The increase of methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant *Enterococcus* (VRE) poses a worldwide and serious health threat. Although new antibiotics, such as daptomycin and linezolid, have been developed for the treatment of infections of Gram-positive pathogens, the emergence of daptomycin-resistant and linezolid-resistant strains during therapy has now increased clinical treatment failures. In the past few years, studies using quantitative proteomic methods have provided a considerable progress in understanding antibiotic resistance mechanisms. In this review, to understand the resistance mechanisms to four clinically important antibiotics (methicillin, vancomycin, linezolid, and daptomycin) used in the treatment of Gram-positive pathogens, we summarize recent advances in studies on resistance mechanisms using quantitative proteomic methods, and also examine proteins playing an important role in the bacterial mechanisms of resistance to the four antibiotics. Proteomic researches can identify proteins whose expression levels are changed in the resistance mechanism to only one antibiotic, such as LiaH in daptomycin resistance and PrsA in vancomycin resistance, and many proteins simultaneously involved in resistance mechanisms to various antibiotics. Most of resistance-related proteins, which are simultaneously associated with resistance mechanisms to several antibiotics, play important roles in regulating bacterial envelope biogenesis, or compensating for the fitness cost of antibiotic resistance. Therefore, proteomic data confirm that antibiotic resistance requires the fitness cost and the bacterial envelope is an important factor in antibiotic resistance.

Keywords: quantitative proteomics, methicillin resistance, vancomycin resistance, linezolid resistance, daptomycin resistance

Introduction

Antibiotic resistance has posed a serious threat to the worldwide public health in the past two decades. The gradual increase in resistance rates of several important pathogens, including methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant *Enterococcus* (VRE), multidrug-resistant (MDR) *Pseudomonas aeruginosa*, imipenem-resistant *Acinetobacter baumannii*, and third-generation cephalosporin-resistant *Escherichia coli* and *Klebsiella pneumoniae*, has become an increasingly severe problem in many hospitals worldwide (Lee et al., 2013). However, the decline in novel antibiotics that are introduced in the market weakens the hope of overcoming this threat by the development of new antibiotics. Most of the antibiotic classes used in hospitals today were discovered during the period 1930–1960. Only two new systemic classes of antibiotics that were developed during the past 30 years were linezolid and daptomycin, which are used only in the treatment of Gram-positive pathogens (Lee et al., 2013). Because many Gram-positive pathogens increasingly develop resistance against currently available antibiotics such as methicillin and vancomycin, these new antibiotics have become valuable for the treatment of various infections of methicillin- or vancomycin-resistant *S. aureus* and *Streptococcus pneumoniae* (Ament et al., 2002; Mendes et al., 2014). However, the emergence of daptomycin-resistant or linezolid-resistant strains has recently been described in some Gram-positive pathogens (Fischer et al., 2011; Mendes et al., 2014). In this review, we summarize resistance mechanisms to four clinically important antibiotics (methicillin, vancomycin, linezolid, and daptomycin) used in the treatment of Gram-positive pathogens, and highlights recent important studies using comparative proteomic tools to understand resistance mechanisms of these antibiotics in more detail.

Action and Resistance Mechanisms of Methicillin, Vancomycin, Linezolid, and Daptomycin Resistance

Methicillin

Methicillin is a narrow-spectrum β -lactam antibiotic of the penicillin class. Like other β -lactam antibiotics, methicillin prevents the synthesis of bacterial cell walls by inhibiting peptidic cross-linkage between the linear peptidoglycan polymer

chains, which provides rigidity to the cell wall of Gram-positive bacteria (Chambers, 1997) (Table 1). Methicillin and other β -lactam antibiotics are structural analogs of D-Ala-D-Ala, which is the terminus of a short amino acid chain attached in *N*-acetylmuramic acids; so, they interact with and irreversibly inhibit the transpeptidase enzyme [also called penicillin-binding protein (PBP)] that crosslinks the linear peptidoglycan polymer chains (Lee et al., 2012). This process leads to loss of osmotic integrity and makes the bacterial cells susceptible to lysis. Although most β -lactam antibiotics are inhibited by bacterial enzymes that hydrolyze the β -lactam ring (named β -lactamases), due to a modification of the original penicillin structure methicillin is resistant to β -lactamases (Lee et al., 2012). Therefore, since the late 1950s when methicillin was first introduced in markets, this antibiotic has been used to treat infections caused by *Staphylococcus* pathogens such as *Staphylococcus aureus*, most of which produces β -lactamase (Newsom, 2004).

Today, methicillin is not as effective against these organisms due to resistance (Cordwell et al., 2002; Newsom, 2004). Although the resistance phenotype of methicillin is influenced by numerous factors, including *mecA*, *glmM*, *fmtAB*, *murE*, *llm*, β -lactamase (*bla*) regulatory elements, and *fem* factors (Chambers, 1997; Cordwell et al., 2002; Hao et al., 2012), one major reason for methicillin resistance is the expression of the *mecA* gene, encoding penicillin-binding protein 2a (PBP 2a) that is not inhibited by classical β -lactam antibiotics including methicillin (Katayama et al., 2004) (Table 1). PBP 2a works in a similar manner to other PBPs, but it is bound by β -lactams with very low affinity (Katayama et al., 2004). Expression of PBP 2a confers resistance to all β -lactams. A variety of factors such as MecI and MecR1 controlled the *mecA* expression (Chambers, 1997). Resistance to methicillin exhibited by strains lacking the *mecA* gene is associated with modifications in native PBPs, β -lactamase hyperproduction, or possibly a methicillinase (Chambers, 1997). In pathogenesis, it has been reported that some virulence factors (Panton-Valentine leukocidin, phenol-soluble modulin, arginine catabolic mobile element, and other toxin elements) and two-component regulation systems (*agr*, *saeRS*, and *vraRS*) involved in pathogenesis can enhance the fitness of methicillin-resistant pathogens (Hao et al., 2012).

Vancomycin

Vancomycin made by the soil bacterium *Amycolatopsis orientalis* is a member of the glycopeptide antibiotic class and has an

TABLE 1 | Modes of action of four clinically important antibiotics (methicillin, vancomycin, linezolid, and daptomycin) and resistance mechanisms to these antibiotics.

Antibiotics	Target	Mechanism of action	Resistance mechanisms found by non-proteomic approaches
Methicillin	Transpeptidase enzyme [penicillin-binding protein (PBP)]	Inhibition of peptidoglycan biosynthesis	Expression of penicillin-binding protein 2a (MecA), efflux pump
Vancomycin	D-Ala-D-Ala dipeptide terminus of the nascent peptidoglycan	Inhibition of peptidoglycan biosynthesis	Alteration of the D-Ala-D-Ala dipeptide
Linezolid	23S rRNA	Inhibition of translation	Alteration of 23S rRNA
Daptomycin	Cell membrane	The formation of holes that leak intracellular ions	Remained to be elucidated

important role in the treatment of serious infections caused by Gram-positive bacteria such as *Staphylococcus* and *Streptococcus* (Woodford, 1998). It is a complex compound consisting of a branched tricyclic glycosylated peptide and is a rare example of a halo-organic natural compound containing two covalently bonded chlorine atoms (Levine, 2006). Vancomycin inhibits the peptidoglycan synthesis by binding at the D-Ala-D-Ala dipeptide terminus of the nascent peptidoglycan in Gram-positive bacteria (Healy et al., 2000; Levine, 2006). This binding of vancomycin to the D-Ala-D-Ala prevents the peptidic cross-linking between the linear peptidoglycan polymer chains by inhibiting the proper interaction with the transpeptidase enzyme (Healy et al., 2000) (**Table 1**).

Most Gram-negative bacteria are intrinsically resistant to vancomycin because it cannot penetrate the outer membrane of Gram-negative bacteria. In Gram-positive bacteria, one mechanism of resistance to vancomycin is the alteration of the terminal amino acid residues (D-Ala-D-Ala), to which vancomycin binds (**Table 1**). The D-Ala-D-Ala dipeptide terminus of the nascent peptidoglycan is replaced by D-Ala-D-Lac or D-Ala-D-Ser. The D-Ala-D-Lac variation results in a 1000-fold decrease in the affinity between vancomycin and the peptide, and the D-Ala-D-Ser variation causes a 6-fold loss of affinity, most likely due to steric hindrance (Courvalin, 2005). These alterations of the D-Ala-D-Ala dipeptide terminus require the coordinate action of several enzymes encoded by the *van* genes. Alternative ligases catalyze the formation of the D-Ala-D-Lac peptide (VanA, B, and D type enzymes) or D-Ala-D-Ser peptide (VanC, E, and G type enzymes) in peptidoglycan synthesis. VanH protein (α -keto acid reductase) reduces pyruvate to D-Lac, and the D,D-dipeptidase VanX selectively removes the D-Ala-D-Ala produced by the native ligase to enhance the incorporation of the D-Ala-D-Lac or D-Ala-D-Ser into the peptidoglycan precursor. VanR and VanS constitute a two-component regulatory system that activates the transcription of the *van* gene cluster (Marcone et al., 2010).

Linezolid

Linezolid is a first synthetic oxazolidinone antibiotic used to treat infections caused by VRE and MRSA. Although the mechanism of action of linezolid is not fully understood, it seems to bind to the 50S subunit of the bacterial ribosome through interaction with the central loop of the 23S rRNA and block the formation of protein synthesis initiation complexes (Swaney et al., 1998; Ament et al., 2002) (**Table 1**). Because linezolid binds to the 23S portion of the 50S subunit different from the binding sites of other ribosome-binding antibiotics such as chloramphenicol, cross-resistance between linezolid and other protein synthesis inhibitors is highly rare (Herrmann et al., 2008). The crystal structures of linezolid bound to the 50S subunit in 2008 showed that linezolid binds to the A site of the 50S ribosomal subunit and induces a conformational change perturbing the correct positioning of tRNAs on the ribosome (Ippolito et al., 2008; Wilson et al., 2008).

Most Gram-negative bacteria have an intrinsic resistance to linezolid due to the high activity of efflux pumps, which actively pump linezolid out of the cell (Schumacher et al., 2007). In

Gram-positive bacteria, the acquired resistance to linezolid was first reported in 1999 in multidrug-resistant *Enterococcus faecium* (Mendes et al., 2014). High-resolution structures of linezolid with the 50S ribosomal subunit showed that it binds to a deep cleft that is surrounded by the central loop of domain V of 23S rRNA (Long and Vester, 2012). Therefore, the most common resistance mechanism of Gram-positive bacteria to linezolid was a point mutation known as G2576T, in which the G2576 position of 23S ribosomal RNA is converted to thymine (Mendes et al., 2014). In addition to mutations in 23S rRNA, other mechanisms have been identified in Gram-positive bacteria, including a six base pair deletion in the ribosomal protein L4, mutations in the ribosomal protein L3, mutations in an RNA methyltransferase (encoded by the *cfr* gene) that methylates G2445 of the 23S rRNA, and mutations causing increased expression of ABC transporter genes (*patA* and *patB*).

Daptomycin

Daptomycin is a lipopeptide antibiotic consisting of a lipid molecule conjugated with anionic peptide and is a natural compound found in the soil bacterium *Streptomyces roseosporus* (Miao et al., 2005). Daptomycin absolutely requires Ca^{2+} for activity, making this agent a cationic antimicrobial peptide functionally (Baltz, 2009). The poorly calcium-decorated form of daptomycin is 10 times less active microbiologically than the heavily calcium-decorated form (Baltz, 2009). The calcium-bound daptomycin interacts with phosphatidylglycerol in the bacterial membrane and inserts into the cell membrane, leading to the formation of holes that leak intracellular ions (Pigliano et al., 2012). A loss of membrane potential causes inhibition of protein, DNA, and RNA synthesis, which results in bacterial cell death (Pigliano et al., 2012). Because of a distinct mechanism of action of daptomycin, it is used in the treatment of life-threatening infections caused by multiple drug-resistant Gram-positive bacteria (Baltz, 2009). Because vancomycin and daptomycin have molecular weight (MWs) of more than 1000 Da (vancomycin of 1449 Da and daptomycin of 1620 Da), they cannot penetrate the outer membrane of Gram-negative bacteria (Lee et al., 2013). Therefore, two antibiotics are used to control infections caused by Gram-positive bacteria.

Although daptomycin was clinically introduced in 2003, clinical treatment failures by the emergence of daptomycin-resistant strains during therapy have now been described (Hobbs et al., 2008; Fischer et al., 2011). Up to now, specific genetic determinant of the daptomycin-resistant strain remained to be elucidated, despite the finding of several phenotypic and genetic determinants (altered phospholipid synthesis, thickened cell walls, alteration of cell membrane fluidity, and the acquisition of mutations within the *mprF* or *yygG* gene) (Mishra et al., 2009; Fischer et al., 2011). The *mprF* gene encodes a dual functional enzyme that catalyzes the coupling of lysine to phosphatidylglycerol (PG) and transfers the lysyl-PG (LPG) to the outer leaflet of the membrane. The LPG is less acidic than PG, and membranes lacking LPG are more acidic than those containing PG and LPG (Baltz, 2009). Daptomycin-resistant strains with *mprF* mutations have membranes with increased levels of LPG (Jones et al., 2008). Therefore, the increased positive

charge caused by increased LPG in the *mprF* mutant (gain-of-function) reduces the binding of Ca²⁺-bound daptomycin to bacterial membranes by a less favorable electrostatic interaction. YycG is a membrane spanning sensor histidine kinase of a two-component signal transduction system that partners with the YycF response regulator. YycFG functions as a master regulatory system for cell wall metabolism and biofilm formation and is the only two-component system required for viability in many Gram-positive bacteria (Winkler and Hoch, 2008; Baltz, 2009).

Comparative Proteomic Analyses of Methicillin, Vancomycin, Linezolid, and Daptomycin Resistance

Quantitative proteomics have been considerably improved during the past decade and have been employed for investigation of the differences in whole protein expression dynamics of cells grown under a variety of growth conditions or stress conditions such as antibiotics (Radhouani et al., 2012). Therefore, by studies using quantitative proteomic approaches in the past few years, a considerable progress has recently been made in the study of antibiotic resistance mechanism. To summarize recent updates to understand the resistance mechanism to four clinically important antibiotics used in the treatment of Gram-positive pathogens, we used the Preferred Reporting Items for Systematic Review and Meta-Analysis (PRISMA) in our review (Figure 1) (Moher et al., 2009). We conducted a systematic literature search in the following databases: Medline via PubMed and Embase. We used keywords as search terms. We combined terms for selected indications (methicillin, vancomycin, linezolid, daptomycin, and proteomics). The literature search included all studies published

in English between 2000 and 2015. We identified 13 proteomics studies comparing proteomic profiles in antibiotic-resistant and antibiotic-sensitive strains or exploring proteomic profiles in cells treated with or without antibiotics.

Methicillin

Two studies exploring proteomic profiles of methicillin-susceptible *S. aureus* (MSSA) and methicillin-resistant *S. aureus* (MRSA) in the absence of methicillin were reported (Cordwell et al., 2002; Enany et al., 2014). Cordwell et al. compared the protein profiles between *S. aureus* strains COL (methicillin-resistant) and 8325 (methicillin-susceptible) in the absence of methicillin (Cordwell et al., 2002). Interestingly, among proteins previously known as resistance-related factors (e.g., *mecA*, *glmM*, *fmtAB*, *murE*, *llm*, *bla*, and *fem* factors), only FemA protein, which is known as a host-mediated factor essential for methicillin resistance in *S. aureus* (Berger-Bächi et al., 1989), was more highly expressed in methicillin-resistant cells (Cordwell et al., 2002). However, upon growth of both strains in the presence of Triton X-100 (TX-100), a detergent that has been shown to reduce methicillin resistance, no difference on the production of the essential methicillin-resistance factor FemA was detected (Cordwell et al., 2002). Instead, expression levels of stress-related proteins including cold-shock proteins (CspABC) and alkaline-shock protein 23 (Asp23) increased in the methicillin-resistant *S. aureus* strain COL (Cordwell et al., 2002). Notably, the amount of CspB, CspC, and Asp23 proteins was affected in cases of vancomycin and daptomycin antibiotics, despite being down-regulated in the vancomycin-resistant strain and up-regulated in the daptomycin-resistant strain (Table 7). This study also showed that three proteins linked to the alternative

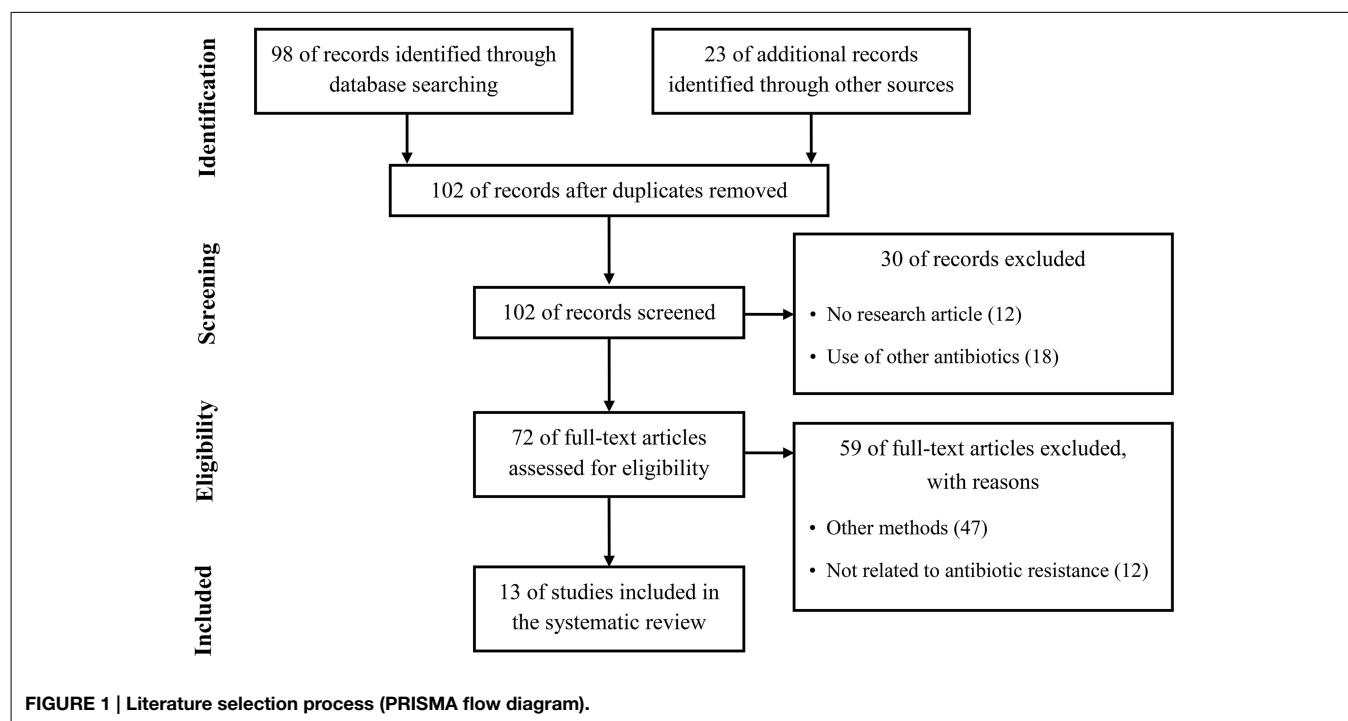

FIGURE 1 | Literature selection process (PRISMA flow diagram).

sigma factor σ^B , Asp23, anti-anti- σ^B factor RsbV, and conserved hypothetical protein SA0772, were also present at significantly higher levels in methicillin-resistant cells (Cordwell et al., 2002). In the presence of TX-100 weakening the methicillin resistance, the comparative proteomic analysis showed that proteins of the σ^B and SarA (a regulator of virulence genes) regulons are involved in methicillin resistance of *S. aureus* (Cordwell et al., 2002). The level of SarA protein also increased in vancomycin-resistant and daptomycin-resistant cells (Table 7). This study also showed that the stage V sporulation protein G (SpoVG), originally identified in *Bacillus subtilis* as being involved in the formation of the spore cortex (Matsuno and Sonenshein, 1999), was up-regulated in the methicillin-resistant *S. aureus* strain COL. In the non-sporulating *S. aureus*, SpoVG contributes to stimulate capsule synthesis, and was recently shown to regulate a small σ^B -subregulon comprising mainly excreted virulence factors including the highly up-regulated virulence factor EsxA (Schulthess et al., 2012). Recently, it has been reported that SpoVG was involved in resistance mechanisms to methicillin and glycopeptide (Schulthess et al., 2009). Together with this report, a comparative proteome analysis showed that the expression level of SpoVG increased in strains resistant to methicillin, vancomycin, and daptomycin (Table 5), indicating that SpoVG may be involved in resistance mechanisms to other antibiotics as well as methicillin and glycopeptide.

Another report explored proteome profiles of extracellular proteins in methicillin-sensitive and methicillin-resistant *S. aureus* (Enany et al., 2014). They identified some proteins increased in MRSA; Asp23 (10-fold more in MRSA than MSSA), alkyl hydroperoxide reductase subunit C (AhpC) (2-fold), D-lactate dehydrogenase (LdhD) (2-fold), general stress protein 20U (3-fold), L-lactate dehydrogenase (LdhA) (2-fold), pyruvate dehydrogenase E1 component beta subunit (PdhB) (2-fold), superoxide dismutase (SodA) (2-fold), triacylglycerol lipase precursor (LipA) (2-fold), triosephosphate isomerase (TpiA) (2-fold), and universal stress protein family protein (7-fold) (Enany et al., 2014). Notably, among them, most proteins (AhpC, SodA, LdhA, LipA, and TpiA) also have altered expression levels in other antibiotic-resistant strains (Table 7). In addition, elongation factor G (encoded by the *fusA* gene) was also increased in MRSA. Our analysis showed that PusA is one of the three proteins affected in all four antibiotic-resistant strains (Table 5).

Although elongation factor G is a major target of fusidic acid which has been used as a topical agent for skin infection and for some systemic infections caused by *S. aureus* (Howden and Grayson, 2006), and had a contribution to fusidic acid resistance mechanisms evolved in MRSA (Koripella et al., 2012), the relationship between elongation factor G and resistance mechanisms of other antibiotics has not yet been identified.

Vancomycin

There were two studies exploring proteomic profiles in vancomycin-susceptible *S. aureus* (VSSA) and vancomycin-intermediate *S. aureus* (VISA) with a minimal inhibitory concentration (MIC) of 4–8 $\mu\text{g}/\text{ml}$, one study exploring proteomic profiles in VSSA and heterogeneous vancomycin-intermediate *S. aureus* (hVISA) with a vancomycin MIC of $\leq 2 \mu\text{g}/\text{ml}$, one study exploring proteomic profiles in VISA and vancomycin-resistant *S. aureus* (VRSA) with MIC of $\geq 8 \mu\text{g}/\text{ml}$, one study analyzing global proteomes of vancomycin stress in *S. aureus*, and two studies examining vancomycin-induced proteomes of *Enterococcus faecalis* under vancomycin treatment (Pieper et al., 2006; Scherl et al., 2006; Drummelsmith et al., 2007; Wang et al., 2010; Chen et al., 2013; Hessling et al., 2013; Ramos et al., 2015). Many proteins previously known as resistance-related factors, including VanA, VanB, VanX, and VanR, were also identified in comparative proteomic analyses (Table 2). Scherl et al. (2006) showed that a total of 155 proteins are differentially expressed between two vancomycin-susceptible *S. aureus* strains (MRGR3 and 14-4Rev) and the vancomycin-intermediate *S. aureus* strain 14-4, and most proteins play a role in energy metabolism, cell envelope biosynthesis, protein turnover, amino acids transport, and metabolism, and inorganic ion transport. Genes or gene products known to be involved in resistance mechanisms to different antibiotics, such as PBP 2a (MecA), O-nucleotidyltransferase(9) [Ant(9)], UDP-N-acetylmuramyl tripeptide synthetase (MurE), and penicillin-binding methicillin resistant-related protein (FmTA), were up-regulated in the VISA strain (Scherl et al., 2006). All of them are involved in peptidoglycan biosynthesis. Levels of many other proteins involved in peptidoglycan metabolism also increased in the VISA strain, such as glycosyltransferase (SgtB) and CHAP

TABLE 4 | Differentially expressed proteins identified by the quantitative proteomic approach: proteins involved in amino acid, nucleotide, coenzyme, and inorganic ion metabolism.

Biological process	Protein name	Gene	Antibiotics	Regulation	Frequency of difference	References	Protein description
Amino acid transport and metabolism	Threonine deaminase	<i>lvaA</i>	Met	Down	1	Cordwell et al., 2002	Threonine metabolism
	Aspartate kinase	<i>lysC</i>	Van	Up	1	Hessling et al., 2013	Biosynthesis of lysine, methionine, threonine
	Aspartate semialdehyde dehydrogenase	<i>asd</i>	Van	Up	1	Hessling et al., 2013	Biosynthesis of lysine, methionine, threonine
Dihydridipicolinate synthase	<i>dapA</i>	Van	Up	1	Hessling et al., 2013	Biosynthesis of lysine	
Tetrahydridipicolinate acetyltransferase	<i>dapD</i>	Van	Up	1	Hessling et al., 2013	Biosynthesis of lysine	
Diaminopimelate decarboxylase	<i>lysA</i>	Van	Up	1	Hessling et al., 2013	Biosynthesis of lysine	
Arginine deiminase	<i>arcA</i>	Van	Down	1	Ramos et al., 2015	Arginine metabolism	
4-Hydroxy-tetrahydridipicolinate reductase	<i>dapB</i>	Van	Up	1	Hessling et al., 2013	Biosynthesis of lysine	
Cystathione β -lyase	<i>metC</i>	Van	Up	1	Wang et al., 2010	Biosynthesis of methionine	
Cystathione γ -synthase	<i>metB</i>	Van	Up	1	Drummelsmith et al., 2007	Biosynthesis of methionine	
Chorismate mutase	<i>aroA</i>	Van	Down	1	Drummelsmith et al., 2007	Biosynthesis of aromatic amino acids	
Urease α subunit	<i>ureC</i>	Van	Up	1	Drummelsmith et al., 2007	Urea metabolism	
Urease accessory protein	<i>ureE</i>	Van	Up	2	Scherl et al., 2006; Drummelsmith et al., 2007	Urea metabolism	
Branched-chain amino acids aminotransferase	<i>lvcE</i>	Van	Down	2	Pieper et al., 2006; Scherl et al., 2006	Biosynthesis of branched-chain amino acids	
Aetylornithine aminotransferase 2	<i>argD</i>	Van	Up	1	Pieper et al., 2006	Biosynthesis of lysine	
Amino acid ABC transporter amino acid-binding protein	<i>glnH</i>	Lin	Up	1	Feng et al., 2011	Glutamine transport	
Tryptophan synthase subunit α	<i>trpA</i>	Lin	Down	1	Feng et al., 2011	Biosynthesis of aromatic amino acids	
Asparagine synthetase	<i>asnA</i>	Lin	Down	1	Feng et al., 2011	Biosynthesis of asparagine	
Aminotransferase	<i>aspC</i>	Lin	Up	1	Feng et al., 2011	Biosynthesis of lysine, methionine, threonine	
Carbamate kinase	<i>arcC</i>	Van	Down	2	Scherl et al., 2006; Ramos et al., 2015	Allantoin degradation	
1-Pyrroline-5-carboxylate dehydrogenase	<i>rocA</i>	Van	Up	1	Feng et al., 2011	Proline degradation	
Serine hydroxymethyltransferase	<i>glyA</i>	Van	Up	1	Fischer et al., 2011		
Glutamine synthetase type 1	<i>glnA</i>	Lin	Down	1	Drummelsmith et al., 2007	Biosynthesis of glycine	
Nucleotide transport and metabolism	Bifunctional pyrimidine regulatory protein /uracil phosphoribosyltransferase	<i>pyrR</i>	Met	Down	1	Fischer et al., 2011	Nitrogen assimilation
	Purine nucleoside phosphorylase	<i>deoD</i>	Van	Down	1	Fischer et al., 2011	
					Cordwell et al., 2002	Salvage pathways of pyrimidine ribonucleotides	
					Pieper et al., 2006	Guanosine nucleotides <i>de novo</i> biosynthesis

(Cysteine, Histidine-dependent Amidohydrolases/Peptidases)-domain amidase (SsaA). SsaA belongs to the CHAP amidase family, members of which such as LysK and LytA have been shown to have D-alanyl-glycyl endopeptidase activity, cleaving between the crossbridge and the stem peptide (Delaune et al., 2011), and protein levels of SsaA were also changed in cases of methicillin and linezolid (**Table 6**), indicating the importance of this protein on peptidoglycan metabolism and antibiotic resistance.

They also identified several regulatory systems contributing to the VISA phenotype, such as the two-component system (VraSR) regulating expression of a set of genes involved in the cell wall biosynthesis or degradation (Boyle-Vavra et al., 2013), the signal transduction protein TRAP acting on quorum sensing (Gov et al., 2004), the DivIVA protein known to regulate cell division in *B. subtilis* (Perry and Edwards, 2004), and putative transcription factors SA2296 and SarH1. VraSR (vancomycin resistance associated regulator) was up-regulated under vancomycin treatment (Kuroda et al., 2003) and in the VISA strain when compared with an isogenic vancomycin-susceptible strain (Kuroda et al., 2000). In addition, inactivation of the *vraSR* gene increased vancomycin susceptibility (Kuroda et al., 2003). Interestingly, VraSR was also induced by other antibiotic classes that target the cell wall, including β -lactam (Gardete et al., 2006; Yin et al., 2006), mersacidin (Sass et al., 2008), certain cationic peptides (Pietiäinen et al., 2009), and daptomycin (Muthaiyan et al., 2008). Inactivation of the *vraSR* gene attenuates resistance to various antibiotics, such as vancomycin (Kuroda et al., 2003; Gardete et al., 2006), daptomycin (Mehta et al., 2012), and β -lactams (Kuroda et al., 2003; Boyle-Vavra et al., 2006; Gardete et al., 2006). The expression of many genes, such as *ctpA*, *drp35*, *fmtA*, *opuD*, *pbp2*, *prsa*, *sgtB*, and *vraX*, is regulated by VraSR (Utaida et al., 2003; McAleese et al., 2006; Dengler et al., 2011). Among them, FmtA is typically known as a factor involved in methicillin-resistant phenotype of *S. aureus* (Fan et al., 2007), and PrsA (foldase precursor) was recently reported to be involved in both glycopeptide and oxacillin resistance in *S. aureus* (Jousselin et al., 2012). Similarly, at three independent studies of comparative proteomic analysis, it has been proven that the expression level of PrsA is up-regulated in VISA when compared with VSSA (**Table 5**), indicating that proteomic studies can support the identification of targets involved in antibiotic resistance. They also identified another important protein VraX (a hypothetical protein which encodes a 55-amino acids protein) differentially expressed between vancomycin-susceptible *S. aureus* strains and the vancomycin-intermediate *S. aureus* strain 14-4 (Scherl et al., 2006). This gene was up-regulated by multiple cell wall and/or membrane active compounds (bacitracin, d-cycloserine, oxacillin, tunicamycin, flavomycin, fosfomycin, teicoplanin, vancomycin, daptomycin, lysostaphin, epicatechin gallate, ranalexin, and antimicrobial peptides) (Utaida et al., 2003; Pietiäinen et al., 2009; Dengler et al., 2011; Cuaron et al., 2013). The *vraX* gene belongs to the *vra* operon together with the *vraA* gene encoding for a long chain fatty acid-CoA ligase, which was up-regulated in the VISA. Additionally, this gene seems to be involved in resistance

mechanism to vancomycin (Hanaki et al., 1998; Buntaran et al., 2013). Finally, stress-related proteins such as proteinases (CtpA), methionine sulfoxide reductase A (MsrA2), and the methionine sulfoxide reductase regulator MsrR, were over-expressed in the vancomycin-intermediate *S. aureus* strain 14-4 (Scherl et al., 2006). In other studies, MsrA2 was also up-regulated in hVISA (Chen et al., 2013).

Pieper et al. showed that purine ribonucleotide biosynthesis (PRNBS) pathway enzymes, which are under the control of the PurR regulator, strongly increased in protein abundance in the vancomycin-resistant *S. aureus* strain VP32 having a vancomycin MIC of 32 µg/ml when compared with the vancomycin-intermediate *S. aureus* strain HIP5827 (MIC = 8 µg/ml) (Pieper et al., 2006). Notably, among them, several proteins such as amidophosphoribosyltransferase (PurF), phosphoribosylamine-glycine ligase (PurD), phosphoribosylglycinamide cyclo-ligase (PurM), phosphoribosylaminoimidazole-succinocarboxamide synthase (PurC), adenylosuccinate lyase (PurB), and bifunctional purine biosynthesis protein (PurH), were also changed in protein abundance in cases of other antibiotics such as daptomycin and linezolid (**Table 4**). Microarray transcription analysis of clinical VISA isolates already showed that among the 35 genes with increased transcription in vancomycin-resistant *S. aureus* strain VP32 when compared with those of their VISA parent strains HIP5827 and P100, 15 were involved in purine biosynthesis or transport (Mongodin et al., 2003). They hypothesized that increased energy (ATP) is required to generate the thicker cell walls that characterize resistant mutants (Mongodin et al., 2003). However, contrary to these results, other comparative proteomic analyses between vancomycin-susceptible strains and vancomycin-intermediate *S. aureus* strains did not show similar results (Scherl et al., 2006; Drummelsmith et al., 2007; Chen et al., 2013). Therefore, these results imply that VRSA may more efficiently compensate for a fitness cost of antibiotic resistance such as ATP requirement than VISA.

Abundance changes were also found in proteins such as the single-stranded DNA binding protein (TraM), DNA gyrase subunit B (GyrB), and topoisomerase IV subunit B (ParE), which catalyze or influence the fidelity of DNA replication and repair (**Table 5**). This result is consistent with the increasing evidence that exposure to antibiotics in bacteria leads to increased mutation rates in the genome, to favor their survivals under antibiotic pressure (Napolitano et al., 2000; Friedberg et al., 2002; Pieper et al., 2006). Expression levels of many enzymes involved in energy metabolism, including L-lactate dehydrogenase (LdhA), glucose-6-phosphate isomerase (Pgi), succinyl-CoA synthetase (SucCD), phosphoglycerate kinase (Pfk), nitrate reductase alpha chain (NarG), and aconitate hydratase (CitB), were also changed. In fact, comparative proteomic analyses show that proteins involved in energy metabolism, protein synthesis, and envelope biogenesis, most frequently exhibit abundance change in antibiotic-resistant strains (**Table 3**). In many cases, proteins playing a role in energy metabolism were up-regulated in antibiotic-resistant strains (**Table 3**). This phenomenon may be explained by a prior hypothesis that increased energy (ATP) is required to generate the thicker cell walls or to pump antibiotics out of the cell using efflux pumps. This study

also showed the changes of proteins involved in cell envelope biogenesis, such as D-Ala-D-Ala ligase (Ddl), D-Ala-D-Lac ligase (VanA), peptidoglycan hydrolase (LytM), cell division and cell wall biosynthesis protein (MraZ), putative cell wall transglycosylase (SceD), and glucosamine-fructose-6-phosphate aminotransferase (GlmS) (Pieper et al., 2006).

Similar to prior reports, Drummelsmith et al. showed the high level inductions of cell wall metabolism-related proteins such as MecA, LytM, GlmS, and SceD in the VISA type strain Mu50 when compared with the vancomycin-sensitive strain CMRSA-2 (Drummelsmith et al., 2007). In particular, they selected SceD for further study based on its high level of induction (approximately 16-fold) in VISA, and relative *sceD* mRNA expression levels were compared between 25 VSSA and VISA clinical isolates by real-time RT-PCR (Drummelsmith et al., 2007). The *sceD* mRNA was significantly induced in all VISA isolates relative to all VSSA strains, and they suggest that SceD expression level could serve as a molecular diagnostic marker for the rapid detection of VISA (Drummelsmith et al., 2007). Interestingly, SceD was also up-regulated in both daptomycin-resistant (Song et al., 2013) and linezolid-resistant strains (Bernardo et al., 2004), suggesting the importance of this protein in antibiotic resistance. They also identified other proteins involved in cell envelope metabolism as a highly up-regulated protein in VISA; UDP-GlcNAc 1-carboxyvinyltransferase 1 (MurA), bifunctional autolysin (Atl), immunodominant antigen A (IsaA), UDP-glucose/GDP-mannose dehydrogenase (CapO), and UDP-N-acetylglucosamine 2-epimerase (CapG) (**Table 6**). Among them, IsaA was also up-regulated in VISA at other two studies (Scherl et al., 2006; Chen et al., 2013). In addition, its expression level increased in both methicillin-resistant and daptomycin-resistant strains (Cordwell et al., 2002; Fischer et al., 2011), and decreased in linezolid-resistant strains (Bernardo et al., 2004), suggesting the importance of this protein. The housekeeping protein IsaA is a highly immunogenic, non-covalently cell wall-bound lytic transglycosylase that is co-regulated with a glycylglycine endopeptidase LytM (Stapleton et al., 2007; Lorenz et al., 2011). *S. aureus* has two putative peptidoglycan hydrolases, IsaA and SceD, and SceD can compensate for the loss of IsaA (Stapleton et al., 2007). The fact that both peptidoglycan hydrolases (IsaA and SceD) are involved in antibiotic resistance strongly indicates the importance of cell wall dynamics in antibiotic resistance mechanism.

To identify the resistance mechanisms of hVISA with a vancomycin MIC of ≤ 2 µg/ml, Chen et al. compared proteomic profiles of six pairs of isogenic hVISA and VSSA strains and unrelated hVISA ($n = 24$) and VSSA stains ($n = 30$) (Chen et al., 2013). They identified five proteins up-regulated in the hVISA strains; IsaA, MsrA, Asp32, 2,3-bisphosphoglycerate-dependent phosphoglycerate mutase (GpmA), and AhpC. Consistent with this result, MsrA was up-regulated in a prior study using comparative proteomics (Scherl et al., 2006) and in the DNA microarray study, and the *msrA* gene was also over-expressed in VISA strains (Cui et al., 2005). MsrA, catalyzing the reversible oxidation-reduction of methionine sulfoxide to methionine, has a key function as a repair enzyme for proteins inactivated by oxidation (Chen et al., 2013). The *msrA* gene is highly

induced by cell wall-active antibiotics, such as oxacillin and vancomycin (Chen et al., 2013). The increased level of *MsrA* can enhance peptidoglycan biosynthesis which results in cell wall thickening, and gene knockout of the *msrA* gene weakened vancomycin and β -lactam resistance of *S. aureus* strains (Cui et al., 2005). In addition, *MsrA* is involved in virulence in several bacteria (Sasindran et al., 2007). Taken together, these observations suggest the important role of methionine sulfoxide in antibiotic resistance. Although in other studies, the abundance of *GpmA*, which plays a physiological role in glycolysis, has been reported to be changed in VISA (Table 3), its exact role in antibiotic resistance has not been determined. *AhpC*, an alkyl hydroperoxide reductase subunit C, plays an important role in oxidative-stress resistance of *S. aureus* (Cosgrove et al., 2007). Interestingly, it was reported that *AhpC* is up-regulated in strains resistant to methicillin, vancomycin, and daptomycin antibiotics (Table 7). However, up to now, there is no report investigating the direct role of *AhpC* in antibiotic resistance. It is noteworthy that several proteins involved in oxidative-stress resistance, such as *AhpC*, *SodA*, catalase (*KatA*), and superoxide dismutase (*SodM*), show the abundance change of proteins in antibiotic-resistant strains (Table 7), and in most cases, their expression is up-regulated. In spite of these interesting results, the relationship between these proteins and antibiotic resistance was not determined.

Hassling et al. analyzed proteomic profiles of vancomycin-susceptible *S. aureus* strain COL under the sublethal vancomycin exposure (4.5 μ g/ml) (Hessling et al., 2013). They found the specific increase of proteins involved in the synthesis of lysine which are essential for the synthesis of the peptidoglycan precursor pentapeptide; aspartate kinase (*LysC*), aspartate semialdehyde dehydrogenase (*Asd*), dihydridopicolinate synthase (*DapA*), 4-hydroxy-tetrahydridopicolinate reductase (*DapB*), diaminopimelate decarboxylase (*LysA*), and tetrahydridopicolinate acetyltransferase (*DapD*). An increase of lysine synthesis proteins can lead to an overall increase of peptidoglycan synthesis. Induction of genes involved in lysine synthesis under cell wall stress conditions have been documented before by two transcriptome studies (Kuroda et al., 2003; Sobral et al., 2007). Consistent with the previous report (Scherl et al., 2006), this report also showed that several proteins regulated by the two-component system *VraSR* increased in amount after vancomycin addition (Hessling et al., 2013). Additionally, they identified two important regulators (the alternative sigma factor σ^B and the two-component system *SaeRS* regulating numerous virulence genes) that play a role in vancomycin stress response. The cluster of proteins under positive σ^B control mainly increased, whereas negatively regulated proteins primarily decreased in amount after vancomycin addition (Hessling et al., 2013). The induction of σ^B regulon by vancomycin has been found in another report (Chen et al., 2013). Increase of the σ^B activity has also been observed in strains resistant to teicoplanin (Bischoff and Berger-Bächi, 2001) or methicillin (Cordwell et al., 2002). Hassling et al. also found decreased expression levels of most proteins with a virulence related function (Hessling et al., 2013). However, because the great majority of virulence genes in previous transcriptome studies under cell wall stress in *S. aureus*

have been shown to be up-regulated (Kuroda et al., 2003; Utaida et al., 2003; Sobral et al., 2007), the role of virulence genes in antibiotic resistance needs to be determined.

Lastly, Wang et al. and Ramos et al. performed proteomic analysis of vancomycin-resistant *E. faecalis* strains (V583, V306, and SU18) under 64 μ g/ml vancomycin treatment (Wang et al., 2010; Ramos et al., 2015). Vancomycin induced expression of vancomycin resistance-related proteins such as *VanA*, *VanX*, D-Ala-D-Ala dipeptidase (*DdpX*), *VanR*, and *VanB* (Wang et al., 2010; Ramos et al., 2015). Distinctively, Wang et al. found that six proteins (*Pgm*, *Ldh*, *Gap-2*, *RpsB*, *EF2076*, and sex pheromone *cAD1* precursor lipoprotein) exhibited clear post-translational modifications and vancomycin induced phosphorylation of Ser/Thr in *Ldh*, *Gap-2*, and sex pheromone *cAD1* precursor lipoprotein (*EF3256*) (Wang et al., 2010). Ramos et al. showed that metabolism-related proteins, such as *TipA*, GMP synthase (*GuaA*), and glyceraldehyde-3-phosphate dehydrogenase (*GapB*), were down-regulated under vancomycin treatment (Ramos et al., 2015).

Linezolid

There was one study exploring comparative proteomic profiles in linezolid-susceptible *S. pneumoniae* strains and linezolid-resistant *S. pneumoniae* strains, and one study analyzing global proteomes of a linezolid-susceptible *S. aureus* under linezolid stresses (Bernardo et al., 2004; Feng et al., 2011). Through the comparison between linezolid-susceptible *S. pneumoniae* strains (1974 and R6) with linezolid MICs of 0.5–0.75 μ g/ml and linezolid-resistant *S. pneumoniae* strains (1974M2-LZD and R6M2-LZD) with MIC of 32 μ g/ml, Feng et al. showed that the proteomic and transcriptomic approaches were poorly correlated with previously known resistance factors (23S rRNA, ribosomal proteins L3 and L4, RNA methyltransferase *Cfr*, and ABC transporter *PatA* and *PatB*), as modulated proteins rarely had significant concomitant changes at the expression level (Feng et al., 2011). They found increased expression of proteins involved in the metabolism and transport of carbohydrates in linezolid-resistant *S. pneumoniae* strains (Feng et al., 2011). Through inactivation of target genes in the linezolid-resistant strains (1974M2-LZD and R6M2-LZD), they identified two ABC transporter substrate-binding proteins (*Spr0083* and *Spr1527*) and the catabolite control protein A (*CcpA*) as factors associated with resistance to linezolid (Feng et al., 2011). *CcpA* is known to function as the global regulator controlling the efficient utilization of sugars through carbon catabolite repression (CCR) in Gram-positive bacteria (Stülke and Hillen, 2000). Inactivation of the *ccpA* gene in *S. aureus* affected growth, glucose metabolism, and expression of virulence genes (Seidl et al., 2006). *CcpA* inactivation was also linked to the down-regulation of glycolytic genes in *Bacillus cereus* (van der Voort et al., 2008; Feng et al., 2011). Therefore, the increased level of *CcpA* may cause the increased expression of glycolytic enzymes in linezolid-resistant *S. pneumoniae* strains. In *S. aureus*, the correlation between antibiotic resistance and *CcpA* has already been reported, as *CcpA* inactivation significantly reduced the oxacillin resistance levels in MRSA and the teicoplanin resistance level in a glycopeptide-intermediate-resistant *S. aureus* strain (Seidl et al.,

2006). **Table 3** shows the possibility that CcpA may also be involved in methicillin and vancomycin resistance. Together with CcpA, inactivation of two ABC transporters putatively involved in the sugar transport (Spr0083 and Spr1527) also reduced resistance to linezolid of *S. pneumonia* (Feng et al., 2011). Notably, *S. pneumoniae* is predicted to be highly dependent on external sugars to fulfill its energy requirements by substrate-level phosphorylation as it lacks functional electron transport chain and tricarboxylic acid cycle (Tettelin et al., 2001; Feng et al., 2011). This process eventually leads to the formation of lactate and acetate by the lactate dehydrogenase and lactate oxidase enzymes and these proteins were also found to be overexpressed in linezolid-resistant *S. pneumonia* strains (Tettelin et al., 2001; Feng et al., 2011). Therefore, these results imply increased energy requirements associated with resistance mechanism to linezolid in *S. pneumonia* (Feng et al., 2011). To sustain a fitness cost associated with resistance mechanisms such as the 23S rRNA mutations (Besier et al., 2008), *S. pneumonia* seems to select an increased metabolism of sugars as a secondary adaptation.

This study also showed that several genes involved in the biosynthesis of fatty acids, including enoyl-CoA hydratase (PhaB), 3-ketoacyl-ACP reductase (FabG), acetyl-CoA carboxylase biotin carboxyl carrier protein subunit (AccB), acetyl-CoA carboxylase subunit alpha (AccA), and hydroxymyristoyl-ACP dehydratase (FabZ), were down-regulated in linezolid-resistant strains (Feng et al., 2011). Whether this is directly related to linezolid resistance remains to be established, but it is intriguing that the cell wall inhibitor penicillin also causes a down-regulation of several genes of this pathway in *S. pneumoniae* (Rogers et al., 2007; Feng et al., 2011). Interestingly, expression levels of FabZ are changed in all cases of the four antibiotics (**Table 6**), even though its expression increased in methicillin-resistant strains and decreased in strains resistant to other antibiotics. Many numbers of ribosomal proteins were found to be overexpressed or down-regulated in linezolid-resistant strains, but whether this pattern is due to the mechanism of action of linezolid (which targets the ribosome) remains to be established. Although recent several lines of evidence indicate the presence of functional selective ribosomal subpopulations that exhibit variations in the RNA or the protein components and modulate the translational program in response to environmental changes (Byrgazov et al., 2013), it is difficult to obtain any information from variation patterns of ribosomal proteins in this study.

Bernardo et al. compared the change of proteomic profiles of a linezolid- susceptible *S. aureus* strain ATCC 29213 (MIC = 2.5 µg/ml) under linezolid stresses (12.5, 25, 50, and 90% of MIC) (Bernardo et al., 2004). They found that linezolid reduced in a dose-dependent manner the secretion of specific virulence factors, including bifunctional autolysin (Atl), immunoglobulin G binding protein A (Spa), and α-hemolysin (SAV1163), CHAP-domain amidase (SsaA), and immunodominant antigen A (IsaA). This result is similar to the proteomic result that analyzes protein profiles of *S. aureus* under the sublethal vancomycin exposure (Hessling et al., 2013).

Daptomycin

There were one study examining comparative proteomic profiles in daptomycin-susceptible and daptomycin-resistant *S. aureus* strains, and one study analyzing global proteomes of daptomycin-susceptible *B. subtilis* under daptomycin stress (Wecke et al., 2009; Fischer et al., 2011). Unlike other three antibiotics (methicillin, vancomycin, and linezolid), specific genetic determinant of the daptomycin-resistant strain was not determined. Probable daptomycin resistance-related proteins (MprF, YycG, RpoB, and RpoC) identified in previous reports (Jones et al., 2008; Baltz, 2009) were not identified in comparative proteomic analyses (**Tables 2–8**). In 2011, Fisher et al. compared proteomic profiles in the daptomycin-susceptible *S. aureus* strain 616 with a daptomycin MIC of 0.5 µg/ml and the daptomycin-resistant *S. aureus* strain 701 with MIC of 2 µg/ml (Fischer et al., 2011). Comparative proteomics and transcriptomic approach revealed a differential abundance of proteins in various functional categories, including cell wall-associated targets and biofilm formation proteins (Fischer et al., 2011). Phenotypically, daptomycin-susceptible strains, and daptomycin-resistant strains showed major differences in their ability to develop bacterial biofilms in the presence of the antibacterial lipid, oleic acid (Fischer et al., 2011). Transcriptomic approach showed different expressions of some important genes, such as the key genes (*yycFGHI*) affecting cell membrane lipid homeostasis, cell wall metabolism and biofilm formation, and two-component regulation system genes (*agr*, *saeRS*, and *vraRS*) involved in pathogenesis of methicillin-resistant strains (Fischer et al., 2011). However, through proteomic research, only several proteins, including Asp23, 3-oxoacyl-ACP synthase II (FabF), GTP-sensing transcriptional pleiotropic repressor (CodY), and PurH, was identified as proteins involved in daptomycin resistance.

Wecke et al. searched proteins induced by daptomycin, through the proteomic approach of a daptomycin-susceptible *B. subtilis* strain W168 under daptomycin treatment of sublethal amount (1 µg/ml) (Wecke et al., 2009). They identified LiaI and LiaH proteins exclusively and strongly induced (429-fold) by daptomycin. This result is in good agreement with data analyzing genes induced by daptomycin through transcriptome profiling (Muthaiyan et al., 2008). LiaH is a conserved membrane protein similar to a phage shock protein A (PspA) of *E. coli*, and its expression is regulated by the cell envelope stress-sensing two-component system LiaRS (Jordan et al., 2006; Hachmann et al., 2009; Wecke et al., 2009). Inactivation of *liaH* leads to 3-fold increased susceptibility to daptomycin and this susceptibility was further exacerbated in cells additionally lacking the paralogous gene *pssA* (Hachmann et al., 2009). In *E. coli*, the *pssA* gene is induced upon phage infection, osmotic shock, exposure to ethanol, or temperature increase, and functions to help cells manage the impacts of agents impairing cell membrane function (Joly et al., 2010). A recent report showed that deletion of the response regulator LiaR regulating expression of *liaH* in daptomycin-resistant *E. faecalis* reversed resistance to daptomycin, and resulted in hypersusceptibility to daptomycin (Reyes et al., 2015). Therefore, these results indicate

that LiaR is a master regulator protecting cell membrane to diverse antimicrobial agents, through regulating expression of various genes such as the *liaH* gene (Reyes et al., 2015).

Conclusion

Although specific genetic determinants of resistance mechanisms to methicillin, vancomycin, and linezolid were identified through non-proteomic approaches (e.g., *van* genes in vancomycin resistance) (Table 1), recent comparative proteomic methods provide new opportunities to understand the antibiotic resistance mechanism. In particular, in the case of recently used antibiotics such as daptomycin, specific genetic determinant(s) of antibiotic resistance was not fully determined through non-proteomic approaches. Therefore, quantitative proteomic methods can be a good tool to find an important protein involved in daptomycin resistance. Actually, a proteomic research identified LiaH as a highly induced protein by daptomycin treatment (Muthaiyan et al., 2008) and a subsequent report showed that the expression level of this protein is important to daptomycin-resistant phenotype (Reyes et al., 2015). These results show that quantitative proteomic analysis can be used as an effective tool to find novel resistance mechanisms.

Interestingly, comparative proteomic approaches in methicillin, linezolid, and daptomycin, except for vancomycin, were poorly correlated with known resistance-related factors found by non-proteomic approaches (Table 2). This result may be caused by a lack of comparative proteomic studies in three antibiotics, or imply the existence of novel resistance mechanisms different from previously known resistance mechanisms found by non-proteomic approaches. Through summarizing recent data of comparative proteomic researches of four clinically important antibiotics, we can find proteins of which expression levels are changed only in the resistance mechanism to specific antibiotic, such as LiaH in daptomycin resistance and PrsA in vancomycin resistance. It is necessary to determine whether these proteins affect antibiotic resistance through regulating previously known resistance-related determinants or by a novel mechanism. Another interesting result is that many proteins identified by comparative proteomic analyses seem to be simultaneously involved in resistance mechanism to two or more antibiotics (Tables 2–8). These proteins include cold shock proteins (CspABC), sporulation protein G (SpoVG), alkyl hydroperoxide reductase subunit

C (AhpC), L-lactate dehydrogenase (LdhA), triacylglycerol lipase precursor (LipA), superoxide dismutase (SodA), catalase (KatA), elongation factor G (FusA), CHAP-domain amidase (SsaA), two component system (VraSR), penicillin binding methicillin resistant-related protein (FmtA), adenylosuccinate lyase (PurB), glucose-6-phosphate isomerase (Pgi), catabolite control protein A (CcpA), putative cell wall transglycosylase (SceD), immunodominant antigen A (IsaA), bifunctional autolysin (Atl), the σ^B regulon, and hydroxymyristoyl-ACP dehydratase (FabZ). These proteins can be divided into two groups, proteins involved in bacterial envelope regulation and proteins compensating for a fitness cost of antibiotic resistance. Proteins such as LipA, VraSR, FmtA, SsaA, SceD, IsaA, Atl, and FabZ, are directly or indirectly involved in envelope regulation. In order to modify or thicken the bacterial cell wall for antibiotic resistance, cells require abundant energy, and proteins involved in stress adaptation are necessary to neutralize various damages by antibiotic. To sustain these fitness costs associated with resistance mechanisms, proteins involved in energy metabolism (LdhA, FusA, Pgi, PurB, and CcpA) and stress-related proteins (CspABC, SpoVG, AhpC, SodA, KatA, and the σ^B regulon) seem to be identified in resistance mechanisms to several antibiotics. Therefore, these proteomic results confirm that antibiotic resistance requires a fitness cost.

Detailed studies on the mechanism by which these proteins affect antibiotic resistance are required. In particular, because these proteins can act as the global factor affecting resistance mechanisms to most antibiotics, it is necessary to examine whether they affect resistance mechanism of other antibiotics having different action modes. These studies will provide important clues for understanding and managing antibiotic resistance.
