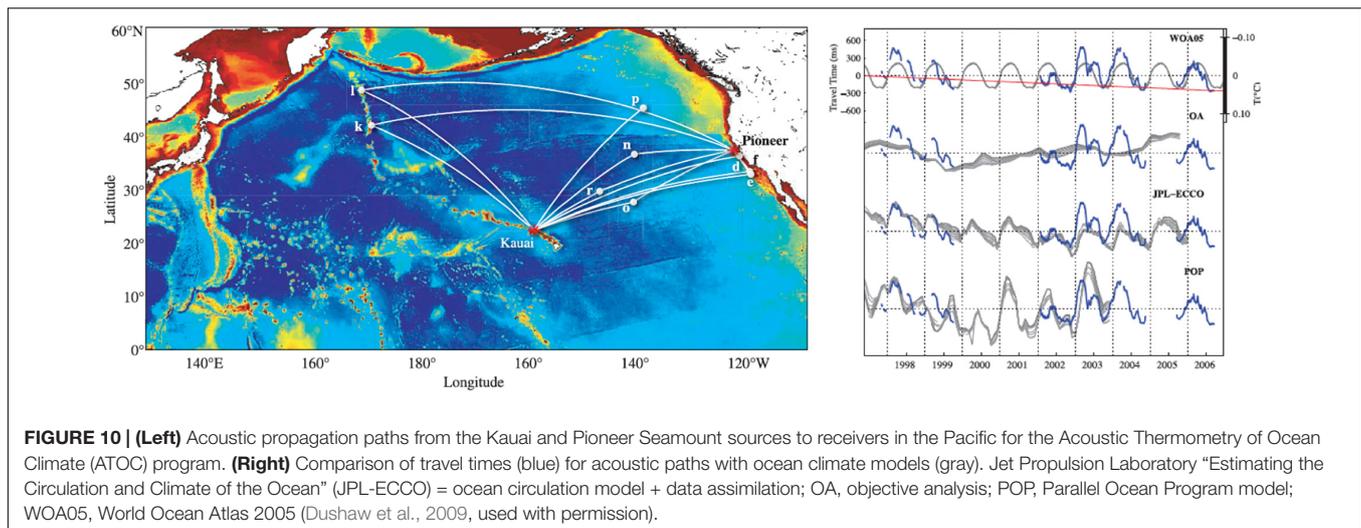

Although these results were favorable, at the time it was not understood how the early time fronts could be stable in the presence of internal-wave-induced scattering of the acoustic signals. In the (non-linear) geometric optics approximation, rays were expected to become chaotic at long ranges. Subsequent analyses showed that scattering tends to occur along wave

fronts, rather than across them, giving resolvable, stable wave fronts (Godin, 2007). Further, wave-theoretic modeling, using normal mode and parabolic equation methods, has been applied to obtain travel-time sensitivity kernels (TSKs) without making the geometric optics approximation describing how travel times are affected by localized sound-speed perturbations anywhere in the medium (Skarsoulis and Cornuelle, 2004). Investigations of the structure and stability of the TSK in the presence of small-scale oceanographic variability that scatters acoustic signals show that ray-based travel-time inversions are valid even in this case (Dzieciuch et al., 2013). There is now a firm theoretical basis for the application of ray inversion methods.

Long-Range Transmissions and Ocean Models

Early attempts to use gyre- and basin-scale travel times to constrain ocean models were made by Menemenlis et al. (1997) and the Acoustic Thermometry of Ocean Climate (ATOC) Consortium (1998). At the time, primitive equation ocean general circulation models (OGCMs) did not have the vertical resolution needed to characterize ocean acoustic propagation and permit the accurate calculation of travel times. Statistical inverse methods were therefore used to convert the travel times to range-averaged ocean temperatures, which were then used as data to constrain primitive equation models.

The ATOC project continued over the decade 1996–2006, using sources installed off central California (1996–1999) and north of Kauai (1997–1999, 2002–2006) that transmitted to bottom-mounted and moored receivers in the North Pacific. These measurements were subsequently used to test more modern OGCMs (Dushaw et al., 2009, 2013). When attempting to compare the travel-time variability observed at bottom-mounted receivers for the duration of the ATOC project with model estimates, Dushaw et al. (2009) found that calculations based on the climatology in the *World Ocean Atlas 2005* (WOA05) were able to reproduce the observed acoustic arrival patterns. The OGCM estimates available at the time proved incapable of doing so, however. The critical parameter for acoustic propagation calculations is the vertical sound-speed gradient, which was sufficiently unrealistic in the OGCM estimates to make the acoustic calculations fail. In order to proceed, the time means of the model temperature and salinity fields were removed and replaced with the annual mean fields from WOA05, making the assumption that the variability in the model estimates was realistic even though the mean fields were not. The differences between the observed travel time variability and that calculated from the models were sometimes substantial. Dushaw et al. (2013) subsequently used receptions on three vertical hydrophone arrays that were installed for about a year each in 1996 and 1998 to test the time-mean properties of the OGCM estimates. The observed acoustic arrival patterns were found to be in relatively good agreement with those computed for state estimates made by the Estimating the Circulation and Climate of the Ocean, Phase II (ECCO2) project, indicating that the numerical ocean models had reached a level of maturity by the time of Dushaw et al. (2013) such that the acoustic data could

be used to provide useful additional constraints for ocean state estimation.

Ice-Covered Seas

The case for using acoustic methods to study climate variability is especially compelling in ice-covered regions, where long-term, large-scale, continuous observations of the ocean interior are difficult to obtain using other approaches. Most attention to date has focused on the rapidly changing Arctic (e.g., Jeffries et al., 2013), but acoustic methods are equally applicable in the seasonally ice-covered Southern Ocean around Antarctica.

Satellite images show a large reduction of sea ice in the Arctic (e.g., Meier et al., 2014). The satellites cannot observe the interior of the ocean underneath the sea ice, and less is therefore known about what is occurring in the ocean under the ice. Just below the sea ice there is a cold, fresh water layer that protects the ice from the warmer, saltier waters deeper in the ocean. Point measurements in some areas of the Arctic indicate that this layer is disappearing (Lique, 2015; Polyakov et al., 2017). This change can accelerate the melting of the sea ice. Additionally, it is not known how much heat is stored in the water masses under the protective water layer.

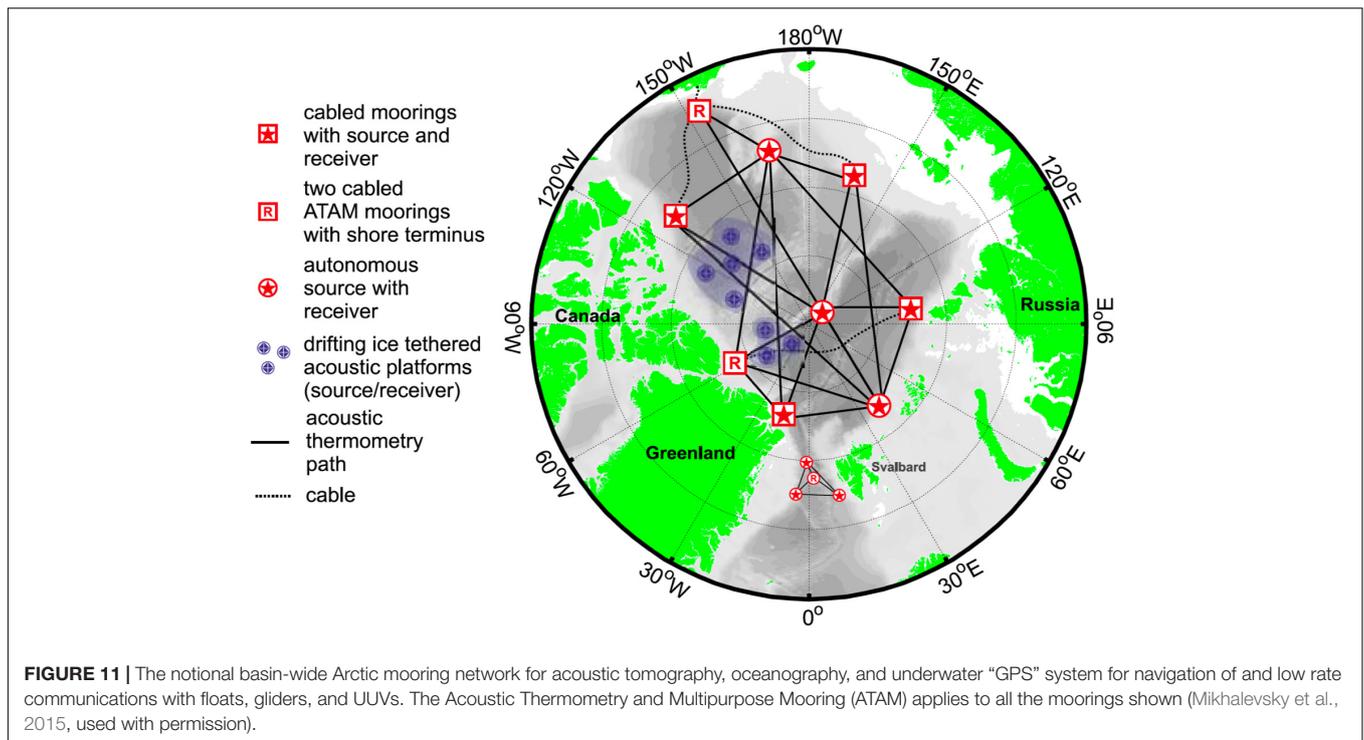

Previous basin-scale acoustic measurements made in the 1990s showed that the Atlantic Intermediate Water (Atlantic Layer) was warming. During the 1994 Transarctic Acoustic Propagation (TAP) experiment, ultralow-frequency (19.6 Hz) acoustic transmissions propagated across the entire Arctic basin from a source located north of Svalbard to a receiving array located in the Beaufort Sea at a range of about 2630 km (Mikhalevsky and Gavrilov, 2001). Modal travel-time measurements yielded the surprising result that the Atlantic Layer was about 0.4°C warmer than expected from historical data. Acoustic data collected on a similar path during April 1999 as part of the Acoustic Climate Observations Using Underwater Sound (ACOUS) project indicated further warming of about 0.5°C. These results were subsequently confirmed by direct measurements made from icebreakers and submarines (Mikhalevsky and Gavrilov, 2001).

Mikhalevsky et al. (2015) advocated the application of multipurpose acoustic networks in an integrated Arctic observing system (Figure 11). Several year-long experiments in Fram Strait (Sagen et al., 2016, 2017) and the Canada Basin have demonstrated the technology at a regional scale. It is now 20 years since the TAP and ACOUS measurements were made. The Coordinated Arctic Acoustic Thermometry Experiment (CAATEX), jointly funded by the United States, Norway, and Canada, will repeat these basin-scale measurements during 2019–2020. In addition to acoustic remote sensing (tomography), an integrated acoustic system would provide passive monitoring of ambient sound (ice, seismic, biologic, and anthropogenic) and under-ice navigation for drifting floats, gliders, and AUVs. Given the rapid rate at which the Arctic is changing, implementation of a sustained integrated observing system is urgent.

Straits and Climate Choke Points

Geographically constrained regions of the ocean function as gateways for important exchanges of heat, salt, nutrients, and marine life itself, with implications for climate change and variability. For example, water mass exchanges between the Arctic Ocean and the Atlantic and Pacific Oceans occur through the Fram Strait, Bering Strait, Davis Strait, and the Canadian Archipelago. Long-term acoustic tomography measurements can help determine heat and salt fluxes through these straits, taking advantage of the integrating property of acoustic data.

For example, models show a series of complex interactions within Baffin Bay in which melting Greenland ice sheets lead to decreased southward transport of cold Arctic water via the Canadian Archipelago and increased northward transport of fresh Atlantic water via Davis Strait due to a strengthening of the gyre circulation in Baffin Bay. A positive feedback cycle develops as warmer water enters Greenland fjords, further enhancing the melting of marine-terminating glaciers (de la Guardia et al., 2015). Clearly, monitoring the long-term changes in heat content, salinity, and mean circulation are paramount to evaluating the importance of this feedback cycle.

In another example, Pacific Waters (PW) represent one-third of all Arctic freshwater and supply and 10–20% of the oceanic heat to the Arctic Ocean. The large Arctic sea-ice retreat of 2007 was likely caused by extreme oceanic flux of PW. Remotely sensed sea surface temperature (SST) is insufficient for quantifying the variability in estimating the heat content in the Bering Strait region (Woodgate et al., 2012), which suggests an opportunity for temperature estimates from measurements of acoustic travel time to contribute to estimates of heat content in that region.

A study in Fram Strait showed that while point measurements from moorings and integrated measurements from acoustic tomography lead to similar uncertainties in sound speed (from which salt water properties are retrieved), objective estimates using combined mooring and tomographic measurement lead to a threefold reduction in uncertainties. Further, unlike a 2-D mooring array, adding tomographic measurements offers the opportunity to capture the 3-D variability necessary to fully understand transports through Fram Strait (Dushaw and Sagen, 2016).

Tomographic measurements have been made in other Straits as well, in locations of climatic importance. For 3 months in 1996, 2 kHz transceivers were deployed in the Strait of Gibraltar. Reciprocal travel-time measurements diagonally across the Strait performed best for determining path-averaged velocity, while sum travel times provided good temperature measurements (Send et al., 2002). For the last decade, investigators led by A. Kaneko conducted many measurements in coastal seas. Most recently, the focus has been on measuring in the straits associated with the Indonesian Through Flow (ITF). Measurements in the Bali Strait resolved a five-layer vertical structure of flow as well as strong non-linear tides (Syamsudin et al., 2017). Future plans are

to sustain these measurements and extend them to the Lombok and other straits. In this application, the remote sensing capability of the acoustics comes into play as nearshore (e.g., pier-mounted) equipment has a much higher probability of surviving than do instruments in the strait itself.

Hazards and Maritime Safety

The Comprehensive Nuclear-Test Ban Treaty Organization (CTBTO) is supporting the scientific use of International Monitoring System (IMS) data for disaster warning, marine hazard prevention and overall promotion of human welfare. The IMS functions as a Global Alarm System designed to detect not only nuclear explosions but also earthquakes able to produce tsunamis (CTBTO website: Disaster Warning and Science¹).

The verification regime of the Comprehensive Nuclear-Test-Ban Treaty (CTBT) regime relies on the IMS, which consists of 337 facilities worldwide and provides global coverage for signs of nuclear explosions. Of the 337 facilities, 11 are hydroacoustic stations responsible for covering the oceans. The hydroacoustic stations include five T-stations, which use on-shore seismometers to detect waterborne signals coupled into the Earth's crust, and six cabled hydrophone stations with two triplets of moored hydrophones in a horizontal triangular configuration with a separation of 2 km (with the exception of one station in Australia which has a single triplet). At present, 100 IMS stations, both hydroacoustic and seismic, provide near real-time data to tsunami warning centers in 14 countries to enhance their capability to issue timely and precise warnings (Figure 12).

¹<https://www.ctbto.org/verification-regime/spin-offs-for-disaster-warning-and-science/>

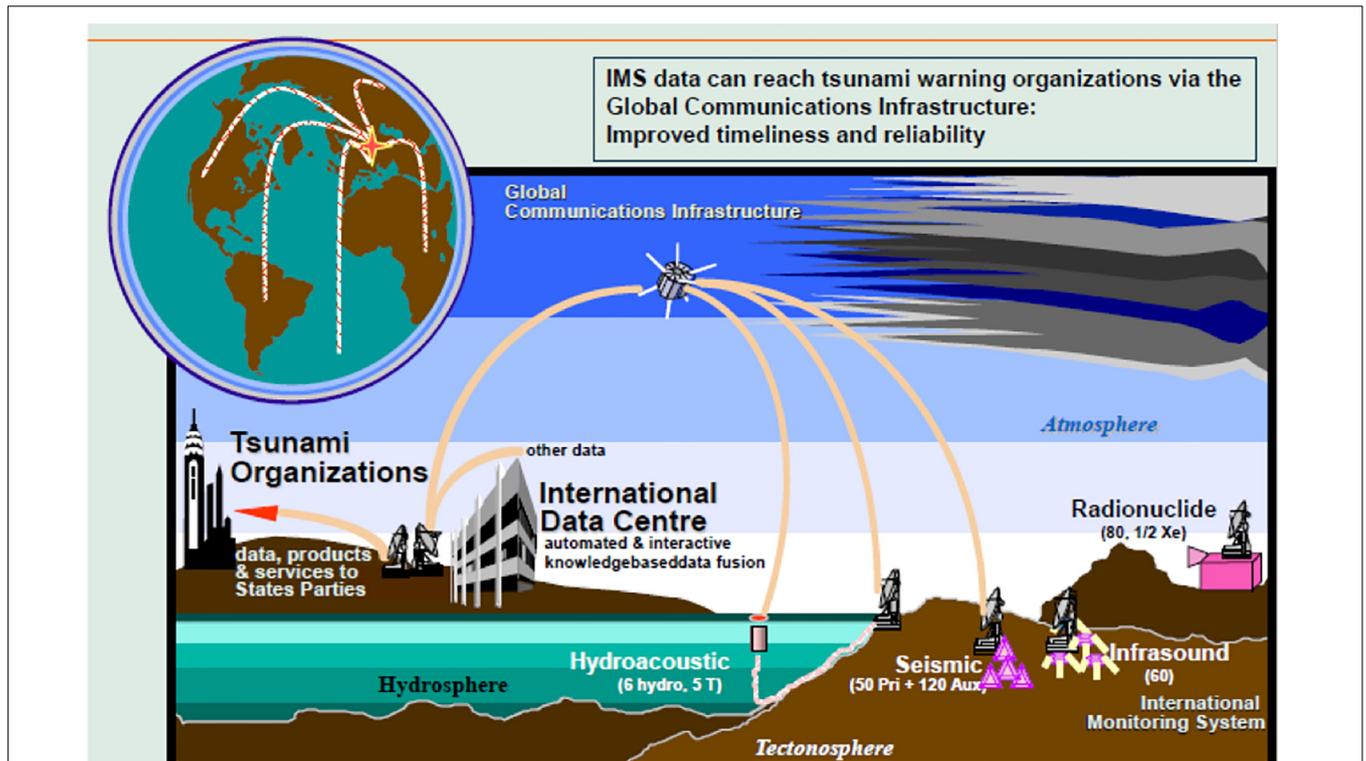

FIGURE 12 | Data flow within the CTBTO IMS, with appropriate data and products forwarding to tsunami warning centers in real time (Figure provided by G. Haralabus, used with permission).

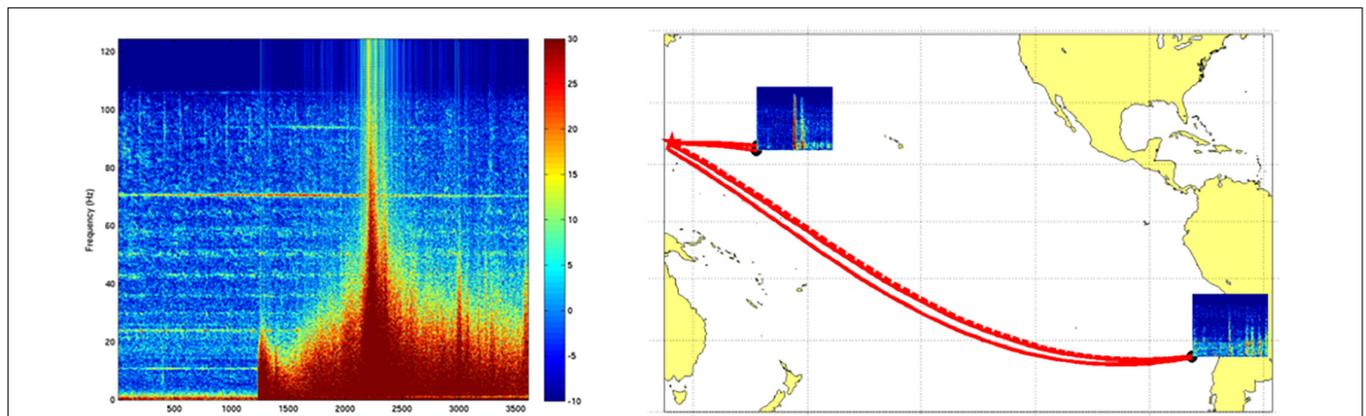

FIGURE 13 | (Left) Frequency content of the 1 April 2014 northern Chile earthquake signal on an HA03 hydrophone (Juan Fernandez, Chile) versus time (in seconds) on the horizontal axis. The color scale is in decibels (dB), with red denoting higher energy content. Early arrivals are attributed to seismic waves traveling through the ocean crust and leaking acoustic energy into the water, however, most of the acoustic energy arrived later in the form of T-phase propagation in the SOFAR. **(Right)** Hydrophone recordings at HA11 (Wake Island, United States) and HA03 (15,000 km away) pertaining to bursting underwater gas bubbles emitted by an undersea volcano near the Mariana Islands (Figure provided by G. Haralabus, used with permission).

Hydroacoustic station warnings of underwater volcanic eruptions or undersea earthquakes could bring significant benefits to maritime traffic. For example, during the Tōhoku earthquake and the subsequently induced tsunami that struck Japan on 11 March 2011, the HA11 Wake Island (United States) hydrophone station helped track the wave as it propagated across the Pacific Ocean. Another example

of the multitude of natural signals recorded at the IMS hydroacoustic stations is the magnitude 8.2 earthquake that occurred on 1 April 2014 in Northern Chile and was recorded at the HA03 Juan Fernandez (Chile) hydrophone station (Figure 13).

One of the greatest advantages offered by hydroacoustic stations is that they cover exceptionally large areas, compared to

other technologies, due to the efficient way sound propagates in the water (Figure 3). In April 2014, underwater explosion-like signals emitted by an undersea volcano near the Mariana Islands in the North Pacific Ocean were received at HA03, more than 15,000 km away (Figure 13).

Hydroacoustic data from the IMS network provided assistance in the search for the missing Argentine submarine ARA *San Juan* (S-42). On 15 November 2017, two CTBTO hydroacoustic stations, namely HA10 (Ascension Island) and HA04 (Crozet), detected an unusual signal in the vicinity of the last known position of the submarine. The signal had the characteristics of an underwater impulsive event and occurred at 13:51 GMT on 15 November. Details and data were made available to the Argentinian authorities to support the ongoing search operations. The mutually beneficial collaboration between Argentinian researchers and hydroacoustic experts at CTBTO continues with further analysis of this unusual acoustic event (CTBTO, 2017a,b).

Passive acoustic monitoring is also currently being applied at a local and regional level to alert the shipping industry to the presence of hazards in the form of large whales. Off the east coast of the US, the endangered North Atlantic right whale migrates up and down the coast annually. Their surface behavior related to foraging puts them at high risk for ship collisions (Parks et al., 2014), which is costly to both the animal and the ship. The Right Whale Listening Network² implements a smart acoustic buoy system to continually listen for whale calls. If a right whale call is detected any time in the last 24 h, it is reflected on the website, and this information is also broadcast to mariners to reduce vessel speeds below 10 knots in an effort to reduce ship strikes. This technology has expanded in the form of a Whale Alert app³, which aims to reduce lethal whale ship strikes worldwide and across all large whale species.

DISCUSSION

The implementation of a global multipurpose acoustic ocean observing system is beginning. The establishment of ocean sound as an Essential Ocean Variable is an important milestone in this process. Ocean sound is uniquely suited to observing ocean ecology and biology, both in passive and active forms. The infrastructure for positioning, navigation, timing (PNT) and communication, which is so critical to effective operations of all observing platforms in the ocean, directly leads to tomographic observations. With these active and passive components, the multipurpose system can be realized.

The elements to accomplish this have sufficient technical readiness and feasibility to implement the system. Passive receivers, often with arrays, are now commonplace; accurate timing and geo-referencing are required for them to be coherent elements of the larger system. Active sources suited to long-range acoustic propagation necessary for PNT and tomography are now off-the-shelf. Similarly, autonomous echosounder systems

for short-range monitoring of water column biology are now commercially available. Acoustic signal processing is up-to-the-task, though the “big data” aspects are already somewhat daunting. The assimilation of tomographic travel time data into ocean models is understood but needs to be made routine with sustained data streams from operational systems. The same applies to acoustically determined high-resolution float and vehicle tracks; this needs to be done as a joint estimation problem.

A large proportion of PAM research programs and applications focus on questions pertaining to coastal waters due to the relatively easy access compared to outer continental shelves, concentration of human activities along the coasts, and regulatory/management concerns under national, regional, and local jurisdictions. PAM networks, like the CTBTO, demonstrate the value of global coverage, but have historically been limited to low frequency recordings due to constraints in power, sensor data storage capacity, required post-processing resources, and data management services. As discussed in this work, many of these obstacles have been overcome or are presently being addressed through advances in technology or repurposing methodologies from other fields. Consequently, PAM is a mature tool for ocean monitoring that is expanding in bandwidth, geographical scope, and application.

Future innovation related to PAM technology and applications is likely to come in the form of combining PAM with other non-acoustic sensing methods. For example, over the past 2–3 years, environmental DNA (eDNA) techniques, which have been used more in freshwater ecosystems, are now being explored in marine environments (Andruszkiewicz et al., 2017; Bakker et al., 2017; Gargan et al., 2017). The eDNA from targeted marine mammal species is detectable and comparable to both visual and acoustic surveys 2 h after an animal has swum through a volume of water (Baker et al., 2018). As eDNA technology and methodologies continue to develop in association with marine ecosystems, it is possible to envision an ocean observation system systematically addressing questions of ecosystem connectivity from estuarine habitats to deep ocean environments far offshore (Levin et al., 2019). Combining PAM with eDNA or genomic sensing is only one of the non-acoustic techniques that hold future promise in enhancing our ability to autonomously observe the ocean, and the likelihood of future generations developing completely new methods that are presently inconceivable is high.

To be used effectively, multipurpose acoustic observing systems should be deployed where they can uniquely make the largest contributions, filling gaps in the present observing system. Polar regions, near and under the ice in the Arctic and Antarctic are in desperate need of observations and sustained monitoring that only acoustics can provide. Such systems would simultaneously observe the changing heat content and effects on melting ice using tomography while at the same time providing positioning and navigation capability for under-ice floats and vehicles. It is especially important that broadband acoustic sources be used in conjunction with accurate clocks.

At the same time, the multitude of widely distributed PAM receivers in non-polar regions (e.g., CTBTO) can motivate multipurpose systems on global scale, perhaps with a longer time constant to implement. Judiciously

³www.whalealert.org

locating cabled sources and using sources deployed from GO-SHIP vessels (providing sustained repeat hydrographic sections on decadal repeat timescales) can quickly provide wide-scale coherent tomographic coverage and derived heat content estimates, supplementing and complementing other, often incoherently sampled, observing elements. SMART telecommunication cables with integrated sensors will play a role as well (Howe et al., 2019).

Observing the ocean acoustically creates strong synergies with other observing programs, as reflected in the white papers in this Special Issue for OceanObs'19. Closing the sea-level budget (Leuliette, 2015; WCRP Global Sea Level Budget Group, 2018) requires accurate knowledge of ocean bathymetry (Woelfl et al., 2019), ocean sea level (Ponte et al., 2019), barystatic changes (mass of freshwater added or removed; Palmer et al., 2019), and thermostatic changes (e.g., changes in heat content; Meyssignac et al., 2019). Multipurpose acoustic observing systems will contribute to improved monitoring of volume, freshwater, and long-term heat fluxes, as well as monitoring long-term heat content changes at basin-scale, as well as in specific regions of global importance (e.g., Indonesian throughflow; Ravichandran, 2011; Sprintall et al., 2019). Multipurpose acoustic systems can provide ground-truth for ecosystem modeling and forecasting. Acoustic *in situ* rainfall and wind speed estimates can improve our observations of air-sea fluxes (Centurioni et al., 2019), particularly in sparsely sampled regions such as the Southern Ocean (Swart et al., 2019) and polar regions (Smith et al., 2019) as well as improve our ability to monitor wind/current/wave interactions (Villas Bôas et al., 2019). The direct estimates of ocean state variables from acoustic tomography and acoustically located and navigated autonomous platforms operating in undersampled high-latitude regions will improve ocean state estimation (Heimbach et al., 2019). The rich applications of hydroacoustic monitoring from the CTBTO IMS demonstrate that additional observations from fixed acoustic transceiver nodes, coupled with soundscape maps provided by PAM, are important components of Eulerian observational systems, including tsunami warning (Angove et al., 2019).

SUMMARY AND RECOMMENDATIONS

We have outlined the current status of multi-purpose acoustic systems, noted the contributions they are making now and can make in the future, and discussed what gaps they can fill in the current ocean observing system. Based on this, we suggest that the following recommendations be included in the outcomes from the OceanObs19 conference.

Recommendation 1: OceanObs'19 recognizes the utility, both in terms of observing system capability as well as reduced effort and cost, of multipurpose acoustic observing systems, and recommends implementation in GOOS.

Recommendation 2: GOOS must develop a community capability to evaluate the present observing system and proposed additions thereto and apply the same to evaluating the benefits of precision acoustic navigation (of mobile

platforms) and tomography. This could be accomplished by transitioning GODAE Ocean View to operational status as part of GOOS.

Recommendation 3: OceanObs'19 encourages implementation steps related to the ocean sound EOV, e.g., the incorporation of suitable acoustic receivers in general purpose instrument packages with necessary timing and geo-positioning capability and improved data access.

Recommendation 4: OceanObs'19 recognizes the extreme urgency of observing and monitoring the polar oceans, made difficult by ice cover, and recommends that multipurpose acoustic observing systems, along with other complementary systems including cabled ones, should be brought to operational status.

DEDICATION

This article is dedicated to Walter Munk, Oceanographer and Geophysicist, 1917–2019.

AUTHOR CONTRIBUTIONS

BH led the effort and wrote the Introduction, Discovery, Discussion, and Summary. BH and ER wrote the Ocean Technology section. JM-O wrote the Ecosystem section. PW wrote the Climate Variability section. GH and JM-O wrote the Hazards and Maritime Safety section. All authors contributed to overall editing.

FUNDING

(2019) Data Interoperability Between
Elements of the Global Ocean
Observing System.
Front. Mar. Sci. 6:442.
doi: 10.3389/fmars.2019.00442

The data management landscape associated with the Global Ocean Observing System is distributed, complex, and only loosely coordinated. Yet interoperability across this distributed landscape is essential to enable data to be reused, preserved, and integrated and to minimize costs in the process. A building block for a distributed system in which component systems can exchange and understand information is standardization of data formats, distribution protocols, and metadata. By reviewing several data management use cases we attempt to characterize the current state of ocean data interoperability and make suggestions for continued evolution of the interoperability standards underpinning the data system. We reaffirm the technical data standard recommendations from previous OceanObs conferences and suggest incremental improvements to them that can help the GOOS data system address the significant challenges that remain in order to develop a truly multidisciplinary data system.

Keywords: interoperability, data management, data lifecycle, data preservation, standards, metadata

INTRODUCTION

Ocean observing programs of varying geographic or disciplinary scope have been coordinating globally for decades in an effort to develop an efficient, sustainable, and complete Global Ocean Observing System (GOOS) of systems. Many efforts focus on national or regional priorities that are often limited in geographical scope. Others are globally focused but constrained by sampling methodologies such as through the use of profiling floats [e.g., Argo (Riser et al., 2016)] or by sampling geometry such as time series measurement at one location [e.g., OceanSITES (Send et al., 2010)]. These programs are independently governed and funded and can serve different stakeholders, though they often have commonalities. Addressing the needs of the individual stakeholders influences how the observing programs design the information systems that manage and distribute the observations. This individuality of the stakeholders leads to individuality of the information systems, which contributes to a lack of interoperability across systems.

The Framework for Ocean Observation (FOO) (Lindstrom et al., 2012) defines a set of key processes to guide the ocean observing community toward the establishment of an integrated, sustained ocean observing system with fit-for-purpose data/information streams for societal and scientific benefit. It provides a set of overarching principles and conceptual structures useful in guiding the coherent development of ocean observing systems and coordinating their supporting data infrastructures in a manner that mitigates the aforementioned structural issues. The FOO is based on observing system success stories and best practices, a collaboration-focused governance structure, and the concept of Essential Ocean Variables (EOVs). Global progress is measured through maturity/readiness levels which are central organizing principles for the establishment of coherent requirements for observing system elements consistent with systems engineering approaches. The FOO also highlights the critical role of data management and data interoperability standards in addressing the enormous challenge of open access to harmonized, integrated data across a very diverse ocean observing “system of systems,” comprised of multi-scale, multi-platform/sensor observations supporting various applications and science domains. Given the associated highly heterogeneous data landscapes and data management infrastructures, “the desire to ‘measure once and use many times’ requires that standards be developed and adopted by observing components.” Data interoperability across the data lifecycle and information value chain, from raw observational data through modeled synthesis products, is seen as a foundational element of ocean observing systems that are efficient and fit for purpose. Efficient, fit for purpose, observing systems provide useful inputs to science-based, data-driven decision support processes of societal importance, relevant to ecosystem management, food security, maritime safety, energy, climate monitoring, and other emerging areas of the Blue economy. The FOO additionally recognizes the role of international entities such as the WMO-IOC Joint Technical Commission for Oceanography and Marine Meteorology (JCOMM), and the International Oceanographic Data and Information Exchange (IODE) in coordinating such data management efforts for physical, geological, chemical, and biological observing system elements of the GOOS, leveraging also work done by Earth science data standards authorities. Finally, the Framework identifies the importance of education, outreach, and capacity building, including in the area of data interoperability standards and best practices for oceanographic data management.

While the Framework acknowledges the importance of data interoperability and provides a structure for global collaboration toward better interoperability, it does not describe specific steps, tools, or actions to be taken. In this paper we focus on data interoperability across the global ocean observing community. We first describe this global community and define interoperability between community members. We then examine several use cases that demonstrate various levels of interoperability in an effort to distill best practices that can be widely adopted. The use cases also help demonstrate limitations of our current understanding of data interoperability that we suggest can be opportunities for future work or investment.

Finally, we close with listing recommendations for evolving the information management systems supporting the GOOS.

SIGNIFICANCE OF DATA INTEROPERABILITY FOR OCEAN OBSERVING

Defining the GOOS Data System

The GOOS¹ is a global system for sustained, interdisciplinary observations of the ocean comprising the oceanographic component of the Global Earth Observing System of Systems (GEOSS)². It is a coordinated but highly decentralized system and organizational network overseeing the planning and implementation of observations for the world's oceans, aimed ultimately at delivering data, related services, and information products in support of research and applications. By necessity and design, it leverages heavily from regional and national programs and infrastructures but also from community partnerships that are related to specific observing system elements under the umbrella of JCOMM. Data is managed in a federated manner and accessible via regional observing system nodes, JCOMM partnership program data assembly centers (DACs), space agency satellite data centers, integrated DACs and designated IODE/International Council for Science (ICSU) World Data Centers (WDC) (Figure 1). Data offerings are diverse in type, coverage, and extent. They include multi-variate observational data from *in situ* and remote sensing platforms that are sustained, and often available in near real-time, and data from research field campaigns that are more ephemeral in nature. Data from numerical models are also an important data type that differ from observational in some important ways (e.g., model data are less diverse in structure but typically much higher volume). The ability to integrate across such a distributed and complex, multi-agency data management landscape, in support of GOOS, hinges critically on the widespread adoption of data interoperability standards.

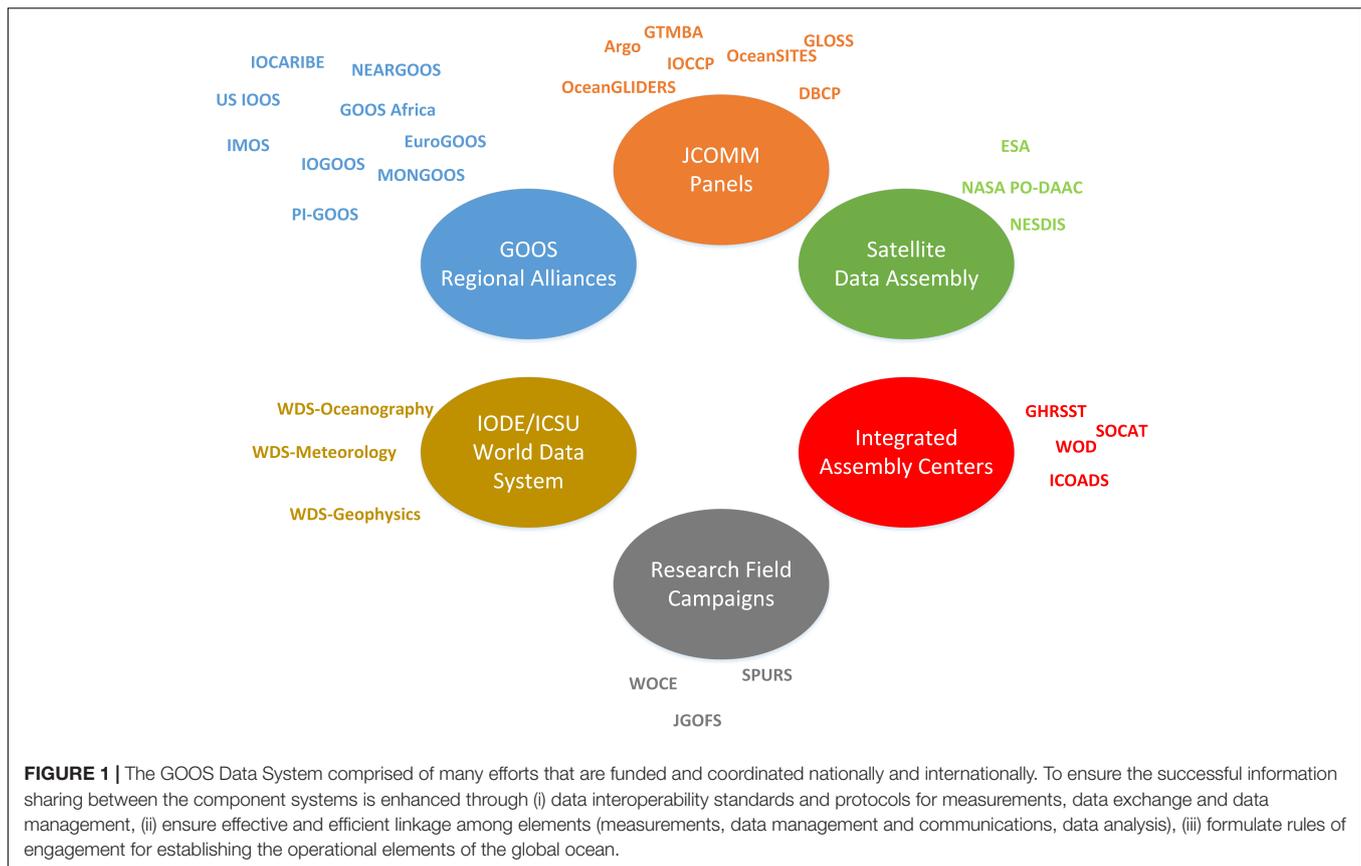

Through national efforts such as the U.S. Integrated Ocean Observing System, or through GOOS Regional Alliances like EuroGOOS, system are being built that integrate data from across numerous observing system elements in an attempt to provide integrated products to regional or local customers. These efforts frequently result in more customer focused relationships and products. However, integrating across different platforms taxes the data interoperability standards which are often not general enough to span use cases across platforms and across disciplines. Maintaining a strong standards foundation while still providing flexible enough tools to tailor products to local customer needs is an ongoing challenge for the global ocean observations community.

Why Is Interoperability Important?

While we are unaware of any single effort to design and construct a monolithic GOOS Data System, in this paper we use this term

¹<http://www.goosocan.org/>

²<https://www.earthobservations.org/geoss.php>

to collectively and generically refer to the independent but often coordinated efforts across all of the organizations in **Figure 1**. It is a distributed data system with responsibilities for different stages of the data management lifecycle spread across myriad organizations. We make a few assumptions about the principles that each of the component efforts share. If these assumptions are true, they serve as design principles for the GOOS Data System. Enhancing data interoperability then becomes a means to achieve these design principles. There are efforts that will not ascribe to these principles and for those efforts, we must exclude them from consideration in the GOOS Data System for pragmatic reasons. However, we believe that the trend toward embracing these principles will increase as policy and technology evolve.

Data Reuse

Data reuse is one of the Guiding Principles for the FOOs (see section “Web Service Based Data Exchange: Data Access Services,” Lindstrom et al., 2012). The measure once/use many times philosophy underpins the entire FOO and is increasingly driving policy at federal levels. For example, the United States Government has committed to an Open Data policy³ predicated on the notion that open accessible data will spur innovation and lead to efficiencies. Examining the global policy landscape for data sharing is beyond the scope of this paper but we note that increased data sharing may be motivated by recognition that

reusing data has potential economic benefits and encourage open data sharing across the GOOS Data System.

Data Preservation

A further, often unappreciated benefit stemming from Earth science data standards adoption is that long-term preservation of archive quality data with associated metadata and provenance information is facilitated. This ensures protection not only of significant public investments in costly data collection but also preservation of observations that are unique in time and space and thus irreplaceable. Understanding and alleviating underlying challenges and constraints to widespread adoption of applicable data standards, whether technical, capacity or resource related, will be central to ensuring sustained contributions to and effective usage of a vibrant and integrated ocean observing system data commons.

Data Integration

Many data management efforts are organized around an observing platform such as research vessels, profiling floats (Argo⁴) or particular satellites (e.g., AVHRR Pathfinder⁵). This organization is sensible because in the early stages of the data lifecycle, there are efficiencies to be gained by managing all data from a single platform in a single place. However, for

³<https://www.data.gov/developers/open-data-executive-order/>

⁴<http://www.argodatamgt.org/>

⁵<https://podaac.jpl.nasa.gov/datasetlist?ids=&values=&search=Pathfinder>

scientific or operational applications, stakeholders are often more interested in obtaining data organized around a sampling method (e.g., all ocean profile data in World Ocean Database⁶) or by EOY (e.g., Sea Surface Temperature data from the Group for High Resolution Sea Surface Temperature, GHRSSST⁷). Creating these integrated data sets is made easier if all of the source data sets are available in interoperable standards compliant formats. It is worth noting that Argo, World Ocean Database (WOD), and GHRSSST have all adopted common conventions for representing data and metadata in file formats that enhance system wide interoperability.

Minimizing Lifecycle Costs

The importance of data interoperability for the development of an operationally sustainable GOOS lies in the significant cost saving and scalability that automated data discovery, access and processing pipelines provide. Data conforming to established Earth science data interoperability standards have the necessary structural, syntactic and semantic characteristics rendering them searchable, more easily integrated within software systems and amongst themselves, and generally more usable. Standards compliance increases the likelihood that custom, unmaintainable and invariably costly to implement one-off solutions for handling of data are averted.

Software development is an essential and expensive part of the data management lifecycle. Widespread adoption of data standards encourages the development of generic rather than single purpose software tools. Generic tools, especially when developed using Open Source Software principles and methods, can attract more developers because they can focus their time as a team working on a common tool rather than individually on their particular application. This often results in higher quality, better documented, and better tested software which has implications for the efficiency of the global community. Open Source software policies should accompany Open Data Sharing Policies in the GOOS governance framework. This recommendation should not be adopted without consideration of long term implications. For example, the legal framework for software licensing is complex and potentially conflicts with some institutional policies. Further, open source software may not have dedicated technical support. In sum, the authors believe that Open Source Software is a net positive for the community but acknowledge that some caution is warranted.

FAIR Principles

These considerations are effectively embodied by the FAIR guiding principles for the improved data management, stewardship and accessibility of science that have recently been advanced (Wilkinson et al., 2016) and that are gaining increased traction. FAIR emphasizes: (1) *Findable* data, with machine-readable metadata essential for automated discovery and utilization of data and metadata by software services. (2) *Access* to data and persistent metadata records using open/free, standards-based protocols that support authentication. (3)

Interoperable such that data are machine interpretable and can be automatically combined with other data, leveraging standard vocabularies and ontologies for knowledge representation accessible via semantic Web technologies. (4) *Reusable* data: well-characterized, rich community metadata enabling traceable, reproducible, and easily integrated data in support of research and applications into the future. FAIR provides a high-level conceptual framework useful to the design of contemporary information systems in support of ocean observation, the more detailed technical underpinnings of which are based on widely applied Earth science data interoperability standards that we now describe. While the focus of this paper is on data interoperability, it is difficult to decouple Interoperability from the other elements of FAIRness when describing the GOOS Data System current and future states (Tanhua et al., 2019).

DEFINING INTEROPERABILITY FOR OCEAN DATA STAKEHOLDERS

Interoperability in a general sense can be defined as the “*degree to which two or more systems, products or components can exchange information and use the information that has been exchanged*” (ISO/IEC/IEEE, 2017). It is the ability by which coupled software systems can communicate and exchange data via common formats and protocols and also meaningfully interpret and reproducibly act on exchanged data. This definition prompts an important recognition: interoperability is a characteristic of a relationship between two or more systems. It is not a characteristic of a single data file or data set. The two (or more) systems in this relationships are both stakeholders in the exchange of information. Generically, these stakeholders can be classified as Data Producers/Providers or Data Consumers.

Data Producers/Providers are responsible for generating data, typically through observation or simulation and make it available to a consumer. The scope of these activities can be local to an individual Principal Investigator conducting a lone experiment, or globally coordinated efforts like the World Ocean Circulation Experiment of the 1990s or the Argo program of today. These stakeholders have common objectives, to plan and design their experimental or sampling scheme so that the data addresses the scientific or operational objective. As noted above, we also assume that these Producers/Providers subscribe to the principles listed above. They wish to see their data maximally reused, preserved for the future, combined with other data into integrated products, and they want to minimize costs in the process. If Data Producers/Providers do not subscribe to these common principles, then the significant overhead of adopting and using global data interoperability standards is a resource drain that is often un- or under-funded. It is a requirement for national and international governance groups and funding agencies to encourage adherence to these common goals and to resource the work adequately if the GOOS Data System is to become more interoperable. However, it is also critical for the scientific Information Management community to help bridge the gap between data producers and the relevant metadata and data standards by providing tools that can improve conformance

⁶https://www.nodc.noaa.gov/OC5/WOD/pr_wod.html

⁷<https://www.ghrsst.org/>

of their data to well-established data interoperability standards. This will facilitate integration of data in a range of software applications and Web services including data distribution, processing, modeling and visualization capabilities, thus enabling more widespread usage of data.

Data Consumers require data to solve problems or make decisions. They could be interested in obtaining data for scientific study, for assimilation into a numerical model, or to create a web based visualization. A scientist likely requires all available data and extensive metadata to ensure that they understand as much as possible about how the data was generated. They are interested in ingesting the data into their analysis tool of choice and may be willing to wait to download enormous file collections. A web developer on the other hand may only require a small subset of a data set but they need it on demand with minimal latency. For the scientist, downloading a large collection of files from an FTP server may be an acceptable access method while the web developer requires a web based Application Programming Interface (API) with flexible query methods and extremely fast response. By observing and documenting different types of Provider – Consumer relationships that are successful, we can generalize strategies that enhance the likelihood that future relationships are successful – i.e., interoperable. The following sections describe principles or design patterns that have underscored successful interoperable Provider – Consumer relationships and offer background for the Use Cases that follow.

Common Elements of Data Interoperability

Typical Provider-Consumer exchanges occur when a file subset or a file are transferred from one system to another. The ability of the consumer system to understand and use the information received has both syntactic and semantic elements. Syntactic elements describe the Consumers ability to decode the electronic data file and accurately access the objects within the file. Semantic elements describe the Consumer's ability to understand the data objects. Simple semantics include understanding parameter names and units while more complex semantics allow for translating between colloquial names for species types and standardized registries of species names like the World Register of Marine Species (WoRMS). Interoperability standards for Earth science data are comprised of three core elements (**Figure 2**):

- File standards, based on self-describing scientific data file formats;
- Common data and metadata models;
- Controlled vocabularies and ontologies that define terms, concepts and their relationships for a given science domain.

Much of the emphasis on the data file stems historically from its ubiquitous usage as the storage and exchange medium for science instrument data, including from ocean observing systems. Widely used scientific data file formats such as HDF⁸ and netCDF⁹ provide compact, binary formats optimized for efficient storage and access of large, complex datasets. They

include features such as internal compression, and support hierarchical structuring of data within files. Significantly, from a data interoperability and data preservation perspective, they are, or can be made to be, self-describing. A self-describing file includes metadata that describes both the data and data structures comprising a file. Further, self-describing files minimize or eliminate the need for external sources of information (e.g., quality control code tables) allowing the file stand alone and be understood by a consumer. Common data models (CDMs) are important enablers of interoperability because they allow generic software to predict the structure of these self-describing files and access the encoded data as the author intended. Interoperability has been further facilitated by the parallel community development of metadata models supporting a broad range of geospatial Earth science data that have been built around or are compatible with the CDM. These include the Climate Forecast (CF) conventions¹⁰, the Attribute Conventions for Data Discovery (ACDD)¹¹, and the ISO 19115¹² standard metadata schema for geographic information and services. These conventions provide a standard set of attributes and technical framework for the encoding of metadata and data in self-describing data files. Such common data and metadata models have in turn promoted the development of an ecosystem of broadly used, open source software libraries, APIs, web service standards and Web server technologies. Hankin et al. (2010) describe the important role that the Climate and Forecast Conventions and the netCDF file format fill in our global data management and dissemination framework. In the decade since OceanObs '09, CF/netCDF has been further cemented as the de facto standard for file based storage and exchange of *in situ*, remotely sensed, and model generated data. Further progress since OceanObs '09 is nicely summarized in Tanhua et al. (2019).

The third ingredient for data to be interoperable relates to the semantic interpretability of the metadata that qualify or describe the geophysical data values themselves via the use of controlled vocabularies. Of particular importance is the application of a standard term for the observable parameter and its associated units, but also the use of standard vocabularies for metadata attributes relating to the sampling platform, sensor, and other categorical keyword descriptors. Application of standard terms is vital from a data interoperability perspective because it ensures valid interpretation of values by human users and enables correct aggregation and computation on integrated sets of data to be performed. Examples of actively maintained and widely used vocabularies include the CF standard names¹³ and the UDUnits library¹⁴ and the NASA Global Change Master Directory (GCMD) keywords. There are also specific science domain ontologies that are being developed by particular expert communities that once integrated provide a refined set of terms applicable to broader types of ocean science data. Vocabulary

¹⁰The CF Conventions are a set of guidelines for creating netCDF files with good interoperability characteristics (<http://cfconventions.org/>).

servers, such as those maintained by the British Oceanographic Data Center (BODC)¹⁵ and the Marine Metadata Interoperability project (MMI)¹⁶, aggregate and systematically organize such curated lists of standardized terms covering a broad spectrum of oceanographic disciplines that are machine query able and can help resolve metadata definitions or reconcile ambiguity in terms being applied.

In describing the key elements underlying Earth science data interoperability standards appropriate to the ocean observing domain, it is important to understand that there a couple of levels at which these are applicable and between which there are some differences: the dataset and granule levels. A dataset or collection is an aggregation comprised of data files or granules of a common type. While the definition of granule can be somewhat arbitrary, it is simply a convenient building block for the complete data set. For example, the Aquarius L3 Sea Surface Salinity V5.0 dataset¹⁷ is a collection of the entire series of data files (“granules”) over the course of the Aquarius/SAC-D satellite mission spanning 2011-Aug-25 to 2015-Jun-07. The individual granules in this dataset represent 7-day averaged snapshots covering the entire globe. Similarly for *in situ* data, there is an analogous collection of over 2000 profiles (granules) from an underwater glider that are aggregated together into a complete dataset that represents a glider deployment between November 11 and 15, 2015¹⁸. Metadata characterizing the complete dataset is different in composition and detail to that of the constituent data files comprising the collection, although both will ideally conform to the same ISO19115 geospatial metadata standard framework that enables interoperability. The use of files as a basic element of designing an information system is based on their use in common data management systems today, and because their ubiquity makes it easier to describe some of the conceptual

elements of interoperability. However, this is not meant to preclude the use of other Information Technology staples such as Relational Database Management Systems, sometimes referred to as geodatabases. Geodatabases can be equally well-suited to interoperable data systems.

Web Service Based Data Exchange: Data Access Services

Data exchange between the nodes of the distributed system shown in **Figure 1** requires APIs that are designed for Web protocols. Downloading collections of files published as hyperlinks on web pages or on FTP sites cannot scale to address the types of exchanges needed for distributed global science and operational needs. Machine to machine APIs, or Web Services, enable querying, subsetting, and other advantages over bulk download of files.

Mature, well-supported software to enable web based APIs for data and metadata access exists for use by the entire GOOS Data System. Hankin et al. (2010) describe the utility of the OPeNDAP protocol for serving data. OPeNDAP¹⁹ has become ubiquitous in the earth science community and several software packages implement this protocol. For example, THREDDS²⁰, Hyrax¹⁹, and ERDDAP²¹ are three data servers that ingest data files in various formats and publish data to the web using the OPeNDAP protocol.

The THREDDS Data Server, developed by Unidata, is an implementation of the OPeNDAP protocol which enables aggregations of WMO GriB files and netCDF files to be aggregated and served as a single data resource. The APIs implemented by THREDDS allow subsetting in space and time. THREDDS is particularly well-suited to gridded data collections and is currently being enhanced to serve unstructured and

²¹<https://upwell.pfeg.noaa.gov/erddap/information.html>

staggered grids common in modern ocean models (see section “Operational and Research Modeling”).

Another example is the ERDDAP data platform that was developed by NOAA’s Southwest Fisheries Environmental Research Division²². As an open source data platform, one of the functions ERDDAP performs is to serve data to users through web-based services. Similar to the THREDDS Data Server, ERDDAP supports the OPeNDAP protocol, allowing for remote accessing of data. To the data consumer, ERDDAP provides a uniform, RESTful service for accessing data that allows for machine-to-machine exchange. Many interesting tools have been built to take advantage of the services that ERDDAP provides²³ and ERDDAP is a key element of the TPOS 2020 strategy (see section “TPOS 2020”).

Both THREDDS and ERDDAP are developed as open source software projects that encourage outside developers to contribute feature enhancements and bug fixes.

Web Service Based Metadata Exchange: Data Discovery Services

While the focus of this article is on interoperability, the need to support data discovery is also an important driver for developing and adhering to interoperability standards. Well-structured and well-populated granule and dataset metadata makes discovery possible. Tools exist that extract information from data files to create discovery metadata records that can be indexed into queryable metadata catalogs.

Support for common metadata standards at both file and dataset levels, allow geospatial metadata services to make data discoverable through efficiently queryable metadata repositories. Furthermore, support for common metadata standards across repositories facilitates integration and unified search horizontally, agency-wide or even across inter-agency repositories. NASA’s Common Metadata Repository (CMR)²⁴ and NOAA’s OneStop²⁵ system are examples of distributed metadata systems that integrate information on holdings across distributed data archives conforming to the aforementioned enterprise architecture and interoperability standards that enables unified search and access to science data enterprise-wide. Taking this approach to an even broader level are schema.org-based approaches like the new Google Dataset Search²⁶ utility. While schema.org limits the amount of metadata to a relatively narrow set of searchable fields, that simplification makes it easier for many distributed groups to ensure their holdings are available to the big commercial search engines and other interoperable data systems. It also makes it possible for data access services that support schema.org markup, to be discoverable from Google searches.

Support for common metadata standards in turn enables integration of distinct agency metadata repository systems for discovery and access to data by users centrally with much greater

efficiency across agency, national, or other jurisdictions. An example of cross-jurisdictional discovery is the Committee on Earth Observation Systems (CEOS) Common Data Assets (CDA) infrastructure, which facilitates federated search of interagency data holdings, including, NASA, NOAA, ESA, and other space agencies. This general architecture and approach, fundamentally enabled by data interoperability across systems that stems from the harmonized use of International Organization for Standardization (ISO) geospatial metadata standards, serves as a scalable implementation model for GEOSS, of which GOOS is a part. Improved integration of distributed ocean observing systems should leverage such existing development models, data system architectures and their associated data interoperability standard frameworks. Currently, these appear to implemented more at the regional and national level by responsible entities such as IOOS²⁷ for the US, the Integrated Marine Observing System (IMOS)²⁸ for Australia and the European Marine Observation and Data Network (EMODnet)²⁹ for Europe, or for particular observing system elements, such as the JCOMMOPS³⁰ asset monitoring system.

USE CASES

Long Term Preservation at US National Centers for Environmental Information

The FOO places high importance on data preservation, so those data can be reused in the future. Long term preservation is the mandate of archive centers such as the US National Centers for Environmental Information (NCEI). In this use case, NCEI is the Data Consumer, receives data from the Data Producers and assuming the responsibility for data stewardship. This transfer of stewardship responsibility places a heavy burden on the archive centers, because they must ensure future users, who will undoubtedly use different tools than today’s users, can find, access, and understand the data. The archives cannot rely on personal connections to Data Producers, who won’t be around decades into the future to explain their methods. Instead, the archives must ensure that the necessary information is captured today and encoded, preferably in machine readable data systems, so it is usable for solving tomorrow’s problems.

Long term preservation requires managing data through information technology evolutions. Over the next 50 years the storage system will evolve from spinning disks to some yet to be envisioned technology. Similarly the software libraries enabling the use of scientific data formats will evolve. For example, the netCDF libraries in use today are primarily version 3.0 and 4.0. As hardware architectures evolve it is reasonable to assume that netCDF 3.0 will no longer be supported at some point and the archive center will need to undertake a mass migration of millions of data sets encoded in netCDF 3.0 to netCDF 5, 6, or 7, or some other representation suitable for cloud-based

²²<https://upwell.pfeg.noaa.gov/erddap/information.html>

³⁰<https://www.jcommops.org/>

processing, for example. The scale of a task like that underscores the need for the archive data holdings to be as interoperable as possible to allow for more automated data migration. For highly heterogeneous holdings, data migrations involving substantial individual analysis and human interventions will be prohibitively expensive.

To address these concerns, and to facilitate the broader adoption of these Earth science data interoperability standards components within the oceans community, NOAA/NCEI developed the netCDF templates³¹. These templates, along with documentation and examples, serve as a practical roadmap for the implementation of existing CF and ACDD standards to the range of spatial feature types characteristic of ocean and other environmental data: point, profile, trajectory, time series, and combinations of these discrete geometry types. These templates are being leveraged by other agency data centers such as NASA/PODAAC to ensure that oceanographic field campaign datasets submitted are archive quality and interoperable, such that they can be readily assimilated and disseminated via standards-aware tools/services and consumed by remote software applications. Regional data management efforts such as IOOS and IMOS have also adopted these templates as the de facto standard for data formats, supporting both current dissemination and long term preservation strategies. Global adoption of the NCEI templates would greatly enhance GOOS Data System interoperability.

TPOS 2020

The tropical Pacific Ocean has hosted some of most innovative ocean data and information management initiatives over the last 30 years (McPhaden et al., 1998). Smith and Hankin (2014) examined user requirements for the 2014 Tropical Pacific Observing System (TPOS) 2020 review and Smith (2018) undertook a similar task for the review of the Tropical Atlantic Observing System. One common finding was that neither observing system had significant gaps or issues at a technical level that were peculiar to that region; globally implemented systems such as those overseen by WMO and IOC data and information systems and including those under JCOMM oversight (Pinaridi et al., 2019), were the best route for improvement, innovation and enhancements. Routine ocean and climate productions systems (data assembly, analyses, forecasts) and associated downstream users drove real-time data and information system requirements, but in both cases, research remained an important pathway for impact.

There are no systems or components that are TPOS specific. Rather TPOS information is managed and delivered by the information systems that support the platforms comprising the tropical Pacific observing system: Argo, tropical moorings, the Voluntary Observing Ship Program (VOS), the Ship-of-Opportunity Program (SOOP) (Goni et al., 2010), and surface drifters (Elipot et al., 2016). Independently, these data are collected, subjected to automated Quality Control and submitted to the Global Telecommunication System. For moorings, the infrastructure developed for TAO/TRITON (and for PIRATA

in the Atlantic) continue to be supported, for delayed-mode QC and for reprocessing, among other things. Standards have been developed so that tropical observations are intercomparable across the basins, but interoperability across platforms is more problematic. Knowledge of the climate of these basins is needed for this process. The arrays are at different levels of maturity, and involve multi-national efforts, so basin-centric coordination is needed. As well, the various components that comprise the TPOS are at different levels of maturity in terms of meeting the FAIR guidelines. Data systems, such as the aforementioned Argo and tropical mooring systems, are rather mature and therefore have higher levels of conformity to those guidelines. Interoperability among the various networks, however, is an issue that needs improvement and that the JCOMM community is working to improve (Pinaridi et al., 2019). The most successful data systems, such as Argo, tend to be those systems that are also widely used by the community for which they were built. The Argo community uses the Argo data system, and therefore has provided feedback on the completeness of the data and metadata, and on the utility of the data system. This feedback, and the enhancements it provides, benefits the global community of users as well, and therefore improves overall interoperability – both of the data and the data system.

Remote sensing data are generally global in coverage and are provided without any distinction between basins. For more experimental data streams, e.g., research vessel measurements of pCO₂, BioGeoChemical-Argo, there is a transition from PI-based to regional and then global data systems.

Opportunities for improved efficiency, robustness and effectiveness were identified in both cases. “We want it now” was a common theme among users which impacts consideration of timeliness, efficiency, and simplicity. Systems that deliver services through multiple channels, and with different offerings in terms of integration and quality, were seen as a priority (for example, ERDDAP Pinaridi et al. (2019), Tanhua et al. (2019), and Harscoat and Pouliquen for AtlantOS, personal communication). A significant finding was that complexity was a barrier to stakeholder engagement, either as a provider or as a user.

That complexity arose as a barrier to engagement should not be surprising. The tropical Pacific Ocean is home to a variety of observing elements, particularly when compared to the design of the original mooring array. As other systems, such as unmanned autonomous surface vehicles, become more common, the complexity of integrating data streams from these heterogeneous platforms will increase. Though TPOS 2020 recommends the use of CF compliant netCDF formatted data files, as previously noted, in some cases this can provide a barrier to stakeholder engagement. Typically, the barrier is in the creation of data files that conform to a standard, such as CF, by a data producer that doesn't typically use those types of files, either in their own work or within their community. However, there is clearly a big advantage to having metadata attached to the data file, as it is in netCDF. In order to successfully engage all data providers, it is advantageous to allow providers to work in the data formats they are comfortable with, while still providing the data to the global community via data standards, conventions and web services. This is possible with brokering tools such as

³¹<https://www.nodc.noaa.gov/data/formats/netcdf/v2.0/>

ERDDAP (see section “Recommendation for Addressing Some Gaps”). It is important to note, however, that such tools are less able to broker metadata between communities, such as physical oceanography and ecology communities. This is a role in which linked semantic data concepts, as discussed later in this paper, are very relevant.

National and institutional data policy also remains an issue despite successive OceanObs conferences highlighting the value of a data sharing paradigm being adopted across all systems. In the tropical Pacific it is mainly an institutional/research issue, while for developing countries in both basins it has both technical capability and historical roots. Because of this, it will be important for TPOS 2020 to embrace a distributed data landscape.

Smith (2018) noted that the FAIR Principles do provide a basis for defining a set of essential characteristics for data and information system. Such principles, and the best practice efforts, might provide a more effective pathway for improved harmonization and performance; maturity levels are useful for individual technical elements but are very uneven across the data system. Finally, both papers highlight the need for improved knowledge and use of systems architecture. Improvements over the next decade will be difficult without this.

Fisheries Data From Trawl Surveys

Surveys for fish, plankton and zooplankton have a long history, and some time series are more than 100 years old. Examples include the Norwegian beach seine survey from 1921, the Sir Alister Hardy Foundation for Ocean Science (SAHFOS) continuous plankton recorder survey from 1931, the Norwegian spring spawning herring series and the northeast arctic cod series, both from 1900. The series serve as input to fisheries stock assessments (Gulland, 1988; Beamish et al., 2009), and are important for studies addressing fish and nekton responses to climate change, ecological regime shifts etc. (Cury et al., 2008). The series are typically tracking regional populations of a species (fish stocks), and is typically regional in extent.

Several data centers are hosting the data from these surveys, including international bodies like the International Council for Exploration of the Sea and national institutions like NOAA Fisheries, CSIRO Australia, and Institute of Marine Research, Norway. The data sets typically consist both of sample data at a station or transect level, and integrated time series that tracks the abundance of a fish stock used as input to assessment or other models. Discoverability metadata is implemented to a varying degree, for example at the International Council for the Exploration of the Sea (ICES) data center.

Data Access solutions for fisheries data can vary significantly. The sample data from the joint Norwegian-Russian winter survey underpinning the advice for the North East Arctic Cod are only partially available due to a strict Russian data policy. The SAHFOS data is freely available, but only upon request. The data from most European trawl surveys are typically available through the ICES data center, and the data is accessible for automated downloads via web services. There are also standard vocabularies available, and fields like platform or vessel, species and gear types

are in some cases available through web services, e.g., from the ICES data center.

Since most of these surveys are regional, the emphasis has been to ensure that data time series are consistent rather than trying to harmonize between the various interoperability standards. There is, however, a push from data managers to employ metadata standards to facilitate better discoverability and interoperability. Physical oceanography has been leading this field and advanced much further than the biological component in this respect. However, when moving forward with the biological data, employing existing standards that were developed for data from other disciplines may pose some challenges and impart additional costs. This can be in terms of costs in developing mechanisms to host the information, adding additional labor costs during data collection, or costs for make historical data compliant to the new standard. This may be less of a problem if the sensors can supply this information directly, but any manual labor is costly.

The other challenge is that it may create a false conception of interoperability in cases where a given metadata standard is used to accommodate data types that it was not designed for. An example may be trawl survey data, where the information from each trawl station is available (the primary sampling unit), but where no standard exists for the other key parameters, like survey design, survey area, stratification, data filtering parameters etc. Without this information and in the absence of suitable accompanying documentation, the data cannot be correctly used even if the metadata on the individual trawl station, from a data center point of view, conforms to the FAIR principles.

What would be the best way forward to obtain more complete interoperability for such complex datasets? Trawl surveys have one great strength: the data is tightly linked to management decision. This allows us to map out, machine to machine, if necessary, the pipeline from raw data to the data product and ensure that the information crucial to derive the desired data product, being indices of abundance for fisheries assessments or biodiversity indices for ecosystem state studies, are in place. At IMR the process of making open source software for the processing, e.g., the StoX program (Johnsen et al., 2019), relied on this approach, and it offered an approach to prioritize what was critically important for the process. It does not necessarily mean that other metadata fields are not important, but it offered a method to prioritize what was needed to obtain interoperability.

The next step would be to review the process and define a best practice guide for coding trawl survey data that is based on the actual processing pipeline. Rather than adopting a standard that was fit for another field and data type, we argue that this process would be more efficient when moving trawl surveys toward true interoperability. It may turn out that there are large overlaps with existing standards, but that should not be the prior assumption.

Cross-Disciplinary Research Cruises

The Ministry of Science, Technology and Productive Innovation (MINCyT Argentina) established a national initiative to promote improved scientific understanding of the Argentine Sea as a scientific basis for defining a national policy of biodiversity conservation. The initiative, known as Pampa Azul, was officially launched in 2014 to link interdisciplinary oceanographic cruise

datasets and develop repositories capable of disseminating Marine data (SNDM³²) and biodiversity data (SNDB³³) from National Data Systems. These systems were created to integrate historical, current, and future information consistent with national policy and international programs. For oceanographic data, SNDM uses the Ocean Data Portal³⁴ with BODC vocabulary servers and for biodiversity data SNDB uses the Darwin Core standard.

In this policy and technical framework of stakeholders, the principal investigators began by planning cross-disciplinary oceanographic cruises. The implementation of interoperability concepts from the beginning had different levels of maturity in each discipline. In the case of physical oceanography, the maturity is high because principal investigators are familiarized with interoperability concepts and have history of participation in global projects (e.g., SAMOC, ATLANTOS, IPCC). Chemical oceanography adopted the BODC vocabulary (I1 and I2) for laboratory analysis and the IODE developed training courses to highlight best practices, but there is no data currently being uploaded to the systems (low maturity). Fisheries biology data has some mature elements, but is not currently widely accessible and is administered by the National Fisheries Agency (acronym INIDEP). They apply acoustic methods, perform validations of abundance and biomass data, and have developed protocols defining processes from the acquisition to the analysis of importance commercial species.

In this attempt to integrate all data types into a single system, it is important that new cross disciplinary oceanographic cruises, recognize the interoperability challenge and plan in advance, where possible, to comply with FAIR principles.

The steering committee of the Pampa Azul adopted the IMBER recommendations which elaborated protocols for cross-disciplinary cruises and explained, in detail, the processes for each stage of a cruise [see IMBER Cookbook (Pollard et al., 2011)]. The IMBER recommendations were the starting point for the design of the data acquisition system which was shared between the members of the cruise. The acquisition system managed the various types of data collected: (1) continuous shipboard data; (2) observation data collected by principal investigators; (3) the analysis of samples in the laboratory; and (4) the derived products. Ideally metadata describing transect design, data collection activities, the instruments to be used and the different surveys at each station should be integrated in a single platform. However, this can be a challenge because often the surveys are conducted from different vessels and equipment across vessels can vary. Therefore, the presence of the data manager, starting in the early stages of planning project, is helpful to coordinate and simplify the collection of data and metadata.

One of the first post-cruise responsibilities is to submit the report to the co-participants. It is at this stage where a non-integrated system reveals its limitations. Due the heterogeneity of the observational data, as well as the laboratory analyzed

data, unless the metadata has clearly documented the processes, modeling groups that use the data may struggle in understanding it. Often, this disruption of the data life cycle can be traced back to the origin of the data. If, at that time, the data was not documented properly using standards, there is little hope for improvement as the data moves toward access and archival.

At the system level, the SNDM and SNDB work as two separate worlds and due to these drawbacks we propose improving the interoperability with the use of Linked Data (LD) (Janowicz et al., 2014).

Linked Data as a paradigm describes how to break up data silos³⁵ and support the publication, retrieval, reuse, and interlinkage of data on the Web. Together with other Semantic Web (SW) technologies, Linked Data shows promise to address many challenges that have affected semantic interoperability between repositories and services within and across domains that are highly heterogeneous in nature (Berners-Lee et al., 2001).

We develop an oceanographic linked dataset following the life cycle proposed by Villazón-Terrazas et al. (2011) with information provided by national cruises. For this we use the controlled vocabularies NERC³⁶, ISO19115 standard to represent metadata records in conjunction with the geospatial standard for the SW GeoSPARQL³⁷ and the reuse of the ontology design pattern (ODP) for oceanographic cruises (Krisnadhi et al., 2014). Publishing the vocabularies and metadata in standard RDF XML and exposing SPARQL endpoints renders them five-star Linked Data repositories.

In addition to enabling FAIR principles for these datasets, the benefits of this approach include: greater interoperability between the metadata created by cross-disciplinary projects; improved data discovery and newly developed tools can be used to explore the data. Here we have shown that the linked data provide a framework for better discovery and access to data, and it is possible to provide the highest standard of linked oceanographic data, and some of the benefits of the approach. Particularly when the results of the research have multiple stakeholders or are used by non-experts for manage and conservation purposes.

The interaction of biological, physical, geological, and chemical data in a single platform leads to the loss of information in the generalization of some parameters. From the technical point of view, each discipline has international formats and, as in the case of biological ones, they have extensions that avoid the loss of complementary information. With the use of linked data it is possible to keep the distributed system and solve the problem of the combination of different disciplines and sources of information.

There is no doubt, from a technical perspective, that solutions exist. However, often the problem lies in the fact that policies are required for actual implementation of those solutions. For example the permanent position of data manager in government agencies facilitate curation of data. For collecting new data, it is

³²<http://www.datosdelmar.mincyt.gov.ar/>

³³<https://datos.sndb.mincyt.gov.ar/ala-hub/search>

³⁴<http://www.oceandataportal.org/>

³⁵An information silo, or a group of such silos, is an insular management system in which one information system or subsystem is incapable of reciprocal operation with others that are, or should be, related.

³⁶https://www.bodc.ac.uk/resources/vocabularies/vocabulary_search/P01/

³⁷<http://www.opengeospatial.org/standards/geosparql>

necessary to promote traceability throughout the whole data life cycle and ensure the availability of essential and observational metadata collected during cruise surveys.

As a final recommendation, international coordination entities should encourage national agencies to implement FAIR and ISO standards in their data systems as a requirement for project funding.

Operational and Research Modeling

Operational and research numerical modeling efforts form a critical source of information to complement ocean observations. Numerical models are consumers of observational data and they are providers of data sets generated through simulation. They require observational data for model validation and verification and they increasingly ingest observational through data assimilation methods during the model integration. As such, they provide a use case for testing the efficacy of data interoperability standards for both ingesting observations and publishing model results.

Operational modeling centers typically access observational data through private networks governed by the World Meteorological Organization (WMO) standards, like the Global Telecommunications System (GTS) (Blanc et al., 2010; Hankin et al., 2010). While these networks are built upon different standards than are described here they serve their intended purpose for a very specific, and important, group of stakeholders. The broader research community does not have easy access to the GTS and therefore requires an alternative access pathway. Wilkin et al. (2017) describe a framework that would advance coastal modeling in the US and advocate for an open access portal that serves quality controlled near real time observations for ingestion into ocean models. Ideally these portals also include deep archives of long time series observations in addition to near real time data. These comprehensive access portals are a challenge to design because they involve integrating data from many individual data sources with their own data stewardship lifecycles. Nevertheless, providing a reliable source of quality observations to both operational and research modelers will accelerate the transition of modeling advances from the research community to the operational community. Ensuring both communities are served should be a requirement for the GOOS Data System. The JCOMM Open Access to GTS project is taking steps to address this inefficiency by simplifying the process of getting data onto and off of the GTS for the research community (Pinardi et al., 2019). NOAA's Observing System Monitoring Center (OSMC)³⁸ provides access to near real-time ocean observations through the ERDDAP data platform. The interoperable web services that ERDDAP provides allows consumers of varied technical levels to access and use the real time data stream from the GTS through the software clients with which they are most familiar. Capabilities like these become ever important as the WMO community continues to require complicated, binary, table-based data formats for distribution on the GTS.

³⁸<http://www.osmc.noaa.gov>

Signell and Snowden (2014), describe a framework for model data dissemination built on CF/netCDF/THREDDS that provides standards compliant data through a THREDDS Data Server. The THREDDS data service provides access to data through, among others, the OPeNDAP protocol which has been a popular tool for providing access to model data on a regular horizontal grid (Hankin et al., 2010). Recent developments in standardizing the encoding of unstructured grids (UGRID)³⁹ and staggered grids (SGRID)⁴⁰ have led to proposed improvements in the CF conventions. These improvements are at the Concept phase of maturity but are prompting debate within the standards governance community and development of software libraries to further test the concepts. Further development of software tools, along with adoption of these standards by the community modeling developers, is necessary to advance UGRID and SGRID to the Mature phase.

Standards for model data, and their inclusion in web service tools is critical due to the high volumes of data models provide. Increasingly it is infeasible to download and entire simulation for scientific or operational application. Therefore it is essential to support development of robust flexible server side subsetting tools if data consumers are to fully exploit the high volumes of information created by the modeling community. A promising area of development is in server side processing, especially when combined with cloud computing architectures (Vance et al., 2019).

LIMITATIONS OF CURRENT SYSTEMS

Challenges to Data Interoperability Adoption

There are several constraints, conceptual and practical, to the broader adoption of the kinds of established data interoperability standards described to projects involved in ocean observation, which in turn impacts the usability and accessibility of the data, and the advancement of GOOS more generally.

Importance of Standards Not Understood

First, the importance of data standards often are not fully understood, and the broader value of publicly sponsored data collection efforts beyond the specific science purpose for which they may have been collected and as part of an important data commons may not be adequately appreciated. This plus the implementation of data management practices that ensure the preservation and usability of data assets long-term must motivate and be promoted amongst stakeholders at all levels and further reinforced both by engineering requirements and governing program policies.

Data Standards Are Hard to Understand and Use

A second significant constraint is the lack of understanding of the applicable technical data interoperability standards that we have previously described (e.g., TPOS 2020) and which are

³⁹<http://ugrid-conventions.github.io/ugrid-conventions/>

⁴⁰<http://sgrid.github.io/sgrid/>

integral to ocean observing data management best practices. For non-experts, just understanding Earth science/geospatial data standards such as CF, ACDD, Darwin Core, ISO19115, and then how to practically apply them in the context of one's own particular datasets is a significant effort. Therefore, implementation of these standards is non-trivial. Our experience in working with oceanographic field campaigns and other *in situ* data producers is that even with resources such as the NCEI netCDF templates, implementing the necessary custom software routines to correctly undertake the necessary conversions and validate outputs for individual datasets is often involved and an iterative process. Even with the availability of compliance checker utilities online⁴¹, the process often requires multiple consultations with experts at data archives to resolve issues. The effort and resources necessary to do this is typically underestimated, and often included in project data management plans as an afterthought. Increasing the focus on data management and stewardship to ensure adequate technical skills and funding, at the proposal stage is a strong recommendation of this article.

Recommendation for Addressing Some Gaps

Addressing these issues will require a multifaceted approach, including further outreach, education, resources and practical tools, promoting improved data interoperability best practices. As has been emphasized, tackling interoperability issues as early on in the data lifecycle and as close as possible to the time of production is important. An area that can be improved upon and can have significant impact is greater engagement and partnership with *in situ* instrument and platform manufacturers to facilitate production of standards compliant data file outputs natively at source as an option in their processing software. Manufacturers are responsive to market demands, and so should be receptive to user, project and program sponsor requests in this space given the necessary awareness. There are examples where this has been achieved and produced the desired outcomes. Invariably, however, it is a process to secure the necessary buy-in to affect change if the business case and incentive for doing so is unclear.

Tools facilitate file creation and translation

While well-structured, complete, self-describing data files that comply with accepted metadata content models are a building block of a more interoperable data system, the complexity of these files is a barrier to adoption for many data providers. Tools are needed to enable conversion from commonly used formats like Comma Separated Value into netCDF and to augment the converted files with rich metadata complying with modern data content standards. ROSETTA⁴² and ERDDAP are two examples of software that facilitate file creation.

ROSETTA is a Web-based data format transformation service developed by Unidata and available Open Source⁴³. It provides an easy, wizard-based interface⁴⁴ and service for data providers to interactively transform their ASCII output instrument data into

Climate and Forecast (CF) compliant netCDF files. ROSETTA also provides a RESTful web service interface (API) for bulk data conversion⁴⁵. In addition to CF, ROSETTA supports also ACDD, the NCEI templates, a metadata standard profile developed for the bilogging community, and is readily extensible to support metadata profiles for other science domains. ROSETTA provides full support for all spatial feature types associated with the range of discrete sampling geometries characteristic of *in situ* data consistent with the CF standard and NCEI templates. ROSETTA is built upon the netCDF-Java library, which is an implementation of the CDM, and which underlies widely used data access technologies such as THREDDS. It also employs commonly used web-based technologies such as Spring and JavaScript for the Web-front end.

ERDDAP takes a slightly different approach to creating standards compliant netCDF files. In addition to functioning as a data access service to publish data on the web, ERDDAP acts as a data broker that can convert between dozens of scientific file formats, including CF compliant netCDF files. For example, ERDDAP can ingest a collection of CSV files and serve the same information to users as a CF/netCDF file. The dataset can be augmented with additional metadata through a markup language that is part of the server configuration file. ERDDAP also provides automatic generation of ISO 19115 metadata, and can create BagIt⁴⁶ archive packages which can automate submission to national archive data centers.

Limitations of Existing Technical Standards

Earth science data interoperability standards that govern the production of archive-quality data files support a broad range of oceanographic data types and are integral to ocean observing system data management infrastructures. However, as has been illustrated in some of the use cases above, there are some limitations to current standards such as CF/ACDD and the associated oceanographic NCEI netCDF template implementations that constrain their more universal application.

One issue is that these standards focus primarily on geospatial characteristics of data and their metadata representation. There is a need to extend standards specifications so as to additionally support richer sets of metadata that may be specific to certain science domains and to package such augmented metadata in a non-*ad hoc*, machine-readable manner within self-describing science data files (nc, HDF). Such metadata attributes would document more fully for example critical information on aspects of instrument deployment, sampling and other protocols necessary to properly and reproducibly interpret the associated file data. This is important because dataset level metadata used to catalog collections of data files invariably do not capture this necessary information with sufficient granularity for *in situ* datasets that will differ in descriptive content between files. This is also likely to be particularly important for certain classes of data, such as biological datasets. The ability to package richer metadata in a machine-readable

⁴⁵https://youtu.be/_4jIDvrqiZo

⁴⁶<https://tools.ietf.org/html/draft-kunze-bagit-17>

manner will inevitably have broader applicability and facilitate improved, more granular data search. It can also enable the integration of the existing SensorML metadata framework to better describe instrument characteristics with associated data and then potentially expose that information via Open Geospatial Consortium (OGC) Sensor Web Enablement⁴⁷ (SWE) standards. There are already examples of satellite missions such as SMAP utilizing Group structures in HDF5 data files to organize hierarchically related sets of metadata attributes and encode these consistent with ISO standards. An analogous approach has also been implemented to support community metadata specifications for animal telemetry data involving 130 attributes organized thematically within 10 categorical Groups and dispositioned as required/recommended/optional. The biodiversity community uses the Darwin Core metadata standard to encode several categories of attributes related to the discrete sampling events, their geospatial characteristics, taxonomic composition and associated quantitative metrics for which the aforementioned framework will also be applicable for. A further example comes from the marine bio-acoustics community in which the international MESOPP⁴⁸ (Mesopelagic Southern Ocean Prey and Predators) project has delivered acoustic backscatter and related modeled data products as netCDF files with CF metadata supplemented with ICES metadata conventions for active acoustic systems⁴⁹.

A further interoperability challenge relates to frequently observed partial overlap of certain categories of attributes used by different science domain metadata frameworks. Several schemas share certain categories of attributes (e.g., Geospatial) that may conflict. There are also examples where even closely related communities (Biodiversity and Ecological sciences) may be using different metadata models (Darwin Core and EML) to represent even the exact same types of data. There is also considerable overlap in geospatial attributes across domain metadata conventions and Earth science such as CF/ACDD. This highlights the importance of establishing mappings across these schemas to facilitate semantic reconciliation of attributes between datasets produced by different communities, and to be able to do so in an automated service-based manner so as to enable also improved granule level search.

Improved support for provenance information is another important area for extensions to existing Earth Science data standards. This is becoming increasingly important as greater integration of data occurs and there is a proliferation of derived products. Currently CF foresees only a single History attribute to capture provenance and processing information, invariably implemented in ad hoc ways that are generally also undocumented. PROV⁵⁰ is a W3C standard for the representation of provenance information that could be leveraged here, and implemented using groups in a manner consistent with the aforementioned suggested approach to

support richer metadata more generally. Tracking of provenance in the evolution of metadata standards themselves and their inter-relationships is another area that can be improved upon to facilitate improved granule level search across data series where a blend of metadata profiles and versions may have been employed over time.

There is considerable interest in the inclusion of measurement uncertainty and data quality information in data files. CF standards provide a framework for quality flagging of observational data at a very granular level within variables of self-describing data files. Furthermore, certain communities (e.g., GHRSSST) have worked to develop a standardized approach to the representation of uncertainty in geophysical data. However, there is a need to extend these approaches to also represent error in geolocation variables given that positional determination (and in some cases estimation) may be a particular issue for *in situ* datasets and may take the form of a qualitative category code or quantitative error estimate. The Argo profiling float data format standard makes extensive use of category codes, including beyond geolocation variables.

The trawl survey use case discussed in the previous section highlights the broader issue of how to better support complex datasets in a manner that better captures inter-relationships between recorded data elements when Earth Science data interoperability standards and typical system architectures focus on simple collections of discrete data files. Even with support for hierarchical structured data in the nc4/HDF5 data models, the ability to comprehensively represent complex event-based datasets such as cruise data in a single data file is an unrealistic expectation. Instead there may be more promise in developing a framework in which time course and functional relationships between data files are represented in a standard manner so as to better define a given dataset or file collection.

SUMMARY AND RECOMMENDATIONS

The use cases in the previous section lead to several key considerations for charting the course ahead for the next 10 years of ocean data management, specifically in enhancing interoperability across components of the GOOS Data System. These issues impact stewardship, discoverability and access to ocean data. In general, we recommend adherence to the FAIR data principles, though the details of what precisely that entails may differ between communities, and specific definitions of what FAIR compliance means within a community are still under discussion (Tanhua et al., 2019). The coming decade should do much to provide more specific implementation details for FAIR compliance.

Hankin et al. (2010) asserted that the combination of the netCDF file format, the Climate and Forecast Conventions, and the OPeNDAP network protocol formed the basis of a data management strategy for GOOS. Although at that time, the strength of this combination was gridded data. In the last 10 years the importance of netCDF/CF/OPeNDAP has grown and the capabilities now extend to *in situ* data types (points, profiles, time series etc.). The standards and

⁵⁰<https://www.w3.org/TR/prov-overview/>

the tools have evolved methodically and deliberately to address important data management problems. We conclude that a netCDF/CF/OPeNDAP remain the building blocks for ocean data management and that by focusing on incremental enhancements to mature technologies will be a sustainable path for the global community. The NCEI templates are the gold standard examples for many of the common data types encountered in GOOS and should be the starting point for any data management effort.

This collection of standards is complex and incomplete. The complexity requires strategies to simplify adoption through education and tool development. Communities of practice help spread knowledge and focus development efforts on tools of general utility, especially when combined with Open Source development practices. The incompleteness requires evolving the family of standards and finding ways to cross-reference and link to data that is managed according to other discipline specific but mature technologies. The issues surrounding multidisciplinary observations in general (see section “Cross-disciplinary Research Cruises”) and trawl surveys in particular (see section “Fisheries Data from Trawl Surveys”), shed light on the differences between community data standards across science disciplines and suggest that pragmatic ways to bridge those standards is more likely to garner adoption than attempting to develop one standard for all data types. Further, the balance between global interoperability and local project priorities is a factor that should be considered in the funding and policy framework nationally and internationally. Linked Open Data strategies show promise in bridging discipline specific communities but those capabilities are nascent and at a relatively low maturity level.

Standards provide a framework to record and share essential metadata, but without concerted effort to populate the files with metadata, interoperability is still lacking. Strategies to incorporate metadata into the data stream automatically and without human

intervention will be critical to automating work flows and dealing with growing volumes of data. Engaging the sensor and platform manufacturers and applying market pressure is an essential step.

Finally, the information management and data science skills needed to develop a truly global and interoperable system require an influx of talent from outside traditional marine disciplines. Incorporating data science and system engineering perspectives into the global policy framework can help identify areas for collaboration in the future. Balancing an operational perspective based on mature technologies (e.g., CF/netCDF/OPeNDAP) against the need for research into new technologies (e.g., the semantic web and Linked Open Data) to bridge communities will be essential.

AUTHOR CONTRIBUTIONS

DS, VT, NH, MZ, KO'B, and KC helped to conceive the manuscript, coordinate author contributions, wrote text, and edited and contributed figures. NS, HS, KB, ML, and SA contributed manuscript ideas and text.

FUNDING

This work was partially funded by the Joint Institute for the Study of the Atmosphere and Ocean (JISAO) under the NOAA Cooperative Agreement NA15OAR4320063, Contribution No. 2018-0178.
