*Macrobrachium rosenbergii* is an important cultured shrimp worldwide, and its precocious puberty has led to serious economic losses. Although reproductive sterilization can avoid this problem, little is known about the molecular mechanisms underlying gonadal development and gametogenesis in *M. rosenbergii*. Here, we conducted transcriptome analysis of the ovaries, testes, and male/female brain tissues of *M. rosenbergii* to discover germ cell development-related genes. A total of 60,607 unigenes were identified, of which 20,963 unigenes could be functionally annotated. Eighteen candidate genes were identified by Venn diagram analysis, keyword, and known marker search, followed by elimination of low-expression and repetitive genes. Subsequent real-time quantitative reverse transcription polymerase chain reaction and *in situ* hybridization identified five genes (*RAD51*, *vasa*, *SPDS*, *MRR*, and *Fem-1C*) associated with germ cell development—*RAD51*, *vasa*, and *SPDS* were expressed in both male and female gonads, whereas *Fem-1C* was specifically expressed in the ovary and *MRR* in the testis. In the ovary, *vasa*, *SPDS*, and *Fem-1C* were mainly expressed in stage 1–3 oocytes, while *RAD51* was expressed in stage 2–3 oocytes. In testis, *vasa* were significantly expressed in spermatogonia and primary spermatocytes, whereas *RAD51* and *SPDS* were only enriched in spermatogonia and *MRR* in vas deferens. Our research indicates that these five genes are important germ cell development-related

genes, of which *RAD51*, *SPDS*, and *Fem-1C* were proven to function in germ cells of this species for the first time. The discovery of these genes could help develop molecular breeding techniques to overcome precocious puberty in *M. rosenbergii*.

macrobrachium rosenbergii, transcriptome, germ cell, RAD51, Fem-1C, SPDS, vasa

## 1 Introduction

Giant freshwater prawns (*Macrobrachium rosenbergii*) are native to the Mekong River basin in Southeast Asia. Because of its rapid growth, large size, and delicious flavor, it has gradually become one of the main shrimp species in freshwater aquaculture in Asia. In China, the total annual output reached 171, 263 tons in 2021 (China Fishery Statistical Yearbook, 2022). Recently, the production of *M. rosenbergii* in China has increased to a certain extent; however, some key problems such as germplasm degradation and various diseases still affect the aquaculture industry of *M. rosenbergii* in China, and its industrial development has encountered certain bottlenecks.

Initially, our research team conducted a series of market research in China to identify the key bottlenecks in the industrial development of *M. rosenbergii*. Our research revealed that in addition to the traditional problems such as the lack of seed supply caused by the degradation of germplasm and the low emergence rate, there is a frequent occurrence of gonadal precocity (female shrimp weighing only 6 g already held eggs in their abdomen, and males weighing only 2 g held mature sperm in their testes) was a major factor hindering the healthy development *M. rosenbergii*. Precocious maturity leads to stagnated growth, compromised health, and flesh quality (O'Brien, 1984; Jin and Xie, 2001), as the resources and energy are diverted to gonadal development, gamete production, mating, and reproduction. Reproductive sterilization strategies such as sterile or single-sex group breeding can preclude the deterioration of growth and stagnated size associated with precocious maturation (Basavaraju et al., 2002). In mollusks and fish such as *Crassostrea hongkongensis* (Zhang et al., 2017), *Crassostrea rivularis* (Yang et al., 2008), and *Oncorhynchus mykiss* (Wang et al., 2005), chemical or physical tools have been used to induce triploids to construct sterile populations. However, the progress in developing a sterile population in *M. rosenbergii* is limited. *M. rosenbergii* has a special reproductive mode: egg holding and hatching, and at present, there is no established technology for *in vitro* culture of fertilized eggs. Although *in vitro* embryo shock treatment is easy to perform, it may lead to high mortality. In addition, the gonads of

artificially induced triploid individuals can still develop normally and produce normal functional aneuploid gametes, which have potential ecological risks. Therefore, researchers attempted to obtain a neo-female *M. rosenbergii* population by removing the gonads of immature male *M. rosenbergii* to build a unisexual population (Sagi et al., 1990). However, this method is difficult to operate and has a high threshold, making it difficult to popularize on a large scale.

With the continuous advancements in molecular biotechnology and sequencing technologies, the focus of aquatic animal-related research has shifted to the genome and transcriptome levels. RNA interference (RNAi) has become a new effective tool to induce infertility in aquatic animals and has been widely used in various species. For example, in teleost fish, the agate phenotype of loach (Fujimoto et al., 2010) and sturgeon (Linhartová et al., 2015) has been achieved by inactivating the mRNA necessary for the formation of primordial germ cells using the morpholino method, in which the dsRNA of *vasa* was injected into the ovaries of the fully mature female *Pinctada fucata*, and the mother was induced to lay eggs 6 h later. The gonads of the injected offspring were significantly smaller than those of the control group (Iwai et al., 2015). In *Eriocheir sinensis*, a crustacean, RNAi with the *DMRT*-like gene inhibited the normal development of the testis (Zhang and Qiu, 2010). In *Fenneropenaeus chinensis*, closely related to *M. rosenbergii*, interference with the doublesex (*DSX*) gene significantly reduced the expression of the androgen-promoting gene (*AGH*) (Li et al., 2018). In *M. rosenbergii*, RNAi has been successfully used for silencing of insulin-like AG (*Mr-IAG*) gene of male *M. rosenbergii* to reverse its sex into full-functional neo-female individuals, which could mate with normal male individuals to produce an all-male population (Ventura et al., 2012). Levy et al. (2016) successfully constructed an all-female population by injecting hyperplastic gonad (hAG) cells into female juvenile *M. rosenbergii* to obtain neo-male individuals. Recently, Xu et al. (2022) obtained a fully functional neo-female individual by RNAi-based silencing of *MroDmrt11E*, which is upstream of *Mr-IAG* in *M. rosenbergii*. However, these studies focused on developing parthenogenetic populations of *M. rosenbergii*, and reports on sterile populations

of *M. rosenbergii* are scarce. Collectively, these results indicate that mRNA inhibition required for reproductive development at various stages of the life cycle of various animals can affect their normal reproductive development and even change their sex phenotypes. However, the limited knowledge of the gonad development and gametogenesis mechanism of *M. rosenbergii* and the lack of the corresponding breakthrough point hinders the application of potential tools such as RNAi to achieve reproductive sterilization in this species.

Therefore, screening and identifying key genes that play a role in germ cell development, then clarifying the developmental molecular mechanisms of germ cells is an important prerequisite for the future development of sterility induction methods in *M. rosenbergii*. Recently, related research has made certain progress on other crustacean species: Wei et al. (2021) found that *PIWI* plays a role in the formation of germ cell nucleus of *E. sinensis*, and can maintain the apoptosis of abnormal germ cells to remove abnormal germ cells, which is different from its function in mammals; In *Penaeus vannamei*, a newly discovered maternal gene *MnTdrd* has been proved to function in the formation and differentiation of reproductive cells in *P. vannamei*, and can be used as a new germ cell marker to track the origin and migration of germ cells (Dong et al., 2021); Meanwhile, *KIFC1* was found to be possibly involved in mitosis of spermatogonia, meiosis of spermatocytes, and acrosomal formation during spermatogenesis in *Penaeus japonicus*, and its reduced expression may induce abnormal assembly of microtubules and lead to apoptosis of spermatogonia and spermatocytes (Hao and Yang, 2019). Additionally, the research of *foxl2* (Wan et al., 2022), *IAG2* (Liu et al., 2021) and *DDX52* (Li et al., 2018) genes in the germ cells of crustaceans has also made considerable achievements. However, recent research on *M. rosenbergii* are scarce, and the isolation of germ cell-related key marker genes needs to be further promoted.

Previously, the conventional method for isolating genes in non-model organisms was polymerase chain reaction (PCR) amplification based on the conserved sequences of homologous genes. Because this method is time-consuming, inefficient, and probably not applicable to highly differentiated target genes in different species, screening for target genes has been a major bottleneck in molecular biology research (Bar et al., 2016). In recent years, large-scale parallel transcriptome sequencing platforms, such as ABI solid, Roche 454, and Illumina Solexa platforms, have been gradually popularized, providing new methods and ideas to encounter various research problems (Oghenekaro et al., 2016). In addition to model organisms, large-scale transcriptome sequencing has been applied to different types of research on an increasing number of aquatic species such as *Thunnus maccoyii* (Bar et al., 2016), *Sepiella japonica* (Wang et al., 2020), *Fenneropenaeus merguensis* (Prasert et al., 2021) and *Salmo salar* (Trine et al., 2021). In *Macrobrachium nipponense*, large-scale transcriptome

sequencing technology was used to explore the molecular mechanisms of stress resistance (Li et al., 2021), sex differentiation (Abu Abayed et al., 2019), and immunity (Ou et al., 2021). In contrast, transcriptome resources of *M. rosenbergii* are scarce, which is the main obstacle to the molecular biology research of this species— As of September 27, 2022, there were only 4,576 expressed sequence tags (ESTs) in the National Center for Biotechnology Information (NCBI) database. In this study, we aimed to explore and discover genes in the key regulatory organs of *M. rosenbergii*, which may be related to germ cell development. To this end, we performed transcriptome sequencing and analysis of the brain and gonad tissues in *M. rosenbergii*. We employed different strategies, such as various gene screening methods, quantitative real-time PCR (qRT-PCR), and *in situ* hybridization (ISH), to identify the target genes. The findings will provide key information about germ cell development and contribute to the sustainable development of RNAi research on *M. rosenbergii*.

## 2 Materials and methods

### 2.1 Ethics statement, experimental fish and sample collection

All experiments were conducted at the Pearl River Fisheries Research Institute of the Chinese Academy of Fishery Sciences (Guangzhou, China). The study was approved by the Animal Experiment Ethics Committee of Pearl River Fisheries Research Institute, Chinese Academy of Fishery Sciences (Guangzhou, China).

To avoid the gonadal atrophy caused by over-ripening, and ensure that the sample contains germ cells at different developmental stages, 30 males and 30 females were obtained from Foshan Sanshui Baijin Seedling Co., Ltd. (Foshan, China) as normal three-month-old *M. rosenbergii* specimens with a body weight of  $10.3 \pm 2.1$  g and a body length of  $7.6 \pm 1.5$  cm. The brains, gonads, and other tissues (including intestine, gills, muscle, stomach, liver, and heart) of specimens were immediately collected on ice with disinfected scissors and tweezers. Every tissue group had three sets of biological replications; and each replication contained samples from 30 individuals. All tissue samples were soaked in RNAlater (Thermo Scientific, Waltham, MA, USA) and stored at  $-20^{\circ}\text{C}$  for transcriptome sequencing and expression analysis. A portion of gonad samples was soaked in Bouin's solution for 4 h and stored in 70% ethanol at  $4^{\circ}\text{C}$  for ISH.

### 2.2 RNA extraction, library construction, and illumina sequencing

Total RNA was extracted from tissues using TRIzol reagent (Invitrogen, Waltham, MA, USA) according to the

manufacturer's protocol. Then the sample mRNA was enriched with Oligo (dT) magnetic beads. Fragmentation buffer was added to break mRNA into short segments, mRNA was used as a template to synthesize the first cDNA strand with six-base random primers, and then buffer, dNTPs, RNase H, and DNA polymerase I were added to synthesize the second cDNA strand. After purification with QiaQuick PCR kit (Qiagen, Venlo, Netherlands) and elution by EB buffer, terminal repair, addition of poly(A) and connection of sequencing linker were carried out, then fragment size selection was carried out using agarose gel electrophoresis, and finally PCR amplification was carried out. The built sequencing library was sequenced by Illumina HiSeq™ instrument at SAGENE Biotech Co., Ltd. (Guangzhou, China).

### 2.3 Illumina read processing and assembly, functional annotation, and classification

To obtain high-quality reads for further analysis, reads containing adapters or poly(A) sequences and low-quality reads were removed from the raw data using the FastQC v0.11.5 software to generate clean data. The N50 and GC percentages of the cleaned data were calculated. Then, high-quality reads were reconstructed and assembled into a single genome using Trinity v2.2.0 with default parameters (Cabau et al., 2017). First, Trinity was used to connect the reads with a certain length of overlap into longer segments, and these assembled segments without N obtained through the relationship of reads overlap were used as the assembled unigenes. Lastly, the National Center for Biotechnology Information non-redundant (Nr, <ftp://ftp.ncbi.nih.gov/blast/db/>), Swiss-Protein (SwissProt, <https://www.uniprot.org/>), Kyoto Encyclopedia of Genes and Genomes (KEGG, <https://www.genome.jp/kegg/>), and Gene Ontology (GO, <http://geneontology.org/>) databases were used to obtain the feature and annotation information for all assembled unigenes (Figure 1A).

### 2.4 Gene expression distribution and identification of candidate genes

Reads in RNA-Seq analysis were normalized to the fragments per kilobase of transcript per million mapped reads (FPKM) to estimate gene expression levels (Mortazavi et al., 2008). Results were subjected to multiple-test correction using an error-finding rate (FDR) threshold < 0.05 (Benjamini and Yekutieli, 2001; Lu et al., 2015). A gene is defined as specifically expressed in a single tissue (SEGs) if FDR in that single tissue is ≤ 0.05 and  $\log_2$  ratio = 0 (the FPKM value of the gene in one sample is at least twice that of the gene in the other sample).

Genes with  $FDR \leq 0.05$  and  $\log_2$  ratio < 2 in multiple tissues were classified as co-expressed genes (CEGs). The Venn diagrams were constructed from annotated gene expression profiles of single genes in single or multiple tissues. (Figure 1B). Subsequently, candidate genes were obtained by screening keywords (Figure 1C), comparing expression levels (Figure 1D), sequences and species origin (Figure 1E).

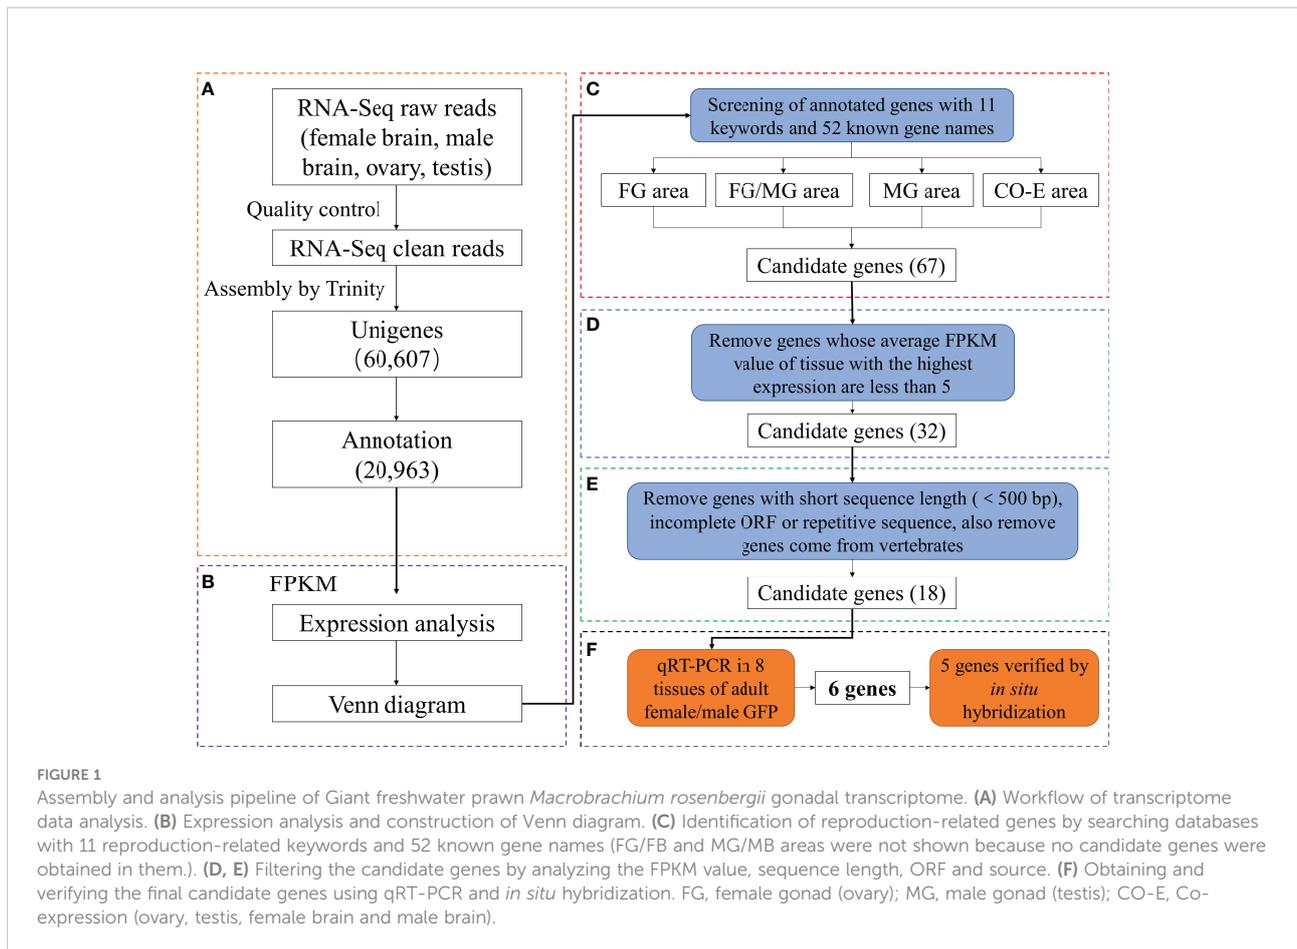

The FPKM values were also used to estimate gene expression levels using the StringTie software (Pertea et al., 2016). Differentially expressed genes (DEGs) between female brain (FB), female gonad (FG), male brain (MB), and male gonad (MG) groups were analyzed using DESeq 2 (Love et al., 2014) with a threshold  $FDR < 0.05$  and absolute fold change (FC)  $\geq 2$  ( $\log_2 |FC| \geq 1$ ).  $\log_2(FC) > 0$  indicated upregulation, and  $\log_2(FC) < 0$  indicated downregulation.

### 2.5 Quantitative real-time PCR (qRT-PCR) analysis

The qRT-PCR was performed to verify the sequencing results of ten randomly selected DEGs and the expression levels of the candidate genes in the male and female gonads, intestine, gills, brain, muscle, stomach, liver, and heart tissues. RNA from each sample (in 3 triplicates) was collected using TRIzol Reagent (Invitrogen, Waltham, MA, USA), as described in section 2.2. First-strand cDNA was synthesized from 1  $\mu$ g of total RNA using an Evo M-MLV RT Premix for PCR Kit (Accurate Biology, China). The specific qRT-PCR primers shown in Supplementary Tables S1 and S2 were designed using online Primer-BLAST from NCBI (<https://www.ncbi.nlm.nih.gov/tools/primer-blast/>). The reaction mix comprised 1  $\mu$ L (50 ng/ $\mu$ L) cDNA, 10  $\mu$ L iTaq Universal SYBR<sup>®</sup> Green Supermix (BIO-RAD, CA, USA), 2  $\mu$ L of upstream and downstream primer, and 7  $\mu$ L of nuclease-free water to adjust the final volume to 20  $\mu$ L. Reactions were performed using the QuantStudio 6 Real-Time PCR System (Applied Biosystems, CA, USA) using the following protocol: 95°C for 5 min; 37 cycles of 95°C for 30 s, 58°C for 30 s, and 72°C for 20 s; and 72°C for 10 min for data acquisition. Each sample was tested in triplicates.  $\beta$ -Actin gene (AY651918.2) was used as the internal reference to normalize the Ct values of each reaction using the  $2^{-\Delta\Delta Ct}$  method (Livak and Schmittgen, 2001) (Figure 1F).

### 2.6 In situ hybridization

Sense and anti-sense RNA probes labeled with digoxigenin were synthesized from the corresponding regions (Table 1). The cDNA fragment of the final candidate gene was subcloned into pGEM T-easy vector. DIG-labeled uridine triphosphate (Roche,

Basel, Switzerland) and T7 RNA polymerase (Promega, WI, USA) were used to transcribe sense and antisense probes *in vitro*. For ISH, tissue samples from gonads were fixed in Bouin's solution at 4°C for 4 h (GenXion, China). After dehydration under the condition of increasing ethanol concentration, a part of each sample was embedded in paraffin, and cut into 7- $\mu$ m slices with Leica RM2016 Microtomes (Leica, Weztlar, Germany). Then, paraffin sections were placed on Thermo adhesive glass slides (Thermo Scientific, Waltham, MA, USA), dewaxed, and dehydrated by dipping in xylene-ethanol series. Staining sections with hematoxylin-eosin (HE) solution (Nanjing Jiancheng Bioengineering Institute, China), or ISH treatment with DIG-labeled RNA probes, followed the previously described protocol (Nagasawa et al., 2009). For subcellular localization of the candidate genes, gonad samples were obtained and pretreated as described in 2.1. We divided oogenesis in the obtained samples into four stages and spermatogenesis into three stages, following the method described in previous studies (Luo et al., 1999; Deng and Hu, 2002; Meeratana and Sobhon, 2007). The resulting ISH sections were observed under a Nikon Eclipse ci upright microscope (Nikon, Japan) equipped with a Nikon DS-U3 digital camera (Nikon, Japan).

## 2.7 Statistical analysis

Microsoft Excel 2021 (Microsoft Corporation, Redmond, WA, USA) and Graphpad Prism 9 (Graphpad Software, San Diego, CA, USA) were used to sort and analyze the experimental data.

## 3 Results

### 3.1 Transcriptome sequencing and assembly

For the use of transcriptome databases for *M. rosenbergii*, four cDNA libraries were produced by applying the stringent quality assessment and data filtering of sequences from the female/male brain, ovary, and testis samples. We obtained 110.7, 104.5, 91.9, and 83.4 million high-quality clean reads, respectively. Using the Trinity assembly program, 60,607 unigenes were generated by hybrid *de novo* assembly with lengths ranging from 301 to 21,012 bp (average length: 1,420 bp) (Table 2). The raw transcriptome sequences generated in this study were uploaded to the NCBI Sequence Read Archive (SRA) with the accession number PRJNA884099.

TABLE 1 Primers for probe synthesis for *in situ* hybridization.

Gene ID	Sequence (5' to 3')	Region	Product length (bp)
Unigene028604_01	AGCTTTGGCAAACGGGTA GGCTGTGGTTGGGTAAGTGA	71-498	428
Unigene041990_01	ACATCAGCTTCAGACGGTCC CCAGCAGGAGATTGACGGTT	494-1,018	525

Unigene063191_01	GACTCGCCTTCCCAACTCA TTCAGGGCTAGAAGTGCGTG	228-731	542
Unigene064862_02	CCGCCCTTAAGCCAGTACAA GTGGTGTGAAAGGCGTGAC	1,330-1,828	499
Unigene041623_04	CCCACTTACTCTTCCTCT GGGAAAGTCAATGAGCCATGC	144-329	186

### 3.2 Functional annotation and classification

For functional annotation of the 60,607 unigenes obtained, these genes were used as query sequences and the nr, SwissProt, KEGG, and KOG (evaluate  $< 1e^{-5}$ ) protein databases were searched using blastx. The results showed that only 34.6% (20,963 in total, NR: 20,792; Swissprot: 14,885; KEGG: 7,387; KOG: 14,063) of the unigenes showed high sequence similarity in these protein databases. The functions of given unigenes were determined by comparing the proteins which had the highest homology with these genes, such as nuclear autoantigenic sperm protein (Unigene045489), round spermatid basic protein 1 (Unigene018151) and male reproductive-related microfibril-associated protein (Unigene026230). Furthermore, using the Blast2GO software, 12.6% of the annotated unigenes (2,642) could be assigned a GO ID (Table 3). According to the GO classification table, the GO annotations of unigenes are analyzed. Among these three ontologies: molecular function, cellular component; biological process, cellular process, cell and catalytic activity are the most gene-rich level 2 GO terms in the three ontologies (Figure S1). Meanwhile, in the KEGG database, the

TABLE 2 Summary of *M. rosenbergii* transcriptome data.

Search item	Number
Total number of clean reads in female brain library	110,724,220
Total number of clean reads in male brain library	104,532,856
Total number of clean reads in ovary library	91,876,886
Total number of clean reads in testis library	83,384,930
GC percentage of unigenes (%)	39.17
Total number of unigenes	60,607
Mean length of unigenes (bp)	1,420
N50 length of unigenes (bp)	2,389
Max length of unigenes (bp)	21,012
Min length of unigenes (bp)	301

pathways with the most annotated gene entries are Ribosome, RNA transport, and Spliceosome, all of which belong to Genetic Information Processing in KEGG A Class (Figure S2).

### 3.3 Verification of DEGs using qRT-PCR

DEGs of six comparison groups were acquired by FDR and  $\log_2FC$  (Table S3). Ten DEGs were randomly selected from different groups for the qRT-PCR analysis. All the tested genes showed similar expression patterns (Figure 2) with their FPKM values, indicating the reliability and accuracy of our transcriptome data and subsequent analysis.

### 3.4 Gene expression distribution and identification and screening of germ cell-related candidate genes

Normalization of the reads in the RNA-Seq analysis to the FPKM identified a total of — SEGs (FG: 755; MG: 197; FB: 32; MB:12) and — CEGs (15,627) in four tissues: FG, MG, FB, and MB. Venn diagram identified 256 unigenes expressed in FG and MG, 755 specifically expressed in FG, and 197 in MG. In addition, 15,627 unigenes were co-expressed in FG/MG/FB/MB (Figure 3A).

Next, to identify the germ cell-related candidate genes, genes identified in the four key regions in the Venn diagram (FG/MG, FG, MG, and FG/MG/FB/MB) were screened using 11 gonadal-related keywords, namely, oocyte, sperm, fertilization, sex, meiosis, male, gonad, germ cell, gamete, female, and egg. In addition, 52 known sex-related gene markers and genes related to gonadal development (Matsumoto et al., 2013; Chen et al., 2015; Yue et al., 2015), including *vasa*, *nanos*, *SPATA*, *DMC1*, *Sox*, and *RAD51*, were searched in Venn diagrams and unigene databases to obtain data on homologous genes. The analyses

**TABLE 3** Functional annotation of unigenes of *M. rosenbergii* transcriptome.

Databases	Annotated transcripts
Total Unigenes	60,607
NR	20,792
Swissprot	14,885
KEGG	7,387
KOG	14,063
Annotated genes	20,963
Without annotated gene	39,644

identified 60 candidate genes in FG/MG/FB/MB region, 4 in MG, 2 in FG, and 1 in FG/MG (Figure 3A and Table S4).

Furthermore, to locate candidate genes that participate in germ cell development, genes with low FPKM values were eliminated by querying the statistical data on their expression levels in the transcriptome database, which identified 32 candidate genes (Table S5). Then the sequence assembly of these genes and gene sources were analyzed and compared. Genes with a length of less than 500 bp or without a complete open reading frame were removed. Simultaneously, to further improve the reliability of candidate genes, homologous genes from vertebrates with relatively distant genetic relationships were removed (Table S5). Finally, 18 candidate genes were identified (Figure 3B and Table 4). Among them, 17 genes, including *Sox14*, sex determination protein fruitless-like isoform X47 (*SDPF*), *Fem-1A*, *RAD51*, *vasa*, spermidine synthase-like (*SPDS*), and ER degradation-enhancing alpha-mannosidase-like 3 (*ER3*), were found in the FG/MG/FB/MB co-expression region. Only the male reproductive-related (*MRR*) gene was identified in the MG region. In addition, no qualified candidate genes were found in the FG region after screening.

### 3.5 Validation of target genes related to germ cell development

Next, to validate the 18 candidate genes, their specific expression in the tissues of adult male and female *M. rosenbergii* were verified using qRT-PCR. As shown in Figure 4, 12 genes, including *ER* (Unigene038520\_03), *ER3* (Unigene045914\_01), *NAS* (Unigene045489\_07), *SN1A* (Unigene037486\_01), *SPATA7* (Unigene052170\_01) and *SPDSCR* (Unigene052832\_05) showed significantly lower expression in ovary and testis tissues than those in some other hermaphroditic tissues. Only *RAD51* (Unigene041623\_04), *vasa* (Unigene059162\_03), and *SPDS* (Unigene064862\_02) showed specific expression in both FG and MG, and their expression in other body tissues was extremely low or undetectable. *Fem-1C* (Unigene041990\_01) and *SDPF* (Unigene028604\_01) specifically expressed in FG were only slightly expressed in the liver, heart, and other body tissues of male *M. rosenbergii*. In addition, the

expression of *MRR* (Unigene063191\_01) was more significant in the testis than in other hermaphroditic body tissues.

According to the qRT-PCR results, five candidate genes (*Fem-1C*, *SDPF*, *RAD51*, *vasa*, and *SPDS*) were selected for further analysis to determine the subcellular localization of these genes in the gonads. A previous study in *M. rosenbergii* has shown that *MRR* is specifically expressed in secretory cells in the inner wall of vas deferens, which may be related to sperm maturation and sperm pod formation (Cao, 2006). Therefore, we did not analyze the localization of *MRR*. Compared with gonad sections after HE staining (Figures 5A, D, G, J; Figures 6A, D, G, J; Figures 7A, D, G, J; Figures 8A, D, G, J), ISH results showed hybridization signals with the anti-sense probes of *RAD51*, *vasa*, *SPDS*, and *Fem-1C* in the germ cells of *M. rosenbergii*. However, no signals were observed in any germ cells using the anti-sense probe of *SDPF* (data not shown). *Vasa* mRNA was detected in stage 1–3 oocytes of the ovaries (Figures 8B, E) and spermatogonia and primary spermatocytes of the testes (Figures 8H, K). *RAD51* mRNA was detected in stage 2–3 oocytes (Figures 5B, E) and spermatogonia (Figures 5H, K). *SPDS* mRNA was mainly enriched in the cytoplasm of stage 1–3 oocytes (Figures 6B, E) and spermatogonia (Figures 6H, K). *Fem-1C* mRNA was only detected in stage 1–3 oocytes (Figures 7B, E), whereas no signal was detected in any germ cells in the testes (Figures 7H, K). In addition, hybridization signals were not observed in any germ cells using the *vasa*, *RAD51*, *Fem-1C*, and *SPDS* sense probes (Figures 5C, F, I, L; Figure 8C, F, I, L; Figures 6C, F, I, L; Figures 7C, F, I, L).

## 4 Discussion

The development of hermaphroditic germ cells is an important physiological process in the life history of sexually reproducing animals. In the recent decade, large-scale transcriptome sequencing has gradually become a powerful, highly repeatable, and cost-effective tool for biomolecular research to understand various molecular mechanisms involved in the development of gonadal germ cells. This study obtained more than 300 million high-quality reads and assembled them into more than 60,000 unigenes. Of these, approximately 20,000 were functionally annotated in the protein database. Compared to other recent studies on the *M. rosenbergii* transcriptome (Jiang et al., 2019; Yang et al., 2022), the average length of unigenes obtained in this study was longer (Our study: 1,420 bps; Jiang et al.'s: 1,196 bps; Yang et al.'s: 1,133 bps). However, the total number of unigenes obtained was slightly lower than those obtained in previous studies (Our study: 60,607; Jiang et al.'s: 115,338; Yang et al.'s: 75,887). This difference could be due to the different versions of the protein database used for functional annotation or different criteria to delete short and partially overlapping sequences to obtain non-redundant sequences.

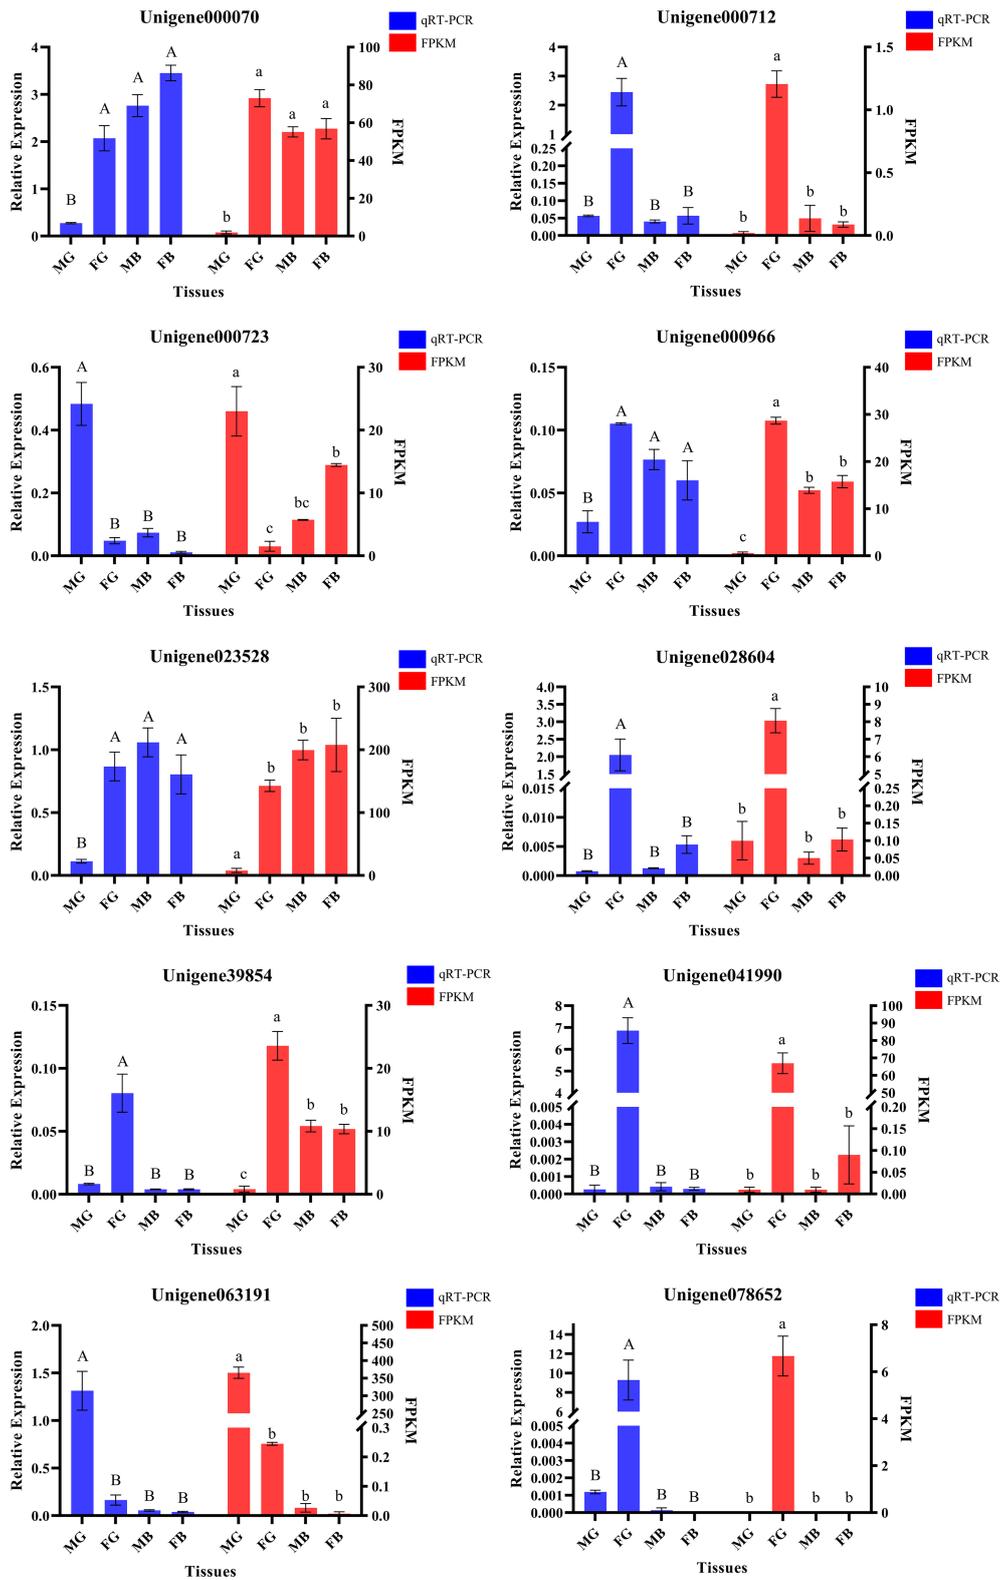

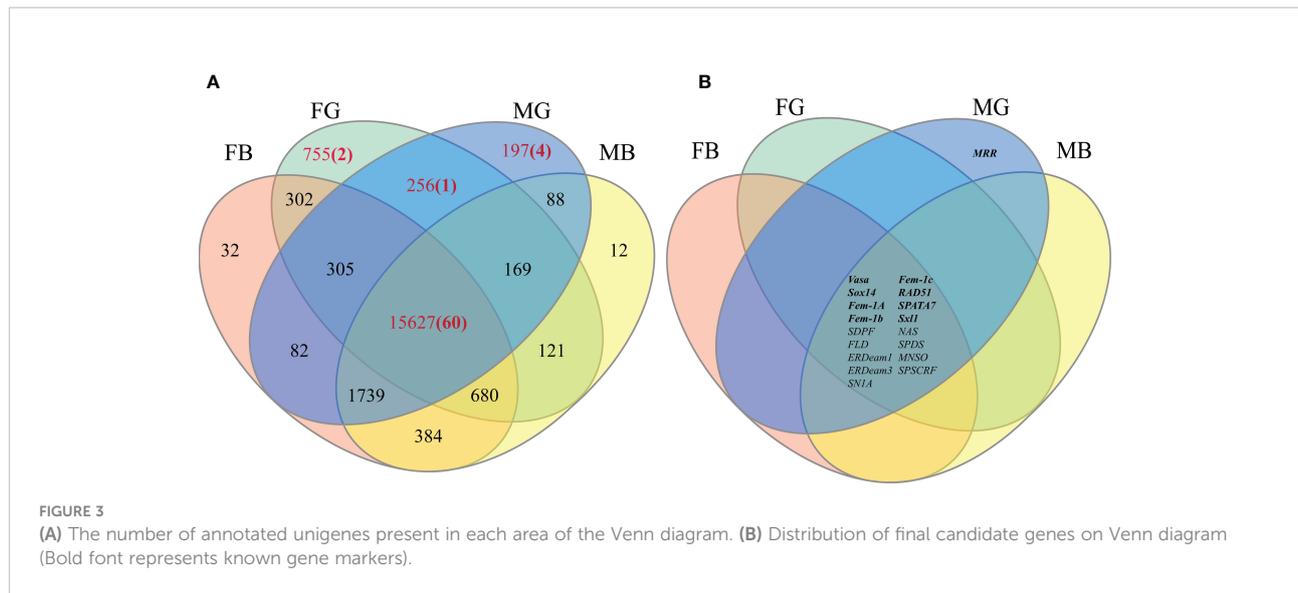

FIGURE 2 Validation of the 10 differentially expressed genes profiles using quantitative real-time PCR (Columns with the same letter above indicate that there is no significant difference between them, if not, there is significant difference).

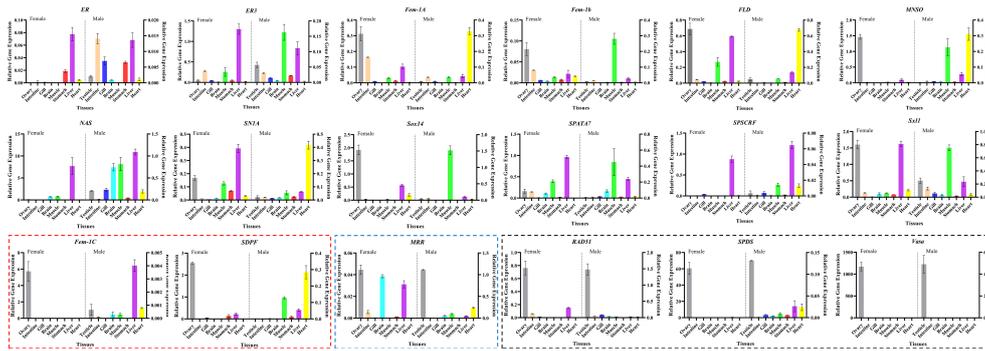

The construction of the Venn diagram provides a convenient way to query the tissue distribution of target genes and identify candidate genes in key regions. In this study, we used two methods to search the Venn map to screen sex-related candidate genes involved in gonadal development in *M. rosenbergii*. As our purpose was to identify genes involved in gonadal development and sex, we focused on genes that were mainly or specifically

expressed in the FG and MG regions. First, based on their functional classification, genes were searched using gonadal, reproductive, or gender-based keywords. Second, based on genes related to germ cell development found in other species, potential cognate genes for these genes were obtained in our species. Some genes are obtained by both methods, such as sex-lethal 1 (*Sxl1*), gametocyte-specific factor 1(*GTSF1*), *MRR*, and

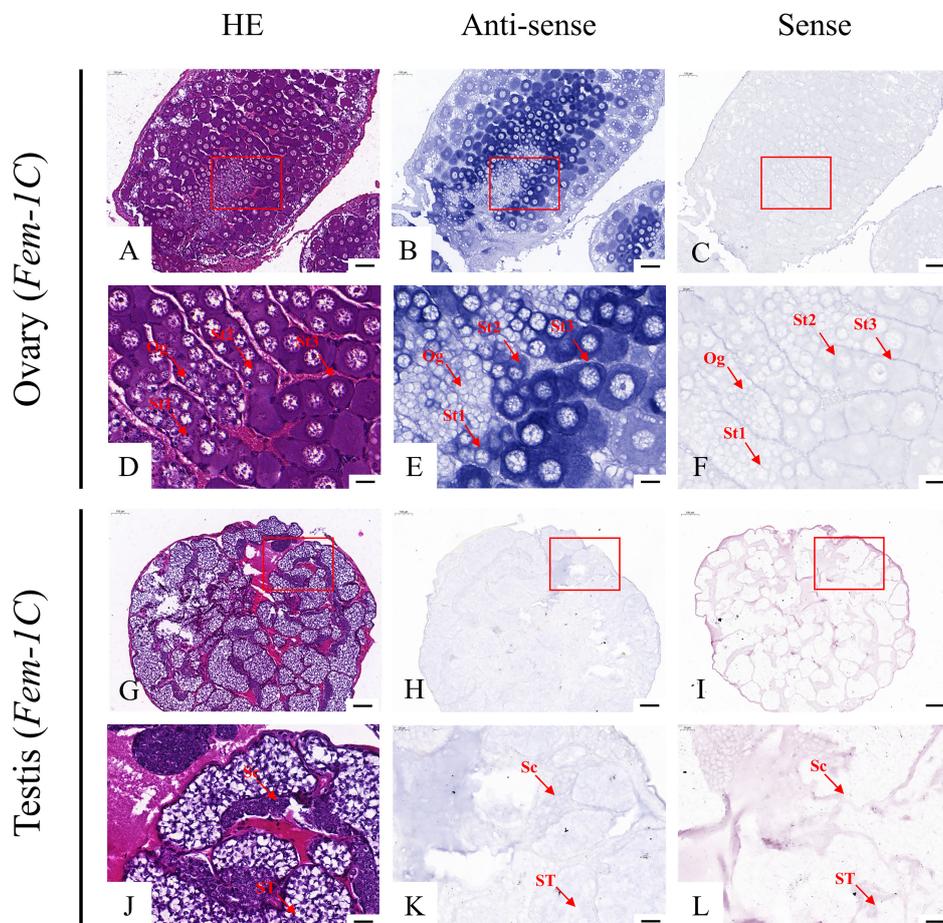

TABLE 4 List of candidate genes found in the databases.

(+: towards the 3' end; -: towards the 5' end).

**FIGURE 4** Tissue expression pattern of the final candidate genes in adult female/male *M. rosenbergii* using qRT-PCR (Boxes indicate that these genes are specifically expressed in female/male gonads. Red box represents the genes with high expression only in ovary, blue box represents the genes with high expression only in testis, black box represents the genes with high expression in both ovary and testis).

**FIGURE 5** Localization of *vasa* mRNA in the ovary (A–F) and testis (G–L) of *M. rosenbergii*. HE staining of ovary (A, D) and testis (G, J) used for *in situ* hybridization. Anti-DIG signals obtained by *vasa*-antisense probes (B, E, H, K) and *vasa*-sense probes (C, F, I, L). (D–F, J–L) High-magnification images of areas enclosed in red boxes in the images to the top (A–C, G–I). Og, oogonia; St1, stage-1 oocytes; St2, stage-2 oocytes; St3, stage-3 oocytes. Sc: spermatogonia; Sg: primary spermatocyte; ST: spermatids. Scale bars 100  $\mu$ m (A–C, G–I); 20  $\mu$ m (D–F, J–L).

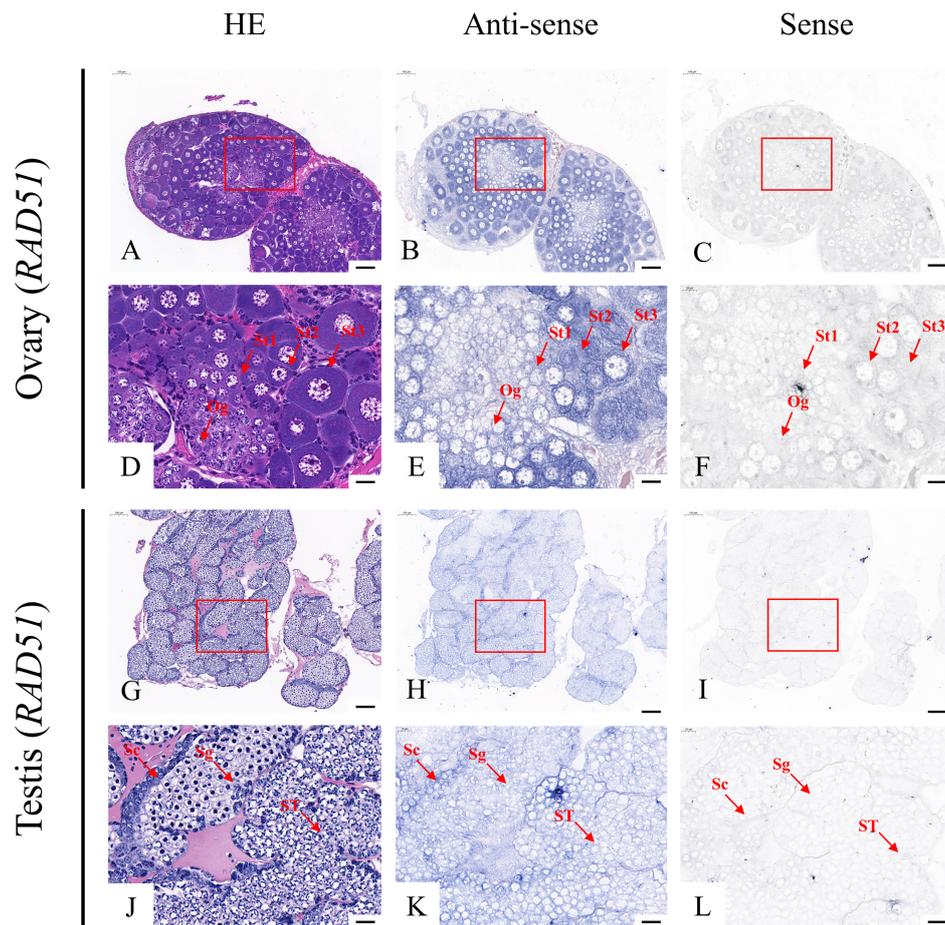

FIGURE 6

Localization of *Rad51* mRNA in the ovary (A–F) and testis (G–L) of *M. rosenbergii*. HE staining of the ovary (A, D) and testis (G, J) used for *in situ* hybridization. Anti-DIG signals obtained by *Rad51*-antisense probes (B, E, H, K) and *Rad51*-sense probes (C, F, I, L). (D–F, J–L) High-magnification images of areas enclosed in red boxes in the images at the top (A–C, G–I). Og, oogonia; St1, stage-1 oocytes; St2, stage-2 oocytes; St3, stage-3 oocytes. Sc, spermatogonia; Sg, primary spermatocyte; ST, spermatids. Scale bars 100  $\mu\text{m}$  (A–C, G–I); 20  $\mu\text{m}$  (D–F, J–L).

Sperm-associated antigen 7-like (*SPATA7*). Nevertheless, the first method complemented the second; it identified additional genes, such as *SPDS*, which could be important for screening new target genes. In addition, it was noted that most of the final candidate genes (17/18) were distributed in the FG/MG/FB/MB region, which might be because the brain of *M. rosenbergii* had certain regulatory effects on gonadal development. The role of brains in gonadal development has previously been reported in several species, such as mammals (Plant, 2015), birds (Tsutsui et al., 2003), fish (Zohar et al., 2010), and insects (Van Wielendaele et al., 2013), including sex differentiation and regulatory maturation; however, related topics have not been well studied in aquatic crustaceans. The transcriptome data of this study (PRJNA884099) can provide helpful information for future relevant studies on the neuroendocrine regulation of reproduction of *M. rosenbergii*.

Through the series of studies described above, we finally obtained five genes that are closely related to germ cells. *RAD51*

is one of the genes that has been shown for the first time to play a role in the germ cells of *M. rosenbergii*. *RAD51* originates from the *RecA* of cell biological ancestors (Lin et al., 2006). It participates in DNA damage repair during meiosis and plays a key role in guiding recombination. When double-strand breaks (DSBs) occur, 5'-3' nucleic acid exonuclease hydrolyzes the single strand end of the broken DNA, and replication protein A (RPA) binds to DSBs (Lewandoski, 2001). *RAD51* replaces RPA and combines with the 3' end of DNA to form ssDNA-*RAD51* nucleoprotein filament, recognizing and mediating the recombinant exchange between the two chains (Takzare et al., 2016). Previous studies on the effect of *RAD51* on meiosis have mostly been conducted in plants and a few model organisms, and deletion of *RAD51* has been confirmed to cause chromosome pairing and synapse defects in *Arabidopsis thaliana* (Li et al., 2004) and *Zea Mays* (Franklin et al., 2003). It also affects the meiotic recombination of *Saccharomyces*

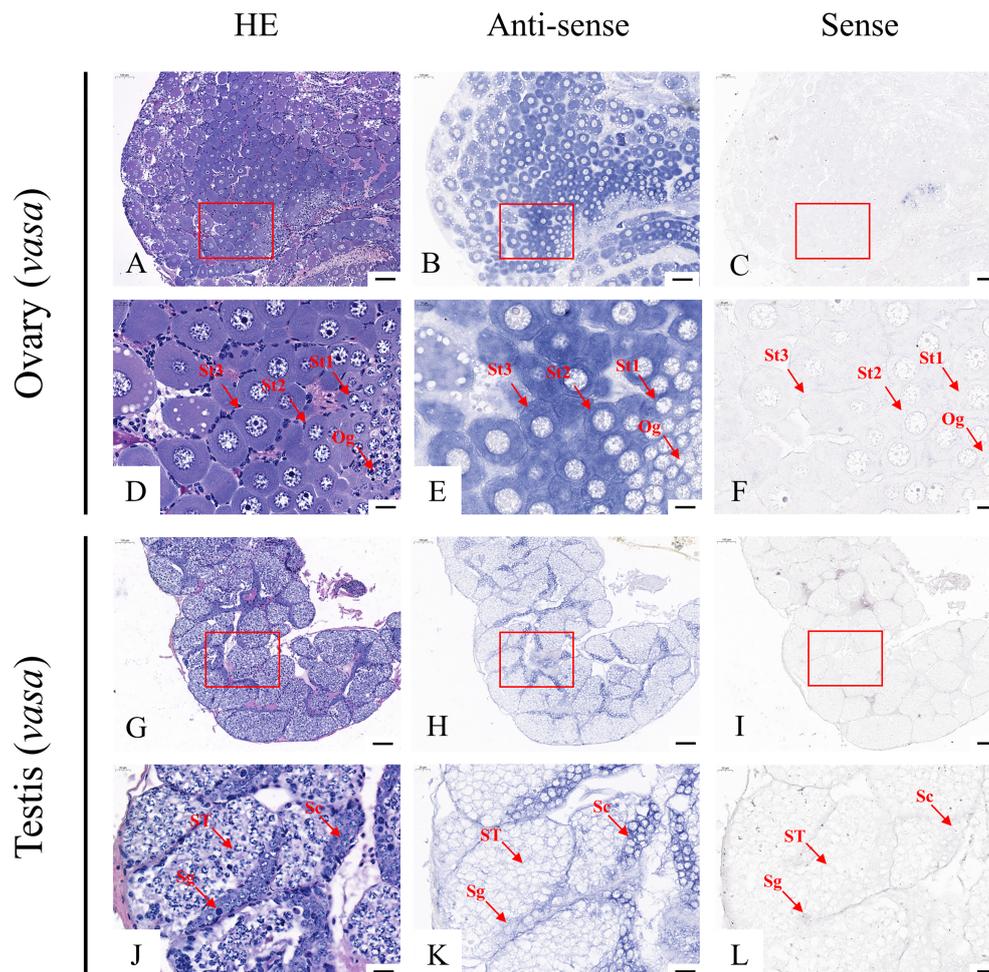

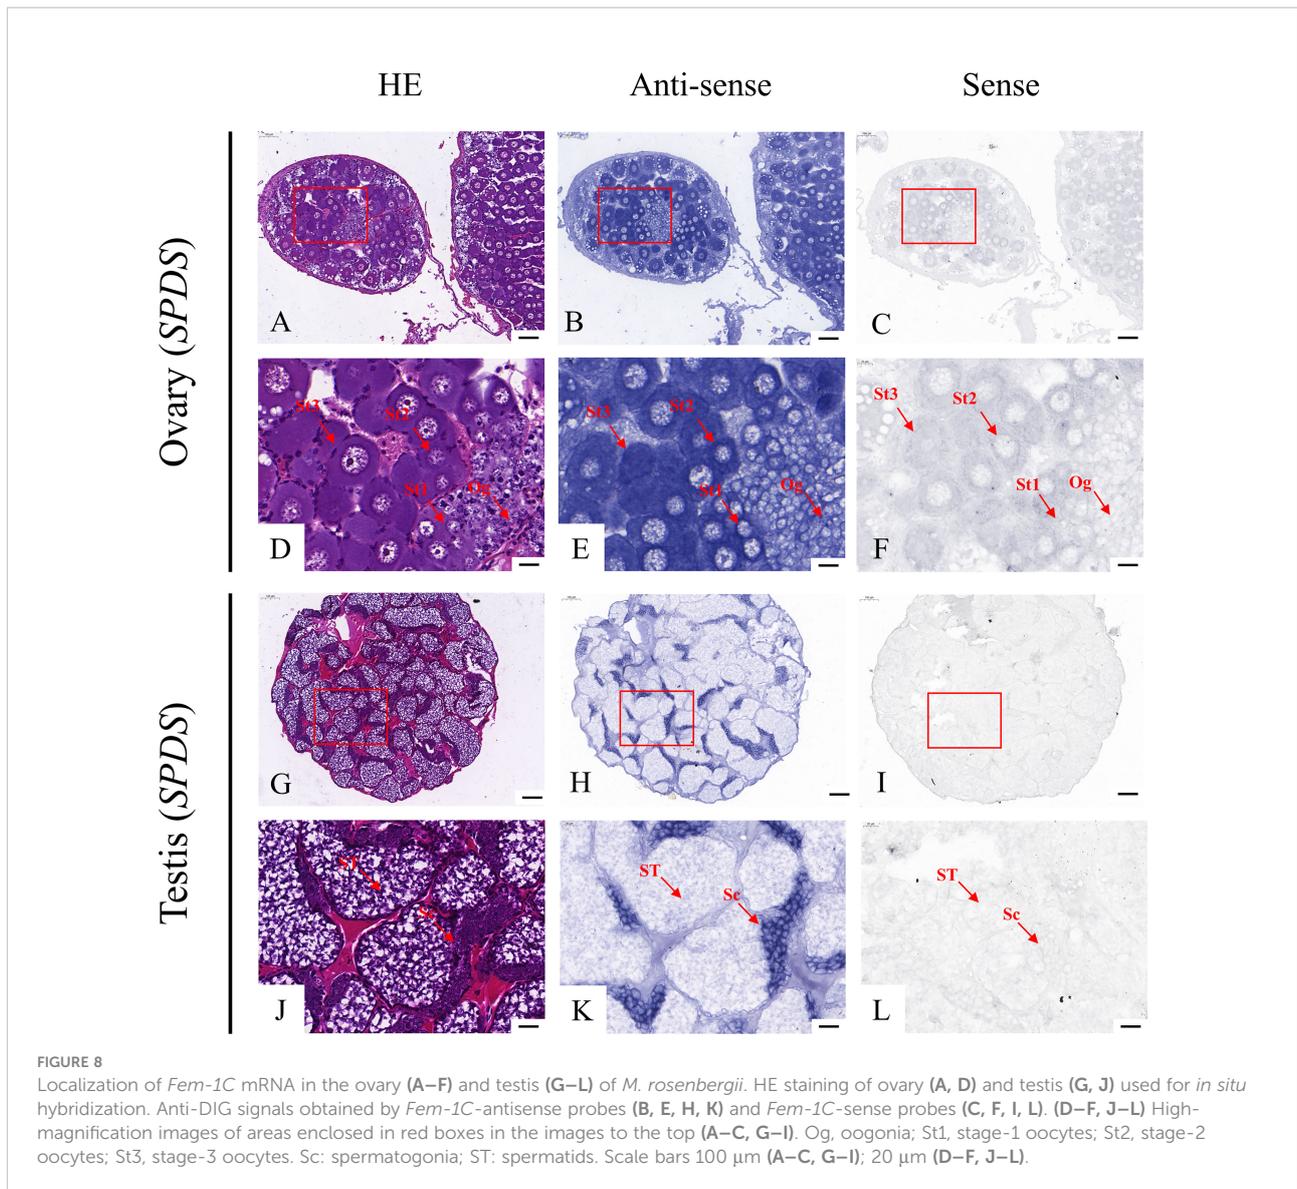

FIGURE 7

Localization of *SPDS* mRNA in the ovary (A–F) and testis (G–L) of *M. rosenbergii*. HE staining of the ovary (A, D) and testis (G, J) used for *in situ* hybridization. Anti-DIG signals obtained by *SPDS*-antisense probes (B, E, H, K) and *SPDS*-sense probes (C, F, I, L). (D–F, J–L) High-magnification images of areas enclosed in red boxes in the images to the top (A–C, G–I). Og, oogonia; St1, stage-1 oocytes; St2, stage-2 oocytes; St3, stage-3 oocytes. Sc: spermatogonia; ST: spermatids. Scale bars 100  $\mu\text{m}$  (A–C, G–I); 20  $\mu\text{m}$  (D–F, J–L).

*cerevisiae* and causes cell cycle arrest (Rockmill et al., 1995). The directional knockout of *RAD51* in male germ cells of *Mus musculus* inhibited meiosis and led to the development of reproduction sterility. These studies have revealed multiple effects of *RAD51* on meiotic recombination in various organisms. In this study, the existence of *RAD51* in *M. rosenbergii* was first discovered, and its tissue expression and subcellular localization were obtained, preliminarily revealing the expression pattern of *RAD51* in *M. rosenbergii*. *RAD51* was widely expressed in male and female germ cells of *M. rosenbergii*, especially in spermatogonia and stage 2–3 oocytes, suggesting that this gene plays a functional role in gamete production of *M. rosenbergii*, which would be of great value for further research.

Another gene that specifically develops color in germ cells through ISH experiments is *vasa*. It was first discovered in

*Drosophila melanogaster* by Schüpbach in 1986 and is involved in forming abdominal segments and developing germ cells in *Drosophila* (Schüpbach and Wieschaus, 1986). Since then, due to its conservation, *vasa* has been successively identified in several other species, including *Caenorhabditis elegans* (CEU62772), *Fenneropenaeus chinensis* (EF206693), *Danio rerio* (AF461759), *Parhyale hawaiensis* (EU289291), and *Scylla paramamosain* (GU187045) and is expressed specifically in germ cells in the vast majority of species. Previously, Nakkrasae and Damrongphol (2007) discovered a *vasa-like* gene (ABC87271) in *M. rosenbergii*, and the results of the neighbor-joining tree showed that the *vasa-like* gene in *M. rosenbergii* was adjacent to *D. rerio* and *Mus musculus*. Molecular phylogenetic analysis of the amino acid sequences of *vasa* family genes, including *vasa*, obtained using the

neighbor-joining method, showed that *vasa* in our study was clustered with those of *Macrobrachium nipponense* and *P. vannamei* (Figure S3). This result indicates that *vasa* identified in this study was the actual *vasa* of *M. rosenbergii*. Moreover, *vasa* has been used as a reliable molecular marker for germ cell lineages (Raz, 2000). In this study, we demonstrated the subcellular localization of *vasa* in the mature gonads of *M. rosenbergii*, and its expression pattern was similar to that of homologous genes of *D. rerio* (Sun et al., 2013), *F. chinensis* (Zhou, 2007), *Chlamys farreri* (Shao, 2007), and *S. paramamosain* (Zhang et al., 2010). Taken together, these results indicated that *vasa* played a vital role in the development of the germ cell lineage of *M.*

*rosenbergii* and could be used as a marker for germ cells in this species.

*Fem-1* (*Feminization-1*) gene family, first discovered in *Caenorhabditis elegans*, plays a crucial role in regulating spermatogenesis in male/hermaphroditic reproductive lines (Doniach and Hodgkin, 1984). The *Fem-1C* gene obtained in this study is a member of the *Fem-1* family. A few studies have shown that *Fem-1C* is involved in the sex regulation of some species and is highly conserved, but its role and mechanism in different organisms are quite different. For example, Xiong et al. (2014) found that *HsFem-1C* was highly expressed in the testes of *Hyriopsis schlegelii*, but it was also expressed in oocytes of *Hyriopsis cumingii* (Wang, 2018). Here, we confirmed that *Fem-*

*IC* was significantly enriched in the ovaries of *M. rosenbergii* using qRT-PCR and ISH. This result is similar to those of previous studies on *Fem-1C* in *Procambarus clarkii* (Zheng et al., 2022) and *Fem-1* in *M. rosenbergii* (Zhou et al., 2020). These findings suggest that *Fem-1C* probably plays a key role in the ovary of *M. rosenbergii* by regulating the development of female germ cells in the middle and late stages.

Spermidine, a natural polyamine, plays an important regulatory role in the animal breeding process, together with its upstream product putrescine and its downstream product spermine. Polyamine levels in human and rat seminal plasma are much higher than those in any other body fluid or tissue (Mann, 1974). Polyamines are widely present in germ cells, Sertoli cells, and Leydig cells of the rat testis, and their concentrations increase during puberty (Shubhada et al., 1989). Furthermore, the activity of ornithine decarboxylase (ODC), the rate-limiting enzyme for polyamine synthesis in female mammals, can be regulated by changes in related estrogen hormones (Moulton and Leonard, 1969; Ramos et al., 2014). Injection of exogenous polyamines into aging female mice significantly reduced their embryonic chromosomal aneuploidy, indicating the importance of polyamines in maintaining female reproductive capacity (Liu et al., 2017). These studies suggested that spermidine and *SPDS* play an important role in the formation of male and female gametes in mammals. The qRT-PCR results of this study showed that *SPDS* was specifically expressed in the gonads of *M. rosenbergii*, but its expression in the ovary was significantly higher than that in the testes. However, ISH showed that *SPDS* mRNA could also be detected in the testis of *M. rosenbergii*. These results indicate that *SPDS* may be conservative and participate in the generation of male and female gametes in this species.

In conclusion, the present study reports the transcriptome of the gonad and brain tissues of *M. rosenbergii*. It provides an in-depth insight into the process of germ cell development in *M. rosenbergii* at the molecular level. It identified 18 germ cell development-related genes, of which five genes were validated. These validated genes include one testis-related gene (*MRR*), one ovary-related gene (*Fem-1C*), and three genes (*RAD51*, *vasa*, and *SPDS*) related to both male and female germ cells in *M. rosenbergii*. Among these five genes, *RAD51*, *SPDS*, and *Fem-1C* were proven to function in germ cells of this species for the first time. The findings of this study will assist in developing suitable methods for producing sterile populations, which can be applied in practical production to preclude precocious puberty. In the future, we plan to silence these genes using RNAi and assess their effect on the development of germ cells and upstream and downstream genes. These potential studies will contribute to exploring a theoretical foundation for future related research in *M. rosenbergii*. However, the research progress is still a long way from causing sexual reversal or infertility in *M. rosenbergii* at present. In addition, the way to obtain sterile population on a

large scale continuously and stably has not been clarified, and a lot of exploration is still needed.

## Data availability statement

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession number(s) can be found below: <https://www.ncbi.nlm.nih.gov/>, PRJNA884099.

## Author contributions

LY and XZ conceived and designed the experiments. JW, KH, and QZ performed experiments. XL, XH, and WL analyzed the data. JW and LY wrote the manuscript. All authors contributed to the article and approved the submitted version.

## Funding

This research was funded by the Central Public-interest Scientific Institution Basal Research Fund, CAFS (Nos. 2021SJXK3, 2022SJ-XT1, 2020TD35 and 2020ZJTD01), China-ASEAN Maritime Cooperation Fund (No. CAMC-2018F), National Freshwater Genetic Resource Center (No. NFGR-2020) and the National key R&D Program of China (SQ2022YFD2400003).

## Acknowledgments

We would like to thank Editage [[webshop.elsevier.com/language-editingservices/](https://www.editage.com/)] for English language editing. I also want to thank Mikoto Misaka for her emotional support.

## Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

## Publisher's note
