Front. Physiol. 12:612770. doi: 10.3389/fphys.2021.612770 <sup>1</sup> Laboratory of Cardiovascular Science, National Institute on Aging, National Institutes of Health, Baltimore, MD, United States, <sup>2</sup> Department of Mathematics and Statistics, Loyola University Maryland, Baltimore, MD, United States, <sup>3</sup> Biomedical Engineering Faculty, Technion–Israel Institute of Technology, Haifa, Israel

 $Ca^{2+}$  and  $V_m$  transitions occurring throughout action potential (AP) cycles in sinoatrial nodal (SAN) cells are cues that (1) not only regulate activation states of molecules operating within criticality (Ca<sup>2+</sup> domain) and limit-cycle ( $V_m$  domain) mechanisms of a coupled-clock system that underlies SAN cell automaticity, (2) but are also regulated by the activation states of the clock molecules they regulate. In other terms, these cues are both causes and effects of clock molecular activation (recursion). Recently, we demonstrated that  $Ca^{2+}$  and  $V_m$  transitions during AP cycles in single SAN cells isolated from mice, guinea pigs, rabbits, and humans are self-similar (obey a power law) and are also self-similar to trans-species AP firing intervals (APFIs) of these cells in vitro, to heart rate in vivo, and to body mass. Neurotransmitter stimulation of β-adrenergic receptor or cholinergic receptor-initiated signaling in SAN cells modulates their AP firing rate and rhythm by impacting on the degree to which SAN clocks couple to each other, creating the broad physiologic range of SAN cell mean APFIs and firing interval variabilities. Here we show that  $Ca^{2+}$  and  $V_m$  domain kinetic transitions (time to AP ignition in diastole and 90% AP recovery) occurring within given AP, the mean APFIs, and APFI variabilities within the time series of APs in 230 individual SAN cells are self-similar (obey power laws). In other terms, these long-range correlations inform on self-similar distributions of order among SAN cells across the entire broad physiologic range of SAN APFIs, regardless of whether autonomic receptors of these cells are stimulated or not and regardless of the type (adrenergic or cholinergic) of autonomic receptor stimulation. These long-range correlations among distributions of  $Ca^{2+}$  and  $V_m$  kinetic functions that regulate SAN cell clock coupling during each AP cycle in different individual, isolated SAN cells not in contact with each other. Our numerical model simulations further extended our perspectives to the molecular scale and demonstrated that many ion

1

currents also behave self-similar across autonomic states. Thus, to ensure rapid flexibility of AP firing rates in response to different types and degrees of autonomic input, nature "did not reinvent molecular wheels within the coupled-clock system of pacemaker cells," but differentially engaged or scaled the kinetics of gears that regulate the rate and rhythm at which the "wheels spin" in a given autonomic input context.

Keywords: single sinoatrial nodal pacemaker cells, local diastolic  $Ca^{2+}$  releases, diastolic depolarization, autonomic receptor stimulation, self-similarity of  $Ca^{2+}$  and membrane potential during action potentials, action potential, firing interval variability

#### INTRODUCTION

The heart is a central player within a hierarchical system of clocks operating within the autonomic neurovisceral axis that creates and synchronizes rhythmic functions ranging from milliseconds to days and beyond (Shivkumar et al., 2016; Lakatta, 2021). The heart's beating rate and rhythm are regulated by autonomic input to sinoatrial nodal (SAN) pacemaker cells that modulates functions within a coupled-clock system intrinsic to SAN cells (Lakatta et al., 2010).

#### What Is the Coupled-Clock System Within Pacemaker Cells and How Do Clocks Couple to Each Other?

The SAN cell coupled-clock system comprised a calcium "clock," the sarcoplasmic reticulum (SR), which continuously oscillates Ca<sup>2+</sup> via a criticality mechanism (Nivala et al., 2012) and phase-like transitions (Maltsev et al., 2011); the Ca<sup>2+</sup> clock is continuously but variably coupled to a "membrane clock," an ensemble of surface membrane ion channels that generates current oscillations via a limit-cycle mechanism (Weiss and Qu, 2020). The criticality mechanisms, in turn, are governed by power law and self-similarity across wide scales (Bak, 1999). The "biochemical engine" of the coupled-clock system is a constitutively active, Ca<sup>2+</sup> calmodulin-dependent adenylyl cyclase (AC) that generates cyclic AMP (cAMP), leading to modulation of cAMP-gated ion channels, exchange protein directly activated by cAMP (EPAC) signaling, and protein kinase A (PKA) and Calcium/calmodulin-dependent protein kinase II (CaMKII)-dependent kinase activities, mechanisms that regulate intracellular Ca2+ levels, Ca2+ dynamics and membrane potential within SAN cells (Lakatta et al., 2003, 2006, 2008, 2010; Maltsev and Lakatta, 2008; Yaniv et al., 2015). Variable rates and rhythms at which SAN cells fire action potentials (APs) are controlled by the kinetics of subcellular

and cell-wide transitions in  $[Ca^{2+}]$  gradients and the membrane potential  $(V_m)$ , and the extent to which  $V_m$  and  $Ca^{2+}$  become coupled during AP cycles in any given epoch. For more details, see **Supplementary Discussion**.

The well-known variability of AP firing intervals (APFIs) of isolated SAN cells *in vitro*, of SAN tissue *ex vivo*, or of heartbeat intervals *in vivo* (Monfredi et al., 2014; Yaniv et al., 2014a) indicates that coupled-clock system  $Ca^{2+}$  and  $V_m$  functions during AP cycles never achieve a true steady state from one AP to the next.

These time-dependent  $Ca^{2+}$  and  $V_m$  domain transitions during APs are cues, which not only regulate activation states of clock molecules, but are also regulated by the activation status of the very molecules they regulate. In other terms, changes in these cues cause changes in clock molecule activation that feed back to change the characteristics of activation cues. This recursive dynamic imparts robustness to SAN cell automaticity (Maltsev and Lakatta, 2009; Lyashkov et al., 2018). The variability in the degree to which  $Ca^{2+}$  and membrane clock molecules couple to each other throughout AP cycles is due to transitions (changes) that occur in  $Ca^{2+}$  and  $V_m$  domain cues throughout AP cycles (Monfredi et al., 2013; Yaniv et al., 2014b).

Spontaneous transitions in subcellular  $Ca^{2+}$  and  $V_m$  domains that emerge during the spontaneous diastolic depolarization (DD) phase of an AP cycle have been conceptualized as the AP "ignition phase" (Lyashkov et al., 2018). The ignition process in the  $Ca^{2+}$  domain is linked to the emergence of local spontaneous, diastolic oscillatory RyR activation, which generates local  $Ca^{2+}$ releases (LCRs) that self-organize to form  $Ca^{2+}$  wavelets that propagate locally (Bogdanov et al., 2001; Vinogradova et al., 2004).  $Ca^{2+}$ -dependent activation of the surface membrane electrogenic Na<sup>+</sup>/Ca<sup>2+</sup> exchanger generates inward current that accelerates diastolic  $V_m$  depolarization and couples the clocks. The time at which the rate of this feed-forward crosstalk acutely accelerates to 0.15 V/s marks the onset of the coupled-clock ignition process (Lyashkov et al., 2018).

Following ignition onset, the extent to which the  $Ca^{2+}$  and  $V_m$  clock become coupled continues to increase throughout the diastolic period as LCRs and  $Ca^{2+}$  wavelets emerge at remote areas across the cell and continue to self-organize in time throughout the cellular space, creating an explosive ensemble  $Ca^{2+}$  signal that progressively depolarizes the cell membrane; i.e., clock coupling progressively increases. This  $Ca^{2+}$ -induced change in  $V_m$  increases in clock-coupling cues the activation of low-voltage activated  $Ca^{2+}$  channels ( $Ca_v 1.3$  and  $Ca_v 3.1$ ), resulting in  $Ca^{2+}$  influx that contributes to the

Abbreviations: AP, action potential; APD<sub>90</sub>, action potential duration from AP overshoot to 90% repolarization; APFI, AP firing interval; APFIV, variability of AP firing intervals; TTIO, time from the previous AP overshoot to the ignition onset when dV/dt = 0.15 (V/S); CaTFI, firing internal of AP-induced Ca<sup>2+</sup> transient; CaT<sub>90</sub>, 90% decay time of AP-induced Ca<sup>2+</sup> transient; LCR, local Ca<sup>2+</sup> releases; SR, sarcoplasmic reticulum; SD, standard deviation; CV, coefficient of variation; PC, principal component; I<sub>CaL</sub>, high voltage-activated, L-type Ca<sup>2+</sup> current; I<sub>f</sub>, hyperpolarization-activated funny current; I<sub>KACh</sub>, acetylcholine-activated K<sup>+</sup> current; I<sub>Kr</sub>, K<sup>+</sup> current exhibiting strong inward rectification; I<sub>NCX</sub>, Na<sup>+</sup>-Ca<sup>2+</sup> exchanger (NCX) current; βARs, β-adrenergic receptor stimulation; CRs, cholinergic receptor stimulation; CCh, carbachol; ISO, isoprotereno]; HR, heart rate; SAN, sinoatrial node.

further organization of the ensemble LCR Ca<sup>2+</sup> signal via feedforward electrochemical  $(Ca^{2+}-V_m-Ca^{2+})$  signaling, when the diastolic V<sub>m</sub> enters a range that cues the activation of L-type  $Ca^{2+}$  channels (Ca<sub>v</sub>1.2). The ignition phase of the coupled- $Ca^{2+}$  and  $V_m$  domain subcellular kinetic transitions culminates in the generation of cell-wide events; a marked transition in the rate of  $V_{\rm m}$  depolarization, due to the activation of Ca<sub>v</sub>1.2, results in the rapid AP upstroke and Ca<sup>2+</sup> influx, which, via Ca<sup>2+</sup>-induced Ca<sup>2+</sup> release from the SR via RyRs, generates an AP-induced cytosolic Ca<sup>2+</sup> transient (CaT). In other terms, spontaneous, cell-wide Ca<sup>2+</sup> signals and APs in SAN cells emerge from spatiotemporal self-organization of spontaneous subcellular  $Ca^{2+}$  oscillations (the criticality mechanism) (Nivala et al., 2012). SERCA2a pumping Ca<sup>2+</sup> into SR and K<sup>+</sup> channel repolarization of  $V_{\rm m}$  return the Ca<sup>2+</sup> and  $V_{\rm m}$  domain cues toward their diastolic levels at which LCRs again begin to emerge, creating the ignition phase of the next AP cycle.

#### **Self-Organized Criticality**

Spatiotemporal self-organization across geometric scales (subcellular to cell-wide) is a manifestation of criticality that has been observed in excitable cells throughout nature (Stožer et al., 2019) including cultured astrocytes (Jung et al., 1998), immature oocytes (Lopez et al., 2012), and mouse cardiac ventricular myocytes (Nivala et al., 2012). Self-similar, scale-free distributions of parameters across wide scales that obey power law behavior (are ln–ln linear) are an indication of their self-ordered criticality (Bak, 1999).

It has recently been discovered that coupling of subcellular  $Ca^{2+}$  signals (cues) generated by the  $Ca^{2+}$  clock within isolated SAN cells to the cell surface membrane proteins during APs to elicit a change in  $V_m$  manifests long-range power law correlations (are self-similar) across species (Sirenko et al., 2021). Specifically,  $Ca^{2+}$  and  $V_m$  domain kinetic transitions (cues) during AP cycles in single SAN cells isolated from mice, guinea pigs, rabbits, and humans are self-similar to each other during APS and self-similar to *trans*-species APFIs of these cells *in vitro*, to heart rate *in vivo*, and to body mass (Sirenko et al., 2021).

Neurotransmitter stimulation of  $\beta$ -adrenergic receptor stimulation ( $\beta$ AR) or cholinergic receptor (CR)–initiated signaling modulates the AP firing rate and rhythm of SAN cells by impacting on coupled-clock protein functions, modulating the degree to which criticality (Ca<sup>2+</sup> domain) and limit-cycle ( $V_m$  domain) mechanisms couple to each other during AP cycles (Maltsev and Lakatta, 2009; Lakatta et al., 2010). APFIs in rabbit SAN cells during autonomic stimulation vary over a fourfold range, from approximately 200 ms during  $\beta$ ARs up to approximately 800 ms during CR stimulation (CRs) (Vinogradova et al., 2002; Lyashkov et al., 2009).

We hypothesized that transitions in  $V_{\rm m}$  and  ${\rm Ca}^{2+}$  domain cues during the diastolic AP ignition (Lyashkov et al., 2018) and recovery phases (**Figure 1**) of APs are (1) not only self-similar to each other in cells without autonomic receptor stimulation (control cells), but are self-similar to  $V_{\rm m}$  and  ${\rm Ca}^{2+}$  cues in other cells during CRs and during  $\beta$ ARs and (2) that Ca<sup>2+</sup> and  $V_{\rm m}$  cues during APs are self-similar to APFI variabilities (and therefore self-similar to mean APFIs) regardless of the presence or absence or type of autonomic receptor stimulation. In other terms, we hypothesized that  $Ca^{2+}$  and  $V_m$  domain clock-coupling cues occurring during all APs are self-similar to each other, i.e., manifest long-range correlations in all isolated SAN cells within populations of cells that differ with respect to autonomic input, and that these  $Ca^{2+}$  and  $V_m$  cues during APs are also self-similar to the rate and rhythm of AP firing across the entire range of APFIs created by these cues in all isolated SAN cells.

To test these hypotheses, we studied a large population (n = 230) of single rabbit SAN cells to which we applied CRs [carbachol (CCh)] to one subset of cells, BARs [isoproterenol (ISO)] to another subset, and no autonomic receptor stimulation to a third subset of cells. This created three populations of SAN cells having APFIs distributed across the entire physiologic range. We measured intracellular Ca<sup>2+</sup> or membrane potential in these cells to (1) characterize the times to ignition onset and times to 90% recovery of  $V_{\rm m}$  and  ${\rm Ca}^{2+}$  parameters during APs in AP time series and (2) to determine the correlations of these  $V_{\rm m}$  and Ca<sup>2+</sup> kinetic parameters to each other during APs, to APFI variability (APFIV; and therefore to mean APFIs). Thus, the data set to be analyzed consisted of 12 different kinetic parameters in each cell population (control, CCh, and ISO); six parameter means, three each in the  $Ca^{2+}$  and  $V_m$  domains; and six parameter variabilities (SDs) around the means. To determine the degree of self-similarity among V<sub>m</sub> and Ca<sup>2+</sup> domain parameters, we constructed density distribution plots and applied correlation, power law, and principal component (PC) analyses to  $Ca^{2+}$  and  $V_m$  domain data sets separately and to the combined  $Ca^{2+}$  and  $V_m$  data sets. We further extended our perspectives from cell population and singlecell levels downward to the molecular scale by performing numerical modeling simulation and analyzing variabilities of ion currents and Ca<sup>2+</sup> with respect to APFI to determine whether these ion currents and Ca<sup>2+</sup> also obeved a power law across autonomic states.

#### MATERIALS AND METHODS

The study was performed in accordance with the Guide for the Care and Use of Laboratory Animals published by the National Institutes of Health (NIH publication 85–23, revised 1996). The experimental protocols have been approved by the Animal Care and Use Committee of the NIH (protocol #457-LCS-2024). Materials and methods briefly presented here are detailed in **Supplementary Material**.

### Isolation of Single Rabbit SAN Cells

Single, spindle-shaped, spontaneously beating SAN cells were isolated from the hearts of New Zealand rabbits (Charles River Laboratories, Wilmington, MA, United States) as described previously (Vinogradova et al., 2000).

#### **Spontaneous APs Recordings**

Time series of spontaneous APs were recorded in subsets of freshly isolated SAN cells using the perforated patch-clamp technique with Axopatch 200B patch-clamp amplifier (Axon

Instruments) (Bogdanov et al., 2001) at  $34^{\circ}C \pm 0.5^{\circ}C$ . AP parameters (**Figure 1**) measured via a customized program (Lyashkov et al., 2018) were APFI, APD<sub>90</sub>, and the time to ignition onset (TTIO) measured by the time at which diastolic membrane potential dV/dt accelerates to 0.15 V/s (**Figure 1**), which reflects the onset of the ignition phase of the AP cycle (Lyashkov et al., 2018).

### Ca<sup>2+</sup> Measurements

In another subset of SAN cells, AP-induced global CaTs and spontaneous LCRs (**Figure 1**) were measured at  $34^{\circ}C \pm 0.5^{\circ}C$  with a confocal microscope (Zeiss LSM510, Germany) in the line-scan mode (Vinogradova et al., 2004; Yang et al., 2012). The interval between the peaks of two adjacent AP-induced CaTs (**Figure 1**) is defined as CaT firing interval, which is highly correlated with the APFI, as demonstrated by simultaneous recordings of  $V_{\rm m}$  and Ca<sup>2+</sup> in a separate subset of cells (**Figure 1**). The LCR period is defined as the time from the peak of the prior AP-induced CaT to an LCR peak in diastole (**Figure 1**); the time to 90% decay of the CaT was defined as CaT<sub>90</sub>.

### **Numerical Modeling**

We performed numerical simulations using a modified Maltsev-Lakatta model that features the coupled-clock

mechanism (Maltsev and Lakatta, 2009). The computer code for the original model is freely available and can be downloaded and run in CellML format<sup>1</sup> using the Cellular Open Resource software developed by Alan Garny at Oxford University in the United Kingdom (Garny et al., 2009) (for recent development of this software)<sup>2</sup>. The original model could not be directly used for APFIV simulations because it is a system of first-order differential equations that is deterministic and showing no APFIV in limit-cycle oscillatory regime of AP steady firing. Thus, we modified the model to generate variability of AP waveforms by supplementing total membrane current  $(I_{tot})$  with an additional randomly fluctuating current around its zero-mean value, known as perturbation current or Iper [as previously implemented by Henggui Zhang (Monfredi et al., 2014)]. Furthermore, we also performed an additional set of simulations with  $I_{per}$ added to Ca<sup>2+</sup> release flux to mimic the effect of stochastic LCRs (Bogdanov et al., 2006; Monfredi et al., 2013). Using the resultant stochastic dynamical system of SAN cell, we simulated fluctuating APFI, ion currents, and Ca<sup>2+</sup> dynamics for three conditions: (i) basal AP firing, (ii) during βARs with ISO (100 nM), and (iii) during CRs with CCh

<sup>&</sup>lt;sup>1</sup>http://models.cellml.org/workspace/maltsev\_2009

<sup>&</sup>lt;sup>2</sup>http://www.opencor.ws/

(100 nM). The effects of autonomic modulation (conditions ii and iii) were modeled as previously described (Maltsev and Lakatta, 2010), except modulation of  $I_{CaL}$  current by CCh that was modeled as described by Zaza et al. (1996). All model equations and parameters are provided in the **Supplementary Material**.

#### **Experimental Design and Statistics**

**Supplementary Figure 1** illustrates schematic of the experimental design to assess long-range correlations of  $V_{\rm m}$  and  ${\rm Ca}^{2+}$  parameters during APs and APFI intervals in cells within and among populations of cells that differed with respect to autonomic input.  $V_{\rm m}$  and  ${\rm Ca}^{2+}$  parameter intervals (milliseconds) are presented as mean  $\pm$  SD. APFIV within a time series is taken as standard deviation (SD) about the mean or as the coefficient of variation (CV) (the ratio of SD to the mean).

Analyses of  $V_{\rm m}$  and  ${\rm Ca}^{2+}$  parameter interval distributions measured in AP time-series in different cells determined the association among pairs of variables using Pearson's correlations for both average and individual data (Howell, 2002). In cells in which  ${\rm Ca}^{2+}$  was measured, the mean interval between AP-induced CaTs was usually longer than the mean APFI in cells in which APs were recorded (due to slight buffering effects of the fluorescent Ca<sup>2+</sup> probe). To allow all the variables to be combined into a single analysis, we matched on the APFI variable Z scores in control, ISO, or CCh populations by "matchit" function in R (Ho et al., 2011).

Density estimates of within-cell standard deviations and means of parameters of cells within each autonomic state population are presented as non-parametric kernel estimates of probability density functions, scaled so that the total area under each curve is unity (Silverman, 1986).

In order to determine whether distributions of parameter means and SDs are self-similar, i.e., obeyed a power law suggesting fractal-like behavior, we constructed ln–ln plots of distributions of the AP and Ca<sup>2+</sup> function means and SDs measured across the broad range of apparent steady states in the absence of, or the presence of,  $\beta$ ARs or CRs (Kucera et al., 2000; Yaniv et al., 2013).

The relationships among all distributions of all parameters (means and SDs) were also assessed in principal component analyses (Johnson and Wichern, 2008).

In a few cells in which experimentally measured parameter interval distributions measured in the  $V_{\rm m}$  and  ${\rm Ca}^{2+}$ domains in the same cell and for numerical simulation of ion currents and  ${\rm Ca}^{2+}$  prior to and during autonomic receptor stimulation Poincaré indices were employed to define long-range correlations among variables, a Poincaré plot graphs a parameter (*n*), in an AP time series on the *x* axis versus the same parameter of the succeeding AP (n + 1) on the *y* axis; i.e., one takes a sequence of parameters and plots each one against the following parameter (Huikuri et al., 2000).

When statistical inference was performed, p < 0.05 was considered statistically significant.

## RESULTS

## Assessment of Self-Similarity of $Ca^{2+}$ and $V_m$ Kinetic Interval Parameters to Each Other During APs and to APFIV

**Figure 1A** illustrates a time series of APs in a SAN cell during which  $Ca^{2+}$  and  $V_m$  were simultaneously measured in the absence of autonomic receptor stimulation. Kinetic transitions in  $Ca^{2+}$  and  $V_m$  parameters as illustrated in **Figure 1B** were assessed during each AP. **Figures 1C,D** shows that  $V_m$  and  $Ca^{2+}$  parameters during AP time series are self-similar to each other and are also self-similar to the APFIs (r = 0.844 in this cell).

**Figure 2** illustrates the time series of AP intervals in **Figure 1A** plotted as phase-plane diagrams in which  $V_{\rm m}$  is depicted as a function of Ca<sup>2+</sup> throughout each cycle. The times at which various channels are activated throughout the  $V_{\rm m}/Ca$  loop are indicated. The times of ignition and 90% recovery are also indicated. The point resolution is 3.072 ms, and the point spread indicates the rates at which the electrochemical signal changes during each cycle. The dashed line in the figure marks the border between the disordered and ordered molecular activation. The arrows indicate the direction of the electrochemical signal emergence.

A Poincaré plot (scatter graph) constructed from consecutive data points in a time series (Figure 3A) is a convenient tool that provides information on correlations (self-similarity) of data across the time series. The x axis defines the parameter (n)occurrence in milliseconds, and the y axis defines the parameter occurrence at (n + 1). The Poincaré plot in Figure 3A depicts the data of the time series of the cell in Figure 1. Note that although the means vary over a threefold range, all six parameter means (the  $Ca^{2+}$  and  $V_m$  interval parameters measured during APs and APFIs) in the absence of autonomic receptor stimulation are described by a line of identity, indicating their self-similarity across the AP time series. Quantitative analysis of short- and long-term variability in a given time series of observations entails fitting an ellipse to each cloud of data points within the Poincaré plot (Figure 3B): The length of a line describing the slope of the long axis of each ellipse is referred to as SD2 of the data points (c.f. Figure inset); the length of the line describing the slope of the short axis, which is perpendicular in direction to the long axis line, is referred to as SD1. Note in Figure 3C that the SD1 is self-similar to SD2 across the fourfold range of Ca<sup>2+</sup> and  $V_{\rm m}$  parameters. The center point of each ellipse, i.e., the intersection of SD1 and SD2, is the average interval between events (AP intervals or other parameters measured in the time series) within the time series. SD1/SD2 (Figure inset) informs on non-linear trends (unequal lengths of SD1 and SD2) across intervals within each ellipse.

**Figure 4** illustrates combined Poincaré plots of TTIO, APD<sub>90</sub>, during APs and APFIs in time series of APs of two representative cells: one cell in control and during CRs by CCh and the other cell in control and during  $\beta$ ARs stimulation by ISO.

Although the range of absolute values of kinetic interval parameters of cells depicted in the Poincaré plot in **Figure 4B** vary by 20-fold, all points (n = 5,673) are self-similar, i.e., fit by

a single line (r = 0.992) with a slope of unity, passing nearly through the origin.

**Supplementary Table 1** lists the SD1s, SD2s, SD1/SD2, the means of the TTIO and APD<sub>90</sub> intervals, and APFIs depicted in **Figure 4B**. Note also that the SD1s, SD2s, and SD1/SD2 of TTIO, APD<sub>90</sub>, and APFIs progressively increase from ISO to control and markedly increase from control to CCh, creating degrees of non-linearity across the combined control, ISO, and CCh states, which is also reflected in the mean APFIs across the three states (**Supplementary Table 1**). The  $V_{\rm m}$  transitions during APs across different autonomic states are self-similar to APFIs across these states (**Figure 5A**). **Figure 5B** shows the self-similarity

of parameter means of SD1s of  $V_{\rm m}$  parameters to their SD2s across autonomic states, indicating self-similarity of short-term (e.g., beat to beat) and long-term (e.g., rhythm across more than two beats) variabilities across autonomic states within the time series. **Figure 5C** shows the self-similarity of all parameter means depicted in **Figures 4**, **5A,B** to their SDs across autonomic states.

The data in **Figures 4**, **5** demonstrate that over the entire range of physiologic APFIs from 192.7 ms in ISO to 305.5 ms in control, and to 910.3 ms in CCh, variabilities of TTIO and  $APD_{90}$  measured during APs are self-similar to each other and are also self-similar to the variability of APFIs within the time series, and therefore self-similar to the mean APFI of the time series.

Self-similarity among  $V_{\rm m}$  variables in the cells in **Figure 4** across autonomic states in control and during ISO and CCh in **Figures 2**, **3A** can also easily be ascertained from the shapes of their population density distributions (**Figure 6**). Note that in the cell superfused with CCh, the distributions of TTIO, APD<sub>90</sub>, and APFIs (**Figures 6A–C**) are broader than in control or during ISO. Note also that the distributions of kinetic transitions during APs and APFI become more synchronized from CCh to ISO (**Figure 6A–C**). In other terms, the degree to which  $V_{\rm m}$  and Ca<sup>2+</sup> parameters are synchronized during APs increases from CCh to control to ISO, similar to the AP firing variabilities and mean APFIs.

#### Self-Similarity of $Ca^{2+}$ and $V_m$ Parameter Means to Each Other During APs and to APFI Variabilities and Mean APFIs Across Autonomic States in Different Cells

We next determined whether the self-similarity (long-range correlations) of Ca<sup>2+</sup> to  $V_{\rm m}$  parameters measured within the same cells as depicted in **Figures 1–6** extends to populations of different cells within and among different autonomic states. To accomplish this, we applied CRs (CCh) to one subset of cells,  $\beta$ AR stimulation (ISO) to another subset, and no autonomic receptor stimulation to a third subset of cells. This created

populations of SAN cells having APFIs distributed across the entire physiologic range.

**Table 1** lists descriptive statistics (means and SDs) of the variabilities and means of  $Ca^{2+}$  and  $V_m$  kinetic parameter intervals measured in different cells within and among populations of cells that differ with respect to autonomic input. The mean SD of  $V_m$  and  $Ca^{2+}$  domain parameters listed in **Table 1A** gives the average time-series variability of each parameter among cells within each of the three cell populations (control, ISO, or CCh). The standard deviation of the SDs (SDSD) in **Table 1A** tells us how variable the SDs of each parameter are among cells within each cell population. The means of each parameter measured within a time series (**Table 1B**) tell us the average level of the parameter among cells within each of the three populations, and the SD of the means tells us the variability of the mean parameter levels among cells within each cell population.

**Figure 7A** illustrates the distributions of SDs of parameters within  $Ca^{2+}$  and  $V_m$  domains during APs and of APFIs in cells listed in **Table 1A** of each of the three populations of cells that differed in autonomic state: control cells (n = 78), cells during superfusion with ISO (n = 27), and in cells superfused with CCh (n = 10). The self-similarity (long-range correlations) of the mean SDs of  $Ca^{2+}$  to  $V_m$  parameter transitions during ignition and recovery phases of APs across the wide range of APFIs induced

by the type of autonomic receptor stimulation, or lack thereof, is evident in the self-similarity of their mean SD distribution shapes (**Figure 7A**).

The distribution of the means listed in **Table 1B** is illustrated in **Figure 7B**. Note that the shapes of the distributions are selfsimilar to each other across the three different autonomic states. Note also that the shapes of the distribution of the means of a given parameter in **Figure 7B** are similar to the distribution of that parameter's SDs in **Figure 7A** (because the interval distribution means stem from the distributions of their SDs). In other terms, the variability in the times at which parameters occur within a time series (their parameter SDs) determines what the mean interval of events in the time series will be.

Also note in **Figure** 7 that compared to cells not superfused with an autonomic receptor agonist (control cells) and those superfused with ISO, the shapes of the distributions of cells superfused with CCh are broad, indicating marked variability among CCh cells within the parameter distributions of both interval means and interval SDs.

**Figure 8A** illustrates the self-similarity of  $V_{\rm m}$  parameter means and SDs to Ca<sup>2+</sup> means and SDs across autonomic states. Heatmaps of the long-range correlations among  $V_{\rm m}$  and Ca<sup>2+</sup> parameter means are shown in **Supplementary Figure 3**. The long-range correlations (self-similarity) between the means of the means and means of SDs given in Table 1 is shown in Figure 8B.

#### Self-Similarity of Ca<sup>2+</sup> and V<sub>m</sub> Parameters Among All Individual Cells Within and Among the Three Autonomic States

Two-by-two correlations of  $V_{\rm m}$  and  ${\rm Ca}^{2+}$  parameter means and SDs of all 230 cells that comprised the three different cell populations in **Figure 7** and **Table 1** are highly significant (**Table 2**).

**Figure 9** shows ln–ln plots of the distributions of means and SDs of  $Ca^{2+}$  and  $V_m$  parameters of all cells across the three autonomic states. The piecewise linear fit of the data in each panel is largely driven by the data from cells superfused with CCh that manifested broad interval distributions and high mean APFIs in **Figures 4–7**. **Figure 8C** shows that the means and SDs of  $V_m$  parameters measured during APs in individual cells (n = 115) are self-similar to  $Ca^{2+}$  means and SDs measured during AP in other individual cells (n = 115) across the three autonomic states.

Although, as noted above, the  $V_{\rm m}$  and  ${\rm Ca}^{2+}$  parameters within and among cells during CCh superfusion were more broadly distributed than those during control or during ISO, the

correlations between  $V_{\rm m}$  and Ca<sup>2+</sup> parameters among all cells within the CCh superfused population of cells were extremely strong for most parameters (**Supplementary Figure 3**). Weaker but still significant correlations between times to 90% recovery and other variables are observed in CCh superfused cells (likely because times to 90% are the most difficult parameters in the data set to measure accurately).

**Figure 8D** shows that  $V_{\rm m}$  and  ${\rm Ca}^{2+}$  parameters measured during APs are self-similar to APFI means and SDs across the three autonomic states.

### Correlation of $Ca^{2+}$ and $V_m$ Domain Parameter Means in Individual Cells to Their SDs Within and Across Autonomic States

The relationship between mean AP firing rate and its SD is known to be non-linear (Monfredi et al., 2014). Whereas the

relationships of all Ca<sup>2+</sup> and  $V_{\rm m}$  parameter means relative to their corresponding SDs measured in the combined set of data derived from different populations of cells in control or during ISO or CCh superfusion are non-linear (**Figures 10A–C**), the ln–ln plots of these combined data (**Figure 10D–F**) are linear, indicating their self-similarity across all 230 cells that differed by autonomic state.

#### **Principal Component Analyses**

Next, we employed principal component analyses to determine whether the self-similarity of parametric measures within the entire data set of variables could be summarized by a smaller set of principal components that contain most of the information in all the variables. PCs are linear combinations of the original variables, and each PC is statistically independent of the others: the first PC explains as much of the total variability in the data as possible, the second PC as much of the remaining variability, and so on. Highly self-similar parameters within the complete data set are explained by the sum of the first few PCs.

In a PC analysis of SDs of the six variables (three in the  $V_{\rm m}$  domain and three in the Ca<sup>2+</sup> domain), the first three PCs explained 91.4% of the total variation within the entire SD data set (**Supplementary Table 2** and **Figure 11A**). Similarly, in a PC analysis of the means of all six measured variables means (three in the  $V_{\rm m}$  domain and three in the Ca<sup>2+</sup> domain) in a PC analysis, the first two PCs explained 92.8% of the variability in the data set of all six means (**Supplementary Table 2** and **Figure 11B**). Finally, in a PC analysis of all 12 variables (six means and six SDs), the first three PCs explained 88% of the variability within the total (means plus SDs) data set (**Supplementary Table 2** and **Figure 11C**).

Because a smaller set of PCs can explain a substantial proportion of the total variability in each set of  $V_{\rm m}$  or Ca<sup>2+</sup> domain means, SDs, and means and SDs, means that these distributions of  $V_{\rm m}$  and Ca<sup>2+</sup> parameters measured during an AP and APFIs in control cells and different cells superfused with ISO or CCh are each self-similar to each other. In other terms, Ca<sup>2+</sup> and  $V_{\rm m}$  domain functions operative within the SAN cells coupled-clock system manifest self-similar scale-free characteristics, i.e., kinetic fractals of each other, across the entire physiologic range of APFIs.

#### Numerical Model Simulations of APFIV, Major Ion Currents, and Ca<sup>2+</sup>

Variability of  $V_{\rm m}$  and  ${\rm Ca}^{2+}$  parameters measured experimentally in cells within and across autonomic states is linked to the respective variabilities of clock molecular availability to respond to  $V_{\rm m}$  and  ${\rm Ca}^{2+}$  cues (**Figure 2**) that cannot be directly measured experimentally during AP firing. To gain further insight into the variability of these biophysical mechanisms, we performed numerical modeling simulations. The APFIV was generated by SAN cell model described as a stochastic dynamical system, i.e., a dynamical system [deterministic Maltsev–Lakatta model (Maltsev and Lakatta, 2009)] subjected to the effects of noise current,  $I_{\rm per}$  (see section "Materials and Methods" and **Supplementary Material** for details).  $I_{\rm per}$  amplitude was tuned

for the model APFIV to match that measured experimentally under respective experimental conditions. We investigated two scenarios of noise generation: when  $I_{per}$  was added to  $I_{tot}$  or when  $I_{per}$  was added to Ca<sup>2+</sup> release flux current in each of the three autonomic states: (i) basal AP firing, (ii) ISO 100 nM, and (iii) CCh (100 nM). Variability of six major currents was simulated and analyzed:  $I_f$ ,  $I_{NCX}$ ,  $I_{Kr}$ ,  $I_{CaT}$ , and  $I_{KACh}$ . Variability of [Ca] under cell membrane was also simulated during the three autonomic states. For all items, we measured variability of their peak amplitudes and amplitudes at -40 mV during DD.

**TABLE 1 | (A)** Mean of SDs and SD of SDs of AP and  $Ca^{2+}$  domain intervals among individual cells in each of the three steady state populations that differ with respect to autonomic receptor stimulation; **(B)** Mean  $\pm$  SD of means of AP and  $Ca^{2+}$  domain interval in each cell population **(A)**.

Model simulation results are presented in **Figure 12**, with their numerical values given in **Supplementary Tables 6**, 7. Regardless of the type of noise generation (via  $Ca^{2+}$  or  $I_{tot}$ ), it affected the variability of ion currents and  $Ca^{2+}$  the same way, and the predicted variabilities for many parameters differed substantially from that of APFI:

- (1)  $I_{\rm f}$  variability was substantial: in the basal state and in ISO  $I_{\rm f}$  variability was similar to or larger than APFIV; the variability of  $I_{\rm f}$  decreased in CCh.
- (2)  $I_{\rm NCX}$  variability was also substantial: at -40 mV, it was substantially larger than that of APFIV (except in CCh when  $I_{\rm per}$  was added to  $I_{\rm tot}$ ); variability of  $I_{\rm NCX}$  peak amplitude (negative, during AP upstroke) was similar to that of APFI in the basal state and ISO, but became reduced in CCh.
- (3)  $I_{\rm Kr}$  variability was substantially less than APFIV under all conditions.
- (4) I<sub>CaT</sub> variability was the largest among ion currents, being similar to that of I<sub>NCX</sub>, in CCh when I<sub>per</sub> was added to Ca<sup>2+</sup> release.
- (5) Peak  $I_{CaL}$  variability was always less than that of APFIV; at -40 mV, it was greater in ISO than in basal state and CCh.
- (6) Variability of Ca<sup>2+</sup> release flux in the basal state and ISO at -40 mV was greater than or similar to APFIV; in CCh, variability of Ca<sup>2+</sup> release flux was less than that of APFI.

Some components exhibited power law behavior over a wide range of APFI over all conditions tested (**Figure 13**).

We next determined whether self-similarity across autonomic states observed for experimental data during the ignition phase is also applied to simulated ion currents or  $Ca^{2+}$  data during this time of the cycle, i.e., at -40 mV. To this end, we applied the statistical tests utilized for experimental data to simulated data (for the scenario when  $I_{per}$  was added to  $I_{tot}$ ).

Simulated ion currents and  $Ca^{2+}$  amplitudes during AP ignition (-40 mV) across the three autonomic states are selfsimilar to each other, strongly correlated to each other, as were experimentally measured parameters (**Table 2**). These

two-by-two correlations of all the simulated components are listed in **Supplementary Table 3**. Selected examples of these correlations are shown in **Figure 14**. As  $I_{\text{NCX}}$  is fully determined by  $V_{\text{m}}$  and  $\text{Ca}^{2+}$ , at a fixed voltage (-40 mV) it is fully determined by only  $\text{Ca}^{2+}$ . That is why we have 100% correlation of  $I_{\text{NCX}}$  and  $\text{Ca}^{2+}$ .  $I_{\text{CaT}}$  strongly correlated with  $\text{Ca}^{2+}$  variations, because the stronger  $\text{Ca}^{2+}$  signal is linked to the higher DD rate and hence stronger (time-dependent) activation of  $I_{\text{CaT}}$ . Surprisingly,  $I_{\text{KACh}}$  amplitude was also highly correlated with Ca variations.

Variations in  $I_{\rm f}$  and  $I_{\rm Kr}$  at -40 mV did not depend on variations of Ca<sup>2+</sup>, but their mean values strongly depended on Ca<sup>2+</sup> across the autonomic states.  $I_{\rm f}$  activation and  $I_{\rm Kr}$ 

deactivation are early DD mechanisms and do not seem to interplay with  $Ca^{2+}$  at the ignition onset at -40 mV in a given cycle.

**Figure 15A** illustrates the Poincaré plots of many simulated parameters (APFI and TTIO;  $I_{NCX}$ ,  $I_{CaT}$ ,  $I_{Kr}$ , [Ca],  $I_{CaL}$ ,  $I_{KACh}$ , and  $I_f$ , all at -40 mV). Although the ranges of absolute values of these simulated parameters substantially vary, all simulated parameters are self-similar, i.e., fit by a single line (r = 0.998) with a slope of unity, resembling Poincaré relationship of experimentally measured AP parameters (**Figures 1, 4**).

Figure 15B illustrates ln-ln plots of the relationships of the means of simulated components to their SDs. Note that this relationship follows power law behavior just as did

the relationship of experimentally measured means for AP parameters versus their SDs (**Figure 10**).

Finally, in PC analyses of the simulated parameters in **Figure 15B**, the first two PCs accounted for 94% of the variation in the eight variables (**Supplementary Figure 4**).

#### DISCUSSION

We measured membrane potential and  $Ca^{2+}$  times to onsets of AP ignition during diastole and times to 90% recovery during APs and APFIs in three populations of single, isolated rabbit SAN cells that differed with respect to autonomic input: those in which CRs were stimulated by CCh, those in which  $\beta$ ARs were stimulated with ISO, and in untreated (control) cells. Absolute values of times to AP ignition onsets and to 90% recovery intervals in Ca<sup>2+</sup> and  $V_m$  domains during APs and APFIs differed within and among individual cells in cell populations and different autonomic states and differential autonomic receptor stimulation. Our novel finding is that although differing

markedly in absolute values,  $Ca^{2+}$  and  $V_m$  parameters were self-similar to each other during APs and self-similar to APFIs, not only within and among different cells within each of the three populations of cells studied, but remarkably, among all cells, regardless of the autonomic receptor stimulation profile. Thus,  $Ca^{2+}$  and  $V_m$  domain kinetic transitions (intervals) during APs, individual APFI, and mean APFIs within AP time series manifest long-range correlations (self-similar scale-free correlations, i.e., obey power law) across the entire broad range of APFIs, regardless of whether autonomic receptors of these cells are stimulated and regardless of the type of autonomic receptor stimulation.

The degree to which molecular activation states within each clock and between clocks are synchronized during APs determines when the next AP will occur, i.e., the APFIV and mean APFIs within a cell and across the entire population of single SAN cells studied: the higher the degree of order (selforganized activation of clock molecules), the more ordered and less variable the aggregate of kinetic functions, the least variability of APFIs, and the shorter the mean APFI; *vice versa*, the lower the degree of order among clock molecular activation states,

TABLE 2 | Correlation matrices of V<sub>m</sub> or Ca<sup>2+</sup> parameters measured in different cells within three different autonomic states (summary data listed in Table 1).

the lower the aggregate synchronization among clock molecular functions, the greater the variability of APFIs, and the longer the mean AP cycle interval.

Self-similar or fractal-like beating rate variability among cardiac cells in culture has been previously identified in a number of studies but only when cells were confluent or electrically connected to each other. This behavior has been attributed to influences of tonic or phasic resetting of membrane potential or to mechanical factors via cell-to-cell connections (Clay and DeHaan, 1979; Jongsma et al., 1983; Kucera et al., 2000). Our novel observation is self-similarity of  $V_{\rm m}$  and Ca<sup>2+</sup> domain intervals during APs and APFIs across diverse populations of single SAN cells that were not physically connected to each other.

Thus, self-similar distributions of order that have been demonstrated to occur in other instances throughout nature (Bak, 1999) also exist within SAN cell coupled-clock system functions. We interpret this power law behavior of SAN cell functions to result from concordant gradations of self-organized order (synchronization) of clock molecular activation across the entire physiologic range of APFIs.

#### **Clock Molecular Activation Cues**

Voltage, time, Ca<sup>2+</sup>, cAMP signaling, and PKA and CaMKIIdependent clock protein phosphorylation are the cues that regulate the activation kinetics of molecules that control pacemaker functions in single SAN cells (**Supplementary Figure 2**; Lakatta et al., 2003, 2006, 2008, 2010; Maltsev and Lakatta, 2008; Yaniv et al., 2015). Some coupled-clock system proteins are activated by  $Ca^{2+}$ , e.g., SERCA2; others by  $V_m$  and cAMP binding, e.g., HCN channels (DiFrancesco and Tortora, 1991) and other cyclic nucleotide-regulated channels; or by  $Ca^{2+}$ and  $V_m$ , e.g., NCX, or by phosphorylation and  $Ca^{2+}$ , e.g., phospholamban and ryanodine receptors and AC type 8, whereas the activation states of still other coupled-clock system proteins are modulated by  $V_m$ ,  $Ca^{2+}$ , and phosphorylation, e.g., L-type and some K<sup>+</sup> channels.

Both voltage and  $Ca^{2+}$  activation cues oscillate in amplitude throughout each AP cycle and command rapid responses from clock molecules. The degree to which activation status of molecules of a given species is synchronized at any given time following the prior AP determines the ensemble response of that molecular species to its activation cues. It is well documented that following a synchronizing event, e.g., the occurrence of an AP, activation states of molecules underlie AP cycle transition through variably inactivated states, altering the availability to respond to a subsequent activation cue. Our new concept of synchronization of functional cues is based on the idea that the coupled-clock system inheres (inevitably) some degree of disorder that stems from its key constituent proteins operating (stochastically switching) intrinsically within

their conformational flexibilities and heterogeneity. The balance of order/disorder is linked to molecule interactions (i.e., effectiveness of their respective cues) that allow them to operate cooperatively as an ensemble or system with various degrees of synchronization (i.e., order) that is reflected in respective variability of the output function of the system, i.e., APFIV in our case.

Thus, we interpret the experimentally measured concordant behavior of surface membrane and  $Ca^{2+}$  regulatory functions

during AP cycles across the entire physiologic range of AP cycles to reflect a concordance in the degrees of activation of molecules that drive these regulatory functions. Importantly,  $Ca^{2+}$  and  $V_m$  cues not only regulate the synchronization clock of molecular activation states but are also regulated by the degree of synchronized activation of molecules determined by these cues (recursion). Because membrane and  $Ca^{2+}$  clocks become coupled in the context of the electrochemical signal that waxes and wanes to cause the AP cycle, the extent of self-organized

molecular activation within each clock indirectly affects selforganization of molecular activation of the other clock operating within the coupled-clock system. And because scaling of mean APFIs among all cells is self-similar to APFIV among cells, AP firing variability and mean APFI are determinants of the Ca<sup>2+</sup> and  $V_m$  cues that determine kinetic intervals during an AP: a recursive, feed-forward process.

#### Mean APFI and APFIV Are Not Only Regulated by but Also Regulate the Degree to Which Clock Molecular Functions Are Synchronized

Changes in  $Ca^{2+}$  and  $V_m$  cues during an AP determine not only the characteristics of that AP but also when the next AP will occur and the mean APFI within an AP time series.

A prolongation of the mean APFIs, itself, contributes to the concurrent increase in the APFIV at a long mean APFI: because an increase in mean APFI reduces net  $Ca^{2+}$  influx and indirectly reduces  $Ca^{2+}/CaMKII-AC$ -dependent phosphorylation of  $Ca^{2+}$  cycling proteins, reducing the SR  $Ca^{2+}$  cycling kinetics and increasing the variability of LCR periods.

Characteristics of the AP that are determined by availability of M clock molecules to respond to a change in membrane potential both directly and indirectly entrain the Ca<sup>2+</sup> and M clock activation: as the mean AP interval shortens, less time elapses between APs, and therefore at shorter intervals, less time is required than at longer intervals for molecules to retain (remember) the synchronizing influences imparted by the preceding AP. This causes the relationship of mean APFI to APFIV of isolated SAN cells to be non-linear (Figure 5 and Supplementary Figure 2), as originally demonstrated by Zaza and Lombardi (2001) and later by Monfredi et al. (2014). Conversely, as time following a prior AP increases, the effectiveness of the Ca<sup>2+</sup> activation cue, itself, wanes because the cell Ca<sup>2+</sup> level and SR Ca<sup>2+</sup> load become reduced because of time-dependent Ca<sup>2+</sup> efflux from the cell. We may speculate therefore that during long AP cycles, fewer molecules of some molecular species are available to respond to Ca<sup>2+</sup> activation cues.

Gradations of self-organized molecular activation within and between clocks regulate the APFI rhythm, i.e., the APFIV. In other terms, the average APFI, kinetics of the AP, AP-triggered  $Ca^{2+}$ -transient, LCR periods and DD kinetics, and beat-to-beat variability of these parameters measured in the present study are readouts of the relative extents to which of clock molecules become activated and the degree to which the clocks are coupled. When the degree to which  $Ca^{2+}$  and M clocks kinetics are

coupled or synchronized is low, the AP firing rate is slow, and APFIV is high, e.g., during CRs. Conversely, when the degree of coupling or synchronization of the Ca<sup>2+</sup> and  $V_{\rm m}$  kinetics of the two clocks is high, e.g., during  $\beta$ AR stimulation, AP firing is rapid, and APFIV is low.

## So, What Factors Affect the Degree of Synchronization of Clock Molecules?

Concordant degrees of self-similar synchronization of M and  $Ca^{2+}$  clock kinetic functions reflect concordant gradations of activation states of specific molecules that govern these functions and how these cues change throughout an AP cycle.

## AP Firing Rate and Rhythm Synchronization of Clock Molecules

The AP that emerges from the diastolic ignition events is, itself, the most potent integrator or synchronizer, not only of surface membrane electrogenic molecules, but also of  $Ca^{2+}$  clock functions: a synchronized global cytosolic CaT that ensues following synchronous activation of voltage-dependent L-type  $Ca^{2+}$  channels is created by synchronized  $Ca^{2+}$ -induced,  $Ca^{2+}$  release from SR via ryanodine receptor activation (Song et al., 1998; Wang et al., 2001; Lakatta, 2004; Zhou et al., 2009).

The efficacy of  $V_{\rm m}$  and  ${\rm Ca}^{2+}$  activation cues that oscillate as electrochemical signal that underlies the  $V_{\rm m}$  change during AP cycle varies with the AP cycle interval or period: shorter periods (i.e., faster AP firing rates or shorter APFIs) are more effective than longer periods (i.e., slower AP firing rates or longer APFIs), because during very long AP cycles,  ${\rm Ca}^{2+}$  activation states of some molecules become more unsynchronized. At very short

times following a large voltage oscillation (i.e., an AP), many molecules of a given molecular species in relatively inactivated state may not optimally respond to activation cues (e.g., impaired excitability/non-excitability). As the time following a prior activation increases, although a subpopulation of molecules of given species may regain full ability to respond to activation cues, substantial variability in the activation status of other molecules of that species still may exist, limiting the number of molecules that can respond to (be recruited by) an activation cue. Our results provide novel clues to the cellular basis for the observation that an AP occurrence, itself, influences the range of APFIs that immediately follow it (Nolasco and Dahlen, 1968). The AP, itself, indirectly affects all Ca<sup>2+</sup> clock functions because it regulates net cell Ca<sup>2+</sup> balance. Functions of M clock molecules that underlie the generation of an AP indirectly regulate the availability for SR  $Ca^{2+}$  cycling by modulation of the level of cell  $Ca^{2+}$ , the SR "oscillatory substrate." Thus, M clock functions also indirectly regulate LCR periods and sizes via their impact on the "steady state" intracellular Ca<sup>2+</sup> level. When the average interval between APs becomes prolonged, a reduction net Ca<sup>2+</sup> influx into efflux from the cell (Lakatta, 2004) reduces the cytosolic  $[Ca^{2+}]$ , the rate of Ca<sup>2+</sup> pumping into SR, and the SR Ca<sup>2+</sup> load. These reductions, in turn, prolong the average time from the prior AP occurrence for spontaneous local diastolic ryanodine receptor activation to occur within SAN cell local microdomains; the randomness of spontaneous local diastolic ryanodine receptor activation occurring within these microdomains also increases, broadening the distribution of LCR periods and shifting these to longer times at a long AP cycle (Figure 4).

Thus, the degree of variability in activation states of M and  $Ca^{2+}$  clock molecules that emerges over time following their

model with noise current (*I*<sub>per</sub>) added to either total current *I*<sub>tot</sub> (A–C) or Ca release flux (D–F).

synchronization by the prior AP is implicated in the cycle length dependence of variability of  $Ca^{2+}$  and M clock functions measured here (**Table 1** and **Figures 3–5**). Heartbeat variability *in vivo* and APFIV of isolated SAN cells *in vitro* indicate that neither autonomic input to SAN cells, nor functions intrinsic to the SAN cell coupled-clock system, respectively, achieve a steady state from one beat to the next.

# Ca<sup>2+</sup>-Dependent Synchronization of Clock Molecules

The local  $[Ca^{2+}]$ , itself, also serves as a powerful synchronizer of clock molecular function: ordered/disordered  $Ca^{2+}$  regulation

has been recently reported for ryanodine receptor-mediated  $Ca^{2+}$  releases (Maltsev et al., 2019).

Studies in permeabilized SAN cells, in which  $Ca^{2+}$  clock function is preserved, but M clock function is abolished, and therefore APs cannot occur and do not influence LCR periodicity, clearly demonstrate that in a fixed, physiologic, free  $[Ca^{2+}]$ , LCR occurrences are random when the free  $[Ca^{2+}]$  is low and that LCR periodicity emerges as the free  $[Ca^{2+}]$  in the system is increased due in part to an increase in the  $Ca^{2+}$  charge of the SR capacitor (Sirenko et al., 2013). The intracellular concentration of the oscillatory substrate,  $Ca^{2+}$ , itself is regulated, in part, by the SAN cell transmembrane Na<sup>+</sup> gradient and membrane potential (Sirenko et al., 2013, 2016).

FIGURE 13 | *I*<sub>NCX</sub> (A), *I*<sub>CaT</sub> (B), *I*<sub>f</sub> (C), and [Ca]<sub>sub</sub> (D) exhibited power law behavior (a linear dependence in the In–In plot here) over a wide range of APFI over all conditions tested. Noise (*I*<sub>per</sub>) was added to *I*<sub>tot</sub> in Maltsev–Lakatta coupled-clock model. Similar dependencies were found when *I*<sub>per</sub> was added to Ca release flux (not shown).

### cAMP Activation or Phosphorylation of Clock Proteins Modulates the Synchronization of and Response to Activation Cues

Autonomic receptor stimulation modulates both the activation cues and responses of clock molecules to these cues. The impact of autonomic receptor signaling on the

effectiveness of clock coupling occurs over several AP cycles and is reflected in time-dependent transitions in the AP firing rate and rhythm. The kinetics and stoichiometry of increases in PKA activity in response to gradations in  $\beta$ AR stimulation predict the kinetics and stoichiometry of concurrent time-dependent increases in AP firing rate (Yaniv et al., 2014b). Prior studies (Lyashkov et al., 2009; Yang et al., 2012) have demonstrated that gradations in the

phosphorylation status of phospholamban at Ser<sup>16</sup> across the three autonomic state mean APFIs of cell populations in the present study (**Supplementary Figure 3**) strikingly resemble gradations of the means of APFIs and APFIVs observed across these autonomic states measured in the present study (**Table 1**).

The extent to which clock molecules respond to  $Ca^{2+}$  or  $V_m$  activation cues during an AP is modulated by  $\beta$ AR- or CRdependent phosphorylation of many of the same proteins that drive SAN cell automaticity in the absence of autonomic receptor activation. These  $\beta$ ARs or CRs impact on the memory of the extent to which clock molecule activation had been synchronized during the prior AP.  $\beta$ AR or CR modulation has two facets: (1) a direct effect, due to cAMP or phosphorylation-dependent activation of clock proteins and (2) an indirect effect by altering the APFI, which alters the cell Ca<sup>2+</sup> activation cues that are directly modulated by autonomic receptor stimulation. Specifically,  $\beta$ ARs and CRs, respectively, not only reduce or increase mean APFI, but also, respectively, shift variability within distributions of Ca<sup>2+</sup> and  $V_{\rm m}$  functions in the same direction (Sirenko et al., 2016) as the shift in mean APFI.

#### **Numerical Modeling**

Because we experimentally measured characteristics of APs in populations of single cells that differed by autonomic input status, we were able to glean insights not only into APFIV in an "average" cell, but also into populations of cells isolated from SAN tissue. Embracing SAN function at the cell population level resonates with recent studies of SAN function at the tissue level (Bychkov et al., 2020; Fenske et al., 2020) that have revealed a novel understanding of the SAN impulse as an emergent property created by

a collective of variable interactions among heterogeneous cell populations within the SAN tissue. On the other end, APFIV per se also emerges at smaller, subcellular scales, due to variability in the functions of individual molecules, such as ion channels, transporters, and pumps, individually and in complex cooperation with each other. These molecular functions cannot be measured directly in our single-cell experiments. Thus, we employed numerical modeling to extend our perspectives from cell populations and singlecell levels downward to the molecular scale. Such broader consideration of variability makes sense when we approach pacemaker function as a multiscale phenomenon (Qu et al., 2011) featuring free scale and fractal-like characteristics (Weiss and Qu, 2020). Considering the SAN cell as a stochastic dynamic system, we examined variability of major ion currents and submembrane [Ca<sup>2+</sup>] during different autonomic states that created a broad range of APFIs, which were measured experimentally.

Our simulations indicate that the APFIV of some ion currents and submembrane Ca<sup>2+</sup> can be close to that of the APFI itself, but also can be substantially lower or higher than the APFIV, depending on the presence or absence of autonomic receptor stimulation, and the time during the AP cycle (Figure 12): components such as  $I_{\rm f}$ ,  $I_{\rm NCX}$ ,  $I_{\rm CaT}$ , and  ${\rm Ca}^{2+}$  exhibit substantial cycle to cycle variability, whereas ICaL, IKACh, and IKr show less or moderate variability. This behavior reflects complex non-linear recursive interactions of  $V_{\rm m}$  and  ${\rm Ca}^{2+}$  that couple the clocks that drive the system (Lyashkov et al., 2018) and as such cannot be directly and definitively interpreted in cause-effect terms. Nevertheless, our simulations confirmed ion channel behavior that could have been envisioned. For example, independent of the nature of the noise added (to  $I_{tot}$  or to Ca<sup>2+</sup> release flux): components contributing to DD ( $I_{\rm f}$ ,  $I_{\rm NCX}$ , and  $I_{\rm CaT}$ ) exhibit a larger cycle to cycle variability, whereas components contributing to generation of all-or-none AP characteristics exhibit less variability (peak  $I_{CaL}$  and  $I_{Kr}$ ). This result is in accord with the

idea of order/disorder transitions during AP cycle (Figure 2, order/disorder dash line), i.e., the DD manifests disorder and transition to order, and hence, a larger variability, and then following the AP upstroke, the AP itself manifests order and hence less variability.

However, our simulations also provided some unexpected, interesting results:  $I_{\rm NCX}$  and submembrane  ${\rm Ca}^{2+}$  amplitudes during DD followed a power law relationship over a wide range of APFI under all conditions tested, indicating that self-similar scale-free or fractal-like behavior is operative within the coupled-clock mechanism via  $I_{\rm NCX}$  (Figure 13). There is also likely to be a secondary effect of  $I_{\rm NCX}$  amplitude itself on DD acceleration in a recursive fashion. Indeed, an increase in  $I_{\rm NCX}$  is expected to accelerate DD but, at the same time, is further accelerated by the very same acceleration it imparts to the ignition mechanism (i.e., diastolic  $I_{\rm CaL}$  and  ${\rm Ca}^{2+}$ -induced  ${\rm Ca}^{2+}$  release). This self-acceleration ignition mechanism results in the power law behavior predicted by the model.

Peak If also followed a power function over a broad range of APFIs, albeit in a noisy manner manifesting some extremely long APFIs in CCh. The current that fluctuated most with respect to variabilities in APFI turned out to be ICaT, the peak amplitude of which also reflects DD dynamics. When DD is rapidly accelerating (as it does at shorter cycles), I<sub>CaT</sub> peak quickly activates and achieves a higher peak amplitude, and vice versa, when DD is slower at longer APFIs, I<sub>CaT</sub> becomes inactivated over time without achieving a peak. In log-log plots, this forms a straight line for almost the entire range of APFIs (power law behavior), except extremely long APFIs when variations in (already) slow DD dynamics have almost no effect on I<sub>CaT</sub> peak. Thus, simulations of biophysical components within the pacemaker cell system exhibited a power law behavior over a wide range of APFIs that encompasses the broad range of APFIs measured experimentally.

Observation of model simulations through analytic lenses applied to experimental data indicated that (as was the case for the experiment data) the simulated variables are self-similar to each other across a broad range of APFIs within the three autonomic states (**Figure 15, Supplementary Figure 4**, and **Supplementary Table 3**).

#### **Model Limitation**

Our  $I_{CaL}$  model was adopted from the Kurata model (Kurata et al., 2002), and although it does include Ca<sup>2+</sup>-dependent inactivation mechanism, it lacks  $I_{CaL}$  facilitation described in 2000 by Mangoni et al. (2000). Also, our numerical model of  $I_{\rm f}$  lacks dynamic regulation by cAMP (DiFrancesco, 1999), Ca<sup>2+</sup>
