Grazing Reduces
the Soil-Atmosphere Exchange
of Greenhouse Gases During
Freeze-Thaw Cycles in Meadow
Steppes in Inner Mongolia.
Front. Ecol. Evol. 9:795203.
doi: 10.3389/fevo.2021.795203

Both livestock grazing and soil freeze-thaw cycles (FTCs) can affect the soil-atmosphere exchange of greenhouse gases (GHGs) in grasslands. However, the combined effects of grazing and FTCs on GHG fluxes in meadow steppe soils remain unclear. In this study, we collected soils from paired grazing and enclosed sites and conducted an incubation experiment to investigate the effect of grazing on soil GHG fluxes in the meadow steppes of Inner Mongolia during three FTCs. Our results showed that FTCs substantially stimulated the emissions of soil N₂O and CO₂ and the uptake of CH₄ in the meadow steppes. However, compared with enclosure treatments, grazing significantly reduced the cumulative N₂O, CO₂ and CH₄ fluxes by 13.3, 14.6, and 26.8%, respectively, during the entire FTCs experiment. The soil dissolved organic carbon (DOC) and nitrogen (DON), NH₄⁺-N and NO₃⁻-N, significantly increased after three FTCs and showed close correlations with N₂O and CO₂ emissions. Structural equation modeling (SEM) revealed that the increase in NO₃⁻-N induced by FTCs dominated the variance in N₂O emissions and that DOC strongly affected CO₂ emissions during thawing periods. However, long-term grazing reduced soil substrate availability and microbial activity and increased soil bulk density, which in turn decreased the cumulative GHG fluxes during FTCs. In addition, the interaction between grazing and FTCs significantly affected CO₂ and CH₄ fluxes but not N₂O fluxes. Our results indicated that livestock grazing had an important effect on soil GHG fluxes during FTCs. The combined effect of grazing and FTCs should be taken into account in future estimations of GHG budgets in both modeling and experimental studies.

Keywords: grazing, freeze-thaw cycles, nitrous oxide, carbon dioxide, methane, meadow steppe

INTRODUCTION

Greenhouse gases (GHGs), including carbon dioxide (CO₂), methane (CH₄) and nitrous oxide (N₂O), can significantly promote climate warming on Earth. Upland soils normally serve as a major source of N₂O and CO₂ but a sink for CH₄ to atmosphere (Holst et al., 2008). Recent studies have reported that soil GHG fluxes vary substantially both spatially and temporally

(Wagner-Riddle et al., 2017; Congreves et al., 2018), which is attributed to the crucial biophysical processes in soil and their responses to external environmental factors (Smith et al., 2018; Jalaludin et al., 2020). For example, short-term N₂O pulse emissions triggered by fertilization, soil freeze-thaw events or soil rewetting can dominate the annual GHG budget in a variety of terrestrial ecosystems (Wolf et al., 2010; Kostyanovsky et al., 2019; Gu et al., 2021).

Freeze-thaw cycles (FTCs), which occur predominantly in the soils of some temperate and most high-latitude and high-altitude regions, can greatly affect soil-atmosphere exchange of GHGs in the soil (Smith et al., 2018; Li et al., 2021). Previous studies have observed increased emissions of N₂O and CO₂ and uptake of CH₄ during soil FTCs both in field investigations and laboratory incubations (Goldberg et al., 2010; Wu et al., 2020). For instance, researchers have reported that more than 50–70% of the annual cumulative N₂O emissions may originate from FTCs (Goldberg et al., 2010; Wu et al., 2014a). Several mechanisms can potentially explain the release of soil GHG fluxes during FTCs: the release of previously generated gases from the unfrozen parts of the soil during soil thawing (Congreves et al., 2018), the increased available carbon and nitrogen substrates (de Bruijn et al., 2009) and the changes in the microbial community during FTCs (Hu et al., 2015). However, the contribution of the mechanisms to the soil GHG exchanges is not well quantified (Congreves et al., 2018).

Grasslands cover nearly 26% of the global land area and account for a large proportion of the global terrestrial carbon and nitrogen pools (Wu et al., 2014a). Grazing is the main anthropogenic management practice applied to grasslands. It has important impacts on various grassland ecological processes, mainly through animal feed intake, excreta deposition and grass trampling (Liu et al., 2021). Field investigations have found that grazing could reduce annual N₂O and CO₂ emissions and CH₄ uptake from grassland soils, which might attribute to the decrease in gas diffusion and the reduction in the microbial biomass, organic carbon and nitrogen contents of the soil, especially for long-term and heavy grazing (Wolf et al., 2010; Chen et al., 2011; Abdalla et al., 2018). Although a large proportion of grasslands worldwide suffered from freeze-thaw events (Holst et al., 2008; Chen et al., 2021), the effects of grazing on the soil-atmosphere exchange of GHGs during FTCs are not well understood.

The semi-arid grasslands of Inner Mongolia cover more than 20% of the total grassland area in China and are representative of the Eurasian grassland belt (Wang et al., 2005). Meadow steppe is one of the local major grassland types, which covers approximately 11% of the Inner Mongolia grassland (Han et al., 2008), and is highly sensitive to climate change and anthropogenic activities (Wu et al., 2020). For example, anthropogenic disturbances, such as over-grazing resulting from the rapid growth in population and food demand in recent decades, may have significantly affected soil carbon and nitrogen turnover, and GHG fluxes. Moreover, previous field studies have shown that soil FTCs are frequently observed in this region from late October to April and have a strong influence on soil-atmosphere GHG exchanges (Holst et al., 2008; Wolf et al., 2010). Although the separate effects of livestock grazing and FTCs on

soil GHG fluxes have been well studied, the combined effect of grazing and FTCs on soil GHG fluxes remains uncertain, especially for the meadow steppes of Inner Mongolia.

Therefore, to better understand the effect of livestock grazing on soil GHG fluxes during FTCs, we collected intact soil cores from three paired grazing and enclosed sites in meadow steppes in Inner Mongolia and then conducted three consecutive FTCs. The main objectives of this study were to investigate the effect of livestock grazing on soil GHG fluxes and to reveal the key soil properties that determine GHG fluxes during FTCs. We proposed three hypotheses: (1) soil FTCs will stimulate the emissions of N₂O and CO₂ and the uptake of CH₄ by meadow steppe soils; (2) livestock grazing might reduce the soil-atmosphere exchange of GHGs during FTCs; and (3) grazing and FTCs might have an interactive effect on soil GHG fluxes.

MATERIALS AND METHODS

Study Area and Soil Sampling

Hulunbair grassland (47°05′–53°20′ N, 115°31′–126°04′ E) is a typical semi-arid grassland in Inner Mongolia, which is selected as the research area. It is located in the western part of the Greater Khingan Mountains. The topography is relatively flat, with an altitude of 650–700 m above sea level. Chernozem and Kastanozem are the main soil types in this region (Wu et al., 2014b). The study area is dominated by *Aneurolepidium chinense*, *Stipa baicalensis*, and *Carex korshinskyi*. The area experiences a temperate continental monsoon climate, and the mean annual precipitation is 339 mm, of which approximately 60% falls in summer (June to September). The average annual air temperature was –2.2°C from 1980 to 2010, and the intra-annual range was from –25.8°C in January to 19.3°C in July. Due to the low temperature in winter, the topsoil normally begins to freeze in mid-October and thaws in the following April.

In late September 2015, three sites with similar soil type, land use history and plant species were chosen to account for spatial heterogeneity in this region. At each site, plots were established in pairs, that was a long-term free grazing plot and a nearby enclosed plot (ungrazed since 2008). Before fencing in 2008, all sites had been continuously grazed with approximate 1–3 sheep unit hm^{–1} yr^{–1} over last decades according to local farmers. The free grazing plots were continually grazed when the soil was sampled. The distance between plots in each site ranged approximately 100–200 m. All the paired plots have the same soil type and similar physiographic conditions, including slope degree, altitude and topography. The average ground covers were about 40 and 85% for long-term grazing and enclosed plots, respectively. The location and the main characteristics of each site are shown in **Supplementary Table 1**. The dominant vegetation in three enclosed plots was *Aneurolepidium chinense*. The dominant species in free grazing plots were *Carex pediformis* and *Stipa baicalensis*. The average bulk density of 0–10 cm soil depth in enclosed plots and grazing plots was 1.13 g cm^{–3} and 1.19 g cm^{–3}, respectively. The size of each plot was about 100 m × 100 m, and the internal plant community was investigated by the line transect method. In each plot, we

selected three sampling subplots (1 m × 1 m) at a distance of 15 m along a random transect. Within each subplot, the surface litter was carefully collected and then the aboveground biomass was harvested by scissors. Subsequently, the root biomass was collected from 3 sampling points to a depth of 30 cm in the main rooting zone with a 5 cm diameter soil auger. Moreover, three replicate intact soil cores (15 cm inner diameter and 20 cm height) were collected from each sampling plot by PVC tubes (15 cm inner diameter and 30 cm height, 3 sites × 2 treatments × 3 replicates = 18 in total) after removing surface vegetation and litter. The top 10 cm of the PVC tubes was left empty for the measurements of trace gas fluxes. The tubes were carefully driven into the soil in order to alleviate inside soil compaction. In addition, we also collected 21 intact soil samples (7 measurements with three replicates, **Figure 1**) in each plot with a soil sampler (5 cm diameter and 10 cm height, 3 sites × 2 treatments × 21 samples = 126 in total) for the continuous analyses of soil chemical and microbial characteristics during FTCs. The 18 intact soil cores and 126 soil samples were stored at a constant temperature of + 4.0°C in laboratory before the freeze-thaw experiments to allow the adaption of soil microbiome to cold temperatures.

Freeze-Thaw Incubation Experiments

All incubation experiments were conducted in incubators (JYH-412F, Jiayu Instrument Co., Ltd., China), which can periodically adjust the temperature to simulate FTCs. In order to prevent the inside gas accumulation, a pump was used to mix together the inside air and the outside air. The external sidewall and bottom of each PVC tube were covered with 2.0 cm thick insulative material (Armaflex, Armacell GmbH, Münster, Germany) to mitigate the temperature fluctuations from sidewalls and bottoms. We set the beginning temperature at 5.0°C for 5 days to activate the microbes and to ensure stable GHG fluxes. Subsequently, three FTCs were stimulated to investigate the effect of livestock grazing on soil GHG fluxes during sequential FTCs. According to the field observations of the study area, the temperature in each cycle was set to - 10°C for 7 days followed by + 5°C for the next 7 days. Using the sensors inserted through the 5 cm depth holes in the soil cores, the soil temperatures were recorded hourly with a data logger. The soil water content for all soil cores and samples was maintained at the same level as in the field. The average water-filled pore space (WFPS) of the grazing and enclosed plots was 41.6 and 47.8%, respectively. Considering that the soil water content would decrease due to evaporation during the experimental period, we weighed the soil cores and samples daily and compensated the lost weight by spraying deionized water on the soil surface.

The parallel incubation was conducted in the same time for the 126 soil samples that were used for the analysis of chemical and microbial characteristics. The concentrations of soil dissolved organic carbon (DOC) and nitrogen (DON), NH₄⁺-N and NO₃⁻-N, microbial biomass carbon (MBC) and nitrogen (MBN) were determined by the destructive harvesting of triplicate soil samples at day 3, 9, 16, 23, 30, 37, and 44 for GHG fluxes measurements throughout the entire incubation period.

Gas and Soil Analysis

Static chamber method was used to determine the soil N₂O, CO₂ and CH₄ fluxes at daily resolution. The PVC tubes were sealed with stainless steel lids to enclose a headspace of about 1.8 L. Each lid was equipped with a circulating fan to completely mix the gas in the headspace and a rubber stopper was used for sampling gases. At 0, 10, 20, 30, and 40 min after the lid was closed, five 10 mL gas samples were collected from the headspace of chamber with gas-tight syringes. The gas samples were analyzed within 8 h using a gas chromatograph (Agilent 7890 A, California, United States). N₂O was detected by electron capture detector, and CO₂ and CH₄ were detected by flame ionization detector. The DN-Ascarite and DN-CO₂ methods described by Yao et al. (2010) were utilized for N₂O analysis. The fluxes were calculated according to the change rate of the gas concentration in the headspace of enclosed chamber with time. When the valid measurement value of gas concentration was fewer than five times, or significant non-linearity was not detected, linear regression was used to calculate the fluxes. Otherwise, the non-linear model ($C_t = k_1/k_2 + (C_0 - k_1/k_2) \times \exp(-k_2t)$, where C_0 is the N₂O concentration at the beginning of the enclosure, and k_1 and k_2 are the fitting parameters) proposed by Kroon et al. (2008) was used. The cumulative gas fluxes during each FTC and all three FTC periods were then calculated as the sum of daily fluxes.

The soil water content was determined by weight loss method and dried the soil samples at 105°C for 24 h. The soil pH was measured using a pH meter (PHS-25, Shanghai, China) with soil:water ratio at 1:5. The soil TN and SOC contents were determined using an automated C and N analyzer (Elementar, Hanau, Germany). Soil ammonium (NH₄⁺-N) and nitrate (NO₃⁻-N) were extracted from 20 g of fresh soil with 1 M KCl (soil: water = 1:5 w/v) and quantified colorimetrically using a flow injection analyzer (Seal AA3, Norderstedt, Germany). The MBC and MBN contents in the soil samples were measured using the chloroform fumigation-extraction method (Wu et al., 2014a).

Statistical Analyses

All data are presented as the mean and the standard error of the mean unless otherwise stated. The data were tested for normality (Kolmogorov-Smirnov test) and homogeneity (Levene's test) before analysis. Pearson correlations and analysis of variance (ANOVA) of soil properties and GHG fluxes following the Student-Newman-Keuls (SNK) test were performed in SPSS 21 (IBM, Armonk, NY, United States). One-way ANOVA was performed to examine the effect of FTCs on the basis of the soil properties before and after the complete FTC experiment. Two-way ANOVA was conducted to test the effect of grazing, FTCs and their interaction on the fluxes of the three gases. In addition, one-way ANOVA was used to test the effect of grazing on the total cumulative fluxes of the three gases during the FTC experiment. Differences were considered statistically significant at $P < 0.05$. Scatter diagrams and bar plots were generated in OriginPro 2018 (Origin Lab Corporation, United States). The joint statistical analysis of the GHG fluxes and soil properties in the form

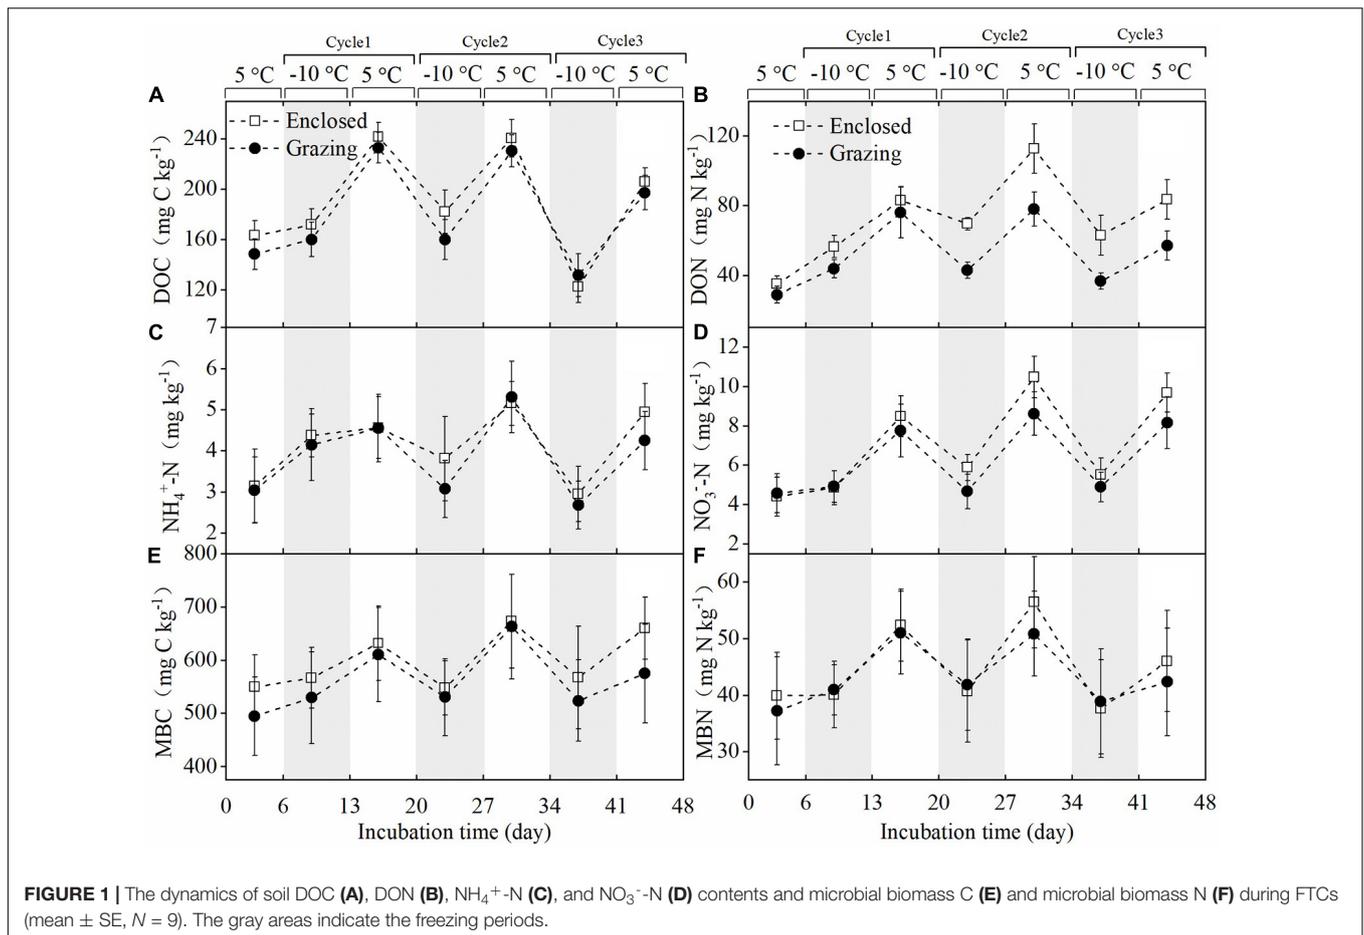

FIGURE 1 | The dynamics of soil DOC (A), DON (B), $\text{NH}_4^+\text{-N}$ (C), and $\text{NO}_3^-\text{-N}$ (D) contents and microbial biomass C (E) and microbial biomass N (F) during FTCs (mean \pm SE, $N = 9$). The gray areas indicate the freezing periods.

of scatterplots and structural equation modeling was matched according to the same sampling time. The scatterplot matrix was mapped with scatterplotMatrix function in the “car” package using R3.4.3. Structural equation modeling (SEM) was used to examine the direct and indirect effects of grazing, FTCs and soil properties on the daily GHG fluxes. The structural equation models were constructed and analyzed using R3.4.3 with the sem.fit and sem.lavaan functions in the “lavaan” and “piecewiseSEM” packages.

RESULTS

Effect of Freeze-Thaw Cycles and Grazing on Plant and Soil Characteristics

The aboveground, litter and belowground biomass were significantly lower in the grazing treatments than in the enclosed treatments, but the soil bulk density in the grazing treatments was significantly higher (Supplementary Table 1). There was no significant difference in pH between the grazing and enclosed treatments. Soil DOC and DON were significantly lower ($P < 0.05$) in grazing treatments than those in enclosed treatments before the FTCs (Supplementary Table 2). However, the $\text{NH}_4^+\text{-N}$, $\text{NO}_3^-\text{-N}$, MBC, and MBN contents showed

no significant differences between grazing and enclosed treatments before the FTCs. As shown in Figure 1, in the first FTC, the contents of DOC, DON, $\text{NH}_4^+\text{-N}$, $\text{NO}_3^-\text{-N}$, MBC, and MBN increased in both the freezing and subsequent thawing periods compared to those in the pre-incubation period, whereas in the second and third FTCs, the contents of the above soil chemicals declined during soil freezing but increased in the following thawing period. In general, after three consecutive FTCs, the contents of DOC, DON, $\text{NH}_4^+\text{-N}$, and $\text{NO}_3^-\text{-N}$ were significantly increased in both the grazing and enclosed treatments (Table 1). The contents of MBC and MBN increased only slightly after three FTCs compared with those at the beginning of the experiment, and the changes were not significant.

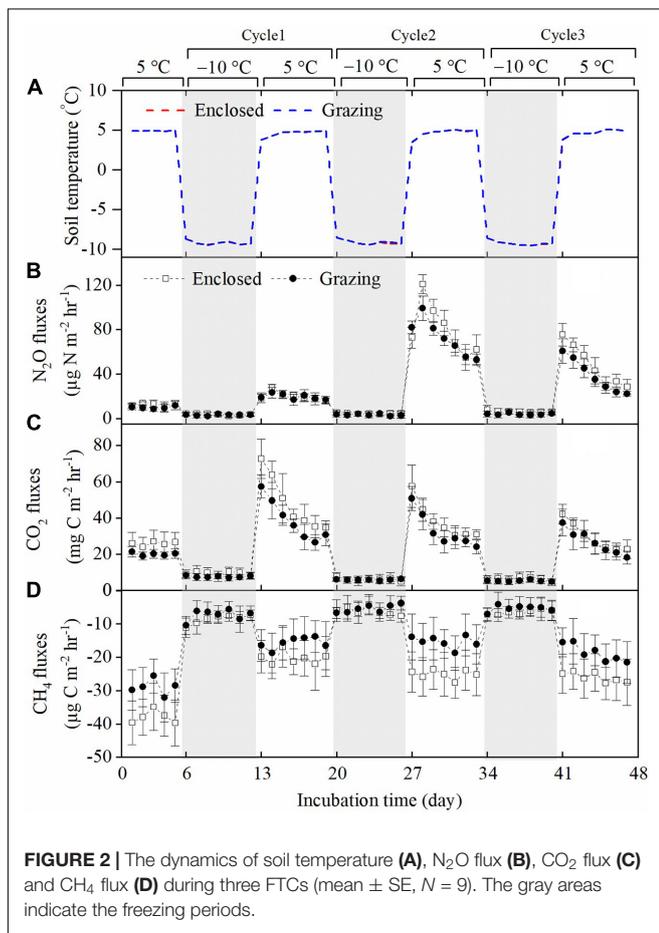

Dynamics of N_2O Flux During Freeze-Thaw Cycles and the Impact of Grazing

The daily N_2O flux ranged from 0.10 to 114.87 $\mu\text{g N m}^{-2} \text{h}^{-1}$ in the grazing treatments and from 1.04 to 127.80 $\mu\text{g N m}^{-2} \text{h}^{-1}$ in the enclosed treatments during the whole incubation period (Figure 2). In the freezing periods, the N_2O emissions were reduced compared to those in the pre-incubation period, and N_2O emissions were substantially promoted in the three thawing

periods. By comparison, the peak N₂O emission value was relatively low in the first thawing period, was highest in the second thawing period and was lower in the third thawing period. In addition, during the three thawing periods, the daily N₂O flux was lower in the grazing treatments than in the enclosed treatments. After three FTCs, grazing significantly reduced the total cumulative N₂O flux by 13.3% (average 23.60 mg N m⁻² in the grazing treatments and average 27.22 mg N m⁻² in the enclosed treatments) ($P = 0.020$, **Figure 3**). Two-way ANOVA (**Table 2**) showed that FTCs had a significant effect on the daily N₂O flux ($P < 0.001$); however, the effect of grazing was not

significant ($P = 0.284$), nor was the interaction between grazing and FTCs ($P = 0.512$).

Dynamics of CO₂ Flux During Freeze-Thaw Cycles and the Impact of Grazing

The range of the daily CO₂ flux was 3.03~68.72 mg C m⁻² h⁻¹ in the grazing treatments throughout the incubation period; among the enclosed treatments, the range was 2.07~91.48 mg C m⁻² h⁻¹ (**Figure 2**). Similarly, the daily CO₂ flux was quite low in frozen soils (< 15 mg C m⁻² h⁻¹) but significantly increased during thawing periods. The peak value of CO₂ emissions occurred in the first thawing period, and CO₂ emissions gradually declined with the sequence of FTCs. The daily CO₂ flux was continuously lower in the grazing treatments than in the enclosed treatments in the three thawing periods. Grazing significantly reduced the total cumulative CO₂ flux (by 14.6%), which was 19.7 g C m⁻² in the grazing treatments and 23.09 g C m⁻² in the enclosed treatments ($P = 0.01$, **Figure 3**). According to the two-way ANOVA (**Table 2**), FTCs had a significant impact on the daily CO₂ exchange ($P < 0.001$); grazing and the interaction between FTCs and grazing also had significant impacts ($P = 0.004$, $P = 0.048$).

Dynamics of CH₄ Flux During Freeze-Thaw Cycles and the Impact of Grazing

The flux of CH₄ was consistently negative, meaning that CH₄ was absorbed by the meadow steppe soil. In the grazing treatments and enclosed treatments, the CH₄ flux ranged from -39.90 to -0.04 and from -49.39 to -0.13 µg C m⁻² h⁻¹, respectively, during the whole incubation period (**Figure 2**). The CH₄ flux also decreased in freezing periods and increased when the soil thawed, while the peaks of the CH₄ uptake rate gradually increased along the sequence of FTCs. The daily CH₄ uptake in thawing periods was consistently lower in the grazing treatments than in the exclusion treatments. Consequently, compared to that in the exclusion treatments, the total cumulative CH₄ uptake in the grazing treatments was significantly reduced, by 26.8% (11.40 mg C m⁻² compared to 15.58 mg C m⁻², $P < 0.001$, **Figure 3**). Two-way ANOVA indicated that FTCs, livestock grazing and their interaction

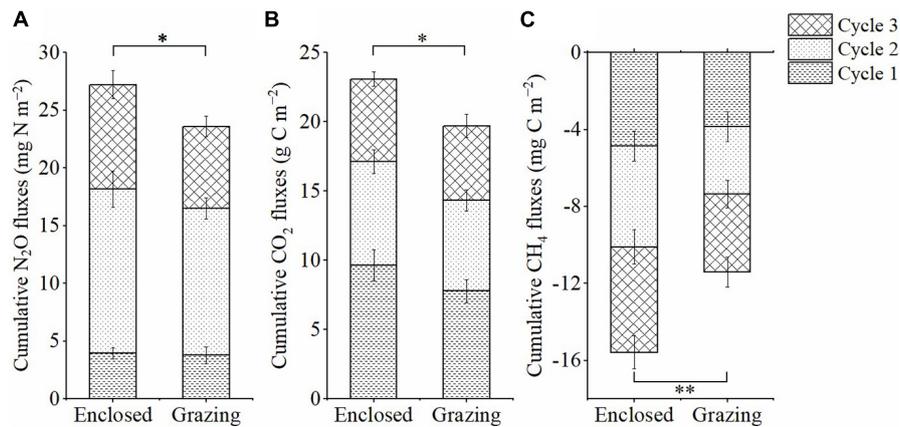

FIGURE 3 | Total cumulative fluxes of N₂O (A), CO₂ (B) and CH₄ (C) during three FTCs (mean ± SE, N = 9). Symbol "*" indicate significant differences ($P < 0.05$) and "**" indicate notable significant differences ($P < 0.01$) between grazing and enclosed treatments.

TABLE 2 | Two-way ANOVA of the effects of FTCs, grazing and their interaction on soil N₂O, CO₂ and CH₄ fluxes during FTCs.

P-values	N ₂ O	CO ₂	CH ₄
FTCs	< 0.001	< 0.001	< 0.001
Grazing	0.284	0.004	< 0.001
FTCs * Grazing	0.512	0.048	< 0.001

Significant effects ($P < 0.05$) are highlighted in bold.

effect all had significant impacts on CH₄ uptake (Table 2, $P < 0.001$).

Effects of Grazing and Freeze-Thaw Cycles on Soil Properties and Greenhouse Gases Fluxes

In the scatterplot matrix (Figure 4), the correlation coefficients between soil chemical and microbial properties and the daily GHG flux are provided in the upper right corner, while the subfigures in the lower left show the smooth fitting curves between the two variables on the diagonal line. The correlations between soil properties and the daily N₂O and CO₂ fluxes were significant, but for CH₄ uptake, the edaphic effects were not significant.

SEM showed that the FTCs had a significant positive effect on soil DOC and NO₃⁻-N ($r = 0.64$, $P < 0.001$; $r = 0.58$, $P < 0.001$), thus stimulating the N₂O flux (Figure 5A), but that grazing had a negative effect on soil DOC, NO₃⁻-N and N₂O fluxes. The standardized total effect of NO₃⁻-N was the highest (Figure 5B), which suggested that soil NO₃⁻-N dominated the variance in N₂O exchange during the FTCs ($r = 0.71$, $P < 0.001$). FTe in grazing plots compCs significantly promoted CO₂ emissions by increasing the soil DOC and MBC contents ($r = 0.66$, $P < 0.001$; $r = 0.35$, $P < 0.001$), while grazing had negative effects on CO₂ emissions (Figure 5C). DOC and MBC were positive influencing factors on CO₂ emissions ($r = 0.28$, $P < 0.001$; $r = 0.25$, $P < 0.001$), with DOC playing a more

important role (Figure 5D). However, for CH₄ uptake, the fitness index (RMSEA = 0.192) failed to meet the requirements of SEM (RMSEA < 0.08), indicating that the proposed soil chemical factors could not explain the variation in CH₄ fluxes during FTCs (Figures 5E,F).

DISCUSSION

Effect of Grazing and Freeze-Thaw Cycles on N₂O Fluxes

Our study detected the stimulation of soil N₂O emissions during FTCs, which is consistent with the results of previous studies in various ecosystems, including grasslands (Wang et al., 2005; Yao et al., 2010), wetlands (Wang et al., 2013) and forests (Goldberg et al., 2010). The substantial enhancement of N₂O emissions following soil thawing in the meadow steppe can be basically explained by several physical factors. First, the expansion of the WFPS leads to increased anaerobic volume, thus favoring N₂O production through denitrification (Bollmann and Conrad, 1998; Yin et al., 2020). Second, it has been well documented that the N₂O emission rate rises exponentially with soil temperature (Yao et al., 2010; Smith et al., 2018). In addition, when soil thaws, the substrate accumulated during the previous freezing period may activate N₂O-producing soil microbes (Chen et al., 2021), which can be justified by the increased DOC and NO₃⁻-N content induced by FTCs and the strong positive correlation between NO₃⁻-N content and N₂O emissions during FTCs. However, SEM showed that DOC had a weak negative effect on N₂O emissions. Denitrification normally starts to occur at 60% WFPS and higher (Wu et al., 2020), thus leading to N₂O emissions. DOC, as the carbon source for heterotrophic denitrifying bacteria, is widely considered to have a positive effect on N₂O emissions when the denitrification process is dominant (Khalil et al., 2004). In this study, under WFPS levels from 41.6 to 47.8%, nitrification and denitrification may occur simultaneously and lead to N₂O release; therefore, DOC did

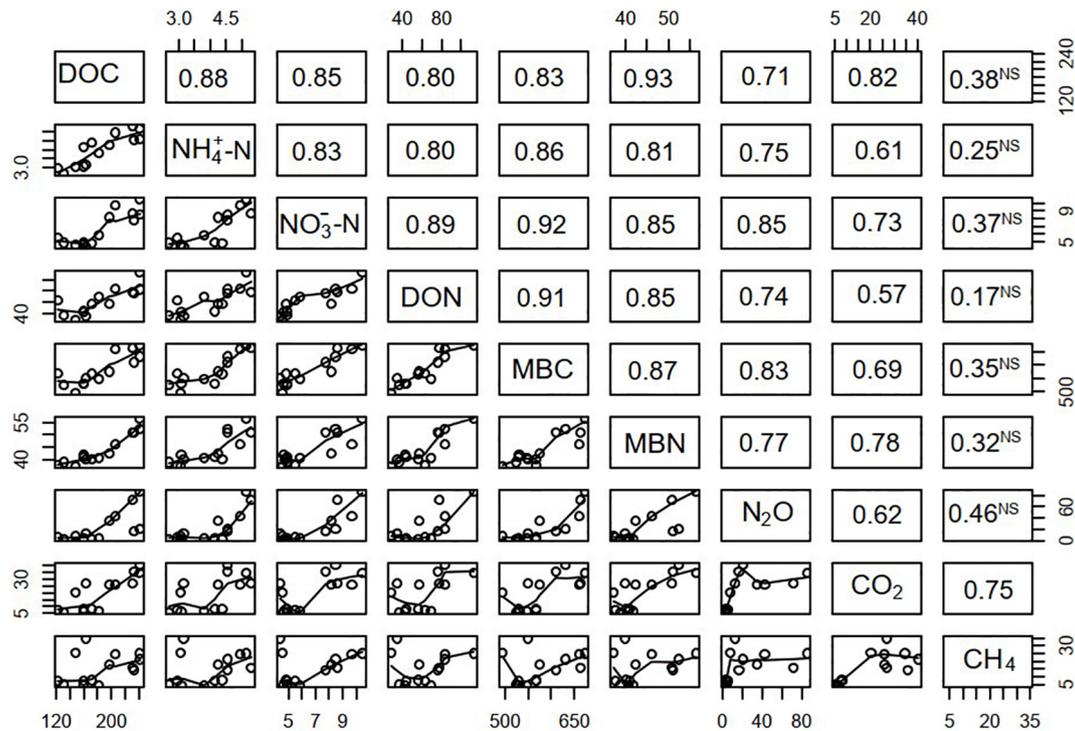

FIGURE 4 | Scatterplot matrix showing the Pearson correlation coefficients between the fluxes of N₂O, CO₂, and CH₄ and soil characteristics during FTCs. The upper right half of the matrix shows the correlation coefficients. The superscript "NS" next to the correlation coefficient indicates non-significance ($P \geq 0.05$); unmarked coefficients are significant ($P < 0.05$). The lower left half shows the scatterplots and smooth curves.

not show a significant effect on N₂O emissions. Taken together, physical mechanisms and the variations in substrate supply are predominantly responsible for the increased N₂O emissions during soil FTCs (Kim et al., 2012).

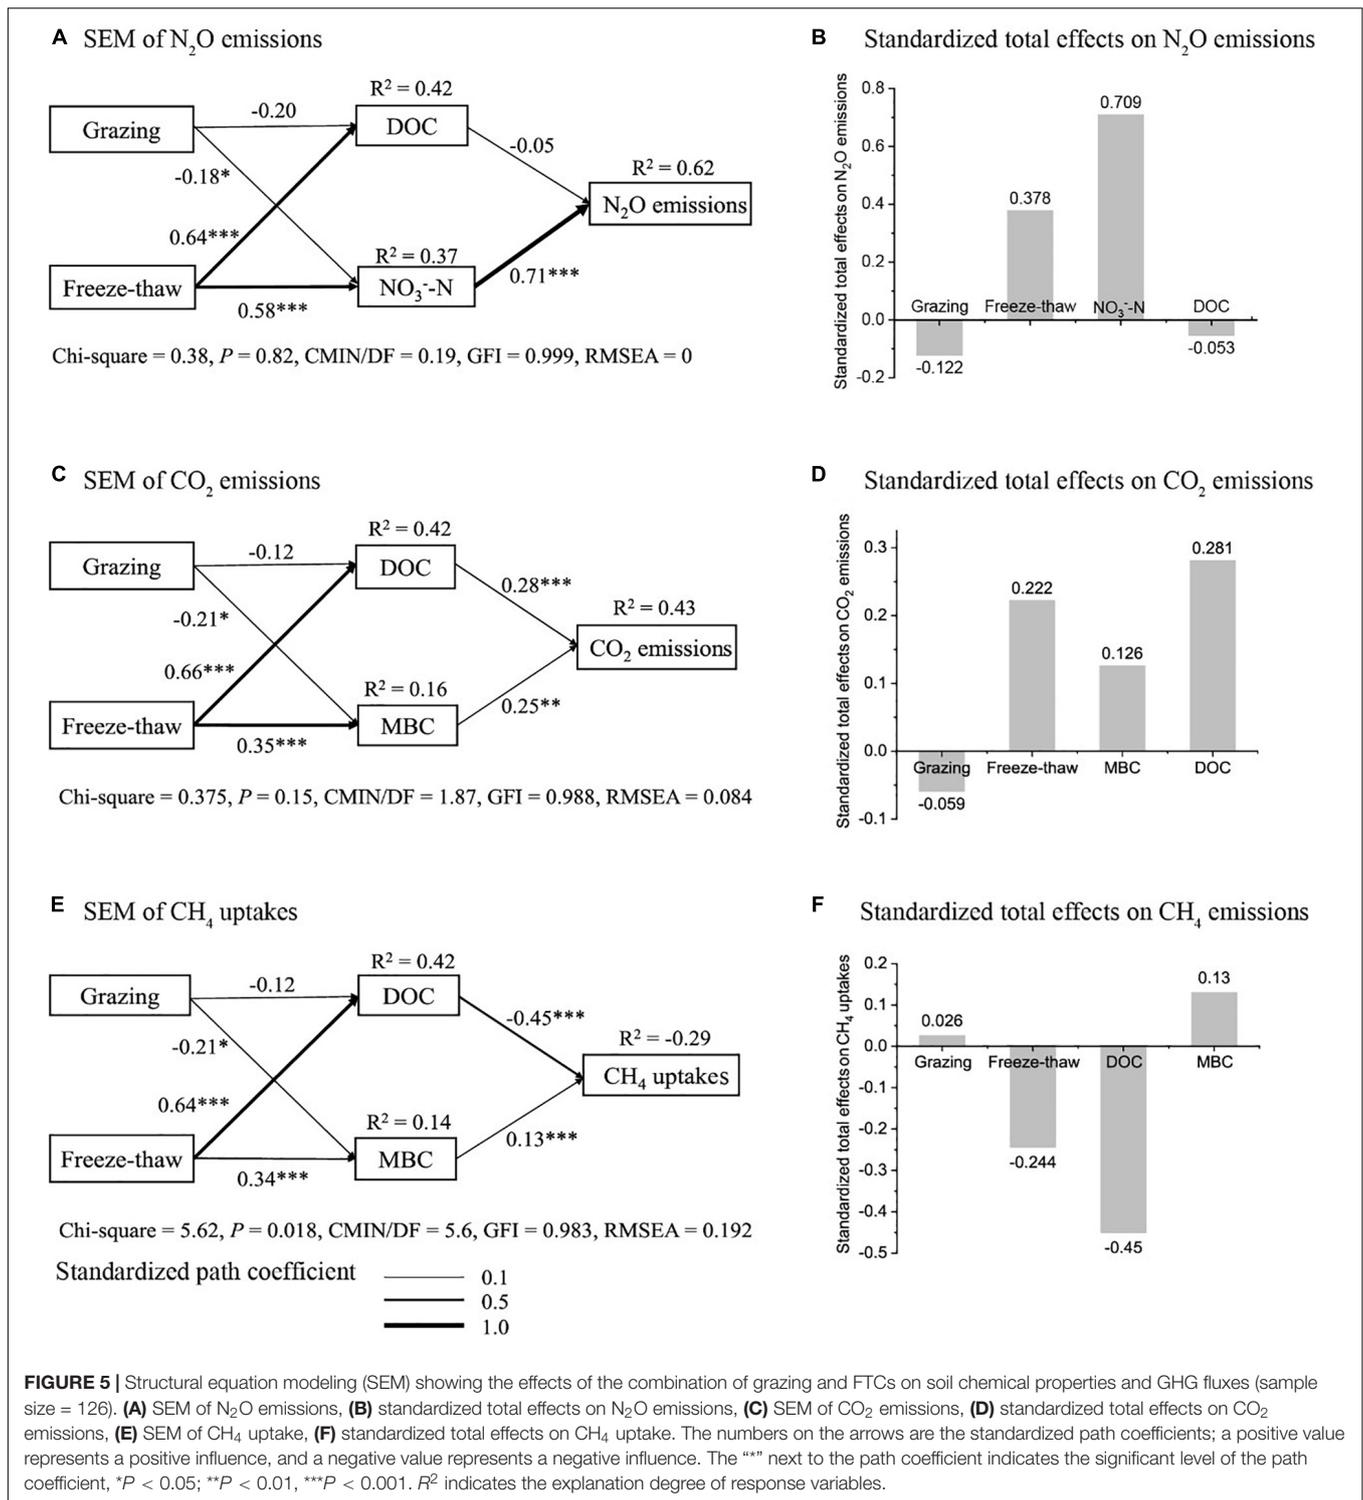

The total cumulative N₂O emissions were significantly lower in the grazing treatments than in the enclosed treatments during FTCs. As long-term grazing will reduce the aboveground vegetation biomass, the resulting lower litter input into the soil will reduce soil nitrogen availability (Liu et al., 2015). Moreover, it has been revealed that long-term grazing will lead to NO₃⁻-N leaching from soil more readily (Steffens et al., 2008). The lack of substrate may limit soil microbial nitrification and denitrification, thus reducing N₂O exchange. This inference can be justified by the SEM result showing that grazing had a negative effect on N₂O emissions through the mediating effect of DOC and NO₃⁻-N. In addition, livestock grazing can increase the soil bulk density (Steffens et al., 2008), as confirmed in this study. Consequently, the relatively limited soil aeration may result in the reduction of N₂O emissions under grazing conditions (Smith et al., 2018).

Effect of Grazing and Freeze-Thaw Cycles on CO₂ Fluxes

In this study, the soil respiration rates were also markedly enhanced during FTCs, which agreed with the findings of previous studies on grasslands (Chen et al., 2019; Wu et al.,

2020). The soil CO₂ emissions were low in the freezing periods and high in the subsequent thawing periods. A strong positive correlation ($r = 0.81$) was observed because the soil microbial respiration rate is driven mainly by soil temperature (Wu et al., 2014a). In addition, during freezing periods, soil aggregates are covered by a thin film of ice that reduces gas diffusivity (Kim et al., 2012; Congreves et al., 2018) and thereby inhibits soil respiration. Upon soil thawing, the release of accumulated substrates can substantially stimulate microbial respiration (Wu et al., 2020). Correlation analysis and SEM revealed the significant impacts of soil DOC and MBC contents on CO₂ fluxes during FTCs. Therefore, the physical conditions and increased DOC and MBC contents may explain the rising CO₂ emissions during FTCs in meadow steppe soils (Kim et al., 2012; Wu et al., 2014a).

Similar to previous studies on meadow steppe soils (Wu et al., 2020), we found reduced total cumulative CO₂ emissions in grazing treatments compared with those in enclosed plots during soil FTCs. One potential reason for this finding is that grazing had significantly reduced the aboveground and underground biomass (Supplementary Table 1), which in turn would cause a decline in soil labile carbon content as revealed by our results (Supplementary Table 2). These will reduce substrate availability for soil heterotrophic respiration (Yu et al., 2019). According to a global meta-analysis, heavy grazing leads to a 10.3% decline in soil organic carbon (Tang et al., 2019). SEM also confirmed that grazing can reduce CO₂ emissions by negatively

affecting soil DOC and MBC. Another possible reason could be the lower soil moisture in grazing plots compared to those in enclosed plots. It is well documented that the grazing-induced decrease in soil moisture could inhibit microbial activities, leading to reduced soil CO₂ emissions (Savadogo et al., 2007; Tian et al., 2016).

Effect of Grazing and Freeze-Thaw Cycles on CH₄ Fluxes

The soil CH₄ flux was consistently negative during FTCs, confirming a previous finding that meadow steppes function predominantly as a sink for atmospheric CH₄ (Chen et al., 2011). Similar to the CO₂ and N₂O fluxes, the soil CH₄ flux

was low during soil freezing and high during soil thawing, which was also observed in previous studies (Wu et al., 2014a). Soil-atmosphere CH₄ exchange is controlled by two opposite biological processes: methane oxidation induced by methanotrophs and methanogenesis induced by methanogens (Holst et al., 2008). However, because methanogens live mainly under anaerobic conditions, methanogenesis was considered negligible in this study. The CH₄ exchange in frozen soil was restricted mainly by low gas diffusivity, substrate availability and soil microbial enzyme activity (Chen et al., 2011; Smith et al., 2018). During soil thawing, the rising temperature and increased soil water availability have a strong stimulatory effect on CH₄-oxidizing microbes, therefore increasing CH₄ uptake in meadow steppes (Wu et al., 2010). The correlation analysis did not find a significant correlation between the contents of DOC, DON, MBC, or MBN and CH₄ fluxes during FTCs in our study area. Therefore, we recommend further research to identify additional potential factors that may drive microbial processes related to soil CH₄ oxidation during FTCs.

Compared to that in the enclosed treatments, the total cumulative CH₄ uptake in the grazing treatments was significantly lower during the three FTCs. This may be partly attributed to the lower soil gas diffusivity caused by animal trampling, since the availability of substrate gases (O₂ and CH₄) is essential for the soil microbial CH₄ oxidation process (Liu et al., 2007). Moreover, the biomass of CH₄-oxidizing bacteria may be lower in long-term livestock grazing sites due to the reduced carbon inputs from plants (Tracy and Frank, 1998). Considering that many soil characteristics can be markedly changed by grazing through herbivore species selection, plant rhizosphere exudation and animal excreta deposition (Clegg, 2006) but that only a few soil characteristics were measured in this study, the potential causes of the difference in CH₄ uptake between grazed and enclosed grasslands during FTCs have not yet been fully explained.

CONCLUSION

The results of our incubation experiments demonstrated that livestock grazing and soil FTCs had significant effects on soil-atmosphere exchange of GHGs in meadow steppes in Inner Mongolia. Although soil FTCs could substantially stimulate soil N₂O and CO₂ emissions and CH₄ uptake, long-term grazing significantly reduced the cumulative N₂O, CO₂ and CH₄ fluxes by 13.3, 14.6, and 26.8%, respectively, during the entire experiment. SEM revealed that the increase in NO₃⁻-N induced by FTCs dominated the variance in N₂O emissions and that

DOC strongly affected CO₂ emissions during thawing periods. These results suggest that the increase in substrate availability induced by FTCs can largely explain the increase in GHG fluxes. Moreover, long-term grazing reduced soil substrate availability and microbial activity and increased soil bulk density, which in turn decreased the cumulative GHG fluxes during FTCs. Therefore, our results suggested that the combined effect of grazing and FTCs should be taken into account for accurately estimating regional GHG budgets in meadow steppes.

DATA AVAILABILITY STATEMENT

The original contributions presented in the study are included in the article/**Supplementary Material**, further inquiries can be directed to the corresponding author/s.

AUTHOR CONTRIBUTIONS

FW, YC, and XW conceptualized this study and led the writing. TL, CW, and DW collected and analyzed the data. BF, YL, and XW interpreted the results and revised the text. All authors contributed to this work and approved the final manuscript before submission.

FUNDING

This study was supported by the National Natural Science Foundation of China (41773070 and 42041005), the Second Tibetan Plateau Scientific Expedition and Research Program (2019QZKK0308), and the Youth Innovation Promotion Association of the Chinese Academy of Sciences (2018056).

ACKNOWLEDGMENTS

We would like to thank the editor and the reviewers for valuable suggestions and comments to improve the previous version of the manuscript.
