β -conglycinin is one of the major soy antigen proteins in soybean meal (SBM) and exhibits growth inhibition and intestinal health damage in grouper, but the underlying mechanisms are still poorly understood. In this study, orange-spotted grouper (*Epinephelus coioides*) was used to investigate whether the poor growth performance induced by dietary β -conglycinin levels is associated with intestinal structural integrity disruption, the intestinal apoptosis and intestinal microbiota. The basal diet (FM diet) was formulated to contained 48% protein and 12% fat without SBM supplementation. Fish meal protein in the FM diet was replaced by SBM to prepare a high SBM diet (SBM diet). β -conglycinin at 3% and 7% were added into FM diets to prepare two diets (B-3 and B-7). Triplicate groups of fish (20 fish/tank) were fed one of the experimental diets twice daily in a feeding period of 8 weeks. Compared with FM diet, fish fed diets SBM and B-7 had decreased the growth rate, hepatosomatic index, whole-body lipid and ash contents, and increased whole-body moisture content. However, the maximum growth was observed for diet B-3 and was not different from that of FM diet. The liver total antioxidant capacity and glutathione peroxidase activity, the muscle layer thickness of middle and distal intestine, and the mucosal fold length of distal intestine were lower, while liver malondialdehyde content, intestinal diamine oxidase activity, d-lactic acid and endotoxin contents, and the number of intestinal apoptosis were higher in SBM and B-7 groups than that in FM and/or B-3 groups. SBM and B-7 diets down-regulated the intestinal expression of tight junction genes (*occludin*, *claudin-3* and *ZO-1*), apoptosis genes (*bcl-2* and *bcl-xL*) and anti-inflammatory factor genes (*I κ B α* , *TGF- β 1* and *IL-10*), but up-regulated the intestinal expression of apoptosis genes (*caspase-3*, *caspase-8* and *caspase-9*) and pro-inflammatory factor genes (*NF- κ B1*, *RelA*, *TAK1*, *IKK*, *MyD88*, *TNF- α* , *IL-1 β* , and *IL-8*) vs FM and/or B-3 diets. The richness and diversity indexes of OTUs, Chao1, ACE, Shannon and Simpson were not affected by dietary treatments. The relative abundances of intestinal bacteria (phylum

Proteobacteria and genus *Vibrio*) were generally higher, and relative abundance of phylum Tenericutes was lower in SBM and/or B-7 groups than that in B-3 group. The above results indicate that high dietary β -conglycinin level, rather than intermediate level could decrease liver antioxidant capacity, reshape the intestinal microbiota, and impair the intestinal normal morphology through disrupting the intestinal tight junction structure, increasing intestinal mucosal permeability, and promoting intestinal apoptosis, which in turn triggers intestinal inflammatory responses and the occurrence of enteritis, and ultimately leads to poor growth performance in fish.

β -conglycinin, inflammatory response, intestinal microbiota, apoptosis, orange-spotted grouper

1 Introduction

Aquaculture is an increasingly important contributor of protein source to meet the demand of the steady growth of the world population and the improvement of people's living standards for high-quality animal protein products (Han et al., 2018; Boyd et al., 2022). As the main types of fish farming to produce food fish, semi-intensive and intensive aquaculture relies heavily on artificial feeds (Han et al., 2018). However, farmed marine fish require more high quality feed protein than terrestrial animals (Zhao et al., 2021). Fish meal (FM), a processed product of marine catches, is the priority of protein ingredients for intensification and shift to farmed marine fish due to its high nutritional value (Tacon, 2020). Over the past decades, however, the limited marine fishery catches resources have caused the stagnant production of FM (Han et al., 2018). Moreover, the rapidly growing global aquaculture industry has exacerbated the tight supply of FM (Han et al., 2018; FAO, 2020). Therefore, there is a consensus in the industry to find suitable feed proteins to replace FM (Hardy, 2010).

Soybean meal (SBM) is widely used in aquafeeds as the major plant protein source, and is the most potential substitute for FM due to its relatively high protein quality, massive production, and availability over other plant proteins (Wang et al., 2017; Zhao et al., 2021). However, most fishes, especially carnivorous fishes have SBM intolerance when they receive a diet with a high level of SBM (Baeverfjord and Krogdahl, 1996; Booman et al., 2018; Zhu et al., 2021). It is well-known that many anti-nutritional factors (ANFs) present in SBM provoke the response of intolerance, usually accompanied with a reduction of fish ability to digest nutrients (Chen et al., 2019), the so-called SBM-induced enteritis (SBMIE) (Carmona, 2008; Bai et al., 2017). Among the ANFs, soy antigen proteins are believed to be the main ANFs that induces SBMIE both in mammals (He et al., 2015; Wu et al., 2016a; Wu et al., 2016b) and fish (Ringø et al., 2006). The proteins have high thermal stability (Soumei et al., 2019) and strong immunogenicity (Hu et al., 2021), and are difficult to deactivate to use conventional methods (Jiang et al., 2015).

Soy antigen proteins belong to soy globulins and can be subdivided into four types: 2S (α -conglycinin), 7S (β -conglycinin and γ -conglycinin), 11S (glycinin) and 15S (polymers of glycinin) according to their sedimentation rates, of which, glycinin and β -conglycinin account for about 40% and 30% of total soy globulin respectively (Renkema, 2001; Zhu et al., 2011). The two types of antigen protein, therefore, have become the major concern for studying sensitization on animals and its underlying mechanisms (He et al., 2015). Recent results showed that soy antigen proteins have high antigenic activity (Li et al., 2017; Hu et al., 2021; Shan et al., 2021), promote intestinal permeability (Han et al., 2019; Scott et al., 2019; Zhang Y. L. et al., 2021), induce specific antigen-antibody reactions and T lymphoid cell-mediated hypersensitivity delay by stimulating the immune system (Gu et al., 2016a; Li et al., 2020; Yin et al., 2021a; He et al., 2022), trigger apoptosis of intestinal epitheliums (Peng et al., 2018; Duan et al., 2019a; Peng et al., 2019; Wang et al., 2022; Yi et al., 2022) through the production of reactive oxygen species (Li et al., 2019; Li et al., 2020; Zhang et al., 2020; Yi et al., 2022), disrupt intestinal microbiota homeostasis (Han et al., 2019; He et al., 2022) and develop into pathological reactions with allergies and enteritis as the main symptoms (Zhang et al., 2013; Booman et al., 2018; Zheng et al., 2020; Zhu et al., 2021), eventually leading to poor growth (Zhao et al., 2021; Yi et al., 2022). Great progress has been made in this regard in recent years, but the research on the negative impact of soy antigen proteins on fish is limited, and the underlying mechanisms involving enteritis and allergy induced by soy antigen proteins in fish are still unclear.

Grouper is an important marine fish that has been farmed along Southeast Asia coasts including the southeast coast of China (Shapawi et al., 2019). The annual production of grouper in China reached 204,119 tons in 2021, ranking third in the production of marine fish farming in China (Bureau of Fisheries and Ministry of Agriculture, 2022). Like other carnivorous fish, grouper also exhibit high sensitivity and low tolerance to soybean by-products (Wang et al., 2017; He et al., 2020; Zhao et al., 2021). As one of the main soy antigen proteins, β -conglycinin has strong immunogenicity and can cause enteritis in fish (Gu et al., 2016a; Li et al., 2017; Peng et al., 2018;

Duan et al., 2019a; Li et al., 2020; Hu et al., 2021). Recently, the effects of dietary soy antigen proteins on intestinal immune function and intestinal microbiota of hybrid grouper (*Epinephelus fuscoguttatus* ♀ × *Epinephelus lanceolatus* ♂) were investigated (He et al., 2022). However, the effects of soy antigen proteins on the apoptosis of intestinal epitheliums and intestinal permeability of grouper have not been reported yet. In the present study, orange-spotted grouper (*Epinephelus coioides*), another important grouper species, was used as target fish was selected to investigate the effects of dietary β -conglycinin inclusion levels on the growth, apoptosis of intestinal epitheliums intestinal permeability and intestinal microbiota of grouper to illustrate the relationship between intestinal health and β -conglycinin and its mechanism of action, which provides a reference for the rational development and utilization of soybean by-products in feed of marine fish.

2 Materials and methods

2.1 Experimental diets and feeding trial

A basal diet (FM diet) was formulated to contain 48% protein and 12% lipid using FM, casein and gelatin as the protein source, fish oil, soy oil and soy lecithin as the main lipid source, and corn starch as the filler. On the basis of the FM diet, 60% FM protein was replaced by SBM in the FM diet to make a high-SBM diet (SBM diet). To determine the effects of antigen protein in SBM, the β -conglycinin was included at two inclusion levels (3% and 7%) in the FM diet to prepare two experimental diets (B-3 diet and B-7 diet). The dietary 3% and 7% β -conglycinin were calculated according to the substitution of SBM for 30% and 60% FM protein, respectively. The β -conglycinin inclusion levels were at the expense of the decrease of casein and gelatin to ensure B-3 and B-7 diets contain protein and lipid levels identical to FM and SBM diets. The β -conglycinin product (purity 90.10%) was provided by Professor Guo Shuntang at China Agricultural University. All feed ingredients were ground in a hammer mill (GH-20B, Jiangyin Kejia Machinery Manufacturing Co., Ltd., Jiangyin, Jiangsu, China) and passed through a 60-mesh sieve, then weighed and uniformly mixed. The liquid ingredients (marine fish oil and soy oil) were added to the dry feed ingredients, and then freshwater was added to make a dough. The dough was then pelleted through a 3 mm die using cold press extrusion (CD4XITS, South China University of Technology, Guangzhou, Guangdong, China). The pellets were dried in a ventilated oven at 55°C for 24 h, then sealed in plastic bags and stored in a refrigerator at -20°C. The feed ingredients and proximate composition of experimental diets are shown in Table 1.

This experiment was conducted in a circulating water rearing system with a temperature control device at Haikang Base of Fujian Dabeinong Technology Company (Zhangzhou, Fujian, China). Before the experiment, juvenile groupers were fed commercial feed for 4-weeks of accommodation. A total of 240 fish with similar size were randomly divided into 4 groups, each with triplicate tanks and at a stocking density of 20 fish per tank. The fish in each group were fed one of the diets twice daily (7:30 and 17:30) for a feeding period of 56 days. Uneaten feed was collected by siphoning 30 min after each

feeding, then feces were removed. The collected uneaten feed was dried for 24 h at 65°C and weighed for the calculation of feed intake. After cleaning, the water body consumed by sewage cleaning was refilled with sand-filtered fresh seawater until the reservoir water returned to the original level. Dissolved oxygen was measured daily and nitrite-N was monitored twice a week using a multi-parameter photome (HI83200; Hanna Instruments, Woonsocket, Rhode Island). During the experimental period, the dissolved oxygen level was > 5.7 mg/L, the water temperature was 28.5°C, and ammonia nitrogen content was < 0.23 mg/L.

2.2 Sample collection

At the end of the 56-day feeding trial, the fish in each tank were caught and anesthetized with a dose of 100 mg/L solution of MS-222 (tricaine methane sulfonate, Sigma-Aldrich Shanghai Trading Co. Ltd., Shanghai) and then the fish number and bulk weight were recorded to determine weight gain rate (WGR), specific growth rate (SGR), feed efficiency (FE), and feeding rate (FR). Ten fish per tank were randomly caught and anesthetized with MS-222 (100 mg/L), followed by individually weighing to determine the condition factor (CF). Blood was then collected using a 2-mL heparinized syringe from the caudal vein, followed by centrifugation (1027 g, 4°C and 10 min). Plasma samples were separated, pooled by tank, and stored in a refrigerator at -80°C for the determination of diamine oxidase (DAO) activity and the contents of d-lactic acid (D-Lac) and endotoxin (ET). After hemostasis, the livers and intestines were aseptically removed. The livers were weighed for the calculation of hepatosomatic index (HSI). The intestine was washed with ice-cold sterile PBS to remove the intestinal digesta. Then the liver and intestinal samples were pooled in a tank and quickly frozen with liquid nitrogen and stored at -80°C for the subsequent biochemical analysis and the assay for intestinal microbiota. For the intestinal histology observation and the terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling (TUNEL) detection, two fish were caught from each tank and dissected to obtain the whole intestinal tract, followed by the removal of digesta. The intestinal tract was then divided into the proximal, middle, and distal segments (i.e. PI, MI, and DI, respectively), according to the method described by Anguiano et al. (2013). Another four fish per tank were randomly captured, put in plastic bags, and stored at -20°C until determination of whole-body proximate composition analysis.

2.3 Proximate composition analysis

The proximate composition of ingredients, diets, and whole-body fish samples were determined according to standard methods of AOAC (1995). Dry matter was determined by drying the samples at 105°C to a constant weight. The crude protein was determined by the Dumas combustion method (Elementar[®] Rapid N, Alpha Resources LLC, Michigan, USA). The crude lipid content was measured by the Soxtec extraction method by using Soxtec Avanti 2050 (Foss Tecator AB). Ash was measured in the residues of samples burned in a muffle furnace at 550°C for 8 h.

TABLE 1 Feed ingredients and proximate composition of experimental diets (on as fed basis, %).

Ingredients	Diets			
	FM	SBM	B-3	B-7
Peru fish meal ¹	52.00	22.00	52.00	52.00
Casein ¹	10.92	10.51	8.73	5.81

Crude lipid	11.77	11.59	11.84	11.71
Ash	15.50	10.14	14.30	14.24

¹Peru fish meal: crude protein 69.01% and crude lipid 9.06%; Soybean meal: crude protein 45.50% and crude lipid 0.72%; Gelatin: crude protein 88.35% and crude lipid 0.21%; Casein: crude protein 89.66% and crude lipid 0.13%; Corn starch: crude protein 0.41% and crude lipid 0.15%. All the ingredients except for β-conglycinin were obtained from Jiakang Feed Co. Ltd., Xiamen, China.

²The β-conglycinin product (purity 90.10%) was provided by Professor Guo Shuntang at China Agricultural University.

³Vitamin premix and mineral premix is prepared according to the study of Qin et al. (2022).

2.4 Liver and plasma component analysis

The glutathione peroxidase (GSH-Px), superoxide dismutase (SOD), catalase (CAT), total antioxidant capacity (T-AOC), and malondialdehyde (MDA) in the liver samples were determined using commercial kits (Nanjing Jiancheng Bioengineering Institute, Nanjing, Jiangsu, China) according to the manufacturer's instructions. The diamine oxidase (DAO) activity and contents of d-lactic acid (D-Lac), endotoxin (ET), and endothelin-1 (ET-1) in plasma were determined using enzyme-linked immunosorbent assay kits according to the protocols of the same manufacturer.

2.5 Histological analysis

After formalin fixation, all the intestine segments were removed and washed with normal saline, then fixed in 4% Bouin's solution for 24 h, rinsed with 70% ethanol solution, and finally immersed in 70% ethanol solution until histological processing was performed (Niu et al., 2021). The fixed intestine segments were embedded in

paraffin and 5-μm sections were cut by using a rotary microtome (KD-2258S, China). The serial histological sections were then mounted on glass slides, and stained with hematoxylin and eosin for morphometric analysis. Pictures were examined under a light microscope (Leica DM5500B, Germany), and digital images were acquired and processed with a digital camera (Leica DFC450) equipped with the image program LAS AF (Version 4.3.0 Leica). Five slides were prepared for each intestine segment sample and 30 measurements were made to determine the mucosal fold number (nMF), muscle layer thickness (tML), and mucosal fold length (IMF).

For the detection of apoptotic cells, the TUNEL staining was carried out using a TUNEL Apoptosis Detection Kit (Vazyme Biotech, Nanjing, China) according to the manufacturer's instruction. Briefly, sections mounted on a slide were deparaffinized with xylene and washed twice with deionized water. The rehydrated sections were digested with proteinase K for 4 min at 37°C. The samples were then covered with TdT Reaction Buffer for 10 min at 37°C, followed by incubation in a TUNEL reaction mix containing EdUTP and TdT enzyme for 1 h at

37°C. After incubation, the samples were washed twice with PBS for 5 min and subsequently incubated with streptavidin-HRP and DAB working solution for 30 min at 37°C in the dark. Finally, the samples were washed with 3% BSA in PBS (pH 7.4) for 5 min and counterstained with DAPI. The slides were viewed under a fluorescence microscope with green fluorescence set at 520 nm. The cells stained red indicated apoptotic cells.

2.6 Intestinal microbiota assay

The total DNA of the intestinal samples was extracted using a DNA extraction kit (Omega Bio-tek, Norcross, GA, USA) according to the manufacturer's instructions. The integrity and quality, purity and quantity of DNA samples were assessed by electrophoresis on a 1% (w/v) agarose gel and the spectrophotometer method (NanoDrop 2000, Wilmington, DE, U.S. 260nm/280nm optical density ratio), respectively. The V3-V4 region of the 16S rDNA of intestinal bacteria was amplified by polymerase chain reaction (PCR) using the forward primer 338F (5'-ACTCCTACGGGAGGCAGCAG-3') and the reverse primer 806R (5'-GGACTACNNGGGTATCTAAT-3'). The PCR amplification system solution included 30 ng DNA sample (X), 1 µL forward primer (5 µM), 1 µL reverse primer (5 µM), 3 µL BSA (2 ng/µL), 12.5 µL 2xTaq Plus Master Mix and 7.5-X µL ddH₂O. The PCR amplification program consisted of pre-denaturation at 95°C for 5 min; denaturation at 95°C for 45 s, annealing at 55°C for 50 s, and extension at 72°C for 45 s, 32 cycles; extension at 72°C for 10 min. Subsequently, high-throughput sequencing was performed using Illumina Miseq PE300 at Beijing Allwegene technology Co., Ltd (Beijing, China). A library of small fragments was constructed using paired-end for sequencing, and the data was passed through QIIME (v1.8.0) for the removal of low-quality sequences and chimeras. Based on 97% sequence similarity, similar sequences were assigned to the same operational taxonomic units (OTU). Species classification information corresponding to each OTU was obtained by comparing with the silva database, and alpha diversity analysis (Shannon, ACE, and Chao1) was performed using Mothur software (version 1.31.2). Based on the weighted uniface distance, the heat map of the R (v3.1.1) software package was used for clustering analysis. After the UniFrac algorithm, the information on system evolution was used to compare the difference of species communities among samples, and beta diversity analysis was performed

2.7 RNA extraction and expression analysis

The total RNA was extracted from the intestinal samples using TRIzol[®] reagent (Invitrogen, Carlsbad, CA, USA) according to the manufacturer's instructions. Isolated RNA was quantified using the NanoDrop ND-2000 Spectrophotometer, and its integrity was confirmed by agarose gel electrophoresis. The cDNA was generated from 1 µg DNase-treated RNA and synthesized by a PrimeScript[™] RT Reagent Kit with gDNA Eraser (TaKaRa, Dalian, China). Real-time PCR was employed to determine

mRNA levels based on the TB Green[™] Premix Ex Taq[™] II (Tli RNaseH Plus) (TaKaRa, Dalian, China) using a QuantStudio[™] Real-Time PCR System (ABI) quantitative thermal cycler. The fluorescent quantitative PCR solution consisted of 10 µL TB Green Premix Ex Taq[™] II (Tli RNaseH Plus) (2×), 0.8 µL PCR forward primer (10 µM), 0.8 µL PCR reverse primer (10 µM), 2.0 µL RT reaction (cDNA solution), and 6 µL dH₂O. The thermal program included 30 s at 95°C, 40 cycles at 95°C for 5 s, 60°C for 30 s, and a melting curve step. The sequences of primers are shown in Table 2. All amplicons were initially separated by agarose gel electrophoresis to ensure that they were of the correct size. β-actin served as the internal reference gene to normalize cDNA loading. The gene expression levels of the target genes were analyzed by the 2-ΔΔCt method (Schmittgen and Livak, 2008) after verifying that the primers were amplified with an efficiency of approximately 100% (Hanaki et al., 2014), and the data for all treatment groups were compared with the data for the control group.

2.8 Statistical analysis

All data were presented as the mean and standard error of the mean (SEM). The data were analyzed using a one-way analysis of variance (ANOVA) to test for differences between treatments and then the Student-Neuman-Keuls multiple comparison test was performed after confirming the normality and homogeneity of variance using the Kolmogorov-Smirnov test and Levene's test in SPSS Statistics 20.0 (SPSS, Michigan Avenue, Chicago, IL, USA). The data expressed as percentages or ratios were subjected to the data conversion before statistical analysis. *P*-values < 0.05 were considered statistically significant.

3 Results

3.1 Growth performance and proximate composition

The results of growth performance are presented in Table 3. The SBM group had the lowest WG, SGR, and CF among all treatments (*P* < 0.05). Group B-3 exhibited the highest WG and SGR, and the values were higher (*P* < 0.05) than that of B-7 group, but were not different (*P* > 0.05) from that of the FM group. The CF in the SBM group was lower (*P* < 0.05) than that of other groups, and there was no significant (*P* > 0.05) difference among other groups. There was no difference (*P* > 0.05) in HSI between groups SBM, B-3 and B-7, but they were higher (*P* < 0.05) than that in group FM. The FR of the SBM group was lower (*P* < 0.05) than that of the B-3 group, but not different (*P* > 0.05) from that in groups FM and B-7. The FE and survival were not affected (*P* > 0.05) by dietary treatments.

Groups SBM, B-3 and B-7 had higher (*P* < 0.05) whole-body moisture contents compared with the FM group, but no variation was observed among the three groups. Groups FM, B-3 and B-7 had higher (*P* < 0.05) whole-body lipid contents compared with group SBM, but there was no variation (*P* > 0.05) among the three groups.

Whole-body ash content followed a pattern similar to whole-body lipid content, in response to dietary treatments. The whole-body protein content did not differ ($P > 0.05$) across dietary treatments.

3.2 Liver antioxidant capacity

The liver T-AOC, GSH-Px activities in FM and B-3 groups were generally higher ($P < 0.05$) than that in SBM and B-7 groups, except that GSH-Px activity in the B-7 group was similar ($P > 0.05$) to that of FM and B-3 groups (Table 4). The changes of liver MDA values were opposite to that of T-AOC, in response to dietary treatments. Dietary treatments did not affect liver activities of SOD and CAT ($P > 0.05$). There were no significant differences ($P > 0.05$) in liver T-AOC and MDA values, liver SOD and GSH-Px activities between the B-3 group and FM group, and the same was true for the values between the B-7 group and the SBM group.

3.3 Gut morphological analysis

As shown in Figure 1, the single-layer columnar epithelial cells were tightly connected and a large number of goblet cells in the intestinal mucosa were observed in the FM group. Compared with

the FM group, the intestinal structure of MI and DI of the SBM group was damaged, and there was an obvious irregular arrangement of single-layer columnar epithelial cells, a significant reduction in the number of goblet cells in the intestinal mucosa, and many intestinal epithelial cells separated from lamina propria. Both B-3 and B-7 groups exhibited slight damage to intestinal structure compared with the FM group and the B-7 group had greater intestinal structure damage in comparison with the B-3 group.

The SBM group had the thinnest tML value for MI among treatments, and the value was lower ($P < 0.05$) than that of the FM group, but not different ($P > 0.05$) from that of other groups (Figure 2). The tML and IMF values for DI of SBM and B-7 groups were lower compared with FM and B-3 groups. There were no differences ($P > 0.05$) in tML and IMF values for DI between the B-3 group and FM group, and the same was true for DI between the B-7 group and SBM group. The tML for PI, IMF for PI and MI, and nMF for PI, MI, and DI were not affected ($P > 0.05$) by dietary treatments.

As shown in Figure 3, the mRNA levels of genes (*occludin*, *claudin-3* and *ZO-1*) related to intestinal tight junction structure in SBM and B-7 groups were down-regulated ($P < 0.05$) compared with FM and B-3 groups. There were no significant differences ($P > 0.05$) in mRNA levels for the three genes between the B-3 group and FM group, and the same was true for the three genes between the B-7 group and SBM group.

¹Statistical analysis was performed by one-way ANOVA, followed by Student-Neuman-Keuls multiple comparison test.

²FM, fish meal diet (basal diet); SBM, high soybean meal diet with 60% fish meal protein replacement and without β-conglycinin supplementation; B-3 and B-7, 3% and 7% β-conglycinin were added in the FM diets, respectively.

³Values are presented as the means ± SEM (n = 3 tanks).

Values in the same row with different superscripts indicate significant differences (*P* < 0.05), while that with the same letter or no letter superscripts indicate no significant differences (*P* > 0.05). WG (weight gain, %) = 100 × (final body weight (g/fish) - initial body weight (g/fish))/initial body weight (g/fish); SGR (specific growth rate, %/d) = 100 × (ln final body weight - ln initial body weight)/days; FE (feed efficiency) = (final body weight - initial body weight)/feed intake (as fed basis, g/fish); FR (feeding rate, %/d) = 100 × (feed intake (g/fish))/((final body weight + initial body weight)/2 × days); Survival (%) = 100 × final fish number/initial fish number; HSI (hepatosomatic index, %) = 100 × liver weight (g/fish)/body weight (g/fish); CF (condition factor) = 100 × body weight (g)/(body length (cm))³; IBW, initial body weight (g); FBW, final body weight (g).

3.4 Intestinal mucosal permeability

Table 5 showed that plasma DAO activity, and plasma D-lac and ET contents in SBM and B-7 groups were higher (*P* < 0.05) than that in FM and B-3 groups. There were no differences (*P* > 0.05) in intestinal DAO activity, D-lac and ET contents between the B-3 group and FM group, and the same was true for the values between the B-7 group and SBM group.

3.5 Distal intestinal cell apoptosis

As shown in Figure 4, the number of intestinal cell apoptosis of DI in groups SBM and B-7 showed obvious positive signaling compared to that of FM and B-3 groups. The SBM group had the highest number of intestinal cell apoptosis among treatments, followed by the B-7 group, and the values of the SBM and B-7 groups were higher than that in FM and B-3 groups.

TABLE 4 Effects of β-conglycinin addition in diets on liver antioxidant indices of orange-spotted groupers in a 56-day feeding period.

¹Statistical analysis was performed by one-way ANOVA, followed by Student-Neuman-Keuls multiple comparison test.

²FM, fish meal diet (basal diet); SBM, high soybean meal diet with 60% fish meal protein replacement and without β-conglycinin supplementation; B-3 and B-7, 3% and 7% β-conglycinin were added in the FM diets, respectively.

³Values are presented as the means ± SEM (n = 3 tanks).

Values in the same row with different superscripts indicate significant differences (*P* < 0.05), while that with the same letter or no letter superscripts indicate no significant differences (*P* > 0.05). T-AOC, total antioxidant capacity; GSH-Px, glutathione peroxidase; CAT, catalase; SOD, superoxide dismutase; MDA, malondialdehyde.

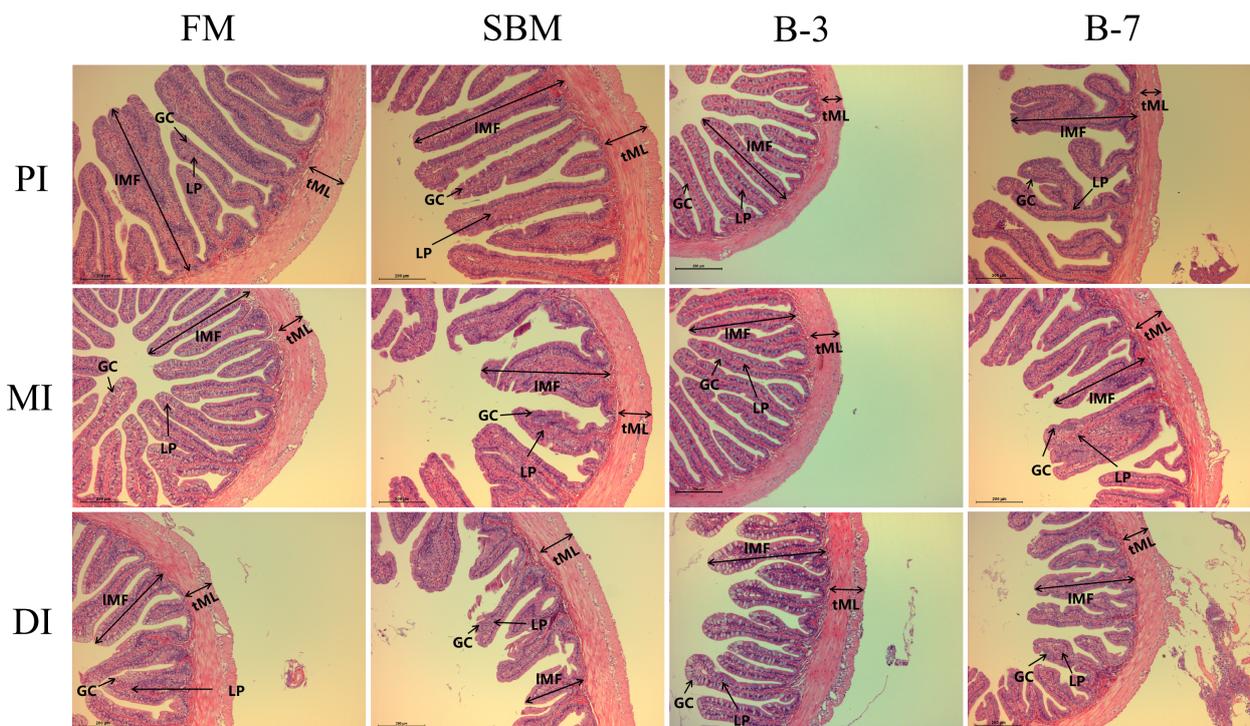

FIGURE 1
 Histological examinations of the proximal intestine (PI), mid intestine (MI), and distal intestine (DI) in the 4 groups of fish fed the diets in a 56-day feeding period (magnification 100). FM, basal diet (control); SBM, high-soybean meal diet; B-3, 3% β -conglycinin addition in FM diet; B-7, 7% β -conglycinin addition in FM diet; LP, lamina propria; GC, goblet cells.

The mRNA levels of intestinal *caspase-3*, *caspase-8* and *caspase-9* genes were higher ($P < 0.05$) and the *bcl-2* and *bcl-xL* genes were lower ($P < 0.05$) in SBM and B-7 groups than in FM and B-3 groups (Figure 5). No differences ($P > 0.05$) in the values for the five genes between the B-3 group and FM group were observed, and the same was true for the five genes between SBM and B-7 groups.

3.6 Gut microbiota

As shown in Table 6, the richness and the diversity of bacterial community in the intestine was not affected ($P > 0.05$) by dietary treatments.

As shown in Figure 6A, the Proteobacteria (relative abundance 62.62%), Tenericutes (19.34%), Actinobacteria (9.92%), Firmicutes

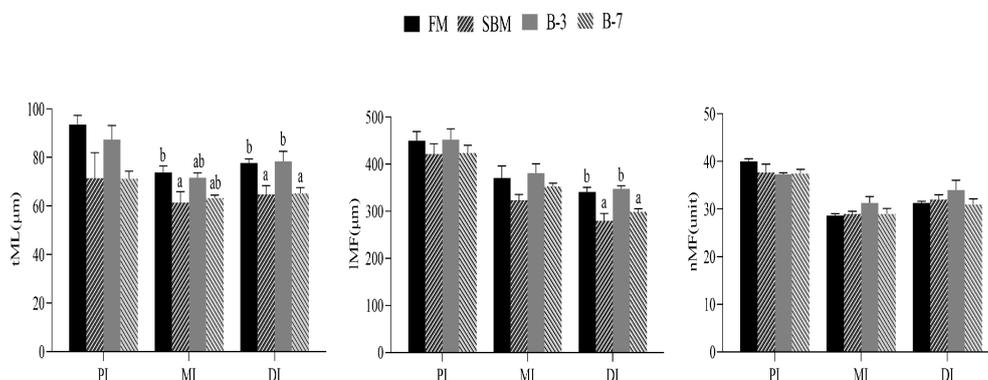

FIGURE 2

Data are represented as means ± SEM (n = 3 tanks) and analyzed by one-way ANOVA. Bars for each gene with different superscripts indicate significant differences ($P < 0.05$), while that with the same letter or no letter superscripts indicate no significant differences ($P > 0.05$). FM, basal diet (control); SBM, high-soybean meal diet; B-3, 3% β-conglycinin addition in FM diet; B-7, 7% β-conglycinin addition in FM diet.

(3.69%), Cyanobacteria (1.42%) and Bacteroidetes (1.12%) are the dominant intestinal bacteria at the phylum level. The relative abundances of the first four dominant phyla were listed in Figure 6B. Compared with the FM group, the relative abundance of Proteobacteria in the SBM group was higher ($P < 0.05$) than that in the B-3 group, but was not different ($P > 0.05$) from those of other groups. However, the relative abundance of Tenericutes in SBM and B-7 groups were lower ($P < 0.05$) than that in FM and B-3 groups. There was no difference in relative abundance of Actinobacteria among treatments ($P > 0.05$). The relative abundance of Firmicutes in the SBM group was lower ($P < 0.05$) than that in the FM group, and was not different ($P > 0.05$) from B-3 and B-7 groups.

As shown in Figure 7A, the dominant bacterial genera in the intestine of all four treatments were *Achromobacter* (relative abundance 31.35%), *Arthrobacter* (9.64%), *Vibrio* (4.98%), *Bacillus* (2.31%), *Hyphomicrobium* (1.50%), *Sediminibacterium* (0.64%), *Chroococcidiopsis* (0.73%) and *Enterovibrio* (0.19%). The relative abundances of the four most dominant genera were listed in Figure 7B. The relative abundance of *Vibrio* in the SBM group was higher ($P < 0.05$) than that in other groups, and there was no difference among other groups. However, the abundances of the *Achromobacter*, *Arthrobacter* and *Bacillus* were not affected ($P > 0.05$) by dietary treatments.

3.7 mRNA expressions of intestinal inflammatory factor genes

As shown in Figure 8, SBM and B-7 groups showed an upregulated ($P < 0.05$) mRNA level for *NF-κB1*, *RelA*, *TAK1*, *IKK*, *MyD88*, *TNF-α*, *IL-1β*, and *IL-8* genes in comparison with FM and B-3 groups. In contrast, SBM and B-7 groups showed a downregulated ($P < 0.05$) mRNA level for *IκBα*, *TGF-β1* and *IL-10* genes. No differences ($P > 0.05$) of the 11 genes between the B-3 group and FM group was observed, and the same was true for the 11 genes between SBM and B-7 groups.

4 Discussion

4.1 Growth performance and proximate composition

β-conglycinin is recognized as one of the main anti-nutritional factors in SBM due to its strong immunogenicity (Hu et al., 2021). In this study, two inclusion levels (3% and 7%) of β-conglycinin identical to the SBM substitution for 30% and 60% FM protein respectively were used to investigate its impacts on the growth

performance of grouper. Unexpectedly, 3% β -conglycinin improved growth and feed utilization in grouper than the FM diet. As expected, 7% β -conglycinin addition lowered the growth rate of grouper compared with those fed the FM diet, the practice achieved better growth and feed utilization in comparison with SBM diets. Similarly, several studies have also reported a negative effect of dietary high levels of β -conglycinin on the growth rate and feed utilization of other fish species (Zhang et al., 2013; Li et al., 2017; Duan et al., 2019a; Yin et al., 2021a; He et al., 2022). However, in this study, fish fed diets 3% and 7% β -conglycinin had the HSI

similar to the SBM group but exhibited reduced HSI vs the control. The similar effect of dietary β -conglycinin addition was observed in a study with Jian carp (*Cyprinus carpio* var. Jian) (Zhang et al., 2013). Furthermore, both SBM and β -conglycinin diets promoted whole-body moisture contents and reduced whole-body ash contents in this study and previous studies with turbot (*Scophthalmus maximus*) (Gu et al., 2016b) and barramundi (*Lates calcarifer*) (Ma et al., 2018), which was generally paralleled with the HSI. This may indicate the lower nutritional status of fish caused by the feeding of high β -conglycinin diets, as observed in fish fed high

SBM diets. Consistent with the study with golden crucian carp (*Cyprinus carpio* × *Carassius auratus*) (Li et al., 2019), whole-body lipid contents of grouper fed β-conglycinin diets were not different from those fed the FM diet, but higher than those fed the SBM diet.

4.2 Liver antioxidant capacity

Like the SBM diet, fish fed 7% β-conglycinin diet exhibited lower T-AOC value and GSH-Px activity, and increased MDA

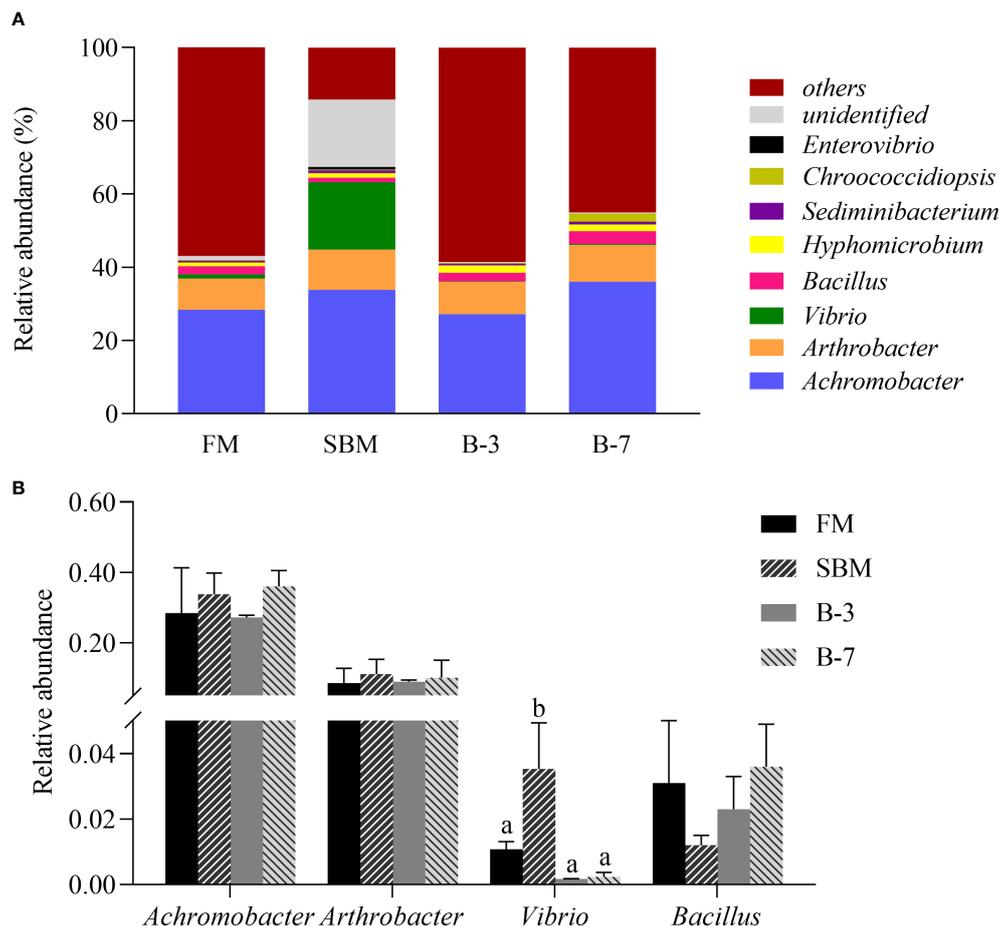

FIGURE 7 The relative abundance of intestine microbiota at genus levels in the 4 groups of fish fed the experimental diets in a 56-day feeding period. (A) Relative abundances of the intestine microbiota and (B) Relative abundances for the top-four genus level. Data are represented as means ± SEM (n = 3 tanks) and analyzed by one-way ANOVA. Bars for each bacterium with different superscripts indicate significant differences (P < 0.05), while that with the same letter or no letter superscripts indicate no significant differences (P > 0.05). FM, basal diet (control); SBM, high-soybean meal diet; B-3, 3% β-conglycinin addition in FM diet; B-7, 7% β-conglycinin addition in FM diet.

content in the liver compared with those fed the FM diet. This result indicates high β-conglycinin addition can cause an enhancement in hepatic lipid peroxidation, a reflection of hepatic oxidative damage to some extent. The enhancement of hepatic lipid peroxidation by high β-conglycinin was paralleled with the elevated MDA contents, and declined T-AOC value and GSH-Px activity in our current study and previous studies with Jian carp (Zhang et al., 2013) and golden crucian carp (Li et al., 2019). However, this negative effect was not rendered in fish fed 3% β-conglycinin diet in the present study, and the same result was observed in golden crucian carp fed 2% β-conglycinin diets (Li et al., 2019). Therefore, the intermediate β-conglycinin level is relatively safe for hepatic antioxidant damage in fish.

4.3 Intestinal structural integrity

The intestinal structure integrity plays an important role in the maintenance of normal digestion and absorption status and intestinal disease resistance as well as a crucial barrier against

exogenous pathogens in fish (Song et al., 2022). For histology and morphology, intestinal tML, IMF and nMF are usually used as indicators to measure its digestion and absorption function (Niu et al., 2021). In this study, 7% β-conglycinin addition decreased tML and IMF of MI and DI, which agreed with the observations in other fish species (Gu et al., 2016b; Duan et al., 2019a; Li et al., 2021; Luo et al., 2023). Unlike 7% β-conglycinin diet, 3% β-conglycinin diet did not show significant alterations in the intestinal morphology vs FM diet. This indicates the dietary intermediate inclusion level of β-conglycinin has no damage to intestinal structure of fish (Li et al., 2021).

TLR2 gene deficient mice develop severe enteritis and bleeding, accompanied by intestinal inflammation and cell apoptosis, as well as intestinal mucosal barrier dysfunction mediated by intestinal junction proteins, ZO-1, and claudin-3 (Gibson et al., 2008). In order to better understand the effects of dietary β-conglycinin on the intestinal structure integrity, the intestinal tight junction function of fish at the mRNA level was determined in the present study. Like high SBM diets, 7% β-conglycinin diets down regulated the mRNA levels of *claudin-3*, *occludin* and *ZO-1* of intestine vs FM

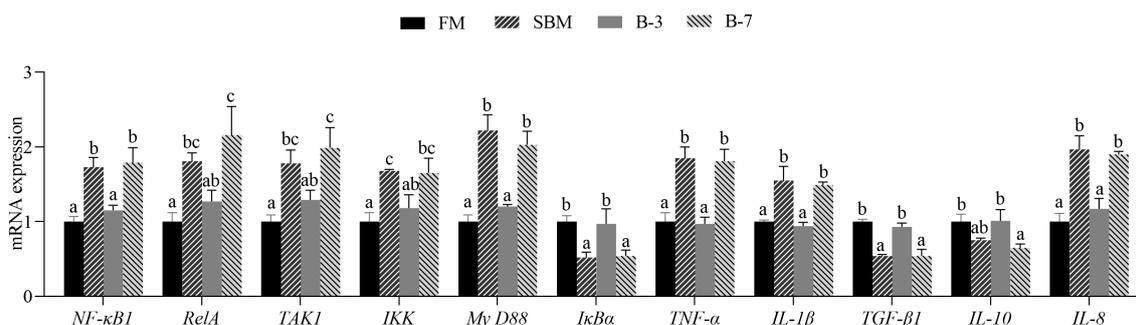

FIGURE 8

The expression of intestinal inflammatory factor genes in the 4 groups of fish fed the diets in a 56-day feeding period. Data are represented as means \pm SEM ($n = 3$ tanks) and analyzed by one-way ANOVA. FM, basal diet (control); SBM, high-soybean meal diet; B-3, 3% β -conglycinin addition in FM diet; B-7, 7% β -conglycinin addition in FM diet; NF- κ B1, nuclear factor kappa-B1; RelA, transcription factor p65; TAK1, transforming growth factor activated kinase-1; IKK, inhibitor of kappa B kinase; MyD88, myeloid differentiation factor 88; I κ B α , inhibitor of κ B alpha; TNF- α , tumor necrosis factor-alpha; IL-1 β , interleukin-1 beta; TGF- β 1, transforming growth factor-beta 1.

diet. Our current results were supported by previous studies with other fish when fed high β -conglycinin diets (Zheng et al., 2020; Yin et al., 2021a). However, the mRNA levels of the three genes in fish fed 3% β -conglycinin diets did not differ from that fed the FM diet. Interestingly, an up-regulation of intestinal mRNA levels of *claudin-3* was reported in hybrid grouper fed 1.5% β -conglycinin diet (Yin et al., 2021a). It can be seen that dietary high β -conglycinin level rather than intermediate β -conglycinin level disrupts the intestinal structure integrity by disrupting the function of intestinal tight junction proteins of fish.

The intestinal mucosa provides an important barrier against external bacterial invasion. When the intestinal mucosa barrier is impaired, bacterial-derived substances such as ET and D-Lac are able to invade deeper intestinal mucosal layers to enter the blood circulation (Han et al., 2020). The increase of plasma DAO activity, ET and D-Lac content caused by SBM addition is associated with the decrease in the integrity of the intestinal structure or the increase of intestinal mucosal permeability (Zhao et al., 2021). In the present study, like SBM diets, fish fed 7% β -conglycinin diets had higher plasma DAO activity, D-Lac and ET contents vs FM diets. This was consistent with the previous study with turbot fed 8% β -conglycinin diet (Zheng et al., 2020). However, the adverse effect was not triggered by 3% β -conglycinin diet. These results indicate that high β -conglycinin could impair intestinal mucosa barrier through increasing the intestinal permeability of fish.

4.4 Intestinal cell apoptosis

Intestinal cell apoptosis caused by dietary high β -conglycinin inclusion is mediated by caspase family (Duan et al., 2019a; He et al., 2022), as observed in other studies, that is, feeding high SBM diets led to the up-regulation of intestinal apoptosis gene expression (*caspase-3*, *caspase-8* and *caspase-9*) (Zhang B. L. et al., 2022; Zhao et al., 2023). In this study, the intestinal TUNEL fluorescence

staining and the intestinal *caspase-3*, *caspase-8* and *caspase-9* mRNA expression levels were used to further determine the effects of dietary β -conglycinin on intestinal apoptosis of grouper. The results showed that both SBM and 7% β -conglycinin diets enhanced the number of intestinal apoptotic cells and the expression levels of *caspase-3*, *caspase-8* and *caspase-9* genes compared with fish fed the FM diet, but this effect did not occur in fish fed 3% β -conglycinin diet. These indicate that intestinal cell apoptosis of fish could be triggered by dietary high β -conglycinin through promoting the activation of intestinal caspases.

Besides the caspase-mediated intestinal apoptosis, the NF- κ B signaling pathway regulating intestinal apoptosis was determined in this study. The activation of NF- κ B can induce an up-regulation of mRNA levels of *bcl-2* and *bcl-xL* genes, as a result of a reduction in mitochondrial membrane permeability and a block of cytochrome C release to inhibit apoptosis (Leber et al., 2007). The cytokine TNF- α acts as an activator of NF- κ B signaling pathway, whose up-regulation will stimulate NF- κ B1/RelA to enter the nucleus and activates genes with DNA binding sites for NF- κ B, leading to the occurrence of apoptosis, which in turn induces the down-regulation of mRNA expression of downstream *bcl-2* and *bcl-xL* genes (Heissmeyer et al., 2001). In this study, down-regulated mRNA levels of *bcl-2* and *bcl-xL* genes and up-regulated mRNA levels of NF- κ B and TNF- α genes were observed in fish fed the SBM and 7% β -conglycinin diets, which agreed with the results in a study with grass carp fed high β -conglycinin diets (Duan et al., 2019a). Although there are few research reports on the effect of dietary β -conglycinin levels on the intestinal cell apoptosis of fish, glycinin, another major antigen protein, has also been found to render this effect in other fish, that is, high glycinin diets down-regulated intestinal *bcl-2* mRNA expression and up-regulated intestinal TNF- α mRNA expression (Zhang Y. L. et al., 2021; Yi et al., 2022). Therefore, dietary high β -conglycinin could enhance intestinal cell apoptosis by down-regulating anti-apoptosis *bcl-2* and up-regulating expression of pro-apoptosis TNF- α through NF- κ B signaling pathway.

4.5 Intestinal microbiota

Numerous and complex intestinal microbiota are interdependent with the host, forming a relatively independent intestinal microbiota homeostasis, which is inseparable from nutrition, immunity and metabolism (McKenney and Pamer, 2015). The intestinal microbiota of fish is affected by the environment, temperature, and especially by the source, composition and type of feed (Bereded et al., 2022). For instance, high SBM diets decreased intestinal abundance of Firmicutes and Actinobacteria and increased intestinal abundance of Cyanobacteria and Tenericutes at the phylum level, as well as lowered the abundances of *Fictibacillus* and *Lactobacillus* and increased *Mycoplasma* at the genus level in largemouth bass (*Micropterus salmoides*) (Chen et al., 2021). In the present study, the predominant bacterial phyla in the intestine of grouper were Proteobacteria, Tenericutes, Actinobacteria and Firmicutes. Interestingly, the abundances of Proteobacteria were generally higher in fish fed the SBM and 7% β -conglycinin diets than those fed the 3% β -conglycinin and FM diets. The increased abundance of Proteobacteria was also observed in largemouth bass fed SBM diets (Ren et al., 2022) and hybrid grouper fed 6% β -conglycinin diets (Yin et al., 2021b). Proteobacteria includes many pathogenic bacteria that produce a large amount of lipopolysaccharides (Lin et al., 2020), and which exacerbate stroke by activating NF- κ B to produce large amounts of pro-inflammatory cytokines (Hakouopian et al., 2021). In contrast, the abundances of Tenericutes were higher in fish fed FM and 3% β -conglycinin diets than those fed SBM and 7% β -conglycinin diets. It is still unclear whether Tenericutes belongs to one of beneficial bacterial phyla in fish, which needs further study (Wang et al., 2021). The intestinal enrichment of Proteobacteria and reduction of Tenericutes may reflect an imbalanced profile of intestinal microbiota (Shin et al., 2015). In addition, our present study showed that SBM and β -conglycinin diets reduced abundance of Firmicutes, which was consistent with the results in hybrid grouper fed 6% β -conglycinin diet (Yin et al., 2021b).

The genus *Vibrio* such as *Vibrio anguallanim* is harmful to many fish species (Frans et al., 2011). In this study, the genus *Vibrio* is one of the dominant bacterial genera in the intestine of fish fed SBM diet (Figure 7A), which was consistent with the results in a previous study with turbot fed SBM diet (Zhang W. et al., 2022). This might partly explain the phenomenon that dietary high SBM can induce enteritis in fish by providing the conditions for the colonization of opportunistic pathogens in the intestine. However, dietary β -conglycinin addition did not render the similar responses to SBM diets, the changing tendency of intestinal bacterial composition of high β -conglycinin diets is generally similar to that of FM diets, which may be related to other anti-nutritional factors.

4.6 Gene expression of intestinal inflammatory factors

The intestinal tract of fish is not only a place for digestion and absorption of nutrient, but also an important organ for immune defense. In addition to acting as a physical barrier, its epithelial cells

can also secrete cytokines and chemokines to regulate immune cells and resist the invasion of pathogens (Ferguson et al., 2010). As an important nuclear transcription factor, NF- κ B is also involved in the regulation of inflammation through inducing the expression of various pro-inflammatory genes including *TNF- α* , *IL-1 β* , *IL-6*, *IL-12* (Liu et al., 2022). IL-1 β receptor-associated kinase is mobilized through Myd88 to activate IRAKs when cells are stimulated by *IL-1 β* . Subsequently, a downstream molecular transformation growth factor TAK1 is triggered. Then activates I κ B kinase, resulting in degradation of the I κ B protein and released of NF- κ B dimer. NF- κ B1 and NF- κ B p65 (RelA) then entered the nucleus and bind to target genes in the nucleus, promoting the release of pro-inflammatory factors (*IL-8*, *IL-1 β* , *TNF- α*) and inhibiting anti-inflammatory factors (*IL-10*, *TGF- β 1*) (Trung and Lee, 2020). In addition, *TNF- α* activates mitogen-activated protein kinase kinases (MAKKs) by binding to their receptors, and subsequently activates I κ B protein, which in turn activates NF- κ B-related pathways and their downstream inflammatory responses (Garg and Aggarwal, 2002).

Previous studies showed that the intestinal mRNA levels of *RelA*, *TNF- α* , *IL-1 β* , *IL-8*, *Myd88*, and/or *IKK* genes of fish were up-regulated by high SBM diets (Gu et al., 2016b; Wang et al., 2017; Zhang W. et al., 2021; Liu et al., 2022). Similarly, in this study, SBM diets exhibited up-regulated intestinal mRNA levels of *TNF- α* , *IL-1 β* , *Myd88*, *IKK- α* , *TAK1*, *RelA*, *NF- κ B1*, and *IL-8* genes similar to 7% β -conglycinin diets did, the down-regulated intestinal mRNA levels of *TGF- β 1*, *IL-10*, and *I κ B α* genes were observed in fish fed both SBM and 7% β -conglycinin diets. This finding was supported by the results of previous studies on other fish fed 7% or 8% β -conglycinin diets with an intestinal up-regulation of *RelA*, *IKK α* , *IKK β* , *IKK γ* , *IL-1 β* , *IL-8*, and/or *Myd88* and a down-regulation of *TGF- β 1*, *IL-10*, and/or *I κ B α* genes (Duan et al., 2019b; Liu et al., 2019; He et al., 2022). The above results showed that high β -conglycinin addition could cause inflammation in the intestine through NF- κ B pro-inflammatory signaling pathway and related anti-inflammatory pathways.

5 Conclusions

The growth performance of fish could be restricted by dietary high β -conglycinin, which was accompanied with the enhancement of hepatic lipid peroxidation. Meanwhile, dietary high β -conglycinin could increase the intestinal mucosal permeability and damage the intestinal structural integrity by disrupting intestinal tight junction structure and inducing intestinal apoptosis through promoting the activation of intestinal caspases. Furthermore, dietary high β -conglycinin could alter intestinal bacterial profile and provide the conditions for the colonization of opportunistic pathogens in the intestine, triggering intestinal inflammatory responses, thereby promoting the occurrence of enteritis of the fish species.

Data availability statement

The datasets presented in this study can be found in online repositories. This data can be found here: NCBI accession number: PRJNA980955.

Ethics statement

The animal study was reviewed and approved by Jimei University, Xiamen.
