<sup>1</sup>Department of Plastic and Reconstructive Surgery, The First Affiliated Hospital of Zhengzhou University, Zhengzhou, China, <sup>2</sup>Shanghai Key Laboratory of Tissue Engineering, National Tissue Engineering Center of China, Department of Plastic and Reconstructive Surgery, Shanghai 9th People's Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, China

Diabetic neuropathy affects nearly half of all diabetics and poses a significant threat to public health. Recent preclinical studies suggest that mesenchymal stem cells (MSCs) may represent a promising solution for the treatment of diabetic neuropathy. However, an objective assessment of the preclinical effectiveness of MSCs is still pending. We conducted a comprehensive search of PubMed, Web of Science, Embase, and Cochrane library to identify preclinical studies that investigate the effects of MSCs on diabetic neuropathy up until 15 September 2023. Outcome indicators consisted of motor and sensory nerve conduction velocities, intra-epidermal nerve fiber density, sciatic nerve blood flow, capillary-to-muscle fiber ratio, neurotrophic factors, angiogenic factors and inflammatory cytokines. The literature review and meta-analysis were conducted independently by two researchers. 23 studies that met the inclusion criteria were included in this system review for qualitative and quantitative analysis. Pooled analyses indicated that MSCs exhibited an evident benefit in diabetic neuropathy in terms of motor (SMD = 2.16, 95% CI: 1.71–2.61) and sensory nerve conduction velocities (SMD = 2.93, 95% CI: 1.78–4.07), intra-epidermal nerve fiber density (SMD = 3.17, 95% CI: 2.28–4.07), sciatic nerve blood flow (SMD = 2.02, 95% CI: 1.37–2.66), and capillary-to-muscle fiber ratio (SMD = 2.28, 95% CI: 1.55 to 3.01,  $p < 0.00001$ ). Furthermore, after MSC therapy, the expressions of neurotrophic and angiogenic factors increased significantly in most studies, while the levels of inflammatory cytokines were significantly reduced. The relevance of this review relies on the fact that summarizes an extensive body of work entailing substantial preclinical evidence that supports the efficacy of MSCs in mitigating diabetic neuropathy. While MSCs emerge as a promising potential treatment for diabetic neuropathy, further research is essential to elucidate the underlying mechanisms and the best administration strategy for MSCs.

diabetic neuropathy, neurological disorder, stem cell therapy, mesenchymal stem cells, meta-analysis

# 1 Introduction

According to the International Diabetes Federation, diabetes mellitus currently affects approximately 425 million people worldwide, with projections suggesting that the number could exceed 700 million by 2045 (Sun et al., 2022). Diabetic neuropathy is an early-developing complication of diabetes characterized by axonal degeneration, demyelination, and impaired nerve regeneration. Rest pain, hyperalgesia, and diminished sensation due to diabetic neuropathy affect approximately half of all diabetics, not only dramatically reducing their quality of life but also placing a significant burden on the healthcare system (Pacífico et al., 2023). Although rigorous glucose control can slow the progression of diabetic neuropathy, it is not effective in restoring the function of damaged nerves (Ismail, 2023). Therefore, innovative strategies to improve nerve function in diabetic neuropathy are urgently needed.

Cell-based therapies are considered a promising approach to disease modification due to their ability to harness the body's healing mechanisms. In particular, mesenchymal stem cells (MSCs), a group of non-hematopoietic stem cells derived from the mesoderm, have attracted considerable attention because of their low immunogenicity, remarkable tissue regeneration potential, and powerful immunomodulatory capacity (Ebrahimi et al., 2023). Furthermore, MSCs are readily available, as they can be isolated from various tissues, including but not limited to bone marrow, adipose tissue, and teeth; they are able to multiply rapidly *in vitro*, undergoing several to a dozen passages (Li and Wang, 2022). Importantly, clinical trials from different countries have demonstrated the safety of MSCs, as evidenced by the fact that no allergic or severe adverse reactions were observed up to years after years of transplantation (Arango-Rodríguez et al., 2023; Razak et al., 2023; Xie et al., 2023). Therefore, treatment of MSCs could offer significant potential in treating tissue damage and functional disorders.

The complexity of diabetic neuropathy derives from its multifaceted interplay of nerve damage, impaired blood supply, and chronic inflammation (Eid et al., 2023). The multifunctional nature of MSCs enables them to exert therapeutic effects through multiple mechanisms. Transplanted MSCs can not only directly participate in tissue regeneration by differentiating into various cell types, such as Schwann cells and vascular endothelial cells, but they can also influence neighboring cells through their paracrine activity (Abuarqoub et al., 2020; Wang et al., 2022). It has been well-established that the secretome of MSCs comprises a diverse array of bioactive molecules that are beneficial for nerve repair. These include neurotrophic factors such as brain-derived neurotrophic factor (BDNF), nerve growth factor (NGF), neurotrophin-3 (NT3), and glial cell line-derived neurotrophic factor (GDNF); angiogenic factors such as vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), and platelet-derived growth factor (PDGF); as well as anti-inflammatory cytokines, particularly interleukin-10 (IL-10) and transforming growth factor-beta (TGF- $\beta$ ) (Trzyna and Banaś-Ząbczyk, 2021; Drobiowa et al., 2023). Consistent with *in vitro* studies, preclinical animal studies have also demonstrated that MSC transplantation significantly relieves the symptoms and slows the progression of diabetic neuropathy, as evidenced by

improvements in both motor and sensory nerve function, increased limb blood flow to the limbs, and a reduced inflammatory response (Shibata et al., 2008; Kim et al., 2011; Waterman et al., 2012; Guimarães et al., 2013; Himeno et al., 2013; Hata et al., 2015; Xia et al., 2015; Han et al., 2016; Omi et al., 2016; Brini et al., 2017; Datta et al., 2017; Monfrini et al., 2017; Omi et al., 2017; Abdelrahman et al., 2018; Evangelista et al., 2018; Xie et al., 2019; Hata et al., 2020; He et al., 2020; Kanada et al., 2020; Hata et al., 2021; Pan et al., 2022; Yigitturk et al., 2022; Yang et al., 2023).

Since the clinical application of MSCs in the treatment of diabetic neuropathy is at an early stage, a thorough and rigorous systematic review and meta-analysis of preclinical evidence can greatly help scientists and clinicians in designing and conducting clinical trials. To this end, we reviewed animal studies focused on the use of MSCs for the treatment of diabetic peripheral neuropathy (DPN), obtained from major databases, including PubMed, Web of Science, Embase, and Cochrane library. The main characteristics of the included articles were summarized, and the effectiveness of MSC transplantation on nerve function, blood supply, and inflammation was assessed. We hope that this systematic review and meta-analysis will serve as a basis for incorporating MSCs into the clinical treatment of diabetic neuropathy.

## 2 Materials and methods

### 2.1 Protocol and registration

The research protocol was officially registered in the International Prospective Registry of Systematic Reviews, under the specific identifier PROSPERO CRD42023474123. Moreover, our systematic review was conducted in strict accordance with the 2020 Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines (Moher et al., 2010).

### 2.2 Eligibility criteria

Before study inclusion, clear eligibility criteria were established, and framed using the PICOS model, which stands for population, intervention, comparator, outcomes, and study design. Setting these criteria in advance in accordance with established meta-research methods, ensures an impartial search, selection, and evaluation of relevant studies.

#### 2.2.1 Population (P)

The systematic review focused on preclinical studies using animal models. These models either spontaneously developed diabetic neuropathy or were experimentally induced by streptozotocin (STZ) injection or a high-fat diet. Notably, we excluded studies that were conducted exclusively *in vitro* or included only human clinical trials.

#### 2.2.2 Intervention (I)

For consideration in this review, studies involving the administration of MSCs had to be conducted. No restrictions were placed on the source, route, dosage, timing or frequency of

MSC administration. Additionally, the MSCs could be utilized as xenogeneic, allogeneic or autologous products.

### 2.2.3 Comparator (C)

Animals receiving no treatment, placebo, or an alternative therapeutic modality.

### 2.2.4 Outcome (O)

The primary outcome of this study was motor nerve conduction velocity (MNCV). Secondary outcomes evaluated included sensory nerve conduction velocity (SNCV), intra-epidermal nerve fiber density (IENFD), sciatic nerve blood flow (SNBF), the capillary-to-muscle fiber ratio in skeletal muscles, neurotrophic factors, angiogenic factors and inflammatory cytokines.

### 2.2.5 Study design (S)

Controlled interventional studies, whether they were randomized, pseudo-randomized, or non-randomized, were incorporated in this system review. However, unpublished gray literature, abstracts, review articles, editorials, commentaries, and letters were deliberately excluded. There were no exclusions based on the publication date.

## 2.3 Literature search strategy

As of 15 September 2023, a comprehensive and systematic search was conducted in several scientific databases, namely, PubMed, Web of Science, Embase and the Cochrane Library. The specific search strategy can be found in [Supplementary Table S1](#). Additionally, an exhaustive manual search of the reference lists of the identified studies was performed to capture all other relevant research sources.

## 2.4 Study selection process

The articles identified through our systematic search were cataloged and managed using EndNote 9 software (Clarivate Analytics, USA). The titles and abstracts were methodically screened by two independent reviewers, who subsequently undertook an in-depth evaluation of the full text for relevant research. When discrepancies arose between the two reviewers, a third team member was consulted to achieve consensus through extensive discussion.

## 2.5 Data extraction

The relevant data from the selected articles were independently extracted by two authors. In cases of discrepancies between them, the differences a third team member was consulted to achieve consensus through extensive discussion. Data collected included: (1) study characteristics such as first author, year of publication, and country of the study; (2) details of the study population, including gender, body weight, method of inducing the diabetes model, and others; (3) intervention specifics such as the source of MSCs, any MSC pre-treatment methods, dosage of MSCs, and the source of

administration of MSCs; (4) elements of the study design, including sample size and group comparison; (5) Outcomes, for example, motor nerve conduction velocity, sensory nerve conduction velocity, intra-epidermal nerve fiber density, sciatic nerve blood flow, neurotrophic factors, angiogenic factors and inflammatory cytokines.

## 2.6 Risk of bias

The risk of bias in animal experiments was evaluated independently by two authors, using the Systematic Review Centre for Laboratory Animal Experimentation's risk of bias (SYRCLE's ROB) tool (Hooijmans et al., 2014). Selection bias was assessed through sequence generation, baseline characteristics, and allocation concealment. Performance bias was evaluated by implementing random housing and blinding of both participants and personnel. Detection bias was examined by conducting random outcome assessments and ensuring blinding of these assessments. We screened for attrition bias based on incomplete outcome data and reporting bias due to selective reporting. Additionally, other potential sources of bias were systematically evaluated.

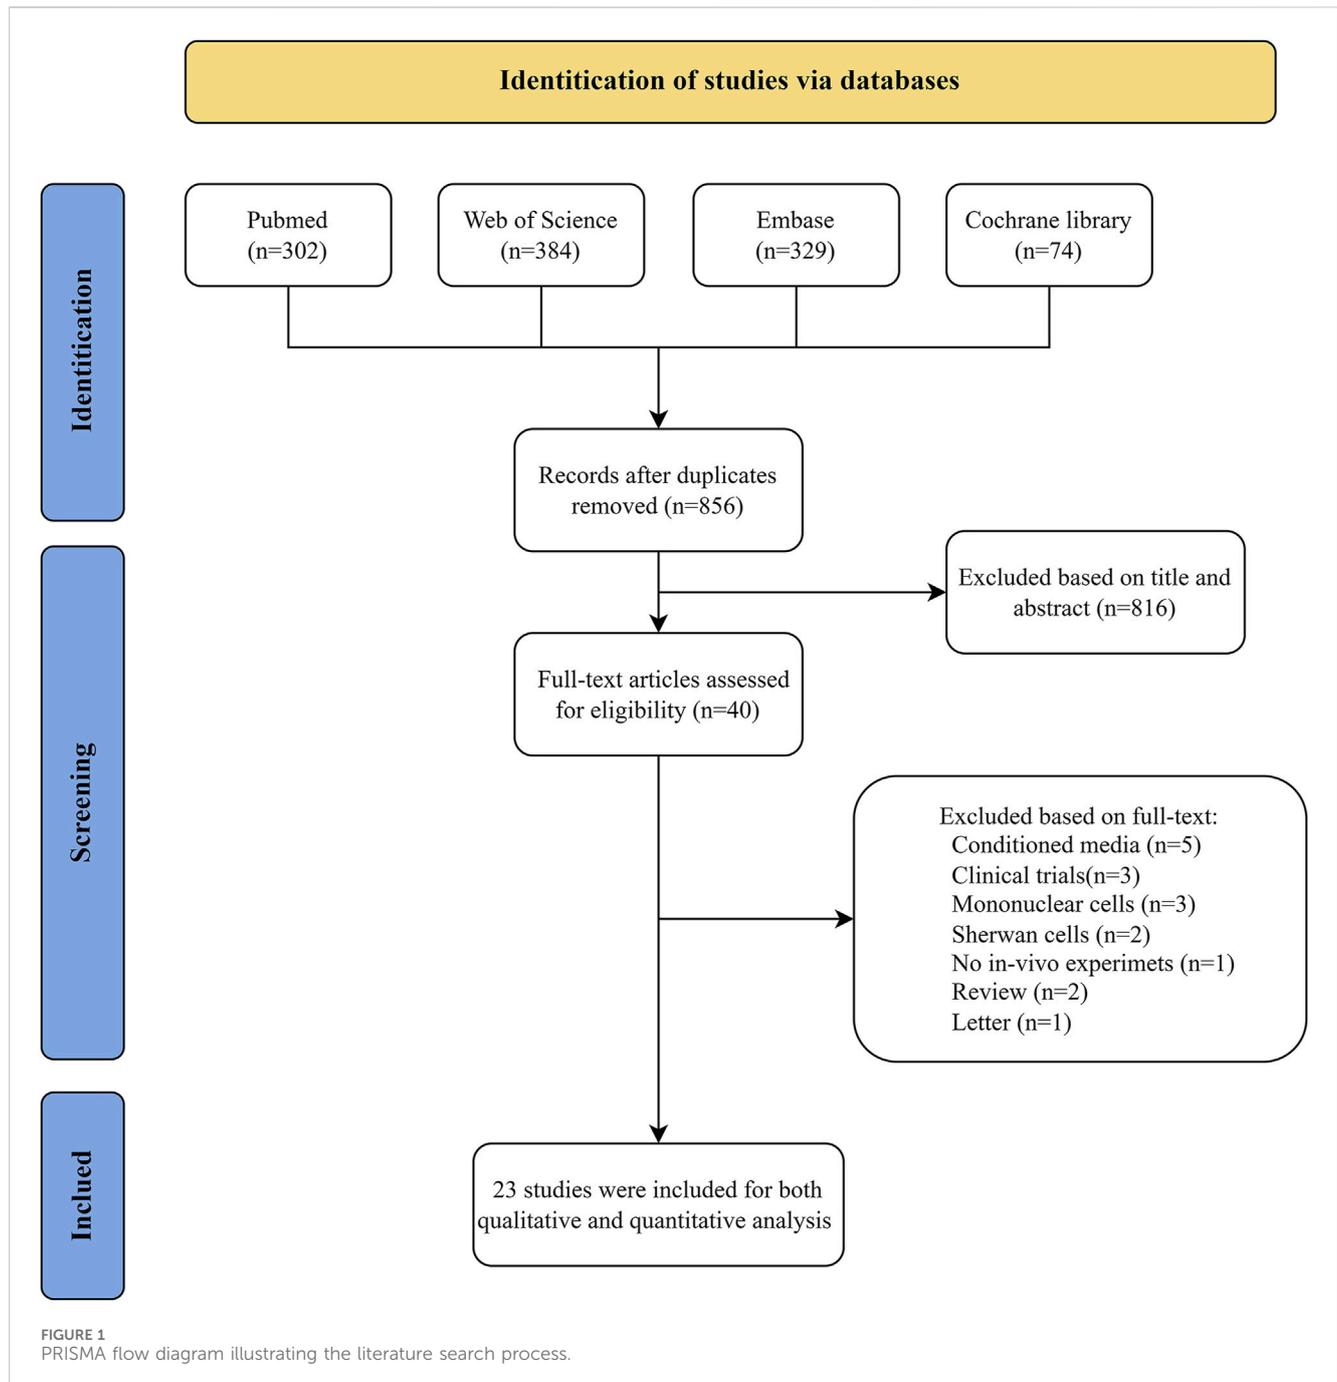

## 2.7 Data analysis

Data analyses were carried out utilizing Review Manager 5.3 software (Cochrane Collaboration, UK) in conjunction with StataMP-64 Software (StataCorp LP, USA). All outcomes were considered as continuous data and articulated using the standardized mean difference (SMD) accompanied by 95% confidence intervals (CIs). We set a pre-defined threshold at  $p < 0.05$  to delineate statistical significance. Considering variations in assessment time points across the reviewed studies, our approach involved adopting the maximum effect estimates from each study, specifically within a consistent 7- to 14-week interval, to facilitate pooled analyses. To evaluate the heterogeneity among the included studies, we employed the  $I^2$ -statistic test. In instances where  $I^2$  was 50% or below, indicating minimal or no significant heterogeneity, a fixed-effects model was chosen. Conversely, if  $I^2$  exceeded 50%, indicating significant heterogeneity, a random-effects model was employed (Higgins and Thompson, 2002).

# 3 Results

## 3.1 Search results

The entire article selection process is summarised in [Figure 1](#). A total of 1,089 studies were identified from the PubMed, Web of Science, Embase and Cochrane Library databases, with 856 records retrieved after removing duplicates. Following the screen of the titles and abstracts, a total of 816 articles were excluded from consideration due to not meeting inclusion criteria. The full text of the remaining 40 studies was examined for eligibility assessment, resulting in 23 records for system review.

### 3.2 Characteristics of the included studies

As of 15 September 2023, a total of 23 eligible studies were included and their salient characteristics are summarized in [Table 1](#) and [Figure 2](#). These studies were sourced from nine different countries and regions, with about a third originating from Japan. Of the 23 included studies, 21 used STZ-induced diabetic rodents (mice and rats), while the other two utilized gene-deficient diabetic rodents with or without a high-fat diet. The strains of included animals encompass Sprague–Dawley rats (n = 7), C57Bl/6 mice (n = 6), BALB/c mice (n = 4), Wistar rats (n = 3), Lewis rats (n = 1), Db/

db mice (n = 1), and Goto-Kakizaki rats (n = 1). The dosages of MSCs across studies ranged from  $5 \times 10^4$  to  $1 \times 10^7$  cells, with allogeneic cells used in 14 studies and xenogeneic cells in nine studies. These cells were isolated from dental pulp (n = 9), bone marrow (n = 8), umbilical cord (n = 2), adipose tissue (n = 2), placenta tissue (n = 1) or differentiated from pluripotent stem cells (n = 1). Of the 23 studies, 13 utilized intramuscular injection only, 6 employed tail vein injection only, 1 utilized arterial injections, 1 employed intraperitoneal injection, 1 utilized orbital plexus injection, and one compared the effectiveness of intramuscular injection *versus* tail vein injection.

### 3.3 Quality assessment of the included studies

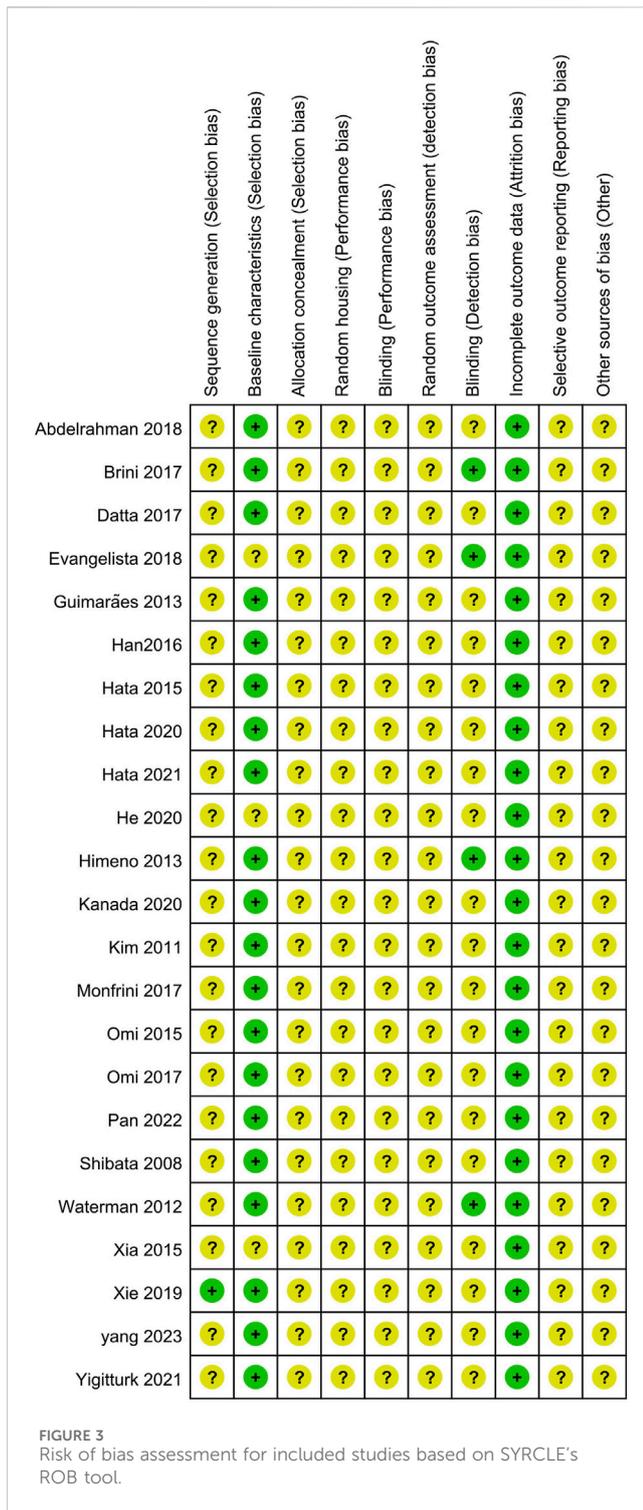

The risk of bias (ROB) among the included studies was assessed using the SYRCLE (Systematic Review Centre for Laboratory Animal Experimentation) tool. However, the majority of domains displayed an unclear ROB. Four studies mentioned the randomization of animal assignments, but only one explicitly reported how they used a random number generator for animal allocation (Xie et al., 2019). Unfortunately, none of the publications explicitly stated the information regarding allocation concealment. 20 studies reported comparable baseline characteristics and were therefore classified as “low risk”. However, three studies were categorized as “unclear risk” due to the omission of age data, making them unevaluable (Xia et al., 2015; Evangelista et al., 2018; He et al., 2020). None of the studies specified whether the allocation was concealed or whether the animals were housed randomly. None of the studies clarified whether

experimental caregivers and researchers were blinded to the interventions each animal received. One study reported that all analyses were conducted by personnel unaware of the animals’ identities (Himeno et al., 2013), while three studies indicated that the experimenter was blinded to the treatment group (Waterman et al., 2012; Brini et al., 2017; Evangelista et al., 2018). All studies showed a low attrition bias; however, it remains unclear whether any of the studies selectively reported outcomes (Figure 3). Other potential sources of bias were not reported; hence, we rated all studies as low risk for other sources of bias.

### 3.4 Outcomes of the meta-analysis

#### 3.4.1 Motor nerve conduction velocity (MNCV)

Neural conduction velocity is a sensitive and objective indicator of neural function, and its abnormality can suggest

the damage of nerve fibres. Twelve studies, involving 168 animals, provided detailed information on MNCV: 11 focused on the sciatic nerve and one on the caudal nerve. As the heterogeneity test revealed low significant heterogeneity ( $I^2 = 18\%$ ), a fixed-effects model was applied for the quantitative synthesis (Figure 4). A statistically significant improvement in MNCV was observed in the MSC-treated groups compared to the control groups (standardized mean difference [SMD] = 2.16, 95% confidence interval [CI]: 1.71 to 2.61,  $p <$

0.00001), suggesting a clear benefit of MSCs on the recovery of motor neural function. Since an adequate number of studies (more than 10) were involved in the quantitative synthesis, the symmetry of the funnel plot was assessed to detect the publication bias. Unfortunately, the funnel plots appeared asymmetrical, suggesting the risk of publication bias in the included studies (Supplementary Figure S1). Consequently, the trim-and-fill method was utilized to evaluate the potential influence of publication bias on the initial conclusion (Supplementary Figure S2). A total of 7 data sets were subjected to the trim and fill procedure, and the recalculated pooled analysis results were similar to the original results (pre-trim-and-fill: SMD = 2.12, CI = 1.68 to 2.57,  $p = 0.0001$ ; post-trim-and-fill: SMD = 5.39, CI = 3.64 to 7.98,  $p < 0.0001$ ). These results provided compelling evidence for the benefits of MSCs on the function of motor nerve fibres.

### 3.4.2 Sensory nerve conduction velocity (SNCV)

The abnormality of sensory nerve function occurs in the early stage of DPN and can be detected before the clinical motor nerve dysfunction. Eight studies, involving 93 animals, provided detailed data on SNCV. Because of the existence of moderate heterogeneity ( $I^2 = 59\%$ ), a random-effects model was applied for the pooled analysis. The pooled analysis demonstrated that a statistically significant increase in SNCV was observed after the transplantation of MSCs (SMD = 2.93, 95% CI: 1.78 to 4.07,  $p < 0.00001$ ), suggesting that MSCs greatly alleviated the dysfunction of sensory nerve fibers (Figure 5).

### 3.4.3 Intra-epidermal nerve fiber density (IENFD)

Damage to the small diameter nerve fibers within the epidermis is considered an important cause of paresthesia caused by DPN. Five of the included studies, involving 60 animals, investigated the effectiveness of MSCs on IENFD. A fixed-effects model was applied for the meta-analysis due to low heterogeneity among these studies ( $I^2 = 35\%$ ). All MSC-treated groups exhibited a significantly higher nerve fiber density compared to the control group (SMD = 3.17, 95% CI: 2.28 to 4.07,  $p < 0.00001$ ) (Figure 6).

### 3.4.4 Sciatic nerve blood flow (SNBF)

Insufficient blood supply is another significant factor contributing to nerve dysfunction in DPN. Detailed information on SNBF was found in 7 studies involving 74 animals. Since there was no heterogeneity among these studies ( $I^2 = 0\%$ ), a fixed-effects model was applied for the quantitative synthesis. Pooled analysis revealed that MSC-treated groups had significant improvement in sciatic nerve blood flow compared to control groups (SMD = 2.02, 95% CI: 1.37 to 2.66,  $p < 0.00001$ ). This demonstrates an enhanced blood supply to the sciatic nerve as a result of MSC therapy (Figure 7).

### 3.4.5 Capillary-to-muscle fiber ratio of skeletal muscles

Microcirculation disorder is one of the primary pathological features of DPN, with the capillary density of skeletal muscles serving as a dependable marker for this process. Data on the

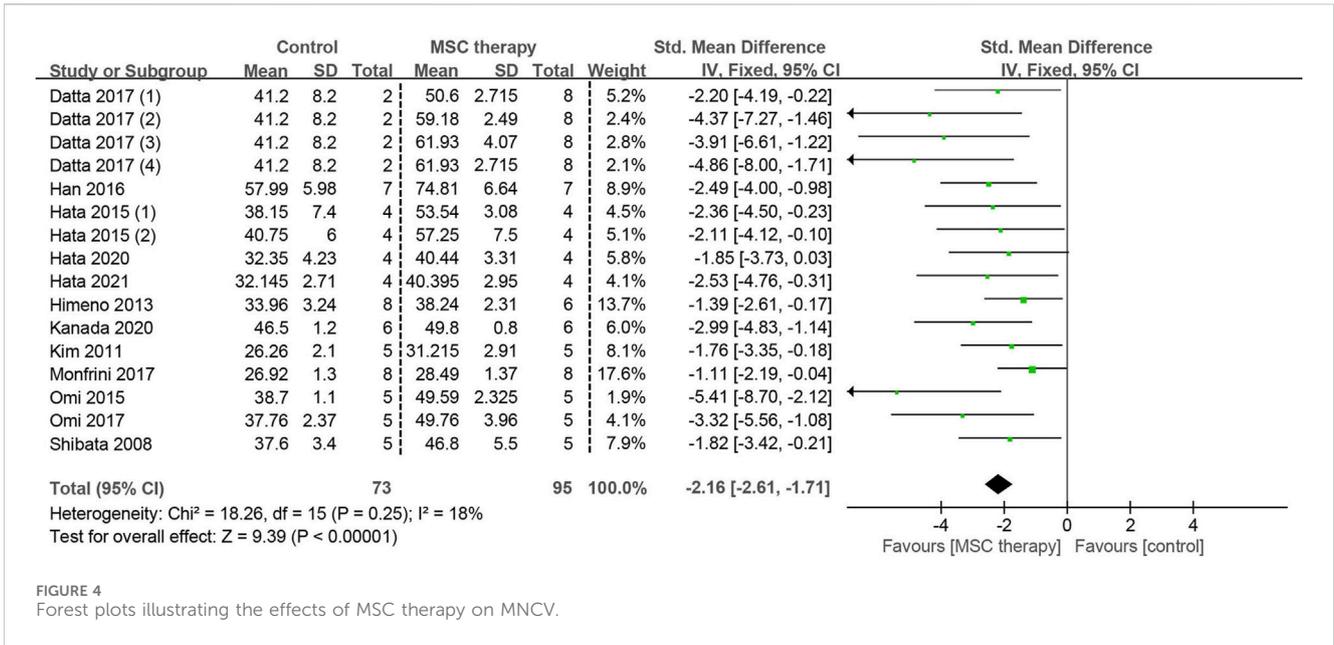

FIGURE 4 Forest plots illustrating the effects of MSC therapy on MNCV.

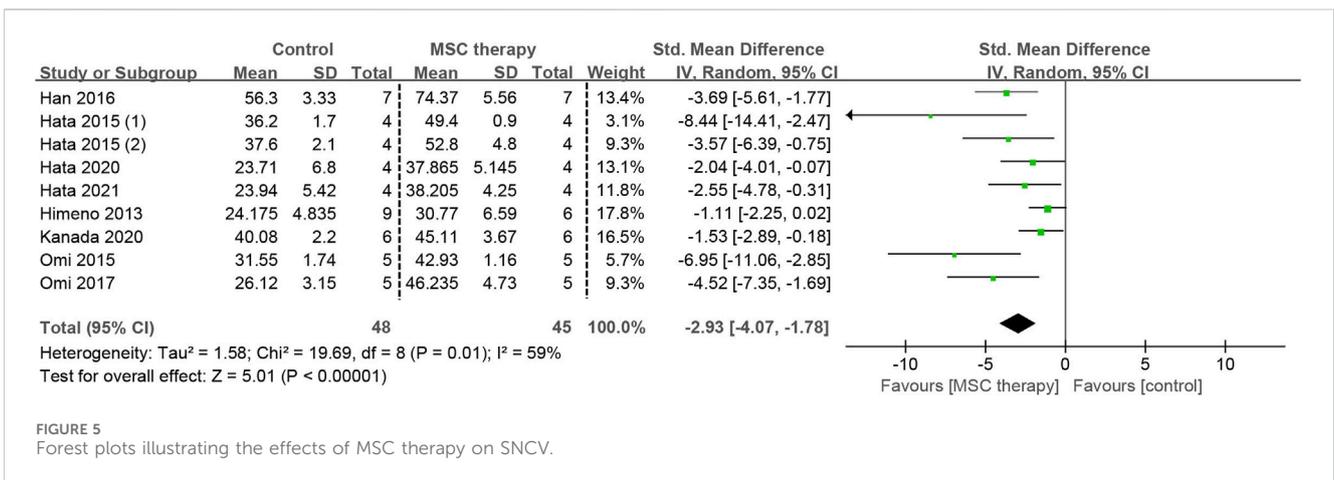

FIGURE 5 Forest plots illustrating the effects of MSC therapy on SNCV.

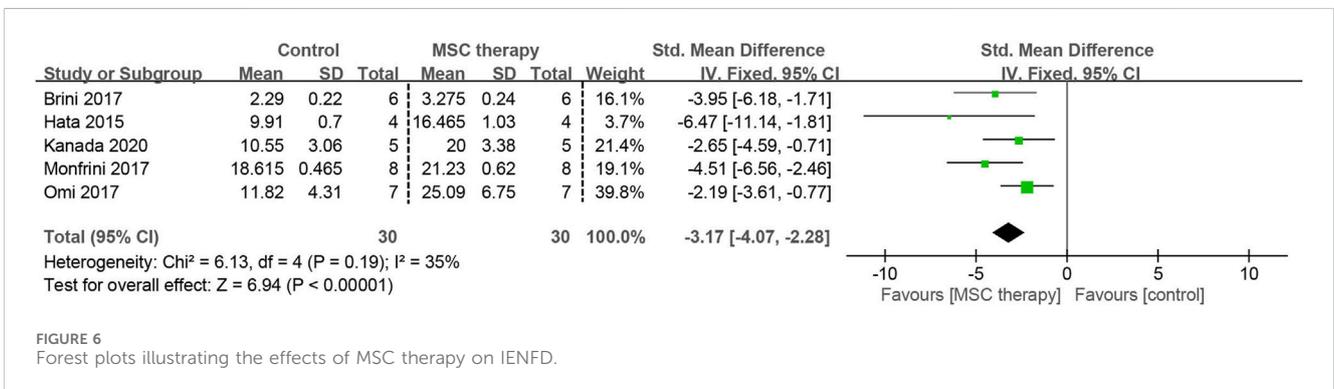

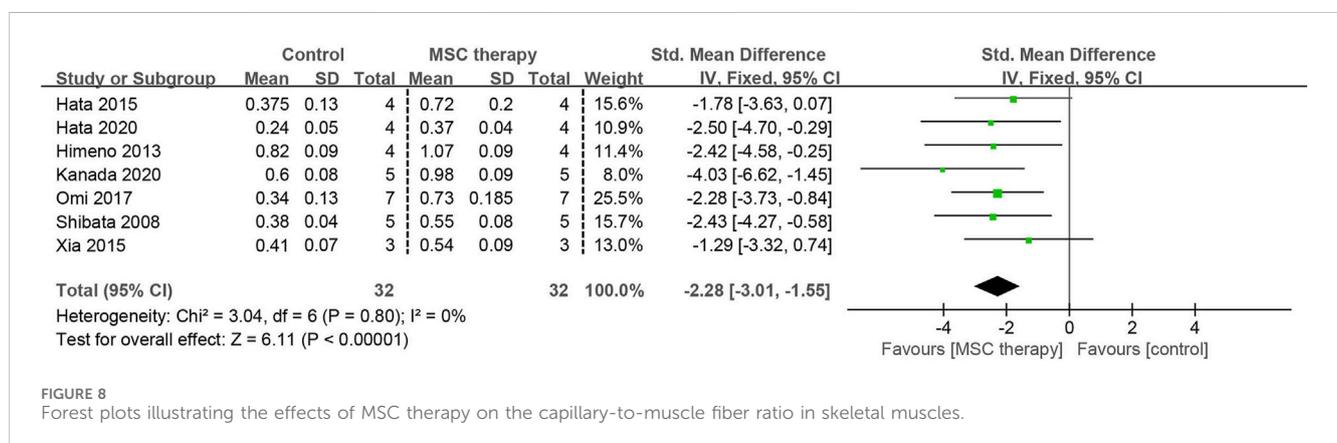

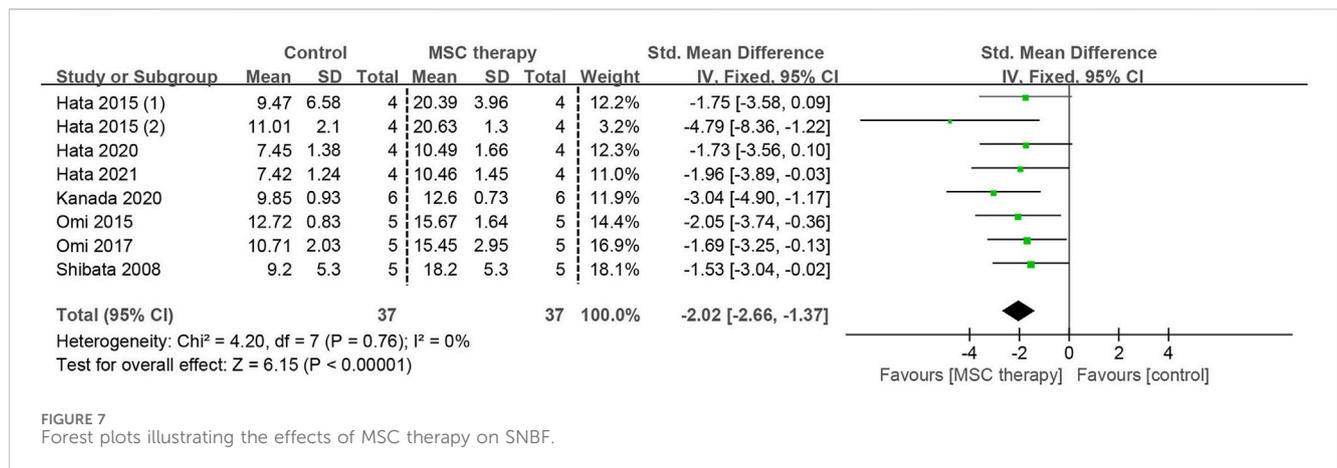

FIGURE 6 Forest plots illustrating the effects of MSC therapy on IENFD.

capillary-to-muscle fibre ratio were detailed in seven studies involving 64 animals. No data heterogeneity was observed among these studies (I<sup>2</sup> = 0%), yet a significant association was

found between MSC therapy and the increase in the capillary-to-muscle fiber ratio (SMD = 2.28, 95% CI: 1.55 to 3.01, p < 0.00001) (Figure 8).

### 3.5 Other indicators

#### 3.5.1 Neurotrophic factors

Nine studies sought to elucidate the benefits of MSCs by measuring the expressions of neurotrophic factors (Table 2). Levels of NGF (n = 9, 118 animals) and NT3 (n = 6, 74 animals) in the sciatic nerves or skeletal muscles were assessed using PCR, ELISA, or immunofluorescence. After MSC therapy, a 0.95- to 3.06-fold increase was observed in NGF expression, while the level of NT3 showed a 1.06- to 1.71-fold increase. These results at least partly explain the mechanism through which MSCs exert their neurotrophic effects.

#### 3.5.2 Angiogenic factors

Seven studies provided detailed information on bFGF (n = 6, 74 animals) or VEGF (n = 5, 70 animals). Data were obtained by PCR from sciatic nerves or skeletal muscles (Table 2). The administration of MSCs resulted in a 1.02- to 3.16-fold increase in bFGF levels and a maximum 4.38-fold increase in VEGF levels. However, the MSC-treated group did not show an obvious change in VEGF expression compared to the control group in the study by Hata et al.

#### 3.5.3 Inflammatory cytokines

The chronic, low-grade inflammatory response plays a crucial role in the onset and progression of DPN, and six studies provided

data on inflammation-related factors, including tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), interleukin-1 (IL-1), interleukin-6 (IL-6), and IL-10 (5 studies, 94 animals; 5 studies, 90 animals; 2 studies, 37 animals and 4 studies, 60 animals respectively). These samples were collected from various sites, including sciatic nerves, blood plasma, dorsal root ganglia, and spinal cord, and the levels of inflammation-related factors were examined using ELISA or RT-qPCR (Table 3). Generally, the MSC-treated groups consistently showed lower levels of pro-inflammatory factors, including TNF- $\alpha$ , IL-1, and IL-6, but higher levels of the anti-inflammatory factor IL-10 than the control groups. The expression levels of TNF- $\alpha$  in the MSC therapy groups were 28%–68% of those in the control group, while the expressions of IL-1 and IL-6 were 10%–86% and 8%–57% of the control, respectively. Moreover, a 1.56- to 3.58-fold increase was observed in IL-10 expression after MSC therapy. These results suggested that chronic inflammation was alleviated by MSC therapy.

#### 3.5.4 Blood glucose concentration

A total of 10 studies, with 16 comparison groups and 188 animals, provided detailed information on blood glucose concentration (Table 4). In seven comparisons, no difference was found between the MSC-treated groups and the control groups. In the remaining nine comparison groups, blood sugar levels were significantly reduced by 10.5%–36.4%. However, blood glucose levels in these groups still exceeded the diagnostic criteria for

TABLE 2 Effects of MSC therapy on the levels of neurotrophic and angiogenic factors.

Study	Method	Site	NGF		NT3		bFGF		VEGF

diabetes, which is a random blood glucose level of  $>200$  mg/dL. These results suggested that although MSC treatment appears to be somewhat effective in alleviating hyperglycemia, it alone may not be sufficient to reduce blood glucose levels to non-diabetic ranges.

## 4 Discussion

To the best of our knowledge, this is the first systematic review and meta-analysis that provides a comprehensive synthesis of the preclinical efficacy of MSCs in the treatment of DPN. Pooled estimates from meta-analyses support the hypothesis that MSCs offer significant therapeutic benefits on neural function (i.e., motor and sensory nerve conduction velocities and intra-epidermal nerve fiber density) and vascularization (i.e., sciatic nerve blood flow and capillary-to-muscle fiber ratio). Additionally, the review revealed that the benefits of MSCs may be associated with an increase in neurotrophic factors and angiogenesis, along with an inhibition of inflammatory reactions. These findings suggest that MSC-based therapy could be a promising strategy for the treatment of DPN.

Among the MSCs sourced from various tissues, dental pulp stem cells (DPSCs) and bone marrow mesenchymal stem cells (BMSCs) are the most favored by researchers, being utilized in about two-thirds of the included studies (DPSCs:  $n = 8$ ; BMSCs:  $n = 8$ ). DPSCs

can be isolated from fallen deciduous teeth or from teeth extracted for orthodontic reasons (e.g., impacted third molars). The easy accessibility of DPSCs makes them a compelling source for cell therapy (Datta et al., 2017). BMSCs were the first MSCs to be discovered, and their safety and efficacy have been confirmed through extensive clinical applications (Chu et al., 2020). Both DPSCs and BMSCs have shown significant potential for restoring nerve dysfunction; however, direct evidence comparing their therapeutic effects on DPN is lacking. Furthermore, the low immunogenicity of MSCs allows the possibility of cross-species transplantation: rodents in nine studies received MSCs derived from human tissue, but no immune rejection was reported (Waterman et al., 2012; Xia et al., 2015; Brini et al., 2017; Datta et al., 2017; Xie et al., 2019; Hata et al., 2020; Hata et al., 2021; Pan et al., 2022; Yang et al., 2023).

Hyperglycemia, the main feature of diabetes, leads to metabolic disorders, redox status imbalance, and cellular dysfunction, all of which contribute to the fundamental pathological basis of DPN (Kaur et al., 2023). 10 of the 23 included studies provide information on the effects of MSCs on hyperglycemia control. After MSC administration, significant decreases in blood glucose were observed in five studies, but rodents in these treatment arms still met the diagnostic criteria for diabetes. MSCs may exert their beneficial effects both by differentiating into pancreatic islet cells

TABLE 4 Effects of MSC therapy on blood glucose level.

Study	Glucose level (mg/dL)		Observation Period

and by secreting an array of growth factors that can rejuvenate pancreatic islet cells, such as insulin-like growth factor 1 (IGF-1), pancreatic and duodenal homeobox 1 (PDX-1), and glucagon-like peptide-1 (GLP-1) (Sionov and Ahdut-HaCohen, 2023). Despite these outcomes, MSCs were unable to normalize the blood glucose levels in diabetic rodents, suggesting that their ability to regulate blood glucose may be not as robust as their neurotrophic and angiogenesis functions. This finding suggests that the therapeutic effect of MSCs could be further enhanced by the simultaneous use of hypoglycemic agents.

DPN usually starts with abnormal sensations in the extremities, often accompanied by gradually worsening pain (Pacífico et al., 2023). In later stages, motor nerve involvement may occur, manifesting as decreased muscle tone and strength, ultimately leading to muscle atrophy and paralysis. The conduction velocity of motor and sensory nerves is a sensitive indicator of the condition of limb nerves, and its abnormality often occurs before the clinical manifestations of DPN. A Meta-analysis of 16 treatment arms from 12 included studies showed that MSC administration significantly alleviated delayed motor nerve conduction. The findings were supported by the pooled estimates of sensory nerve conduction from 9 treatment arms in 8 studies. Furthermore, MSC transplantation significantly increased the density of epidermal nerve fibers, suggesting an improvement in the degeneration of terminal nerves. Several studies attributed the benefits of MSCs to their ability to upregulate the levels of neurotrophic factors, such as bFGF and NGF (Han et al., 2016; Hata et al., 2020; Kanada et al., 2020). It is

believed that the increase in neurotrophic factors originates not only from the MSCs but also from the cells rejuvenated by them (Yue et al., 2016).

In addition to nerve damage, microangiopathy is also a characteristic pathological feature of DPN. This pathological process is associated with endothelial dysfunction, thickening of the capillary endothelial basement membrane, microcirculatory disorders, and impaired angiogenesis (Fang et al., 2018). Nerve cells rely highly on oxygen and energy; consequently, ischemia resulting from diabetic microangiopathy causes them significant harm. As the longest and thickest peripheral nerve, the sciatic nerve is often the first and most severely affected nerve by diabetic microangiopathy (Kender et al., 2023). Seven studies reported an increase in sciatic nerve blood flow after the administration of MSCs, with a meta-analysis of eight treatment arms showing no significant heterogeneity. The results indicated that the increased blood supply to the sciatic nerve plays a crucial role in the beneficial effects of MSCs on nerve conduction velocity and nerve dysfunction. Furthermore, pooled estimates from seven studies showed an increased ratio of blood vessels to muscle fibers in MSC-treated animals, suggesting an improvement in microcirculation disorder due to MSC treatment.

The inflammatory response helps eliminate pathogens and foreign bodies, and can also activate the body's natural repair mechanisms. However, when this inflammation becomes chronic and uncontrolled due to diabetes, it can cause considerable damage to the nervous and circulatory systems (Cheng et al., 2024). The immunoregulatory ability of MSCs is also a key factor in their role in

neuroprotection and tissue regeneration. It has been reported that the secretome of MSCs contains an abundance of anti-inflammatory factors, such as PGE2, IL-10, IL-35, and TGF- $\beta$  (Trzyna and Banaś-Ząbczyk, 2021). Furthermore, recent preclinical evidence has revealed that the administration of MSCs can convert a significant proportion of macrophages from a pro-inflammatory phenotype (M1) to an anti-inflammatory phenotype (M2) (Liu et al., 2022). Indeed, several included studies reported a decrease in pro-inflammatory cytokines, including TNF- $\alpha$  and IL-1, and an increase in the anti-inflammatory factor IL-10 in the peripheral nerves, spinal cord and plasma (Omi et al., 2016; Brini et al., 2017; Datta et al., 2017). However, researchers used different methods when assessing inflammation in different tissues, including PCR, ELISA, Western blotting, and immunohistochemistry. This methodological heterogeneity made a meta-analysis not feasible.

We must acknowledge several limitations in this systematic review and meta-analysis. First, all included studies used rodents as animal models, which may exaggerate the treatment effects of MSCs on DPN. Second, although most meta-analysis results showed low heterogeneity, the sample size in each case was limited; Studies with larger samples are urgently needed to provide more robust evidence. Third, the data extracted using the GetData software may have slight differences from the original data.

Overall, MSC therapy showed significant benefits in both neuroprotection and angiogenesis, as evidenced by a number of improvements in MSCs-treated animals compared with the control animals, including enhanced conduction velocity of motor and sensory nerves, denser epidermal nerve fibers, increased sciatic nerve blood flow, and a higher ratio of blood vessels to muscle fibers. The treatment effects of MSCs could also be related to their anti-inflammatory function, but a meta-analysis was not feasible due to the significant methodological differences across studies. These findings suggest that MSC transplantation holds promise as a strategy for DPN. However, rigorous and well-designed preclinical and clinical trials with larger sample sizes remain essential.

## 5 Conclusion

This systematic review and meta-analysis evaluated the preclinical efficacy of MSCs in the treatment of diabetic neuropathy. A comprehensive analysis of 23 animal studies suggests that MSC therapy holds significant potential to improve various aspects of diabetic neuropathy. Pooled analyses indicated that MSC administration resulted in improvements in motor and sensory nerve conduction velocities, increased intra-epidermal nerve fiber density, improved sciatic nerve blood flow, and favorable modulation of the capillary-to-muscle fiber ratio. Additionally, MSC treatment was associated with the upregulation of neurotrophic factors, an increase in angiogenic factors, and a reduction in inflammatory cytokines. While MSCs emerge as a promising avenue for treating diabetic neuropathy based on preclinical models, further research, particularly well-designed clinical trials, is essential to fully understand their therapeutic potential and facilitate their integration into clinical practice.
