Sexually transmitted infection (STI) of the upper reproductive tract can result in inflammation and infertility. A biomarker of STI-induced upper tract inflammation would be significant as many women are asymptomatic and delayed treatment increases risk of sequelae. Blood mRNA from 111 women from three cohorts was profiled using microarray. Unsupervised analysis revealed a transcriptional profile that distinguished 9 cases of STI-induced endometritis from 18 with cervical STI or uninfected controls. Using a hybrid feature selection algorithm we identified 21 genes that yielded maximal classification accuracy within our training dataset. Predictive accuracy was evaluated using an independent testing dataset of 5 cases and 10 controls. Sensitivity was evaluated in a separate test set of 12 women with asymptomatic STI-induced endometritis in whom cervical burden was determined by PCR; and specificity in an additional test set of 15 uninfected women with pelvic pain due to unknown cause. Disease module preservation was assessed in 42 women with a clinical diagnosis of pelvic inflammatory disease (PID). We also tested the ability of the biomarker to discriminate STI-induced endometritis from other diseases. The biomarker was 86.7% (13/15) accurate in correctly distinguishing cases from controls in the testing dataset. Sensitivity was 83.3% (5/6) in women with high cervical *Chlamydia trachomatis* burden and asymptomatic endometritis, but 0% (0/6) in women with low burden. Specificity in patients with non-STI-induced pelvic pain was 86.7% (13/15). Disease modules were preserved in all 8 biomarker predicted cases. The 21-gene biomarker was highly discriminatory for systemic infections, lupus, and appendicitis, but wrongly predicted

tuberculosis as STI-induced endometritis in 52.4%. A 21-gene biomarker can identify asymptomatic women with STI-induced endometritis that places them at risk for chronic disease development and discriminate STI-induced endometritis from non-STI pelvic pain and other diseases.

**Keywords:** biomarker, mRNA, Chlamydia, gonorrhea, pelvic inflammatory disease

## INTRODUCTION

Pelvic inflammatory disease (PID) occurs when sexually transmitted pathogens ascend from the cervix to the uterus and oviducts, resulting in endometritis and salpingitis. Infection with *Chlamydia trachomatis* (CT), *Neisseria gonorrhoeae* (GC), or both, may lead to PID and associated morbidities including infertility, ectopic pregnancy, and chronic pelvic pain. *Mycoplasma genitalium* has emerged as a pathogen causing PID and its associated long-term complications (McGowin and Anderson-Smits, 2011; Bjartling et al., 2012). PID affects approximately 800,000 women annually in the United States (Centers for Disease Control Prevention., 2017), and yearly medical expenditures for PID treatment approach ~2 billion dollars (Rein et al., 2000).

The diagnosis of PID is imprecise. No single historical, physical, or laboratory finding is both sensitive and specific for the diagnosis of PID (Workowski et al., 2015). A major barrier to the prevention of morbidities is delayed diagnosis due to absence of or presence of mild non-specific symptoms (Wiesenfeld et al., 2005). Still, both clinical and subclinical upper tract inflammation can lead to chronic sequelae (Wiesenfeld et al., 2012). Laparoscopy with coincident biopsies of the endometrium and oviducts can confirm endometritis and salpingitis but this procedure is invasive and requires general anesthesia. Endometrial biopsy via suction catheter can be used to obtain tissue for use in the diagnosis of endometrial infection and inflammation associated with reduced fertility (Wiesenfeld et al., 2012). In fact, histologic endometritis is highly predictive of salpingitis and endometrial biopsy provides a specific diagnosis of PID (Kiviat et al., 1990). Although minimally invasive, the endometrial biopsy procedure is not routinely used for the diagnosis of endometritis because it requires trained clinicians and the biopsy procedure is invasive. A biomarker that identifies women with subclinical PID would significantly improve diagnosis and case management and could be used as a surrogate of upper reproductive tract disease for evaluation of STI therapeutics and vaccines (Poston et al., 2017).

We reported a distinct blood-derived mRNA profile in women with symptomatic PID and endometritis caused by GC and/or CT. Women with STI-induced endometritis exhibited enhanced expression of myeloid cell genes with suppression of genes involved in protein synthesis, mitochondrial oxidative phosphorylation, and T-cell responses compared to uninfected women or women with cervical infection only (Zheng et al., 2018). Women solely infected with CT expressed elevated levels of type I and type II interferon genes. The present study extends these findings by identifying a 21-gene blood biomarker that can aid prediction of STI-induced endometritis in symptomatic and

asymptomatic women. Although insensitive for asymptomatic women with endometritis and low cervical burden, biomarker sensitivity for women with endometritis and high cervical burden was 83.3% (5/6). This biomarker distinguished women with STI-induced endometritis from patients with non-STI-induced pelvic pain, disseminated bacterial infections, lupus, and appendicitis, but failed to distinguish patients with tuberculosis, where a subset of the 21-gene set was also dysregulated.

## METHODS

This study complied with the Declaration of Helsinki guidelines and all study participants provided written informed consent prior to initiation of study procedures. The Institutional Review Boards for Human Subject Research at the University of Pittsburgh, the University of North Carolina, and Johns Hopkins University approved the study.

### Study Population

This study used whole blood collected from female participants recruited into three independent cohorts. The Anaerobes and Clearance of Endometritis (ACE) cohort was comprised of symptomatic women with clinically diagnosed PID, according to the Centers for Disease Control and Prevention diagnostic criteria (Workowski et al., 2015), who participated in a clinical trial (NCT01160640) comparing antibiotic regimens for PID treatment (Zheng et al., 2018). Diagnostic criteria included one or more of the following present on pelvic examination: cervical motion tenderness, or uterine tenderness or adnexal tenderness, in a sexually active young woman experiencing pelvic or lower abdominal pain (Workowski et al., 2015). The T cell Response Against Chlamydia (TRAC) cohort was comprised of asymptomatic women at high risk for STI (Russell et al., 2016). Both cohorts were recruited from clinics and emergency departments in Pittsburgh, PA. The Technology Enhanced Community Health-Nursing (TECH-N) cohort was comprised of women with clinical PID participating in a clinical trial of a nursing text-messaging intervention in Baltimore, MD (NCT01640379) (Trent et al., 2016).

### Data Collection

As described previously for both ACE and TRAC, at enrollment, demographic data, a standardized medical history, and general physical and pelvic exams were performed. Cervical swabs were collected for microbiological molecular testing. Blood was collected for transcriptional profiling, and endometrial sampling was performed for microbiologic and histologic evaluation (Zheng et al., 2018); endometritis was defined according to published criteria (Kiviat et al., 1990). Chlamydial cervical

burden was estimated via quantitative PCR using DNA extracted from reserved cervical swab eluates (Russell et al., 2016). The median cervical burden for the TRAC cohort =  $10^4$  genome equivalents/swab (Russell et al., 2016); high and low burden were defined as values above and below this level, respectively. For patients in TECH-N, clinical, cervical microbiological, and blood transcriptional data were collected, but endometrial biopsy was not performed.

## Microarray Data Acquisition and Processing

Total RNA was isolated from blood of TECH-N participants and analyzed via microarray (Illumina Human HT12 v3.0 expression bead chip) in the Genomics and Proteomics Core Laboratories at the University of Pittsburgh as described previously (Zheng et al., 2018) for ACE and TRAC participants and can be accessed from GEO (<https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE110106>). Transcripts were quantile normalized (Irizarry et al., 2003) and log<sub>2</sub> transformed. Genes were filtered by expression ( $\mu > 6.8$ ) and variance thresholds ( $\sigma^2 > 0.25$ ). Batch effects were measured by guided PCA (Reese et al., 2013), and corrected using ComBat (Johnson et al., 2007). A total of 4952 transcripts passed initial filtering criteria. Array data associated with staphylococcal and streptococcal infections, lupus, appendicitis, and tuberculosis were retrieved from GEO (<https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE19491>; <https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE83091>) for evaluation of biomarker performance. The GSE19491 study was performed using Illumina HT V3 chips (~48,000 probes), our data (GSE110106) and the GSE83091 dataset were derived using Illumina HT V4 chips (~47,000

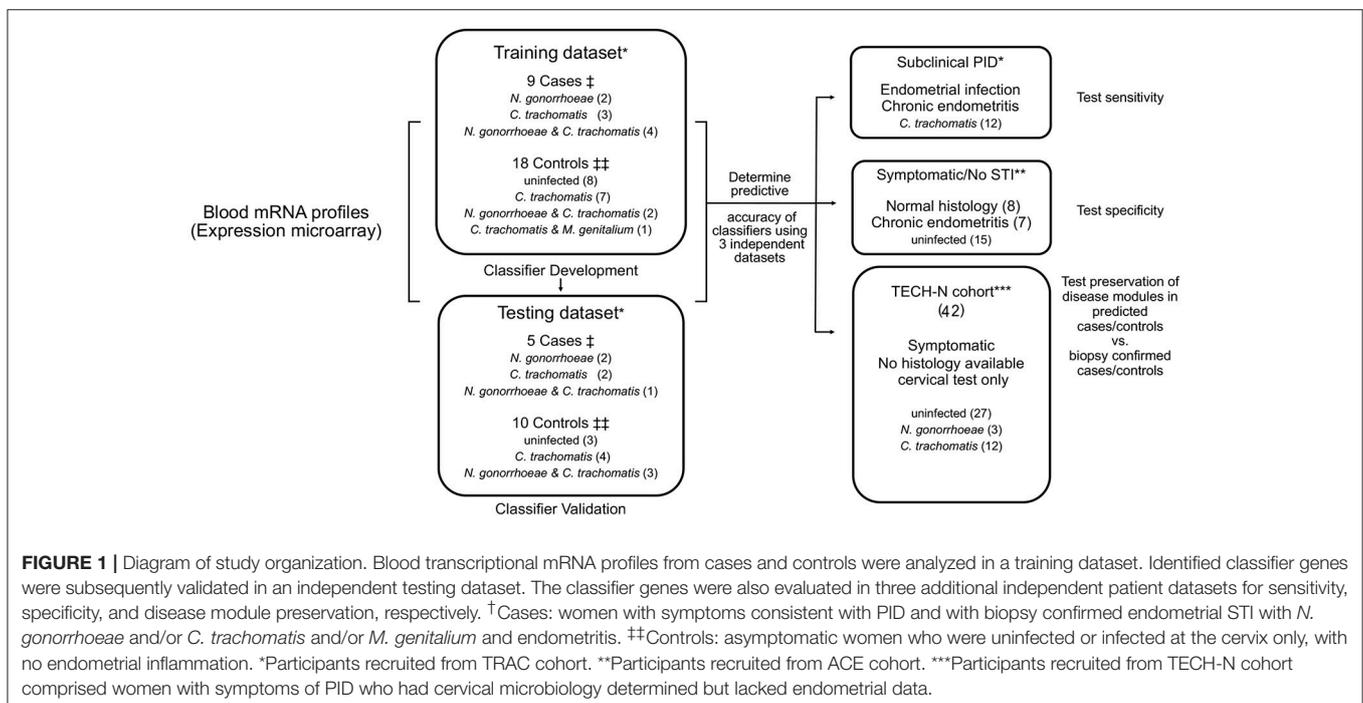

probes). The arrays share an overlapping set of ~40,000 probes that were used for cross-platform normalization. All data were quantile normalized and standardized.

## Study Design

Cases were previously defined as women with a clinical PID diagnosis and biopsy-confirmed endometrial CT/GC (STI) and endometritis, and controls as study participants who did not display symptoms of PID, lacked endometrial infection and inflammation, and included women with cervical CT/GC and uninfected women (Zheng et al., 2018). For this study, two-thirds of cases and controls were assigned to a training dataset and the remaining one-third to a testing dataset based on the temporal order in which they were enrolled (Figure 1). The training dataset was used to derive a biomarker, that was then tested on the remaining cases and controls (testing dataset).

Study participants categorized as subclinical PID ( $N = 12$ ) were asymptomatic with biopsy-confirmed endometrial CT/GC and endometritis. Symptomatic/No STI\*\* indicates women with clinical PID symptoms not infected with STI pathogens ( $N = 15$ ). These independent groups were used to test the sensitivity and the specificity of the biomarker, respectively. An additional cohort of participants in TECH-N were used to test for preservation of disease modules ( $N = 42$ ) (Figure 1).

Lastly, we tested the ability of the biomarker to discriminate STI-induced endometritis from other diseases including staphylococcal ( $N = 40$ ) and streptococcal infections ( $N = 12$ ), lupus ( $N = 28$ ), appendicitis ( $N = 20$ ), and tuberculosis ( $N = 82$ ); and controls for staphylococcal and streptococcal infections ( $N = 23$ ), controls for lupus ( $N = 17$ ) and controls for tuberculosis ( $N = 40$ ) using array data retrieved from GEO.

## Unsupervised Hierarchical Clustering, Principal Component Analysis (PCA), Classifier Identification and Validation

We applied unsupervised cluster analysis and PCA to identify reliable disease subgroups. For hierarchical clustering, genes were clustered via Pearson correlation, while samples were clustered using Spearman's rank correlation with average linkage criterion. To identify classifiers, a hybrid feature selection algorithm which combines two feature selection methods—the filter (moderate  $t$  statistics) and the wrapper (mSVM-RFE) was performed. The 4,952 transcripts that passed initial filtering criteria were used as a starting point for moderated  $t$ -tests using R package “limma”; genes with false discovery rate (FDR) < 0.05 and absolute fold change  $\geq 1.35$  were retained. A cut-off of 1.35 was based on reports that gene changes starting at 1.3-fold using microarray can be reliably confirmed by real-time PCR (Wurmbach et al., 2001; Zhou et al., 2007; Huggins et al.,

2008). Next, Multiple Support Vector Machine Recursive Feature Elimination (mSVM-RFE) (Duan et al., 2005) was used to identify the smallest subset of features with maximal classification accuracy. SVM-RFE (Guyon et al., 2002) is an iterative algorithm that works backward from an initial set of features. At each round, it first fits a simple linear SVM, then ranks the features based on their weights in the SVM solution, and finally eliminates the feature with the lowest weight. mSVM-RFE extends this idea by using resampling techniques at each iteration to stabilize the feature rankings. We began by using the recursive procedure of Duan et al. (2005) to compute the ranking score statistics for each feature, then the top 100 ranked features were selected for further analysis. We used the ranks to define nested subsets of features  $F1 \subset F2 \subset \dots \subset F$ , and determined the best subset of features with smallest generalization error by varying a single parameter: the number of features. Multiple runs of fivefold cross-validation were used for estimation of generalization error.

mSVM-RFE identified the smallest subset of 21-gene with maximal classification accuracy. For prediction, SVM with 21 candidate biomarkers was used with the training dataset to generate a prediction model and to determine predictive accuracy in the testing dataset and three independent, disease-related, datasets. Data were standardized; linear kernel was used in SVM. With the predicted probability of the binary response (elevated risk of PID vs. low risk), a cut point of 0.5 was used. Validation of mRNA transcripts was performed by interrogating total RNA from participants via nCounter assay and were analyzed using NSolver v.3.0 software (Nanostring™). Differential expression between cases and controls was identified using *t*-test.

## Preservation Module, Gene Set Enrichment, and Pathway Analysis

Weighted Gene Coexpression Network Analysis (WGCNA) and a composite preservation statistic  $Z_{\text{summary}}$  (Langfelder et al., 2011) was used to determine if a module present in biopsy-confirmed cases was represented in biopsy-predicted TECHN cases. Gene set enrichment analysis (GSEA) was performed to examine whether any preserved modules were significantly enriched in disease associated sectors generated by differential network analysis using WGCNA (Fuller et al., 2007; Luo et al., 2009; Zheng et al., 2018). Biological annotations of genes differing greatly between groups were explored with Ingenuity Pathway Analysis (IPA) (<http://www.ingenuity.com/index.html>). The significance of the canonical pathway was assessed using Fisher's exact test. Multiple testing was adjusted by Benjamini-Hochberg. All analyses were conducted in R (version 3.1.2).

## RESULTS

### Training and Testing Dataset Patient Characteristics

**Table 1** summarizes the distribution of demographic, clinical and microbiological characteristics of study participants assigned to training and testing datasets. Age, race, education, insurance, contraceptive status, bacterial vaginosis, or infection with *Trichomonas vaginalis* did not differ significantly between the cases and controls in either dataset ( $p > 0.05$ ).

### Transcriptional Profiles Define Patients With STI-Induced PID

Unsupervised hierarchical clustering was conducted in training and testing datasets to determine if profiles grouped according to disease (**Figure 2**), and to visualize gene expression patterns. In the training dataset, transcriptional response profiles for 7 of 9 cases clustered tightly, and were easily distinguished from controls ( $N = 18$ ). In the testing dataset, 4 out of 5 cases clustered and were distinct from 9 of 10 controls. Principal component analysis separated participants in a pattern consistent with the hierarchical clusters, with variance explained by the first principle component 61% and the second principle component 15%. These findings confirm that CT/GC-induced PID elicits a distinct blood transcriptional profile (Zheng et al., 2018).

### Classifier Genes Accurately Diagnose Women With STI-Induced Endometritis

Feature selection identified 21 genes (**Table 2**) that were used as classifiers in an SVM model and 10-fold cross-validation was conducted to determine their performance in the training dataset. Cross-validation achieved 100% accuracy, with 27 out of 27 patients correctly classified. Sensitivity, specificity, and overall predictive accuracy was 100% with the area under the receiver operating characteristic (ROC) curve = 1 (data not shown). We then determined the predictive performance of the panel in an independent testing dataset (**Figure 3**). Biomarker sensitivity was 100% (5 of 5 women with upper genital tract STI-induced endometritis were predicted as positive; 95% CI 80%, 100%), specificity was 80% (8 of 10 women who were negative for upper genital tract STI-induced endometritis by biopsy were predicted as negative; 95% CI 55%, 93%), and the overall predictive accuracy was 86.7% (13 of 15) with the area under the ROC curve = 0.96. Direction and magnitude of differential gene expression between cases and controls were validated for the training ( $P < 0.001$  for all 21 genes) and testing datasets ( $P < 0.1$  for all 21 genes) using nCounter expression array (**Table 3**).

The 21-gene panel includes genes present in immune response pathways we reported as dysregulated in women with STI-induced endometritis (Zheng et al., 2018). The top up-regulated genes in the biomarker panel are involved in interferon signaling (AIM2, GBP2, CASP1, NAMPT, RNF19b), myeloid

cell-mediated inflammation (ADM, LYSMD2, CD58, LIN7A, SIGLEC5, PLAUR), and cell death (DSC2, CYB5R4, FAS). The top down-regulated genes are involved in cell adhesion and migration (TSPAN3), protein synthesis (EEF1D), and lymphocyte signaling (TCL1A, CD79A, FAIM3).

### Utility of the Biomarker for Diagnosing Subclinical STI-Induced Endometritis

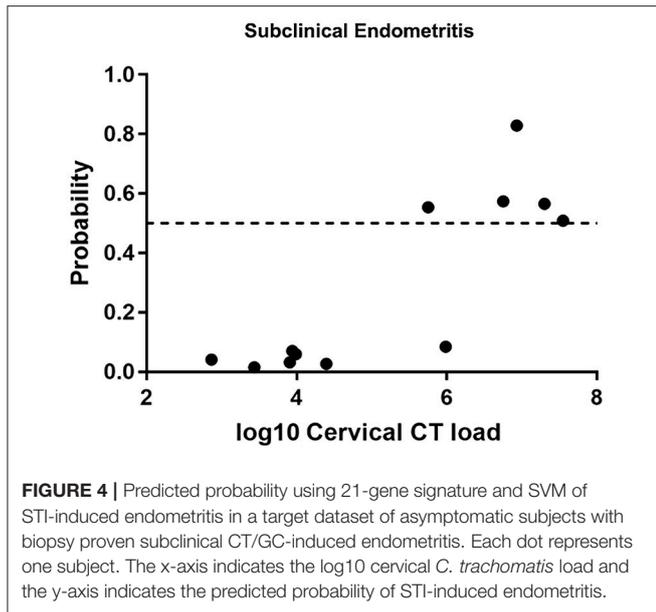

We evaluated the ability of the biomarker panel to diagnose subclinical STI-induced endometritis in asymptomatic women with endometrial infection and histologic evidence of endometritis (Figure 4). Among 12 asymptotically infected women with endometritis, six had high cervical CT burden. The biomarker correctly identified STI-induced endometritis in 5 (83.3%). However, no women with low cervical CT burden were predicted positive. To determine if high cervical bacterial load drives the transcriptional signature, we compared gene expression levels in a group of women with normal histology and cervix-limited CT who differed only with respect to high ( $N = 5$ ) vs. low burden ( $N = 11$ ). No genes were significantly differentially expressed ( $FDR \geq 0.3$ ) after multiple comparison correction, revealing high CT burden was insufficient to drive the transcriptional signature. These data demonstrated the biomarker's ability to detect endometritis in women with elevated cervical CT burden, in the absence of symptoms.

### The Biomarker Can Discriminate Between STI-Induced Endometritis and Pelvic Pain Without STI

Next, we evaluated the biomarker in a group of women with pelvic pain and tenderness consistent with a PID diagnosis (Workowski et al., 2015) but without STI. Endometrial biopsies revealed normal histology ( $n = 8$ ) or chronic endometritis

( $n = 7$ ) (Figure 5). All 8 women with pelvic pain and normal histology were predicted negative (100% specific), and 5 of 7 uninfected women with pelvic pain and chronic endometritis due to undetermined cause were predicted negative (71.4% specific). These data demonstrated the ability of the biomarker to discriminate women with STI-induced endometritis with 86.7% specificity overall.

### STI-Induced Endometritis Modules Are Preserved in a Cohort of Women Predicted Positive by the Biomarker

The biomarker was evaluated in 42 TECH-N study participants (Trent et al., 2016). All TECH-N participants were diagnosed with clinical PID; 15 had documented CT and/or GC infection. Almost all participants were African American (98%) with a median age of 19 years. Of the 42 women, 23.8% were predicted positive for STI-induced endometritis. Among the 15 women with cervical STI, 6 (40%) were predicted positive: 3 of 3 with GC infection (100%) and 3 of 12 with CT (25%). In contrast, 4 of 27 women without STI (14.8%) were predicted positive.

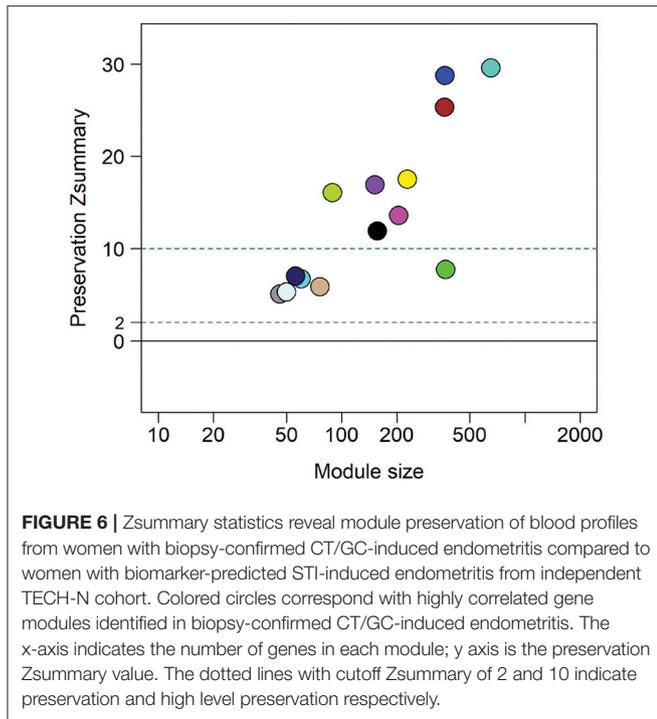

The absence of upper genital tract microbiological and histological data for this cohort prevented direct evaluation of biomarker accuracy. However, we performed an indirect assessment by determining if the gene expression profiles of the 8 predicted cases showed conservation of 14 module networks (highly correlated genes) identified in 14 biopsy-confirmed cases (Zheng et al., 2018). Preservation analysis revealed that 8 modules yielded a zSummary statistic  $> 10$ , reflecting strong conservation (Figure 6). We also performed differential network analysis using WGCNA to detect significant and concordant differences between biopsy-confirmed cases and controls and between predicted cases and controls (Table 4, significance of module enrichment in sectors determined by GSEA). Five modules were differentially expressed (FDR  $< 0.05$ , Table 4) between combined

sets of biopsy-confirmed cases ( $n = 14$ ) and controls ( $n = 28$ ). The top 4 modules were also differentially expressed (FDR  $< 0.05$ , Table 4) between predicted TECH-N cases ( $n = 8$ ) and predicted controls ( $n = 23$ ). Functional annotation of these modules (Table 4) was performed as before using IPA. STI-induced endometritis-associated genes and activated pathways detailed previously were replicated with overexpression of genes in myeloid cell and NF- $\kappa$ B activation pathways and integrin-linked kinase signaling; and suppression of T cell specific genes, and genes for protein synthesis and mitochondrial oxidative phosphorylation (Zheng et al., 2018). These findings indicated that the predicted cases recapitulated the STI-induced endometritis profile of biopsy-confirmed cases, providing further evidence that the biomarker reflects gene changes that occur in patients with STI-induced endometritis.

### The Biomarker Distinguishes STI-Induced Endometritis From Other Infectious and Inflammatory Conditions

The differential diagnosis of PID includes pain due to endometriosis, appendicitis, urinary tract infection, ovarian torsion, interstitial cystitis, and, less commonly, adnexal tumors. Of these diseases, transcriptional profiles were only available for appendicitis. The biomarker correctly identified 15 of 20 appendicitis patients (75%) as negative for STI-induced endometritis. Interestingly, patients with tuberculosis displayed substantial change compared to their healthy controls leading to

52.44% (43 out of 82) being wrongly identified as STI-induced endometritis. Accuracy was improved for patients with systemic infections caused by *Staphylococcus* (97.5%; 1 out of 40) or *Streptococcus* (100%; 0 out of 12), and for patients with lupus (96.4%; 2 out of 28); these patients showed minimal or no change in the biomarker compared to their healthy controls (Figure 7).

To determine overlapping response pathways between patients with STI-induced endometritis and those with appendicitis, we accessed whole blood gene expression profiles published in GEO of male and female patients with appendicitis and others with non-specific abdominal pain who served as controls (Chawla et al., 2016). Using IPA, we performed functional annotation of genes that were differentially expressed between these groups as determined by a moderated *t*-test. We compared the top 10 up- or down-regulated pathways in appendicitis patients and women with PID vs. each group's controls (Tables 5, 6). The top up-regulated pathway in women with STI-induced endometritis was interferon signaling, which was down-regulated in patients with appendicitis. Pathways related to myeloid cell activation were up-regulated in both disease states. Pathways enriched in mitochondrial genes and genes for protein synthesis were down-regulated for both patient groups. T cell signaling pathway genes were significantly down-regulated in STI-induced endometritis patients only.

## DISCUSSION

We previously characterized distinct blood mRNA profiles in STI-induced endometritis (Zheng et al., 2018) that indicated a pathway for biomarker discovery. We have extended our

findings by generating a biomarker that can identify women at high risk for STI-induced endometritis. We identified a 21 gene-panel that accurately identified symptomatic women with upper genital tract CT/GC and inflammation. This panel also accurately identified asymptomatic women with cervix-limited infection and uninfected women as controls, suggesting that the biomarker is not driven by cervical infection. We were able to determine STI-induced endometritis with 83.3% accuracy in asymptomatic women with high cervical CT burden. This demonstrates the ability of the biomarker to detect women with CT-induced, subclinical endometritis but the panel failed to identify women with low cervical burden who had endometritis, indicating that diagnostic sensitivity is positively associated with bacterial load. This suggests that the biomarker identifies women experiencing hyperinflammation (peak illness), while mild or moderate inflammation (initial or recovery phase) may be undetectable. This lack of sensitivity likely reflects restriction of CT infection to the reproductive tract mucosa. Since over 90% of CT infections are asymptomatic in women, identification of enhanced risk for endometritis in any infected woman, regardless of burden, would enhance clinical care by providing the patient with information related to their risk of long-term sequelae.

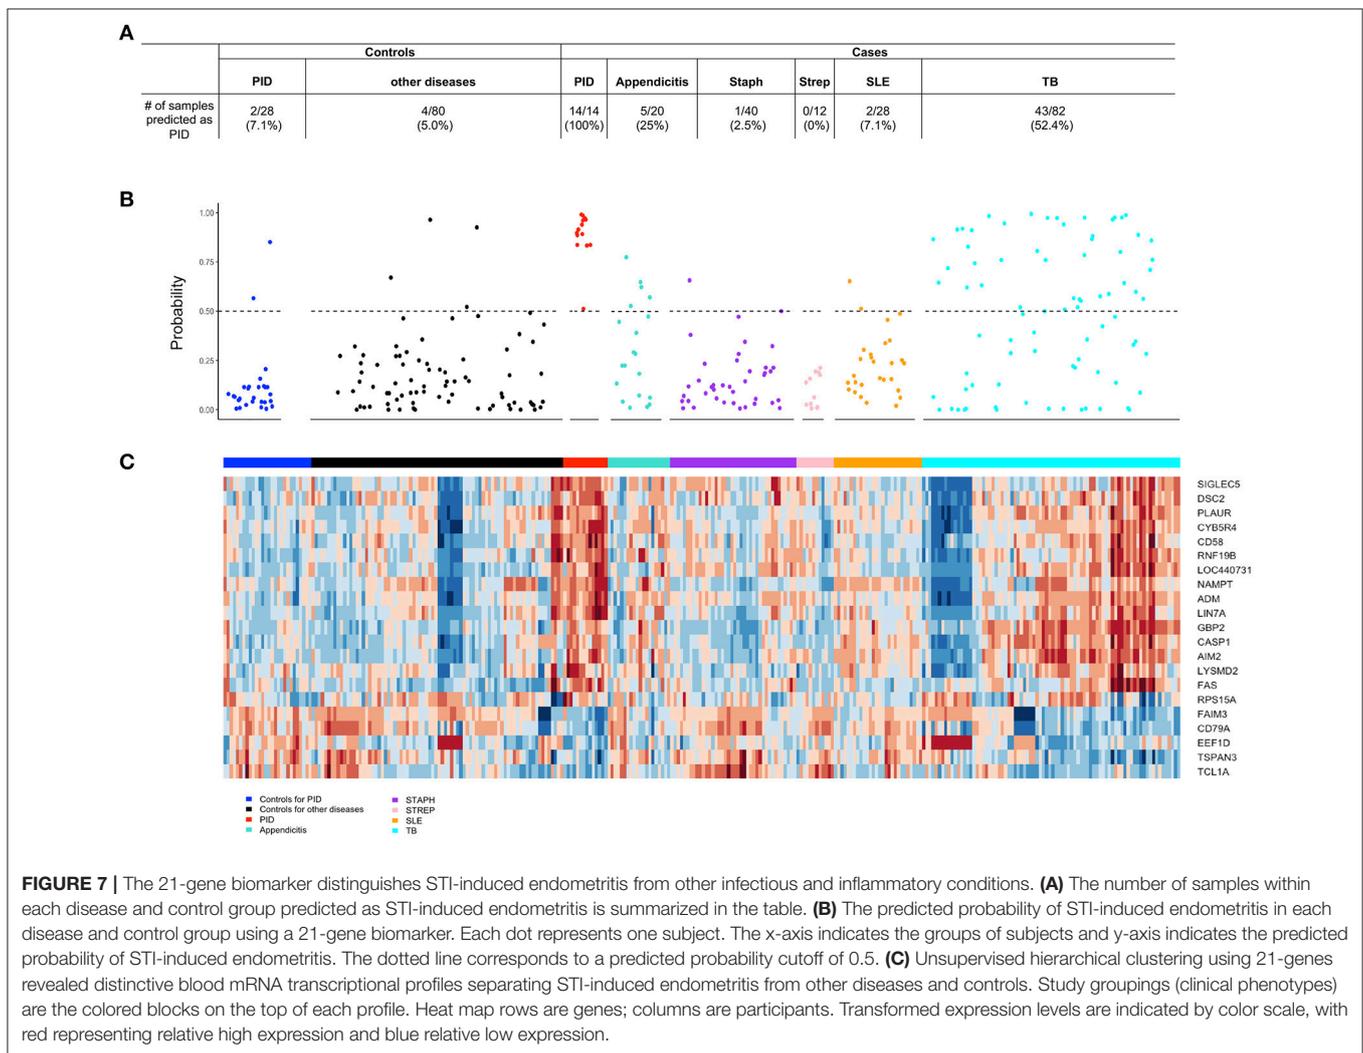

The biomarker correctly identified 100% of women with pelvic pain without infection and without endometritis as negative. Two of 7 STI-uninfected symptomatic women with chronic endometritis were predicted as cases. These misclassifications could reflect PID from infection by microorganisms not evaluated here (Haggerty et al., 2016) or recent resolution of STI before enrollment with residual endometritis. Six of seven had documented GC or CT infection history and two reported prior PID. In addition, using an independent cohort of women with clinically diagnosed PID and cervical CT/GC, the biomarker predicted 40% to have endometritis. This percentage is consistent with morbidity rates after PID (Price et al., 2013). Furthermore, disease-related modules differentially expressed in biopsy-confirmed cases and controls were also differentially expressed in biomarker-predicted cases and controls.

The biomarker successfully distinguished women with STI-induced endometritis from patients with streptococcal or staphylococcal infection, and lupus. Examination of pre-defined blood modular signatures has revealed that patients with lupus and streptococcal infection do not exhibit elevated inflammation transcripts (Berry et al., 2010) while patients with staphylococcal infection demonstrated enhanced inflammation transcripts but minimal change in IFN-inducible transcripts, and B- and T cell transcripts. STI-induced endometritis contrasted with all groups, characterized by enhanced inflammatory transcripts, including IFN-responsive genes, with significantly decreased T cell transcripts (Zheng et al., 2018). However, the biomarker was unable to reliably distinguish tuberculosis from STI-induced endometritis. The blood-derived modular signature of tuberculosis was paralleled in STI-induced endometritis, including enhanced IFN-inducible genes, myeloid inflammatory response genes, and decreased T cell transcripts. Fortunately, our biomarker was quite accurate at distinguishing STI-induced endometritis from appendicitis, which is in the differential diagnosis. The decrease in interferon signaling genes in

appendicitis patients likely provides increased specificity. In sexually active females presenting with abdominal pain, a negative result with the biomarker would suggest possible appendicitis rather than endometritis.

Limitations of our study included small sample size and absence of longitudinal data regarding development of

reproductive tract sequelae in women predicted to have STI-induced endometritis. A large independent cohort is warranted to validate the sensitivity and specificity. The biomarker was unable to detect women with endometritis who had low cervical bacterial burden, indicating the potential to miss women at risk for sequelae who may be in the early

phases of infection and inflammation, or are in a resolution phase.

PID diagnosis is based on clinical criteria and confounded by wide variation in symptoms. Furthermore, asymptomatic CT/GC-infected women may sustain endometrial infection and damaging inflammation (Wiesenfeld et al., 2012). No single test or combination of diagnostic indicators reliably identifies endometritis. The most specific criteria currently

available include endometrial biopsy with histopathologic evidence of endometritis, transvaginal sonography or magnetic resonance imaging showing thickened, fluid-filled tubes with or without free pelvic fluid or tubo-ovarian complex, or Doppler studies suggesting pelvic infection (e.g., tubal hyperemia); or laparoscopic findings consistent with PID, although this also requires endometrial biopsy if no visual evidence of salpingitis is present (Workowski et al., 2015). Although endometrial biopsies

can be performed with a suction pipelle, this procedure is difficult to perform routinely in the clinic, and laparoscopies require general anesthesia.

The nCounter Dx Analysis system (NanoString) used to confirm the mRNA results in this study, provides rapid, reliable, inexpensive, and reproducible molecular sub-grouping of clinical samples (Northcott et al., 2012; Veldman-Jones et al., 2015; Masucci et al., 2016). Results of the assay can easily be available within 24–48 h of obtaining blood from the patient. A blood biomarker that informs the clinician and the patient that the patient has upper genital tract inflammation coincident with their lower genital tract STI indicates increased risk for long term sequelae. This knowledge may prompt more intensive screening for STIs in that patient, with a goal to prevent long-term sequelae. A biomarker of STI-induced endometritis may also be used to monitor the benefit of novel therapies ancillary to antibiotic treatment, such as steroids or other anti-inflammatory medications, or as an end point to evaluate vaccines. Newer larger cohort and longitudinal studies that include evaluation of long-term sequelae are warranted to validate this biomarker.

## AUTHOR CONTRIBUTIONS

XJ designed the study and prepared the manuscript. CO designed the study and prepared the manuscript; She also oversaw preparation of specimens for analysis. WZ assisted with biostatistical analysis. TP and BT contributed to the preparation

of the final manuscript submission. HW, SH, MT, and CG contributed to recruitment, clinical evaluation and diagnosis of study participants. GT assisted with biostatistical analysis. TD designed the study and prepared the manuscript.

## FUNDING

This work was supported by the National Institutes of Health [U19 AI084024 and R33 AI098660 and AI119164 to TD; and U19 AI113170 to XZ; and the National Institute of Nursing Research NR013507 to MT].

## ACKNOWLEDGMENTS

We thank the women who agreed to participate in the contributing studies; Allison Collins, Abi Jett, Melinda Petrina, Carol Priest, Ingrid Macio, and Lorna Rabe for their efforts collecting and processing samples; Antonio J. Amortegi and Giuliana Trucco for pathological assessments, the staff at the Allegheny County Health Department STD Clinic and staff of the Emergency Departments at Mercy Hospital of Pittsburgh and Magee-Womens Hospital of UPMC; the staff of the Center for Adolescent and Young Adult Health at Harriet Lane, Pediatric Emergency Department, and the Adult Emergency Department at Johns Hopkins Hospital; and the staff of the Genomics Cores at the University of Pittsburgh and the University of North Carolina for their efforts.
