Background: Dietary Oxidative Balance Score (DOBS) is an indicator, and on muscle strength remains largely unexplored in existing literature. We aimed to investigate the potential association between DOBS and muscle strength, and to explore possible interactions between DOBS and other covariates.

Methods: The association between DOBS and muscle strength under adjustment for confounders was analyzed using a weighted generalized linear regression model. A stratified analysis was used to conduct a sensitivity analysis of the linear regression.

Results: The positive association between DOBS and muscle strength were found in this study. DOBS was positively associated with muscle strength only in the active activity subgroup. And the association between DOBS and muscle strength was stronger in the non-hypertensive group.

Conclusions: DOBS and muscle strength showed an associated effect, and there was an interaction between DOBS with physical activity as well as hypertension, respectively. Individuals are encouraged to enhance DOBS levels. The findings may provide some potential theoretical references for the prevention of muscle strength loss through oxidative stress.

KEYWORDS

muscle strength, Dietary Oxidative Balance Score (DOBS), NHANES, physical activity, hypertension

1 Introduction

Skeletal muscles, a vital body tissues, is essential for facilitating daily activities. Muscle loss, is characterized by a reduction in both mass and volume of skeletal muscle throughout the body (1), which may affect the ability of the body to move, its nutritional status, and its independence (2). Handgrip strength is a valid measure of muscle strength and can be easily assessed using hand dynamometers in clinical practice (3, 4). Several previous studies indicated that low handgrip strength was associated with increased all-cause and cardiovascular mortality (5), and was also significantly associated with a multitude of adverse health outcomes, including osteoporosis (6), cognitive decline (7), and diabetes (8). Handgrip strength may decline after middle age, and that decline accelerates with age (9). Therefore, the loss of muscle strength represented by low handgrip strength, particularly among older individuals, poses a significant public health concern in our aging society.

In recent years, a growing body of evidence has indicated the pivotal role played by oxidative stress mechanisms in the attenuation of muscle strength (10), which is defined as a state in which the cells and molecules in our body are exposed to excessive amounts of reactive oxygen species (11). Diet plays an integral part in obtaining nutrients and is a key factor influencing oxidative stress. For example, according to a review, the micro-nutrient zinc regulates the level of oxidative stress in the body (12), higher fat intake also may increase oxidative stress levels in the body leading to adverse outcomes (13). Epidemiological studies have shown that appropriate modification of dietary intake may prevent and treat diseases related to oxidative stress (14, 15). Due to the minor effect of a single diet on an individual's level of oxidative stress and the possibility of biological interactions involving multiple dietary oxidative components, assessing the individual effect of a single diet on exposures related to oxidative homeostasis was difficult. Dietary Oxidative Balance Score (DOBS) is an indicator calculated based on the oxidative effects of a wide range of nutrients, including 14 antioxidants and 2 pro-oxidants (16-18), which reflects the oxidative level of the diet in a more systematic and realistic way. In general, diets with higher DOBS typically include plenty of fruits, vegetables, nuts, and dietary fiber, which are components that contribute to lower levels of oxidative stress (19).

Several previous studies have shown that DOBS affects multiple adverse outcomes related to oxidative stress, such as osteoporosis (20), cancer (21), and all-cause mortality (17). The association between DOBS and muscle strength, however, has not been adequately investigated. Previous studies have shown that excessive oxidative stress markers such as reactive oxygen species (ROS) may impair mitochondrial function and reduce protein synthesis, which in turn leads to muscle atrophy and strength loss (22, 23). In addition, chronic inflammation due to oxidative stress promotes muscle catabolism and direct degradation of myofibrillar proteins (24). Higher levels of DOBS suggest that individuals consume antioxidant-based dietary patterns and may influence muscle strength by attenuating oxidative stress-induced muscle damage. Given the ability of DOBS to systematically assess the oxidative homeostatic properties of diets, exploring its association with muscle strength may not only deepen the understanding of the mechanisms of oxidative stress-mediated muscle decline, but also provide key evidence for the development of sarcopenia prevention strategies based on dietary interventions, especially in high-risk populations, which are of great clinical importance. We therefore aimed to investigate the potential association between DOBS and muscle strength using the National Health and Nutrition Examination Survey (NHANES).

2 Materials and methods

2.1 Sample

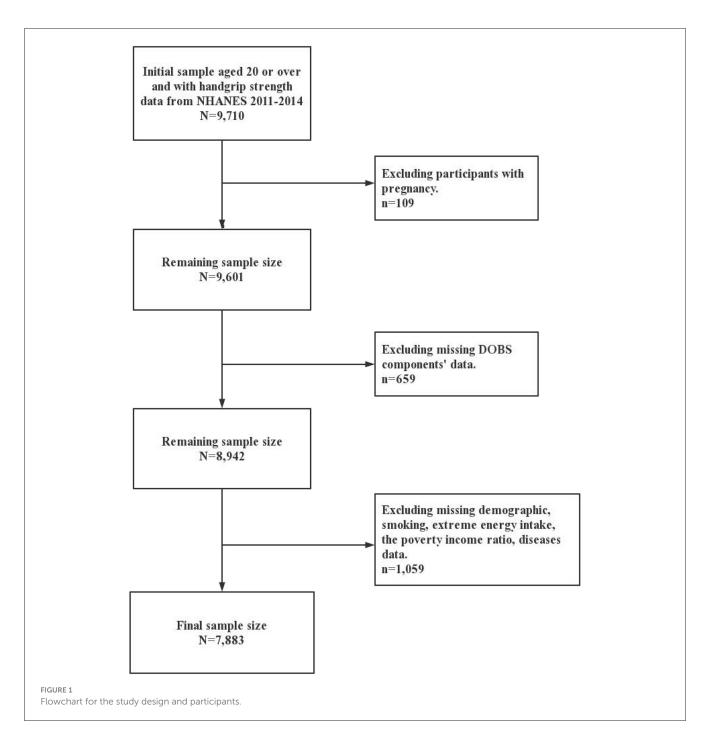

Participants in the present study were selected from the 2011 to 2014 cycle of the NHANES. It utilized stratified multistage probability sampling to collect information from relevant interviews, examinations, dietary questionnaires, and laboratory measurements. The NHANES data are publicly available at: https://www.cdc.gov/nchs/nhanes/index.htm. A total of 9,710 participants aged 20 or over and with complete data on handgrip strength were enrolled in two cycles of NHANES. Furthermore, 109 pregnant participants and 659 participants who missing DOBS data were excluded. Meanwhile, 1,059 participants were excluded due to extreme energy data (total energy intake <500 kcal/day or >5,000 kcal/day for females and <500 kcal/day or >8,000 kcal/day for males) and missing data on demographics, smoking, the poverty-income ratio (PIR), and related diseases (diabetes, hypertension, and arthritis). In this way the impact of unreliable dietary reporting was minimized and the completeness of adjustment for confounders was ensured. Ultimately, 7,883 participants were included in this study and the details were shown in Figure 1. The National Center for Health Statistics Research Ethics Review Board approved the NHANES study protocols. Written informed consent is obtained from all participants.

2.2 Muscle strength

Muscle strength was measured through a grip test using a handgrip Takei Dynamometer (TKK5401; Takei Scientific Instruments, Tokyo, Japan). Following a practice trial, participants were asked to forcefully squeeze the ergometer as hard as possible with one hand, breathing out while squeezing to avoid an increase in intrathoracic pressure. Then repeat the test on the other hand. A total of three tests were performed on each hand, alternating between the two hands between each test, with a 60-s rest period between measurements on the same hand. The combined grip strength was calculated as the sum of the largest reading from each hand, and expressed in kilogram. As the relationship between muscle strength and BMI is closely related (25), we used the relative grip strength calculated from the combined grip strength value to BMI ratio represents muscle strength (26). This adjustment accounts for body size differences and better reflects muscle function relative to metabolic demand, as validated in prior studies (27, 28). Higher relative grip strength values represented greater muscle strength of the participant.

2.3 Dietary Oxidative Balance Score

Two 24-h dietary recall interviews from NHANES were used for dietary antioxidant intake. The first face-to-face at a mobile examination center and the second by telephone 3–10 days later. Both recalls utilized the USDA Automated Multiple-Pass Method to ensure accuracy and minimize underreporting. Nutrient intake values were derived from the Food and Nutrient Database for Dietary Studies (FNDDS), which links food codes to standardized nutrient composition data. The mean value of the data was calculated and utilized as the dietary data for this study, as using non-consecutive days of dietary intake data was more accurate than using single-day data (29). On the basis of previous studies, the DOBS was composed of 16 dietary components (20, 30, 31). The two components, total fat and iron, were identified as pro-oxidants. And the 14 components, dietary fiber, carotene, riboflavin, niacin,

calcium, magnesium, zinc, total folate, vitamins (B6, B12, C, and E), copper, and selenium, were identified as anti-oxidants. The DOBS assignment scheme was described in Supplementary Table S1. Each of the components was divided into three groups according to their tertiles. The scores for the first to third groups were 2, 1, and 0 for pro-oxidants, and the scores were 0, 1, and 2 for anti-oxidants, relatively. The DOBS obtained by summation was positively correlated with the total antioxidant capacity of the participants. Depending on the quartiles of the DOBS, we defined the first DOBS quartile as DOBS Q1 and correspondingly defined its second, third, and fourth quartiles as DOBS Q2, DOBS Q3 and DOBS Q4, respectively.

2.4 Covariate assessment

The selected covariates in this study were logically ordered and filtered based on existing literature and clinical experience. As mentioned previously, data on energy intake at extreme values were excluded. Race was categorized as non-Hispanic White and other race. Educational level was categorized as three groups: below high school, high school, and above high school. Marital status was categorized as married/living with a partner and Others (including widowed, divorced, separated, and never married). PIR was categorized as three groups: ≤ 1.30 , 1.31-3.50, and > 3.50. Serum cotinine levels was used to assess the extent

10.3389/fnut.2025.1563451

of tobacco use and exposure to environmental tobacco smoke. And cotinine was categorized as three groups: ≤0.017 ng/mL, 0.018-0.239 ng/mL, and >0.239 ng/mL. Alcohol consumption was categorized as three groups: 0.0 g, 0.1–30.0 g, and >30.0 g. Physical activity (32) was categorized into two groups: the active group was defined as those who participated in more than 149 min of moderate physical activity, more than 74 min of vigorous physical activity, or more than 599 metabolic equivalents (MET) per week. The MET values were calculated based on the reported activity intensity classifications defined by NHANES, it classifies self-reported activity into predefined intensity levels (moderate/vigorous) based on participant descriptions: Active Work-Related Activity (High Intensity, 8.0), Moderate Work-Related Activity (Moderate Intensity, 4.0), Walking or Bicycling as a Means of Transportation (4.0), Vigorous Recreational PA (8.0), and Moderate Leisure Time PA (4.0). And the rest of the population was defined as the inactive group. If participants self-reported a physician's diagnosis of diabetes, hypertension, and arthritis, they were considered to have a history of these conditions.

2.5 Statistical analysis

In this study, all analyses considered sample weights as well as stratification and clustering methods to satisfy the requirements of the NHANES analysis guidelines for complex sampling designs. The continuous and categorical variables were described by means (standard errors) and quantities (percentages), respectively. To compare differences in categorical variables between different subgroups according to quartiles of DOBS, using the chisquare tests, while for continuous variables, using the one-way ANOVA. The association between DOBS and muscle strength under adjustment for confounders was analyzed using a weighted generalized linear regression model. Model 1 without adjustments; Model 2 adjusted for sex, age and race; And Model 3 additionally adjusted for energy intake, cotinine level, alcohol consumption, education level, marital status, physical activity, PIR, diabetes, hypertension and arthritis. A stratified analysis was used to conduct a sensitivity analysis of the linear regression. We conducted interaction effects by selecting covariates that were adjusted for in the model. Based on the regression model, an interaction term between DOBS and each covariate (e.g., DOBS × physical activity) was added to analyze the interaction, and then the R package "forestplot" was used to draw a forest plot for the hierarchical analysis of the interaction. All analyses were conducted using IBM SPSS 24.0 and R 4.2.1, and a two-sided P-value < 0.05 was considered significant. The statistical significance of interactions was evaluated using Wald tests, with a two-sided P-value < 0.05 indicating significant effect modification.

3 Results

Characteristics of the 7,883 participants included in the analyses are presented in Table 1, grouped according to the quartiles of DOBS. The participants included had a mean age of 46.71 years, with 50.49% being male, and a DOBS range of

2–31. Generally, it was observed that individuals with higher DOBS were predominantly male, Non-Hispanic White, and tended to be married or living with a partner (P < 0.05). Moreover, they exhibited higher energy intake and alcohol consumption, had advanced educational backgrounds, boasted a higher PIR, maintained lower levels of cotinine, and engaged in proactive physical activities (P < 0.05). Additionally, individuals with higher DOBS demonstrated a lower prevalence of both diabetes and arthritis (P < 0.05). Notably, participants in DOBS Q4 exhibited significantly higher handgrip strength compared to those in DOBS Q1.

Table 2 showed the results of linear regression models of DOBS on relative handgrip strength in different models. We found that DOBS (continuous value) was significantly positively associated with handgrip strength in all three models (P < 0.05). In the fully adjusted model (Model 3), the β and 95%CI of the DOBS Q3 and DOBS Q4 groups were 0.078 (0.005, 0.150) and 0.161 (0.059, 0.262) compared with the DOBS Q1 group (P < 0.05), respectively.

To validate the robustness of our findings against potential confounders, subgroup analyses and interaction tests were conducted based on sex, age, race, education level, marital status, PIR, cotinine level, alcohol consumption, physical activity, and the presence of three specific diseases. Interaction tests revealed statistically significant effect modification by physical activity (P <0.001 for DOBS \times physical activity interaction) and hypertension status (P = 0.004 for DOBS × hypertension interaction) by Wald tests, as depicted in Figure 2. The results in Table 3 indicate a significant association between DOBS and handgrip strength in the active physical activity subgroup. Specifically, in the active group, the β and 95%CI of the DOBS Q3 and DOBS Q4 groups respectively were 0.146 (0.067, 0.226) and 0.213 (0.099, 0.328) in the final model (Model 3). However, no significant association was found among inactive individuals. Additionally, the association between DOBS and handgrip strength was more pronounced in non-hypertensive individuals, as shown in Table 4. In the final model (Model 3), the β and 95%CI of the DOBS Q3 and DOBS Q4 groups respectively were 0.095 (0.007, 0.183) and 0.184 (0.065, 0.303) in the subgroup of non-hypertension, and the β and 95%CI of the DOBS Q4 group was 0.112 (0.006, 0.217) in hypertension subgroup compared with DOBS Q1 group (P < 0.05).

In order to further analyze the effect of DOBS combined with physical activity on handgrip strength, we divided the participants into eight subgroups based on the interaction, as shown in Supplementary Table S2. We used the subgroup with DOBS Q4 and physically active (subgroup 1) as the reference group, as it represents the combination of the highest dietary antioxidant level with the best physical activity state, expected to be ideal for muscle strength. Compared with the subgroup 1 (DOBS Q4 and the active activity group), all subgroups showed a statistically significant and negative association with handgrip strength (P < 0.05), except for the subgroup 2 (DOBS Q3 and the active activity group). Similarly, we also categorized the participants into eight subgroups based on DOBS and hypertension as shown in Supplementary Table S3. The results showed that all other subgroups were statistically significantly negatively associated with handgrip strength compared to subgroup 1 (DOBS Q4 and the non-hypertension group; P < 0.05).

Continuous variables were expressed with means (standard error) and categorical variables were described with quantities (percentages). Continuous variables were compared in four groups using One-Way ANOVA and categorical variables were compared using chi-square tests. P < 0.05 was set as the threshold of statistical significance and marked in bold values.

4 Discussion

In the present study, we explored the potential association between DOBS and muscle strength as represented by handgrip strength based on NHANES and found a positive association between DOBS and grip strength after adjusting for a multitude of confounders. In addition, there were interactions between DOBS with physical activity and hypertension, respectively. The findings may provide some potential theoretical references for the prevention of muscle strength loss through oxidative stress.

On the best of our knowledge, this is the first study to explore the potential association between DOBS and muscle strength. The results showed a positive association between DOBS, which represents the antioxidant capacity of dietary sources, and muscle strength. It was consistent with the findings of previous studies. A review study showed that dietary supplementation with antioxidant properties may reduce muscle loss symptoms (33). Muscle strength and function could be effectively improved by consuming antioxidant components such as multivitamins and trace minerals such as magnesium (34). The following related mechanisms provide further support for the findings of this study. Dietary intake could influence the level of oxidative stress and inflammation in the body (35), and ROS and accumulation of inflammatory factors have been implicated as potential mechanisms for loss of muscle strength (23, 36). ROS are generated by adding an electron to an oxygen molecule and exists in almost all tissues of the organism. This reactive element is quite harmful and leads to oxidative stress, thus damaging other components such as DNA, proteins, and lipids, which then causes damage to cells and tissues (37, 38). The loss of muscle strength is precisely due to the overproduction of ROS in the organism, especially in skeletal muscle, and the reduced capacity of the antioxidant system (39). The results suggest that with a higher intake of antioxidant dietary components, it

TABLE 4 Stratified analysis of the associations between dietary oxidative balance score and handgrip strength by presence or absence of hypertension.

Model 1 without adjustments; Model 2 additionally adjusted for sex, age and race; Model 3 additionally adjusted for energy intake, cotinine level, alcohol consumption, education level, marital status, physical activity, PIR, diabetes, and arthritis. The bold indicates a statistically significant *P*-value of <0.05.

may be possible to reduce the harm caused to the organism by the overproduction of ROS, thus protecting muscle strength from damage.

Besides, oxidative stress is closely associated with inflammation and exerts a pro-inflammatory effect through activation of nuclear factor-kappa B, which increases the expression of chemokines and cytokines (24, 40). Several previous studies have demonstrated that higher levels of inflammatory markers, such as TNF- α , and IL-6, are associated with lower muscle strength (41, 42). These inflammatory factors may stimulate the loss of proteins in muscle cells and induce protein denaturation, leading to a reduction in muscle strength (22, 43). Similarly, elevated levels of DOBS may mitigate the decline in muscle strength induced by inflammation, thereby positively influencing muscle strength. Thus, oxidative stress and resulting inflammation play a pivotal role in muscle strength and could be crucial targets for the development of dietary strategies aimed at preventing sarcopenia.

People of all ages, young and old, are known to benefit from regular physical activity. Sedentary lifestyles are risk factors for muscle weakness, and physical activity has been shown to increase the body's aerobic capacity, muscle strength and endurance (44, 45). Our findings suggested an interaction between DOBS and physical activity. DOBS was positively associated with muscle strength only in the active subgroup and not significantly in the inactive. It also suggested that dietary intake with higher antioxidant capacity may increase the positive effects of active physical activity on muscle strength. For example, vitamin C and E supplementation has been shown to reduce exercise-induced oxidative stress and improve muscle recovery (46). Physical activity has frequently been positively associated with healthy dietary intake, with the activebody group's eating habits being closer to the recommended healthy eating guidelines. And active individuals often exhibit higher metabolic rates and nutrient absorption efficiency. Meanwhile, those who increased their physical activity were more likely to report improvements in diet quality (47, 48). This behavioral synergy may create a compounding effect, where DOBS and physical activity jointly mitigate oxidative stress and inflammation, thereby preserving muscle strength.

Our data revealed that there is an association between DOBS and hypertension. The association between DOBS and muscle strength was stronger in the non-hypertensive group than in the hypertensive group, and DOBS paired with non-hypertension revealed a significant positive association with muscle strength. A large cohort research in France (49) found that eating a diet high in antioxidants may lower the chance of developing hypertension and the pathological damage caused by hypertension. Furthermore, given there is a link between hypertension and low levels of muscle strength (50), DOBS may improve muscle strength by avoiding the establishment of hypertension and thus muscle strength. In the hypertensive population, however, the pathophysiology appeared to dampen the beneficial benefits of DOBS on muscle strength. Hypertension is characterized by elevated systemic oxidative stress and chronic inflammation, may impairs endothelial function and microvascular perfusion. These processes may overwhelm dietary antioxidant defenses (reflected by DOBS), reducing their capacity to protect skeletal muscle from oxidative damage. To lower the risk of sarcopenia in the hypertension group compared to the non-hypertensive group, a higher antioxidant diet is required.

This study has several advantages. First, this analysis employed NHANES data weighted for complexity, which is more typical of US population health. Second, we employed DOBS to analyze effects on muscle strength's oxidative potential while simultaneously accounting for numerous dietary components. Third, this is the first study to look at the link between DOBS and muscle strength. The study, however, still had some limitations. First, our individual NHANES data may be prone to recall and selection bias. Second, because this was a cross-sectional study, determining a causal association between DOBS and muscle strength is difficult. Besides, detailed training variables were unavailable in NHANES. Future studies incorporating device-measured PA could better disentangle the effects of training regimens on the DOBS and muscle strength relationship. Although our findings suggest the link between DOBS and muscle strength, randomized controlled trials are essential to confirm causality. The precise nature of their interaction will need to be examined further in the future.

5 Conclusion

In this cross-sectional study, DOBS and muscle strength showed an associated positive effect, and there was an interaction between DOBS with physical activity as well as hypertension, respectively. Our findings suggest that maintaining higher DOBS levels through antioxidant-rich dietary patterns may warrant further investigation for populations at risk of muscle strength decline. Further longitudinal or interventional studies are warranted to explore the potential role of DOBS in mitigating muscle deterioration. The findings may provide some potential theoretical references for the prevention of muscle strength loss through oxidative stress.

Data availability statement

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession number(s) can be found below: the dataset supporting the conclusions of this article is available in the National Health and Nutrition Examination Survey (NHANES), hyperlink to dataset in https://www.cdc.gov/nchs/nhanes/index.htm.

Ethics statement

The studies involving humans were approved by Institutional Review Board approval was waived as NHANES data is deidentified and publicly available. All the participants signed the informed consent before participating in the study. The studies were conducted in accordance with the local legislation and institutional requirements. The participants provided their written informed consent to participate in this study.
