Objective: Atherosclerosis is the most common pathological change of cerebral small vessel disease (CSVD). This study aimed to investigate correlations between carotid atherosclerotic calcification and clinical outcomes of symptomatic CSVD.

Methods: We retrospectively evaluated 210 symptomatic CSVD patients who underwent carotid computed tomography angiography (CTA) and brain magnetic resonance imaging (MRI). Clinical outcomes were evaluated using modified Rankin Scale (mRS) at 90 days after acute event. The presence and characteristics of carotid calcification (including size, number and location), carotid plaque burden and CSVD markers were analyzed. Logistic regression analysis was used to explore associations between carotid calcification and CSVD outcomes. Key confounding variables (age, sex, hypertension, diabetes mellitus, hyperlipidemia, coronary heart disease, smoking history, drinking history, ulceration, positive remodeling and positive soft plaque) were adjusted in multivariate analysis. The areas under the curve (AUC) of receiver operating characteristic (ROC) curves were used to analyze predictive performance of various radiological variables for CSVD outcomes.

Results: A total of 129 patients with poor outcomes and 81 with good outcomes were analyzed. The incidence of calcification plaque in poor outcome group was higher than those in good outcome group ($p = 0.001$). Logistic regression found that the presence of calcification, surface calcification, multiple calcifications, thick/mixed calcifications, carotid stenosis degree and total CSVD score were associated with adverse outcomes in symptomatic CSVD before and after adjusting for confounding factors (all $p < 0.05$). ROC analysis showed that the prediction model with integrated carotid calcification exhibited enhanced performance with a sensitivity of 75.19% and specificity of 70.37% (AUC = 0.752, $p < 0.001$).

Conclusion: Carotid calcification characteristics were associated with clinical outcomes of symptomatic CSVD, which could be used as predictive indicators of CSVD outcomes.

1 Introduction

Cerebral small vessel disease (CSVD) refers to a group of pathological processes affecting the small arteries, venules, and capillaries of the brain (1). With a high prevalence in the elderly, CSVD accounts for approximately one-quarter of all strokes (2). Typical neuroimaging markers of CSVD include recent small subcortical infarct (RSSI), lacune, white matter hyperintensity (WMH), enlarged perivascular space (EPVS), cerebral microbleed (CMB) and brain atrophy (3). Among various subtypes, symptomatic CSVD is a clinical presentation of a lacunar syndrome, confirmed by anatomically corresponding lacunar infarction on brain MRI (4). The clinical manifestation of symptomatic CSVD is complicated, and its clinical outcomes vary substantially among individuals (5). Therefore, early detection of symptomatic CSVD patients with a high risk of developing adverse outcomes is essential.

Atherosclerosis of carotid arteries was a well-established cause of ipsilateral ischemic stroke and was also one of the most common pathological changes of CSVD (1, 6). Arterial calcification, which was an indicator of advanced atherosclerosis (7), has been recognized as an easily identifiable and highly specific imaging feature reflecting atherosclerosis. Historically, calcification has been considered protective and a marker of plaque stability (8, 9). However, several recent studies have emphasized that calcification in specific sizes and locations was associated with increased plaque vulnerability (10, 11), which in turn is related to CSVD (12, 13).

Lots of studies have identified that carotid calcification was an adverse factor for cerebrovascular ischemic events (e.g., stroke, transient ischemic attack) (14–17). However, most of these studies focused on the calcification volume or subtype, and few studies focused on the characteristics of carotid artery calcification. Compared with previous studies, characteristics of carotid artery calcified plaques could comprehensively depict the distribution, shape, stability and other factors of calcification, which may better evaluate the prognosis of patients with cerebrovascular ischemic events. Additionally, prior research has shown that carotid diseases (e.g., carotid vulnerable plaque, carotid stenosis) were associated with poor post-stroke outcomes (18, 19). Nevertheless, it is uncertain whether characteristics of carotid artery calcification are correlated with clinical outcomes of symptomatic CSVD.

Therefore, this study aimed to explore the potential link between carotid atherosclerotic calcification and the clinical outcomes of symptomatic CSVD patients, as well as to determine whether this correlation is dependent on the specific feature of calcification.

2 Materials and methods

2.1 Study population

This study was approved by the Ethical Committee of Shandong Provincial Hospital Affiliated to Shandong First Medical University (SWYX: No. 2024–072), and informed consent was waived due to the retrospective nature of the study. We retrospectively analyzed 305 patients diagnosed with symptomatic CSVD defined as a clinical presentation of lacunar syndrome confirmed by anatomically corresponding lacunar infarct on brain MRI from January 2016 to January 2024. Inclusion criteria: (1) MRI-verified symptomatic lacunar ischemic stroke; (2) typical MRI findings of CSVD, including RSSI, lacune, WMH, EPVS, and CMB; (3) carotid CTA and brain MRI were conducted successively in the short term (≤ 3 months). Exclusion criteria were: (1) absence of acute infarct or acute infarct with diameter > 20 mm ($n = 53$); (2) extracranial or intracranial macrovascular stenosis $> 70\%$ ($n = 33$); (3) intracranial hemorrhage ($n = 2$); (4) cardiogenic infarction ($n = 3$); (5) WMH unrelated to CSVD, such as multiple sclerosis ($n = 1$); (6) comorbid with other neurological disorders, such as Parkinson's disease ($n = 1$); (7) comorbid with systemic diseases, such as tumors ($n = 1$). (8) Renal dysfunction ($n = 1$). The patients' selection flow chart is shown in Figure 1.

Comprehensive data including demographics, clinical features and risk factors were gathered. Patient demographics and clinical data are listed in Table 1. Clinical outcomes were based on the modified Rankin Scale (mRS) score at 90 days after acute event. A good outcome was classified as $mRS \leq 2$, while $mRS > 2$ was considered as a poor outcome.

2.2 CTA and MRI protocols

Carotid CTA was performed with a third-generation dual-source CT scanner (SOMATOM Force, Siemens Healthcare). Contrast medium (Omnipaque-350, GE Healthcare) was injected at 4 mL/s with a volume of 60–80 mL, followed immediately by 40 mL of saline solution at the same injection rate. Bolus tracking was utilized to start the acquisition 5 s after the aortic arch attenuation reached the 100 HU threshold. The following parameters were set for the examination: Tube voltage, 80 kV for BMI ≤ 25 kg/m² and 100 kV for BMI > 25 kg/m²; pitch, 1.0; rotation time, 350 ms; reconstructed slice thickness, 1.5 mm; reconstructed slice interval, 1.0 mm.

The brain MRI examination was performed using a 3.0 Tesla MRI system (Magnetom Prisma, Siemens Healthineers, Erlangen, Germany). The scan sequence included: T1-weighted images (T1WI), T2-weighted images (T2WI), T2-weighted fluid-attenuated inversion recovery (T2-FLAIR), diffusion-weighted imaging (DWI) and susceptibility-weighted imaging (SWI). The sequence parameters are as follows: T1WI: time repetition (TR) = 2000 ms, time echo (TE) = 7.4 ms, and slice thickness (ST) = 5.0 mm. T2WI: TR/TE = 4,300 ms/109 ms, ST = 5.0 mm;

Abbreviations: AUC, areas under the curve; CMB, cerebral microbleed; CSVD, cerebral small vessel disease; CTA, computed tomography angiography; DCA, Decision curve analysis; EPVS, enlarged perivascular space; (MRI), magnetic resonance imaging; mRS, modified Rankin scale; NIHSS, National Institutes of Health Stroke Scale; OR, odds ratio; RI, remodeling index; ROC, receiver operating characteristic; RSSI, recent small subcortical infarct; ST, slice thickness; TE, time echo; TR, time repetition; WMH, white matter hyperintensity.

NIHSS, median (IQR)	3 (2–5)
mRS score at baseline, median (IQR)	3 (3–4)
mRS score at 90 days, median (IQR)	3 (2–3)

mRS, modified Rankin scale; NIHSS, National Institutes of Health Stroke Scale; IQR, interquartile range.

T2-FLAIR: TR/TE = 8,000 ms/81 ms, ST = 5.0 mm; DWI: TR/TE = 2,680 ms/57 ms, ST = 1.5 mm; SWI: TR/TE = 27 ms/20 ms, ST = 1.5 mm.

2.3 Imaging assessment

The CTA and MRI images were independently evaluated by two experienced radiologists (JZ and SZ), each with more than 5 years of specialized experience in neurovascular imaging. Any disagreement was referred to a senior radiologist (XW) for a final decision. All image assessments were performed blinded to clinical data.

2.3.1 Carotid artery CTA

Carotid arteries analyzed mainly included common carotid arteries, extracranial internal carotid arteries, and intracranial internal carotid arteries. Using a postprocessing workstation (Syngovia, Siemens Force, Germany) to analyze and record the presence, number, location, maximum thickness and rim sign of calcified plaques on unilateral or bilateral carotid arteries. Depending on the quantity of plaques, calcified plaques were classified as either single (< 2) or multiple (≥ 2). Based on the location of calcified plaques, they were categorized as surface, deep, or mixed (presence of both surface and deep calcification). Surface calcification was identified when it was situated at or adjacent to the intimal surface, whereas deep calcification was defined when it was positioned at or near the medial/adventitial border with complete encasement by fibrous tissue (20). According to the maximum thickness of the calcified plaque, the morphology of calcification was divided into thin (< 2 mm), thick (≥ 2 mm), and mixed (both thin and thick calcification were present) (21). The rim sign was defined as a thick soft plaque (≥ 2 mm) surrounded by thin calcium (< 2 mm) (22). Examples of various imaging characteristics of calcification were shown in Figure 2.

Additionally, the degree of carotid artery stenosis, plaque ulceration, plaque remodeling index (RI) and positive soft plaque were recorded. A maximum soft plaque thickness of more than 2 mm was

FIGURE 2

Imaging characteristics of carotid calcified plaque, positive remodeling and ulceration. Arrows show plaque with various characteristics: (A–C) illustrate the different positions of calcified plaques in carotid artery. (A), surface calcification; (B), deep calcification; (C), mixed calcification. Panel (D) indicates calcification with a positive rim sign. Panel (E) presents an example of positive remodeling; remodeling index (RI) was computed as a/b . Panel (F) shows ulceration (arrow) of carotid plaque.

considered positive soft plaque (21). According to the North American Symptomatic Carotid Endarterectomy Trial criteria (23), the degree of carotid artery stenosis is classified as mild (0–49.9%), moderate (50–69.9%), or severe (70–99.9%). The last group was excluded because of severe stenosis. Ulceration was defined as contrast media protrusion into the plaque, measuring at least 2 mm (24). RI was defined as the ratio of the maximum wall thickness at the most stenotic location to the wall thickness at the normal proximal vessel and $RI \geq 1.05$ indicates positive remodeling (25).

2.3.2 Assessment of MRI markers of CSVD

Imaging features of CSVD are assessed in accordance with the Standards for Reporting Vascular Changes on Neuroimaging consensus. (1) Lacune, a round or oval structure with a diameter of 3–15 mm located subcortically. The signal of lacune is similar to cerebrospinal fluid on T1WI and T2WI; it exhibits hyperintensity surrounding rims on FLAIR (26). (2) WMH, shown as isointensity or hypointensity on T1WI while displaying hyperintensity on FLAIR and T2WI. It is classified as periventricular WMH (PWMH) and deep WMH (DWMH) according to the Fazekas scale and graded from 0 to 3 (27). (3) CMB, a small round or ovoid low signal on SWI sequences, with a diameter of 2 to 10 mm (28). (4) EPVS, presented as round or linear cerebrospinal fluid signals on T1WI, T2WI and FLAIR sequences with a diameter of < 3 mm. A validated four-point visual

assessment scale (score 0: none; score 1: 1–10; score 2: 11–20; score 3: 21–40; score 4: > 40) was used to assess the EPVS of the basal ganglia (29). The overall CSVD score was assessed by utilizing an established scale ranging from 0 to 4 (30). The presence of the manifestations listed below earned one point: (1) ≥ 1 lacuna; (2) Fazekas score with deep WMH ≥ 2 points and/or periventricular WMH score of 3 points; (3) ≥ 1 deep or infratentorial CMB; (4) severe PVS in the basal ganglia (≥ 2 points).

2.4 Statistical analysis

The Kolmogorov–Smirnov test was used to determine the variable's normality. Continuous quantitative data was presented as mean \pm standard deviation (SD) or median [interquartile range, IQR] based on distribution, and Student's *t*-test or Mann–Whitney *U* test were used for comparison. Categorical variables were described as frequencies (percentages), and intergroup differences are compared using the χ^2 test or Fisher's exact test. Univariate and multivariate logistic regressions were used to explore associations between calcification characteristics, plaque burden, CSVD markers and outcomes in symptomatic CSVD patients. In multivariate analysis, common clinical risk factors and carotid plaque burden were adjusted. Interaction terms were used to investigate whether the

association between carotid calcification and outcomes of symptomatic CSVD differed according to clinical covariates. The areas under the curve (AUC) of the receiver operating characteristic (ROC) curves were reported to evaluate the possible incremental contribution of carotid calcification features (p value < 0.05 in multivariate regression analysis) to identify poor outcomes. Bootstrap method was used to internally validate models with 500 resamples (31). Calibration curves and Decision curve analysis (DCA) were used to evaluate the calibration ability and net benefits of models. Two-sided p values < 0.05 were considered to be statistically significant. The interobserver agreements for CTA data and CSVD markers were assessed using Kappa test, with values greater than 0.75 considered excellent reproducibility. All statistical analyses were conducted using SPSS software (IBM, Inc., version 26.0).

3 Results

3.1 Baseline characteristics

A total of 210 patients (median age 61 years, IQR 54–68) were enrolled; 159 (75.7%) were men; 158 (75.2%) had hypertension, 66 (31.4%) had diabetes mellitus, 88 (41.9%) had hyperlipidemia and 30 (14.3%) had coronary heart disease. More baseline characteristics are presented in Table 1.

TABLE 2 Baseline characteristics between groups with good and poor outcomes.

Variables	Good outcome group (mRS ≤ 2, n = 81)	Poor outcome group (mRS > 2, n = 129)	<i>p</i> value
Clinical risk factors			
Age (≥ 60), <i>n</i> (%)	37 (45.7)	81 (62.8)	0.015*
Sex, male, <i>n</i> (%)	56 (69.1)	103 (79.8)	0.078
Hypertension, <i>n</i> (%)	56 (69.1)	102 (79.1)	0.104
Diabetes mellitus, <i>n</i> (%)	22 (27.2)	44 (34.1)	0.291
Hyperlipidemia, <i>n</i> (%)	38 (46.9)	50 (38.8)	0.244
Coronary heart disease, <i>n</i> (%)	7 (8.6)	23 (17.8)	0.064
Smoking history, <i>n</i> (%)	29 (35.8)	56 (43.4)	0.274
Drinking history, <i>n</i> (%)	39 (48.1)	58 (45.0)	0.652
Medication, <i>n</i> (%)			
Antiplatelet therapy	78 (96.3)	123 (95.3)	0.741
Statins	71 (87.7)	121 (93.8)	0.122

Antidiabetic therapy	18 (22.2)	43 (33.3)	0.084
Clinical variable			
NIHSS, median (IQR)	1 (1–2)	5 (3–6)	<0.001***

Bold values indicate statistical significance. * p < 0.05, *** p < 0.001. mRS, modified Rankin scale; NIHSS, National Institutes of Health Stroke Scale; IQR, interquartile range.

The distribution of mRS scores at baseline and at 90 days were shown in Supplementary Figure S1. As shown in Table 2, 129 patients were identified as having poor outcomes 90 days after acute event and 81 had good outcomes. Compared with patients without good outcomes, those with poor outcomes were more likely to be older (p = 0.015) and to have higher NIHSS scores at admission (p < 0.001). No significant difference was found in other clinical risk factors between two groups (all p > 0.05).

3.2 Comprison of imaging characteristics

Imaging parameters were compared between two groups and exhibited in Table 3. Patients with poor outcomes tended to develop lacune (p < 0.001), severe periventricular and deep WMH (ps < 0.001), CMB (p = 0.003) and higher total CSVD burden (p < 0.001). As for plaque burden, severe carotid stenosis (p < 0.001) and positive remodeling (p = 0.031) were frequently observed in poor outcome group. Moreover, the incidence of calcification (p = 0.001), surface calcification (p = 0.001), multiple calcifications (p < 0.001) and thick/mixed calcifications (p < 0.001) were significantly higher in patients with adverse outcomes compared to those with good outcomes. However, ulceration, the incidence of positive soft plaque, deep/mixed calcifications, single calcification, thin calcification and rim sign showed no significant difference between two groups (all p > 0.05).

Besides, excellent inter-reader agreements were obtained in CSVD markers and CTA variables as well (lacune: k = 0.875; periventricular WMH: k = 0.795; deep WMH: k = 0.836; EPVS: k = 0.894; CMB: k = 0.857; CSVD total score: k = 0.840; carotid stenosis: k = 0.864; ulceration: k = 0.773; positive remodeling: k = 0.773; positive soft plaque: k = 0.886; presence of calcification: k = 1.000; surface calcification: k = 0.800; deep/mixed calcification: k = 0.802; single calcification: k = 0.828; multiple calcificationsrim sign; thin calcification: k = 0.765; thick/mixed calcifications: k = 0.783; rim sign: k = 0.828).

3.3 Logistic regression analyses for poor clinical outcomes

In univariate logistic regression analyses, clinical risk factors did not significantly modify the associations between carotid calcification features and clinical outcomes (all interaction p > 0.05) (Supplementary Table S1); the presence of calcification [odds ratio (OR) = 3.647; 95% CI, 1.598–8.321], surface calcification (OR = 2.648; 95% CI, 1.481–4.735), multiple calcifications (OR = 2.886; 95% CI, 1.574–5.290), thick/mixed calcifications (OR = 3.062; 95% CI, 1.721–5.451), total CSVD score (OR = 2.983; 95% CI, 2.042–4.359) and carotid stenosis degree (OR = 5.300; 95% CI, 2.763–10.166) all showed significant associations with poor outcomes in symptomatic CSVD (Table 4; Figure 3A). After adjusting for sex, age, hypertension, diabetes mellitus, hyperlipidemia, coronary heart disease, smoking history, drinking history and carotid plaque burden (for ulceration, positive remodeling and positive soft plaque), the associations remained (all p < 0.05) (Table 4; Figure 3B).

3.4 Predictive value of carotid calcification characteristics in clinical outcome

As shown in Figure 4, three prediction models including variables of clinical covariates, non-calcified plaque features and calcified plaque features were constructed. The AUC for Model A and Model B was 0.683 ($p < 0.001$) and 0.701 ($p < 0.001$)

respectively. When adding calcification into Model B, the prediction model (Model C) reached an AUC of 0.752 (95% CI, 0.684–0.820, $p < 0.001$), with a bootstrap-corrected AUC of 0.752 (95% CI, 0.681–0.819, $p < 0.001$) (Supplementary Figure S2). Moreover, Model C had higher sensitivity (75.19% vs. 47.29%) but lower specificity (70.37% vs. 91.36%) compared to Model B (Table 5). As shown in Supplementary Figure S3, Model C

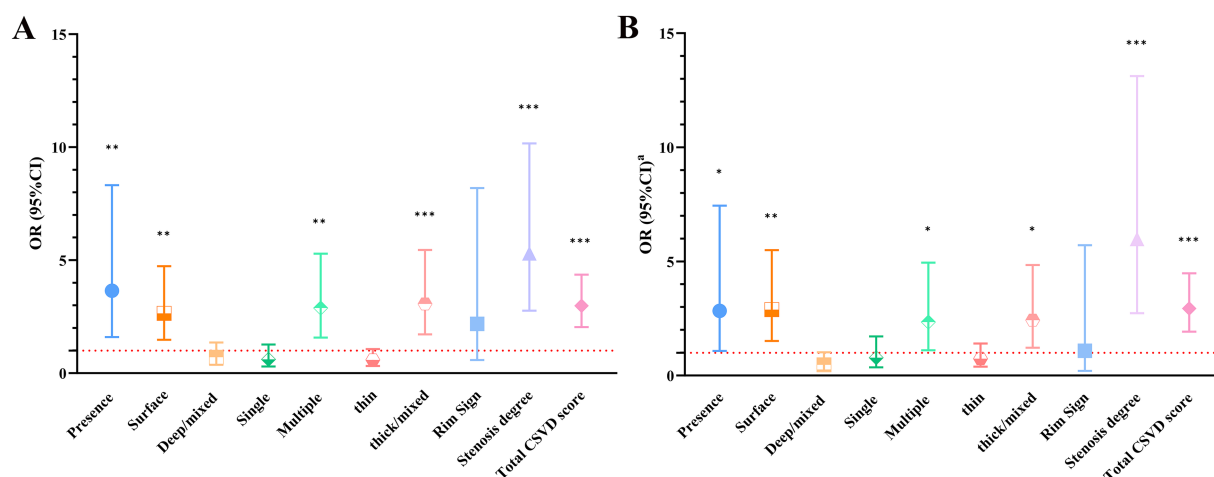

FIGURE 3

(A) Univariable logistic regression results. exhibited good consistency between predicted and actual risks. Moreover, DCA curves suggested that Model C could provide better clinical benefits than other models (Supplementary Figure S4).

4 Discussion

In this study, we observed that the presence of calcification, specifically surface, multiple and thick/mixed calcifications, was

^aThe results were adjusted for age, sex, hypertension, diabetes mellitus, hyperlipidemia, coronary heart disease, smoking history, drinking history and carotid plaque characteristics (for ulceration, positive remodeling and positive soft plaque).
CSVD, cerebral small vessel disease; OR, odds ratio; CI, confidence interval.

TABLE 5 Influence of variables on predictive accuracy of models.

Models	Included variables	AUC (95% CI)	<i>p</i> value	Sensitivity (%)	Specificity (%)
A	Clinical variables	0.683 (0.611–0.755)	< 0.001***	46.51	87.65
B	Clinical variables + non-calcified plaque features	0.701 (0.631 ~ 0.772)	< 0.001***	47.29	91.36
C	Clinical variables + non-calcified + calcified plaque features	0.752 (0.684–0.820)	< 0.001***	75.19	70.37

Bold values indicate statistical significance. ****p* < 0.001.
Model A: Clinical variables (age, sex, hypertension, diabetes mellitus, hyperlipidemia, coronary heart disease, smoking history, drinking history); Model B: Clinical variables + non-calcified plaque features (ulceration, positive remodeling, positive soft plaque); Model C: Clinical variables + non-calcified + calcified plaque features (presence of calcification, surface, mutiple and thick/mixed calcifications).
AUC, areas under the curve; CI, confidence interval; CSVD, cerebral small vessel disease.

associated with clinical outcomes of symptomatic CSVD before and after adjusting for confounding factors. It is suggested that the presence and features of carotid atherosclerotic calcification may be independent risk factors for predicting poor outcomes of symptomatic CSVD.

Atherosclerosis was intrinsically linked to alterations in the microvasculature, which contributed to CSVD development (32, 33). Carotid artery calcification, as an important marker of large artery atherosclerosis, could lead to arterial stiffness, reduced arterial compliance, increased pulse pressure and perfusion pressure in downstream small cerebral vessels. This resulted in damage to the cerebral microcirculation (20, 34–36). Additionally, atherosclerotic calcification was considered as a risk factor associated with plaque instability (37); vascular inflammation was prominent during the early stage of calcification (38) and could also contribute to plaque instability. The aforementioned pathophysiological changes may potentially lead to the formation

of microemboli (39), thereby causing the occurrence of brain parenchymal injury, which may contribute to adverse outcomes of symptomatic CSVD.

Our findings indicated that individuals with surface, multiple and thick/mixed calcifications had a higher likelihood of experiencing poor outcomes. Although relationships between carotid calcification and CSVD markers were gradually established (40, 41), the mechanism underlying associations between characteristics of calcification and clinical outcomes of CSVD was still unclear. Prior research has indicated that the location, amount and size of calcification can influence the mechanical stress of plaque and alter the stability of the cap, potentially shedding light on this connection (42). Specifically, surface calcification will enhance the risk of neovascular rupture and thrombosis by prominently increasing plaque surface stress (43–45). In contrast, deep/mixed calcification has a negligible impact on plaque maximum stress (21, 46).

Multiple calcified plaques exhibit similar mechanisms. Compared with the soft compositions, the region of calcification showed a lower strain rate. This stress imbalance may lead to rupture of neovascularization at the interface between calcification and soft components. In contrast to single calcification, multiple calcifications may increase the interface surface area, thereby potentially elevating the risk of neovessel rupture (46). Additionally, several studies have demonstrated that surface, multiple and thick calcifications are independent risk predictors of intraplaque hemorrhage (21, 47, 48). These calcification features may reflect plaque vulnerability. Vulnerable plaques may cause oxidative stress, inflammation and microembolic dislodgement, leading to cerebral infarction and functional impairment (12, 19). To some extent, these studies support our observation that surface, multiple and thick calcification is an important determinant of plaque vulnerability, which could lead to adverse outcomes for symptomatic CSVD.

In addition to characteristics of calcification plaques, we found that total CSVD load and degree of carotid stenosis could also predict clinical outcomes of symptomatic CSVD. This finding is consistent with prior studies (49–51). These associations can be explained through several underlying mechanisms. Firstly, when individual neuroimaging markers are taken into account, total CSVD burden can dependably represent the extent of brain tissue affected by ischemia or other forms of injury. Chronic ischemia may lead to stroke, gait impairment, and dementia, which can be attributed to a reduced neural reserve capacity. Secondly, carotid artery stenosis may lead to micro infarctions via artery-to-artery embolization (33). When blood flows through the narrow arteries, it could generate turbulence and low vascular wall shear stress (52). These changes may facilitate the formation of microthrombi and subsequent embolism in small perforating arteries, thereby increasing the risk of cerebrovascular accidents and contributing to adverse outcomes.

We observed that Model C exhibited higher AUC (0.752) and sensitivity (75.19%) than Model B, suggesting that adding calcification into model might possess higher predictive performance and lower rates of missed diagnosis.

Moreover, Model C achieved good calibration ability and clinical applicability. This study indicates the potential of utilizing carotid calcification features as clinically practical tools for risk stratification of symptomatic CSVD.

In clinical practice, patients with carotid calcification may require intensified anti-atherosclerotic treatment. Strategies including lifestyle modifications (e.g., quitting smoking, limiting alcohol intake, and engaging in regular moderate exercise), stricter management of blood pressure, glucose, and blood lipid level as well as the use of medications to protect blood vessels, should be implemented to improve prognosis.

This study also has a few restrictions. Firstly, this is a retrospective study and thus only functional outcomes were collected. It is widely recognized that CSVD is a primary cause of vascular cognitive impairment and dementia (53). Therefore, future prospective studies with cognitive outcomes are necessary. Secondly, an independent external validation cohort was not conducted due to single-center nature of current study. Internal validity was assessed through

bootstrap resampling methods. Thirdly, the present study did not comprehensively consider mRS score variations during 90 days after stroke. Categorizing CSVD patients based on mRS score changes (deterioration vs. improvement) would be an innovative method. Finally, it should be noted that the clinical outcomes were only followed up 90 days after stroke, and long-term outcomes (e.g., 1 year) need to be further validated.

In conclusion, carotid calcification was observed to be correlated with clinical outcomes of symptomatic CSVD. This association was determined by the location, quantity, and size of calcification. Evaluation of carotid artery calcification may provide a strategy for clinical prevention and treatment of symptomatic CSVD patients.

Data availability statement

The original contributions presented in the study are included in the article/[Supplementary material](#), further inquiries can be directed to the corresponding authors.

Ethics statement

The studies involving humans were approved by the Ethical Committee of Shandong Provincial Hospital Affiliated to Shandong First Medical University (Approval number: SWYX: No. 2024-072). The studies were conducted in accordance with the local legislation and institutional requirements. Written informed consent for participation was not required from the participants or the participants' legal guardians/next of kin in accordance with the national legislation and institutional requirements.
