Introduction: Lymphoma is a significant cause of mortality among people living with human immunodeficiency virus (PLWH). The objective of our study was to assess the characteristics of lymphomas in PLWH in a single center from the southeast of Romania.

Methods: We retrospectively analyzed the prevalence and clinical and demographic characteristics of patients with lymphoma associated with HIV/AIDS monitored over a period of 15 years. Kaplan–Meier analysis was used to estimate survival rates and evaluate the risk of mortality in lymphoma patients.

Results: Among the 476 new cases of HIV/AIDS registered, 9 cases of lymphoma were identified, representing a prevalence of 1.89%. Overall mortality was 13.6%, with lymphoma contributing to 10.76% of HIV/AIDS-related deaths. The average age at lymphoma diagnosis was 37 years, with most patients being men and smokers with sexually transmitted HIV. Common coinfections included hepatitis B virus (HBV) and tuberculosis. Advanced-stage disease (Ann Arbor stage IV) and type B clinical symptoms were present in half of the cases. Oncological treatment was provided in 5 cases, achieving a survival rate of 30%.

Conclusions: The high mortality highlights the need for early diagnosis and an integrated therapeutic approach to improve the prognosis of patients with HIV-associated lymphomas.

KEYWORDS

HIV, AIDS, lymphoma, antiretroviral treatment, opportunistic infections, non-AIDS co-morbidities

1 Introduction

Globally, the epidemic of the human immunodeficiency virus (HIV) is ongoing, with an estimated 39.9 million people living with HIV (PLWH) (1).

Nowadays, due to the huge scientific advances in the understanding of the viral pathways, as well as their diagnosis, treatment, and prevention, HIV has become a chronic, manageable disease, with a longer life expectancy. However, despite the advancements in public health strategies and treatment, a definitive cure for HIV is not yet available. The persistent viral inflammation in PLWH is related to frailty, in terms of precocious aging and frequent additional chronic conditions, such as cardiovascular, kidney, and bone diseases and various cancers (2).

HIV-positive people have a higher risk of developing various diseases, including cancer. Progressive immunosuppression secondary to HIV infection is a risk factor for the development of a variety of malignancies (3, 4).

The prolonged suppression of HIV replication with undetectable blood viral load under effective antiretroviral therapies (ARTs) has decreased the opportunistic infections and neoplasms associated with severe acquired immunodeficiency syndrome (AIDS).

The pathogenesis of HIV/AIDS-associated lymphoma is multifactorial, involving immune dysregulation, genetic mutations, viral coinfections, and chronic activation of B lymphocytes (2). These lymphomas predominantly originate from B cells and exhibit clonal immunoglobulin rearrangements (5).

Co-infections with HTLV-1, EBV, and HHV8 are oncogenic viruses that increase the susceptibility of PLWH to developing HIV/AIDS-associated lymphomas (5–7). An elevated risk of lymphomas was reported in HIV-positive individuals with HBV and HCV coinfections (8).

As an AIDS indicator, non-Hodgkin lymphoma (NHL) has continued to be the most common type of cancer and a leading cause of mortality in PLWH (9). Furthermore, Hodgkin lymphoma (HL) is not classified as an AIDS-defining illness, but studies have reported an increased incidence of HL in PLWH compared to the general population (10).

NHL is the 12th most common cancer worldwide, with a global incidence of 5.6 cases per 100,000 people in 2022, while HL ranks 26th and has a much lower incidence of 0.95 cases per 100,000 people (11). The incidence of NHL and HL in people living with HIV (PLWH) was 10- to 20-fold higher compared to the general population, but the clinical features and prognostic factors remain poorly differentiated from non-HIV lymphoma (12, 13).

Some types of lymphomas, such as primary diffuse large B-cell lymphoma or primary cerebral lymphoma, are opportunistic diseases considered as indicators for the classification in the AIDS stage (14, 15).

Regarding AIDS-associated lymphomas, it is estimated that more than 40% of patients in the advanced stages of immunosuppression could be diagnosed with one of these hematologic malignancies (16).

In developed countries, NHL is the most common cause of death associated with HIV infection, accounting for 23% to 30% of all AIDS-related deaths (16). HIV-related NHLs occur in patients with advanced HIV infection with a T-lymphocyte ($CD4^+$) count of less than 100 cells/ μ L and a high HIV viral load (17).

HL is the most common type of cancer in HIV-positive patients, not associated with AIDS. HL in non-HIV patients had a bimodal age distribution with an initial peak at 20–30 years and a second peak at 50–65 years, while the mean age of presentation of HL in HIV-positive patients was 41 years in European countries and 34 years in African countries (18, 19). Globally, 0.4% of new cancer cases and 0.2% of cancer-related deaths were due to HL in 2020 (20). The incidence of HL varied by sex, age, and geographic location. People at a higher risk for HL included men, adolescents, young adults, and those with a history of Epstein–Barr virus infection, HIV/AIDS, autoimmune diseases, exposure to pollution, and smoking as well as family history (21–23).

The most common histologic types of HIV-associated lymphomas were diffuse large B-cell lymphoma (DLBCL; 37%), HL (26%), and Burkitt lymphoma (BL; 20%). Low $CD4^+$ T-cell counts and HIV-1 viral replication (VL) are independent risk factors for DLBCL in people living with HIV (24). Other types, such as primary effusion lymphoma (PEL), primary central nervous system lymphoma (PCNSL), and plasmablastic lymphoma (PBL), were less common (24, 25).

The GLOBOCAN database, designed by the International Agency for Research on Cancer (IARC), contains projected national cancer estimates up to 2024 derived from the best available recorded data from national (or subnational) cancer registries and national centralized registry systems in 185 countries or territories around the world (11, 26, 27).

The GLOBOCAN database provides comprehensive global data on cancer epidemiology, including lymphomas (12). However, while significant data exist on HIV-associated lymphomas

globally (28), their epidemiology and clinical profiles in Romania remain poorly understood, necessitating localized studies.

Therefore, the present study provides a comprehensive analysis of the frequency, clinical features, and mortality associated with HIV/AIDS-related lymphomas in a single-center cohort from Romania. By focusing on a population characterized by unique epidemiological and clinical features, including pediatric HIV cohort survivors, the study highlights challenges such as advanced disease stages at diagnosis, high mortality rates, and limited access to innovative therapies like CAR-T. These findings emphasize the urgent need for personalized management strategies and underline the importance of addressing regional challenges in the care of patients with HIV and lymphoma.

2 Materials and methods

2.1 Study design and statistical analysis

This study is an observational, descriptive, and retrospective analysis, which aims to evaluate the survival outcomes of patients diagnosed with lymphoma in the context of HIV/AIDS. We performed a comparative analysis using Kaplan–Meier (K-M) survival curves to assess the prognosis of these patients over a period of 15 years (2008–2022). To conduct the statistical survival analysis, we divided the patients into two groups: one group consisting of patients with HIV/AIDS and lymphoma versus another group with HIV/AIDS only.

Patients with incomplete or missing medical records, especially regarding HIV diagnosis or histological confirmation of lymphoma, were excluded from the study to ensure the accuracy of the data.

The HIV/AIDS database was obtained from the Infectious Diseases Clinic Hospital Galati electronic database, which is a single center for PLWH in the Galati district (29–33). Our center was located on the southeast border of Romania, providing healthcare for PLWH, with an estimated general population of 600,000 people.

We selected the diagnostic-related group codes B.20–24, from 1 January 2008 to 31 December 2022 (34). Additionally, we have identified the HIV/AIDS patients with lymphomas, by the diagnostic code B.21.1, B.21.2, or B.21.3, specifying HIV disease resulting in Burkitt lymphoma, non-Hodgkin lymphoma, or other malignant neoplasms of the lymphoid, hematopoietic, and related tissue (34). All the cases were revised in December 2023, covering at least 1 year of HIV/AIDS follow-up. The cases were categorized as follows: retained in care (patients continuing to be monitored and treated in the center), deaths, and lost to follow-up (patients with no updated information). The endpoint of the study was either death or 31 December 2022. The frequency of lymphomas in PLWH was calculated by dividing the number of HIV/AIDS and lymphoma cases by the total number of HIV/AIDS diagnosed cases during the study time. Mortality was calculated among patients with HIV/AIDS and

lymphomas and was compared with mortality among the cases with HIV/AIDS only.

To achieve the second objective, we have selected cases with HIV/AIDS and lymphoma from our institution's archived records, and we have studied their detailed medical files.

2.2 HIV and lymphoma patient overview

We analyzed demographic data, HIV history, and lymphoma history. We examined whether the lymphoma diagnosis was an indicator of immunosuppression and a reason for HIV testing. HIV history comprised the pattern of transmission, age and year of diagnosis, staging of HIV diagnosis, coinfections, nadir of CD4 count, and antiretroviral treatment (ART) experience. The stages of HIV infection were evaluated using the CDC classification system, considering the immunological level based on CD4 count and the clinical criteria for AIDS-related conditions (35). The nadir of CD4 count means the lowest ever count in an individual with HIV. Antiretroviral therapy was used according to the timeline versions of European guidelines, combining nucleoside(tide) reverse transcriptase inhibitor (NRTI), non-nucleoside reverse transcriptase inhibitor (NNRTI), protease inhibitor (PI), or integrase inhibitor class (II) (36).

2.3 Lymphoma staging and clinical features

In the characterization of lymphoma, the year of diagnosis, concomitant CD4 count, staging of lymphoma, histopathology, oncologic treatment, major complications, and comorbidities were considered. The diagnosis of lymphoma was based on an anatomical-pathological examination supplemented by immunohistochemistry, performed on various relevant tissues, including lymph nodes, skin or mucous membranes, and bone marrow. The lymphomas were staged according to the Ann Arbor classification system. The Ann Arbor staging system classifies HL and NHL by disease extent: stage I (single lymph node region), stage II (multiple lymph node regions on the same side of the diaphragm), stage III (lymph nodes on both sides of the diaphragm), and stage IV (diffuse or disseminated involvement of one or more extra lymphatic organs, or either involvement of the liver, bone marrow, or lungs). Each stage is subdivided into A (no systemic symptoms), B (systemic symptoms—fever exceeding 38°C without a known cause, severe night sweats, or weight loss greater than 10% of body weight within 6 months before diagnosis), E (spread of lymphoma to organs outside the lymphatic system, such as the liver, bone marrow, or lungs), S (spleen involvement), and bulky disease [for HL, bulk is defined as any single node or nodal mass with a diameter ≥ 10 cm or mediastinal mass ratio (maximum width of mediastinal mass/maximum intrathoracic diameter > 0.33); for DLBCL, bulky disease means any nodal or extra nodal tumor mass with a diameter of ≥ 7.5 cm] (37–39).

2.4 Statistical analysis and survival assessment

To analyze data, the K-M survival analysis was employed. To conduct the univariate approach of K-M, we divided the patients into two groups: one group consisting of patients with HIV/AIDS and lymphoma and another group with HIV/AIDS only. Incomplete observations of patients such as those lost to follow-up or without an event occurring by the end of the study were censored, meaning their data were considered incomplete in the survival analysis. The log-rank test was used to compare the survival estimates between groups, considering a p -value lower than 0.05 as significant. We used the SPSS software package version 26 for the Kaplan–Meier survival curve analysis of both groups. We analyzed the characteristics of patients with HIV/AIDS and HL or NHL using the two-sample test due to a small sample size.

3 Results

3.1 The frequency and mortality of HIV/AIDS-associated lymphomas

From 2008 to 2022, 476 PLWH were monitored in our center. These 476 cases were divided into two groups: a group of 9 PLWH diagnosed with lymphoma (7 NHL and 2 HL) (Table 1) and a group of 467 PLWH with HIV/AIDS only, who did not develop lymphoma.

Of the total 476 PLWH, 366 were alive, 65 died, and 45 were lost to follow-up. Thus, the overall death rate was 15.08%. The 45 cases lost to follow-up were not excluded from the analysis.

Among the 476 cases of PLWH, we have identified 9 cases with lymphomas, specified as 7 NHL and 2 HL, meaning a 1.89% ($9/476 \times 100$) prevalence of lymphoma comorbidity. Of the 65 total deaths reported in the study, 7 were PLWH diagnosed with lymphomas, accounting for 10.76% of all deaths. The mortality rate of HIV/AIDS-associated lymphomas was 77.7% ($7/9 \times 100$), compared with 12.41% ($58/467 \times 100$) deaths in the HIV/AIDS-only group.

The analysis of K-M curves identified a chi-square value of 13.456 ($df = 1$), and an associated p -value (Sig.) < 0.001 , indicating that PLWH diagnosed with lymphoma had a significantly shorter life expectancy compared to those with HIV/AIDS only.

The analysis of Kaplan–Meier curves identified a statistically significant difference in survival distributions between the two groups (chi-square = 13.456, $df = 1$, $p < 0.001$), indicating that PLWH diagnosed with lymphoma had a significantly shorter life expectancy compared to those with HIV/AIDS only (Figure 1, Table 2).

3.2 Characteristics of PLWH diagnosed with lymphomas

3.2.1 Demographic characteristics

The demographic characteristics described in this section apply to the PLWH cases diagnosed with lymphoma. Among the nine

cases, seven were diagnosed with NHL and two with Hodgkin lymphoma (HL). All patients were Caucasian, most of them were men (eight out of nine) living in an urban area (five out of nine), and all but one had completed secondary education. According to marital status, most were single (six out of nine), one case was divorced, one was married, and one was widowed. The age at HIV diagnosis for the nine PLWH diagnosed with lymphoma ranged between 2 and 59 years, including four patients with a pediatric pattern of HIV infection and five sexually transmitted cases (Table 1). None of the patients were intravenous drug users. The average age of lymphoma diagnosis was 35 ± 16.18 , varying between 18 and 60 years. The diagnostic age of lymphomas was lower in smokers and patients with a pediatric pattern of transmission, history of tuberculosis, and hepatitis B virus (HBV) coinfection (Table 3).

3.2.2 HIV history characteristics

On HIV diagnosis, seven out of nine patients were late presenters (AIDS stage), while immunosuppression had already progressed in the remaining two patients. As a result, all of them experienced a very low average nadir CD4 count of 32.22 ± 20.65 , ranging between 4 and $66/\text{mm}^3$ (Table 1). A history of tuberculosis was found in five out of the nine cases, and four out of the nine cases had both HBV coinfection and tuberculosis. There was no coinfection with hepatitis C virus (HCV) or syphilis. All patients have experienced at least one line of ART after HIV diagnosis, but three of them had multiple ART treatments. Baseline HIV viral load was variable, and undetectable levels under ART were temporarily achieved in only two cases (P2, P3).

3.2.3 Characteristics of HIV/AIDS lymphoma cases

Lymphoma was an indicator of immunosuppression, as it is frequently observed in individuals with advanced HIV infection, where the immune system is significantly compromised. It was identified as an indicator for HIV diagnosis in four out of nine cases, all of them being “very late presenters” (patients P4, P6, P7, P9) (Table 1). The average CD4 count during the diagnosis of lymphoma was 95.22 ± 50.61 , ranging from 15 to $172/\text{mm}^3$. In patient P3, the small lymphocytic lymphoma was interpreted as part of the immune reconstitution inflammatory syndrome (IRIS) following the diagnosis and treatment of tuberculosis coinfection and HIV. Specifically, the ART regimen of patient P3 included zidovudine + lamivudine + efavirenz and enfuvirtide. In the other cases (patients P1, P2, P5, and P8), the interval after HIV diagnosis to lymphoma occurrence ranged between 2 and 24 years (Table 1).

The diagnosis of lymphoma was confirmed by anatomopathological examinations of biopsy specimens of lymph node (4/9), skin or mucosa (4/9), and bone marrow (1/9). Immunohistochemistry was unavailable in one single case (P5).

The histological subtype of NHL was mostly DLBCL (44.44%). Other subtypes included small lymphocytic lymphoma, BL, and PBL, with one case for each. HL represented 22.22%. The subtypes were determined by microscopic evaluation and confirmation with specific immunohistochemical markers. The staging of lymphomas

*These data correspond to the staging at the time of HIV diagnosis, while the nadir represents the lowest recorded CD4 count from the time of HIV diagnosis until the diagnosis of lymphoma. Although antiretroviral therapy was available, some patients continued to experience immunological decline after HIV diagnosis, potentially contributing to the development of malignant hematological disorders.

revealed invasion of extralymphatic tissues in six out of nine patients (P2, P3, P4, P6, P7, P8), which means stage IV according to Ann Arbor staging (11, 34). The other three patients (P1, P5, P9) were categorized as stage III. The signs of B category (33) were present in four out of nine patients: fever (P4, P5, P8, P9), over 10% of weight loss in the last 6 months (P4), and night sweats (P4) (Table 1).

Chemotherapy was provided to five patients (P1, P2, P6, P7, P8), and two of them had survived (P6, P8). The other three patients (P1, P2, P7) were non-responders to chemotherapy, and the lymphomas had progressed to a fatal outcome. P1 and P6 received cyclophosphamide, doxorubicin, vincristine, and prednisone treatment (CHOP), but P6 also received immunotherapy with

rituximab (R), which may be an important factor in the patient’s profound response and survival (Table 1). The 1-year survival rate was 22.22%, and there were only two survivors: one case each of NHL and HL. The inability to administer chemotherapy in some cases was due to late presentation and the presence of active infections, such as COVID-19 (P9), as well as delays in obtaining immunohistochemical results.

One particular case was a female patient (P7) who had two types of cancers. The first one was an oral PBL, an indicator of HIV diagnosis, and the second was a tumor of the left breast that was detected 3 months later, during the chemotherapy for lymphoma. The breast carcinoma diagnosis was supported by the anatomopathological exam, but the result was available after the patient died.

4 Discussion

4.1 Pathogenesis of HIV/AIDS-associated lymphoma: mechanisms and risk factors

HIV-related chronic inflammation is associated with the disruption of cytokines and chemokines that play a role in the tumor microenvironment (40).

The mechanisms of enhanced death in HIV-infected cells versus uninfected ones are increased apoptosis, pyroptosis, and ferroptosis (41). The HIV-related CD4 T-cell death involves approximately a 95% caspase-1-mediated pyroptosis pattern, while the proportion of cell apoptosis is less than 5% (42). Significant differences in microenvironments were found between sporadic DLBCL and HIV-associated DLBCL, which was highly angiogenic with a higher density of microvessels (43). The type of lymphoma was significantly influenced by the degree of CD4 cell depletion and immune dysfunction (44). Patients with CD4⁺ T-cell depletion are more likely to develop aggressive subtypes such as DLBCL, PEL, or PBL. In contrast, those with higher CD4⁺ counts are prone to centroblastic DLBCL and BL (24).

However, HIV could influence oncogenesis independent of immunosuppression using a direct pro-oncogenic mechanism (45). The dysregulation of the cell cycle influences the non-immune microenvironment by increasing the extracellular matrix, profibrogenic factors, and aberrant lymphangiogenesis (46).

Chronic activation of B lymphocytes during HIV immune dysfunction leads to hypergammaglobulinemia, impaired humoral immunity, and germinal center hyperplasia, which can ultimately result in lymphoma development (47).

The degree of immune dysfunction, particularly reflected by CD4⁺ T-cell counts, plays a pivotal role in the clinical presentation, treatment response, and prognosis of HIV-associated lymphomas. Patients with severe immunosuppression, indicated by nadir CD4 counts below 50 cells/mm³, more frequently present with advanced-stage lymphomas (stages III/IV) and systemic symptoms, complicating management and worsening outcomes. Conversely,

higher CD4 counts at lymphoma diagnosis correlate with better chemotherapy tolerance and longer survival, as observed in our cohort (48). For example, patient 1, with a CD4 count of 165 cells/mm³, exhibited a favorable response and prolonged survival, while patient 4, with a CD4 count of 15 cells/mm³, faced treatment-limiting complications.

Chronic immune activation driven by persistent HIV replication exacerbates immune dysfunction, depleting CD4⁺ T cells, disrupting immune surveillance, and fostering oncogenesis (49, 50).

These findings underline the necessity of integrating immune and virological monitoring into the diagnostic and therapeutic planning for HIV-associated lymphoma patients.

4.2 Epidemiology of HIV/AIDS and lymphoma co-occurrence

Recent updates from the United States (US) on HIV-associated lymphomas during the antiretroviral therapy indicate increasing incidence trends, with DLBCL being the most common subtype, followed by HL, concordant with the results of our study (13).

Some prospective cohort studies on different populations, conducted in Switzerland, the USA, or China, have reported the incidence of lymphomas in PLWH between 2% and 2.14% (51–53). We found an incidence of 1.89%, with a slight difference. It could possibly be explained by the younger HIV age demographics of patients in this study (HIV diagnosis age 2–57 years old). However, it is important to note that the prevalence of lymphomas increases significantly in patients diagnosed with AIDS, where more than 40% are affected by these malignancies (54). This highlights the critical need for early HIV diagnosis and management to prevent progression to advanced stages associated with a higher lymphoma burden (10).

Globally, malignancies, including lymphomas, are more common in men (55). The underlying reasons for this gender difference remain unclear but may involve extrinsic factors such

as exposure to environmental carcinogens and intrinsic factors, comprising different immune and hormonal profiles, body size, and tumor biology in men and women (56). Our study confirms the predominance of lymphomas in men, most of them smokers, with a sexually transmitted pattern and severe immunosuppression. These demographic factors are commonly observed in other cohorts, and several studies suggest that smoking and advanced immunosuppression may contribute to a higher incidence and poor prognosis of lymphoma in HIV-infected individuals (46).

Lymphomas can develop across all age groups. Our study found that the average age at lymphoma diagnosis was 35 years, younger than that of other reports, such as 42 years in a Brazilian study, 48 years in a US study, or 43.6 years in a Chinese Study (18, 57, 58). The comparison may be influenced by the differences in sample size and age distribution across the studies.

Studies from Europe and the USA indicate that lymphomas are frequently diagnosed in patients with advanced immunosuppression, often as a late-stage complication in individuals with poorly controlled HIV (57). Furthermore, all our patients presented with advanced lymphomas (stage III/IV) and severe HIV immunosuppression (CD4 counts < 200/mm³). Although antiretroviral therapy was available, some patients continued to experience immunological decline after HIV diagnosis, potentially contributing to the development of malignant hematological disorders.

Studies in some European countries have identified a lower mortality rate of lymphoma among HIV patients. A French study for 10 years reported a mortality rate of 8.8% among 82,000 HIV patients (59). Another study conducted in the USA found a significantly higher mortality rate for HIV-associated lymphoma than for other HIV-related diseases (60). In Botswana, mortality in HIV HL was comparable to that of non-HIV HL, due to an equal increased access to oncologic care for PLWH and those without HIV (61).

The mortality rate of PLWH with lymphoma in our study was 77.7%, notably higher than the mortality rate of 13.65% in the HIV-only group. This stark difference underscores the severe impact of lymphoma on the survival of HIV Romanian patients.

4.3 Particularities of the Romanian HIV/AIDS epidemic and oncologic risk

Romania is a Central-Eastern European country with 18,359 alive PLWH reported by the Ministry of Health in June 2024 (62, 63). More than half of the cases are survivors of the “Romanian HIV pediatric cohort,” which means that patients were born mainly between 1988 and 1989. Most of them were infected with HIV during early childhood by a small amount of blood transfusions or inappropriate use of syringes and needles in healthcare institutions during the communist era. After the fall of communism in December 1989, the availability of HIV diagnosis tests revealed that Romania accounted for 60% of pediatric AIDS cases in Europe at that time (64).

The “HIV pediatric cohort” is characterized by its homogeneous Caucasian race, with many cases of long-term survival from early childhood to adulthood, predominantly of the HIV-1 subtype F, with a high rate of coinfection with hepatitis B virus and multiple antiretroviral drug experience (65). Growing up with HIV is a complex individual burden, involving physical, functional, psychological, and sociobehavioral development, putting one at high risk of increasing comorbidities. Three subjects with NHL (P1, P4, P5) and one with HL (P8) from our case series were part of this pediatric HIV cohort. They were diagnosed with HIV at the ages of 10 years, 19 years, 2 years, and 14 years, respectively, and developed lymphoma diagnosed at the ages of 18 years, 21 years, 26 years, and 29 years, respectively. Beyond the pediatric cohort (born in the 1990s), the “adult” HIV epidemic has progressed through increased sexual transmission or by intravenous drug use (66). A multicenter national database of oncologic HIV/AIDS-associated malignancies should be developed in Romania to better understand these rare comorbidities in our specific population and improve management strategies.

4.4 Immune reconstitution inflammatory syndrome

IRIS is a hyperinflammatory reaction that occurs when the immune system is recovering under antiretroviral therapy, mostly in PLWH with low CD4 counts and opportunistic infections with tuberculosis or cryptococcosis (67, 68). IRIS occurs in two forms: “paradoxical” IRIS is characterized by the exacerbation of a previously treated infection after ART is started, and “unmasking” IRIS is defined by the activation of a previously undiagnosed infection soon after antiretroviral therapy is started (69).

The “unmasking” IRIS was applied to one of our case series (P3). A study involving a cohort of 482 patients with HIV/AIDS-associated lymphoma from 1996 to 2011 found that 48 patients (10%) met the criteria for unmasking lymphoma. Among these cases, 10 (21%) were classified as HL, 19 (40%) as DLBCL, 4 (8%) as BL, 9 (19%) as PCNSL, and 6 (12%) as other NHL (70).

4.5 Real-life treatment, available options, prognosis, and future perspectives

The treatment of HIV infection and lymphoma requires an integrated approach, given the complex interplay between these two conditions. ARV is essential for the suppression of HIV replication and the recovery of immune function, while chemotherapy is the usual treatment of lymphoma with immunosuppressive adverse events (44).

Since 2018, the National Comprehensive Cancer Network (NCCN) guidelines have included dedicated recommendations for treating HIV-associated B-cell lymphomas (20, 71), highlighting the evolving approach to managing these co-occurring conditions in clinical practice.

The current standard practice is to continue or to initiate antiretrovirals during chemotherapy (66). PLWH who have well-controlled onco-hematologic disease have a life expectancy comparable to the general population. This group remains underrepresented in clinical trials, as seropositive status continues to be an exclusion criterion for most lymphoma trials (72, 73).

Therapeutic protocols such as R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone), R-CDE (rituximab, cyclophosphamide, doxorubicin, etoposide), R-EPOCH, and (DA)-EPOCH-R (dose-adjusted etoposide, prednisone, vincristine, doxorubicin, and cyclophosphamide based on CD4 count plus rituximab) achieved a complete response rate of 69%–91%, with a 2-year survival rate of 62%–75% and low mortality from infectious causes. The addition of immunotherapy proved beneficial for patients with HIV-associated lymphomas (74).

The relationship between the number of chemotherapy cycles and prognosis in HIV-associated lymphomas offers valuable insights into treatment outcomes. In our cohort, patients underwent a range of regimens, including five cycles of CHOP, six cycles of CVP, eight cycles of R-CHOP, three cycles of EPOCH, and six cycles of ABVD. These data underline the importance of treatment intensity and duration in influencing overall survival (OS) and progression-free survival (PFS). Existing literature emphasizes that completing the full prescribed chemotherapy regimen is typically associated with higher rates of complete response and a reduced likelihood of recurrence. However, in HIV-positive patients, severe immunosuppression and associated complications can compromise treatment tolerance, often leading to premature discontinuation of chemotherapy. This underscores the need for personalized approaches to optimize both tolerability and efficacy in this unique patient population (75). The degree of immunosuppression, reflected in nadir CD4 counts and HIV staging, expresses the resources of immune recovery under ART and influences not only lymphoma aggressiveness but also the ability to complete treatment. Advanced immunodepression characterized all patients in our study with HIV-associated lymphomas, suggesting late presentation and delayed diagnosis of both HIV infection and lymphoma. This may reflect systemic deficiencies in screening and early detection within the Romanian healthcare system. Immune function markers such as CD4 counts are valuable prognostic indicators, as they reflect both the host's capacity to tolerate chemotherapy and the biological aggressiveness of lymphoma in HIV-infected patients (76).

Autologous stem cell transplantation (ASCT) is provided equally for both HIV-negative and HIV-positive lymphoma patients from some European countries (77). In recent years, this therapeutic option has also been used in Romania for a few patients with HIV and lymphoma. The first two cases of HIV-associated DLBCL treated with the chimeric antigen receptor T-cell therapy (CAR-T) axicabtagene ciloleucel were reported in 2019. This report demonstrated that CAR-T cells can be successfully produced in HIV patients undergoing ART, even with CD4 counts as low as 52 cells/mm³ (78, 79). In Romania, CAR-T-cell therapy has been available since 2022 for adult patients with relapsed or refractory diffuse large B-cell lymphoma and for acute lymphoblastic leukemia who have failed at least two lines of systemic

chemotherapy. However, this revolutionary treatment has not yet been administered to HIV-positive patients in our country.

4.6 Limitations of the study

The first limitation of our study is the retrospective design and the inconsistent availability of data. The evaluation and treatment decisions were not unitary because the guidelines and protocols for both HIV and lymphomas have been changed, considering the extended duration of the study. The HIV viral load was not systematically available due to either the temporary lack of reagents or the limited procedures caused by the COVID-19 pandemic. The limited population size diminishes the statistical power, and a study involving a larger patient cohort could yield more robust and precise conclusions in future research. Immunohistochemistry and other procedures for cancer diagnosis are missing because these are not covered by the health insurance and patients could not afford them. Serological evaluation of EBV and HHV-8 with oncogenic potential was not available.

5 Conclusions

Lymphoma is a rare comorbidity in PLWH from the South-East of Romania; however, it has a serious impact on life expectancy, due to the high mortality rate. The median age of PLWH with lymphoma was 35 years, ranging from 18 to 59 years old. The most frequent subtype of lymphoma was DLBCL. A low CD4 count is associated with more aggressive forms of lymphomas, with a low survival on 1-year follow-up. Smoking, HBV coinfection, and chronic infection with HIV of patients from “the pediatric cohort” are predictors for the younger age of lymphoma diagnosis. Most cases of lymphomas occurred in men with HIV/AIDS. Delay of the oncohematological diagnostic, the limited access to screening and treatment, and poor education for earlier medical visits are the main difficulties in the management of lymphomas in PLWH in Romania. These challenges highlight the need for sustained health strategies dedicated to this specific population.

Data availability statement

The original contributions presented in the study are included in the article/supplementary material. Further inquiries can be directed to the corresponding author.

Ethics statement

The studies involving humans were approved by Liliana Baroiu Clinical Medical Department, Dunarea de Jos University, Galati, Romania. The studies were conducted in accordance with the local legislation and institutional requirements. The participants provided their written informed consent to participate in this study.
