Water use efficiency (WUE) is considered as a determinant of yield under stress and a component of crop drought resistance. Stomatal behavior regulates both transpiration rate and net assimilation and has been suggested to be crucial for improving crop WUE. In this work, a dynamic model was used to examine the impact of dynamic properties of stomata on WUE. The model includes sub-models of stomatal conductance dynamics, solute accumulation in the mesophyll, mesophyll water content, and water flow to the mesophyll. Using the instantaneous value of stomatal conductance, photosynthesis, and transpiration rate were simulated using a biochemical model and Penman-Monteith equation, respectively. The model was parameterized for a cucumber leaf and model outputs were evaluated using climatic data. Our simulations revealed that WUE was higher on a cloudy than a sunny day. Fast stomatal reaction to light decreased WUE during the period of increasing light (e.g., in the morning) by up to 10.2% and increased WUE during the period of decreasing light (afternoon) by up to 6.25%. Sensitivity of daily WUE to stomatal parameters and mesophyll conductance to CO<sub>2</sub> was tested for sunny and cloudy days. Increasing mesophyll conductance to CO<sub>2</sub> was more likely to increase WUE for all climatic conditions (up to 5.5% on the sunny day) than modifications of stomatal reaction speed to light and maximum stomatal conductance.

# INTRODUCTION

Stomata on the leaf surfaces of higher plants control the fluxes of gases between the atmosphere and the leaf mesophyll. Regulation of stomata by guard cells determines the amount of  $CO_2$ available for photosynthesis (*A*) and the amount of water loss through transpiration (*E*; Lawson et al., 2014). To model the relationship between net assimilation rate and stomatal conductance, several approaches have been developed in the literature. A strong correlation between stomatal conductance and net photosynthesis ( $A_{net}$ ) is often observed (Wong et al., 1979; Ball et al., 1987) and modeling this relationship has been attempted (e.g., Hari et al., 1986; Lloyd, 1991; Arneth et al., 2002; Katul et al., 2009; Medlyn et al., 2011; among others; see also Damour et al. (2010) for review of stomatal models). Most of the proposed models of stomata only capture the steady state stomatal conductance, which may occur only exceptionally in natural environments. However, a steady state model is not suitable for evaluating continuous changes in  $A_{\text{net}}$  and E which define water use efficiency (WUE;  $A_{\text{net}}/E$ , WUE, Hubick et al., 1986).

WUE is one of the traits considered as determinant of yield under water limited conditions and even as a component of crop drought resistance (Blum, 2009). Several studies have reported considerable variations in WUE among crop species (see Ehdaie et al., 1991 and references therein). For steady state conditions, WUE can be determined by gas exchange measurements. However, fluctuations in climatic conditions lead to changes in stomatal conductance and consequently different instantaneous variations of E and  $A_{net}$ . Therefore, WUE varies with fluctuating climate conditions during the course of the day and stomatal behavior. Stomatal behavior is characterized by the speed of aperture/closure and the initial time lag for stomatal response to light stimuli, and related to stomatal morphology, e.g., stomatal size and density (Lawson and Blatt, 2014). For example, modifying stomatal density and stomatal aperture speed might increase chloroplastic CO<sub>2</sub> concentration (C<sub>c</sub>) and therefore WUE (Merlot et al., 2002; Schlüter et al., 2003; Büssis et al., 2006; Lawson and Blatt, 2014). However, the effect of increasing stomatal density on WUE is still difficult to evaluate and it is still unclear if stomatal speed or stomatal density might be more beneficial for WUE because the magnitude of these effects cannot be easily quantified by experiments. Technically, it is difficult to monitor WUE dynamics due to the variation of stomatal conductance to water vapor  $(g_{sw})$  related to environmental factors. Mathematical modeling of stomatal dynamics was proposed to assess the effects of varying conditions on stomatal behavior (Vialet-Chabrand et al., 2013). The model of Vialet-Chabrand and colleagues includes a steady state target function and parameters quantifying stomatal speed and initial time lag for stomatal response. Replacing the steady state target function by a model of stomatal conductance (e.g., Medlyn et al., 2011) may allow us to quantify the influence of stomatal behavior on A<sub>net</sub> and E under fluctuating climatic conditions.

Mesophyll CO<sub>2</sub> conductance  $(g_m)$  is a limiting factor for CO<sub>2</sub> diffusion into the chloroplast and represents therefore a limitation for net assimilation with a comparable magnitude with stomatal conductance (Flexas et al., 2008). Although the relationship between  $g_m$  and WUE under drought stress is still subject to discussion (Hommel et al., 2014), changes in  $g_m$  were interpreted as adaptation strategy for plants under stress (Warren and Adams, 2006; Aranda et al., 2007). Therefore, genotypes with higher WUE were found to have higher  $g_m$ . In contrast to stomatal conductance which influences both water loss and carbon gain, the effect of mesophyll conductance might be predomiantly on  $A_{net}$ , thereby, increasing WUE (Flexas et al., 2008).

The aim of this study was to investigate the influence of stomatal behavior and mesophyll  $CO_2$  conductance on daily WUE for leaves of a cucumber plant grown under non-stress conditions using a modeling approach. The model includes the Farquhar-von Caemmerer-Berry model of  $C_3$  photosynthesis (Farquhar et al., 1980), a steady state target stomata model (Medlyn et al., 2011), dynamics of stomatal reactions to environmental stimuli (Vialet-Chabrand et al., 2013), water

transport in the leaf (Guyot et al., 2012; Sack and Scoffoni, 2012; Scoffoni et al., 2012; Caldeira et al., 2014; Tardieu et al., 2015), and a transpiration model (Steppe et al., 2006; Jones, 2013). This model was used to test the following hypotheses: (1) faster stomatal regulation results in a higher WUE, (2) higher stomatal density (quantified by increasing maximum stomatal conductance) leads to a decrease of WUE for all light conditions, and (3) higher mesophyll CO<sub>2</sub> conductance increases WUE.

## MATERIALS AND METHODS

#### Model Description

Variation in mesophyll water content  $[W_m(t), \text{ mol } H_2\text{O} \text{ m}^{-2}]$  at time *t* is modeled as the difference between water influx  $[F_i(t), \text{ mol } H_2\text{O} \text{ m}^{-2}\text{s}^{-1}]$  and efflux  $[F_O(t), \text{ mol } H_2\text{O} \text{ m}^{-2}\text{s}^{-1}]$ :

$$\frac{dW_{\rm m}}{dt} = F_{\rm i}\left(t\right) - F_O\left(t\right). \tag{1}$$

At the leaf level,  $F_O(t)$  can be assumed to equal the transpiration rate [E(t), mol H<sub>2</sub>O m<sup>-2</sup>s<sup>-1</sup>] (Jones, 2013).  $F_i(t)$  depends on the difference of water potential between the xylem and the mesophyll (Steppe et al., 2006; Jones, 2013):

$$F_{i}(t) = k_{x} \left( \psi_{x} - \psi_{m}(t) \right), \qquad (2)$$

where  $\psi_x$  and  $\psi_m(t)$  are the water potentials (MPa) of xylem and mesophyll, respectively, and  $k_x$ (mol H<sub>2</sub>O m<sup>-2</sup>s<sup>-1</sup>MPa<sup>-1</sup>) is the xylem and mesophyll, determined by water transport pathways through multiple components, environmental conditions and time of day (Guyot et al., 2012; Sack and Scoffoni, 2012; Scoffoni et al., 2012; Caldeira et al., 2014; Tardieu et al., 2015). For example, the circadian rhythm of hydraulic conductance has a peak in the early morning (Caldeira et al., 2014; Tardieu et al., 2015). The hydraulic conductance  $k_x$  (mol H<sub>2</sub>O m<sup>-2</sup>s<sup>-1</sup>MPa<sup>-1</sup>) is modeled as sum of a radiation dependent and a water potential and oscillation dependent component (Caldeira et al., 2014; Tardieu et al., 2015) by:

$$k_{\rm x} = c v_{\rm f1} * (k_{\rm x,0} + k_{\rm x,C}), \tag{3}$$

Where

$$k_{\mathrm{x},0} = a + b \min\left(\frac{\mathrm{PPFD}}{\mathrm{PPFD}_{\mathrm{lim}}}, 1\right),$$
 (4)

and

$$k_{\rm x,C} = \tau_{\rm C} \cos\left(-\frac{\pi}{60}t + \frac{5\pi}{2}\right) * (\psi_{\rm x} - \psi_{\rm m,r}), \qquad (5)$$

where  $k_{x,0}$  (g H<sub>2</sub>O m<sup>-2</sup>s<sup>-1</sup> MPa<sup>-1</sup>) is the component of xylem hydraulic conductance that depends on irradiance, *a* and *b* are empirical constants (g H<sub>2</sub>O m<sup>-2</sup>s<sup>-1</sup>MPa<sup>-1</sup>). A constant water potential in the xylem sap flow is assumed ( $\psi_x =$ -0.08 MPa).  $k_{x,C}$  (g H<sub>2</sub>O m<sup>-2</sup>s<sup>-1</sup>MPa<sup>-1</sup>) is the oscillation dependent component of the hydraulic conductance.  $\tau_C =$ 0.324/15 g H<sub>2</sub>O m<sup>-2</sup>s<sup>-1</sup> MPa<sup>-2</sup> is the sensitivity to the amplitude of  $\psi_x$ ,  $cv_{f1} =$  0.05556 mol g<sup>-1</sup> H<sub>2</sub>O is the conversion factor from g to mole H<sub>2</sub>O and  $\psi_{m,r} = -0.9$  MPa is the mesophyll reference water potential. *PPFD*<sub>lim</sub> = 1000 µmol photon m<sup>-2</sup> s<sup>-1</sup> is the limit PPFD for the plant leaf. Parameters *a* and *b* were estimated using the literature (Caldeira et al., 2014; Tardieu et al., 2015). Assuming that the matric and gravitational components of the water potential in the leaf are negligible,  $\psi_m(t)$  can be calculated by the contributions of solute and hydrostatic pressure to water potential,  $\psi_s$  and  $\psi_p$ , respectively:

$$\psi_{\rm m}(t) = \psi_{\rm s}(t) + \psi_{\rm p}(t) \tag{6}$$

$$\psi_{\rm s}(t) = -c v_{\rm f2} R T_{\rm l}(t) \frac{N_{\rm m}(t)}{W_{\rm m}},\tag{7}$$

$$\psi_{\rm p}\left(t\right) = \alpha e^{-\beta \left(1 - \frac{W_{\rm m}\left(t\right)}{W_{\rm m}_{\rm max}}\right)} \tag{8}$$

where  $N_{\rm m}$  (mol solute) is the total amount of dissolved solutes,  $cv_{f2} = 55.56 \text{ mol } \text{L}^{-1} \text{ H}_2\text{O}$  is the conversion factor from liter to mole H<sub>2</sub>O,  $R = 8.3145 \text{ } 10^{-3} \text{ L}$  MPa mol<sup>-1</sup> K<sup>-1</sup> is the gas constant and  $T_{\rm l}(t)$  is the leaf temperature at time t (in K).  $W_{\rm m}(t)$ is the water content in the mesophyll cell at time t (mol H<sub>2</sub>O m<sup>-2</sup>). The relationship between hydrostatic pressure and relative cell volume  $W_{\rm m}(t)/W_{\rm m\_max}$  is an approximation deduced from Steudle et al. (1977), where  $W_{\rm m\_max}$  is the maximum water content of the mesophyll,  $W_{\rm m}(t)$  is the water content in the mesophyll cell at time t,  $\alpha$  (MPa) is the full hydrostatic pressure and  $\beta$  is a measure of mesophyll elasticity.

Variation of the total amount of dissolved solutes in the mesophyll is given by:

$$\frac{dN_{\rm m}}{dt} = c_{\rm i} N_{\rm xy} F_{\rm i} \left( t \right),\tag{9}$$

where  $c_i$  (unit-less) is a factor for ion exchange, and  $N_{xy}$  denotes the solute concentration in the xylem sap (mol solute mol<sup>-1</sup> H<sub>2</sub>O).

The transpiration rate  $[F_O(t), \text{ mol } \text{m}^{-2}\text{s}^{-1}]$  is modeled as a function of leaf temperature (Maes and Steppe, 2012; Jones, 2013; Tardieu et al., 2015):

$$F_{\rm O}(t) = \frac{1}{r_{\rm tw}} \frac{\rho_{\rm a} c_{\rm p} (\delta e + s \left(T_{\rm l}(t) - T_{\rm a}\right))}{\lambda \gamma},\tag{10}$$

where  $\rho_a = 1.205 \ 10^3$  is air density (g m<sup>-3</sup>),  $c_p = 1.005$  the heat or thermal capacity of air (J g<sup>-1</sup> K<sup>-1</sup>), *s* is the slope of the curve relating temperature to saturated vapor pressure (kPa K<sup>-1</sup>),  $T_a$  is air temperature (*K*),  $\lambda = 4417 \ \text{J} \text{ m}^{-3}$  is the latent heat of water vaporization,  $\gamma = 0.0665 \ \text{kPa} \ \text{K}^{-1}$  is the psychrometric constant.  $r_{\text{tw}} = 1/g_{\text{tw}}(t)$  is the total resistance to water vapor transport (s m<sup>-2</sup>mol<sup>-1</sup>H<sub>2</sub>O) and [ $g_{\text{tw}}(t)$ ] is the total conductance to water vapor transport (mol H<sub>2</sub>O m<sup>-2</sup>s<sup>-1</sup>):

$$g_{\rm tw}(t) = \frac{g_{\rm bw}g_{\rm sw}(t)}{g_{\rm sw}(t) + g_{\rm bw}};$$
 (11)

where  $g_{bw}$  is the boundary layer conductance (mol H<sub>2</sub>O m<sup>-2</sup>s<sup>-1</sup>) and  $g_{sw}$  the stomatal conductance to water vapor.  $\delta e$  is the vapor pressure deficit (kPa) defined by:

$$\delta e = \left(1 - \frac{h_{\rm r}}{100}\right) a_1 \exp\left(\frac{a_2(T_{\rm a} - 273.16)}{a_3 + (T_{\rm a} - 273.16)}\right) \tag{12}$$

where  $h_r$  is the relative humidity of the ambient air (%),  $a_1 = 0.61375$  kPa,  $a_2 = 17.502$ , and  $a_3 = 240^{\circ}$ C. The value of -273.16 is required for the conversion from °K to °Celsius. The slope of the curve relating saturated vapor pressure to temperature is therefore defined by:

$$s = \frac{a_2 a_3 \delta e}{\left(a_3 + T_a - 273.16\right)^2}.$$
 (13)

According to Maes and Steppe (2012) the relation between  $(T_1 - T_a)$  and  $r_{aH} = 1/g_{aH}$ , the resistance to diffusive heat transfer to air, is given by:

$$T_{\rm l} - T_a = \frac{r_{\rm aH} r_{\rm tw} \gamma \left(R_{\rm n} - G_i\right) - r_{\rm aH} \rho_{\rm a} c_{\rm p} \delta e}{\rho_a c_p \left(\gamma r_{\rm tw} + s r_{\rm aH}\right)}, \qquad (14)$$

where  $R_n$  (J m<sup>-2</sup>s<sup>-1</sup>) is radiation and  $G_i$  (J m<sup>-2</sup>s<sup>-1</sup>) is soil heat flux which is here assumed to be zero since an individual leaf is considered. The stomatal conductance to water vapor is assumed to be 1.6 times the stomatal conductance to CO<sub>2</sub> as usually used in the literature (Medlyn et al., 2002, 2011) where 1.6 is the ratio of the diffusivities of CO<sub>2</sub> and water in air. The conductance to diffusive heat transfer to air is related to the boundary layer conductance through the relation  $g_{aH} = g_{bH}/1.15$  where 1.15 is the product of the ratio of the diffusivities of heat and water in the boundary layer (dimensionless). Vialet-Chabrand et al. (2013) proposed a dynamic model to describe the temporal response of stomatal conductance to water vapor, denoted by  $g_{sw}$  (mol H<sub>2</sub>O m<sup>-2</sup> s<sup>-1</sup>) to a change of irradiance over time:

$$\frac{dg_{sw}}{dt} = \alpha_{g} \left( \ln \left( \frac{1.6G(t) - r_0}{g_{sw}(t) - r_0} \right) \right) \left( g_{sw}(t) - r_0 \right)$$
(15)

where  $r_0$  (mol m<sup>-2</sup> s<sup>-1</sup>) is a parameter describing the initial time lag of  $g_{sw}$  after exposure to an environmental stimulus,  $\alpha_g$  is a time constant (s<sup>-1</sup>) for increasing or decreasing of  $g_{sw}$ and *G* is the steady-state target value of stomatal conductance to CO<sub>2</sub> under the current environmental conditions described by Medlyn et al. (2011) and Chen et al. (2014). Incorporating stomatal response to leaf water potential as presented by Tuzet et al. (2003), the steady state target stomatal conductance *G* is defined by:

$$G = g_0 + \left(1 + \frac{g_1}{\sqrt{\delta e}}\right) \frac{A}{C_a} f_{\psi_m} = g_0 + g \mathrm{sc}_b A \qquad (16)$$

where parameters  $g_0$  (mol CO<sub>2</sub> m<sup>-2</sup>s<sup>-1</sup>) and  $g_1$  are species-specific constants of stomatal conductance (for cucumber, 0.009 mol CO<sub>2</sub> m<sup>-2</sup>s<sup>-1</sup>, and 3.51, respectively, see Chen et al., 2014),  $C_a$  is the ambient CO<sub>2</sub> concentration at the leaf surface and  $f_{\psi m}$  quantifies the dependency of *G* to mesophyll water potential (Tuzet et al., 2003).  $f_{\psi m}$  is defined by:

$$f_{\psi m} = \frac{1 + \exp{(s_f \psi_r)}}{1 + \exp(s_f(\psi_r - \psi_m))},$$
(17)

 $\psi_r = -0.9 \text{ MPa}$  is the reference water potential,  $s_f = 4.9 \text{ MPa}^{-1}$  is an empirical sensitivity parameter of the stomatal reaction to

water potential, A (µmol CO<sub>2</sub> m<sup>-2</sup>s<sup>-1</sup>) is the steady-state net photosynthesis rate, i. e., the minimum of the Rubisco-limited ( $A_c$ , µmol CO<sub>2</sub> m<sup>-2</sup>s<sup>-1</sup>) or RuPB-regeneration-limited ( $A_j$ , µmol CO<sub>2</sub> m<sup>-2</sup>s<sup>-1</sup>) photosynthesis rate (Farquhar et al., 1980):

$$A_c = \frac{V_{\text{cmax}} \cdot (C_c - \Gamma_*)}{C_c + K_{\text{m}}},\tag{18}$$

$$A_j = \frac{J \cdot (C_c - \Gamma_*)}{4C_c + 8\Gamma_*}.$$
(19)

Here,  $\Gamma_*$  is the CO<sub>2</sub> compensation point in the absence of dark respiration (43.02 µmol CO<sub>2</sub> m<sup>-2</sup>s<sup>-1</sup>),  $R_d$  is the daytime respiration rate (µmol CO<sub>2</sub> m<sup>-2</sup>s<sup>-1</sup>),  $V_{\text{cmax}}$  (µmol CO<sub>2</sub> m<sup>-2</sup>s<sup>-1</sup>) is the maximum rate of Rubisco activity at the site of carboxylation, and  $K_m$  is the effective Michaelis-Menten constant for CO<sub>2</sub> assimilation that considers the competitive inhibition by O<sub>2</sub> (711 µmol mol<sup>-1</sup>); J (µmol e<sup>-</sup>m<sup>-2</sup>s<sup>-1</sup>) is the rate of electron transport and  $C_c$  (µmol mol<sup>-1</sup>) is the mole fraction of CO<sub>2</sub>, which is calculated by:

$$C_{\rm c}(t) = C_{\rm a} - A_c \frac{G + g_{\rm m}}{Gg_{\rm m}}$$
(20)

where  $g_{\rm m}$  is mesophyll CO<sub>2</sub> conductance (mol CO<sub>2</sub> m<sup>-2</sup>s<sup>-1</sup>) and  $C_a$  is the ambient CO<sub>2</sub> concentration (380 µmol mol<sup>-1</sup>). Therefore, the values of  $A_c$  and G are the analytical solutions which satisfy Equations (18–20, 16) at the same time. Replacing  $C_c$  from Equation (20) in Equation (18) yields,

$$A_{\rm c}(t) = \frac{V_{\rm cmax} \cdot (C_a - A_{\rm c} \frac{G(t) + g_{\rm m}}{G(t) g_{\rm m}} - \Gamma_*)}{C_{\rm a} - A_{\rm c} \frac{G(t) + g_{\rm m}}{G(t) g_{\rm m}} + K_{\rm m}}.$$
 (21)

As shown by Ögren and Evans (1993), the photosystem II electron transport rate that is used for CO<sub>2</sub> fixation and photorespiration, *J*, is related to the amount of incident photosynthetically active irradiance ( $I_{inc}$ ; µmol photons m<sup>-2</sup>s<sup>-1</sup>) by:

$$J = \frac{\kappa_{2LL}I_{inc} + J_{max} - \sqrt{(\kappa_{2LL}I_{inc} + J_{max})^2 - 4\theta\kappa_{2LL}I_{inc}J_{max}}}{2\theta},$$
(22)

where  $J_{\text{max}}$  (µmol e<sup>-</sup> m<sup>-2</sup>s<sup>-1</sup>) is the maximum electron transport rate at saturating light levels,  $\theta$  is a dimensionless convexity factor for the response of *J* to  $I_{\text{inc}}$ , and  $\kappa_{2\text{LL}}$  (µmol e<sup>-</sup> m<sup>-2</sup>s<sup>-1</sup>) is the conversion efficiency of  $I_{\text{inc}}$  to *J* at limiting light.

Because  $C_a$ ,  $\Gamma^*$ , and  $K_m$  are constant, for simplification we set  $p_1 = C_a - \Gamma^*$  and  $p_2 = C_a + K_m$ . For the sake of simplicity, we also set  $g_{0m} = g_0 + g_m$ . Using Equations (18, 20), the steady-state net photosynthesis rate is the solution of the following equation:

$$c_3 A_c^3 + c_2 A_c^2 + c_1 A_c + c_0 = 0, (23)$$

where

$$c_3 = gsc_b,$$
  

$$c_2 = g_{0m} - gsc_b V_{cmax} - gsc_b g_m p_2,$$
  

$$c_1 = g_m p_1 V_{cmax} gsc_b - g_{0m} V_{cmax} - g_0 g_m p_2,$$
  

$$c_0 = g_0 g_m p_1 V_{cmax}.$$

The RuPB-regeneration-limited photosynthesis rate  $A_j$  can be found combining Equations (16, 19, 20), and rearranging the expressions using previous notations and  $k_1 = C_a - \Gamma^*$  and  $k_2 = C_a + 2\Gamma^*$ , it follows that  $A_j$  satisfies the following equation:

$$b_3 A_j^3 + b_2 A_j^2 + b_1 A_j + b_0 = 0, (24)$$

where

$$b_{3} = 4gsc_{b},$$
  

$$b_{2} = 4g_{0m} - Jgsc_{b} - 4k_{2}g_{m}gsc_{b},$$
  

$$b_{1} = k_{1}g_{m}Jgsc_{b} - 4k_{2}g_{m}g_{0} - Jg_{0m},$$
  

$$b_{0} = k_{1}g_{m}Jg_{0}.$$

Equations (23, 24) are solved simultaneously in order to determine the value of A. The target photosynthesis rate A always exists since there is always at least one real solution of Equations (23, 24). The current photosynthesis rate is determined from the current stomatal conductance.

### Plant Materials for Model Evaluation

Cucumber seeds (Cucumis sativus, cv. Aramon, Rijk Zwaan, De Lier, Netherlands) were sown on 10 June 2014 in rock-wool cubes  $(36 \times 36 \times 40 \text{ mm})$  in the greenhouse of the Institute of Horticultural Production Systems, Leibniz Universität Hannover, Germany (52.5°N, 9.7°E). Seven days after sowing, seedlings were transplanted into larger rock-wool cubes  $(10 \times 10 \times 6.5 \text{ cm})$ for another 7 days. Plants were cultivated on rock wool slabs (Grodan, Grodania A/S, Hedehusene, Denmark), which were placed on metal gutters. The day/night temperature for heating was set to 22°C day/20°C night. Ventilations opened at 24°C during daytime. Each liter of nutrient solution contained 0.5 g Ferty Basisdünger 2 (Planta GmbH, Regenstauf, Germany, 0.9 mM NO<sub>3</sub><sup>-</sup>, 1.5 mM NH<sub>4</sub><sup>-</sup>, 2.8 mM K<sup>+</sup>, 3.0 mM Ca<sup>2+</sup>, 0.4 mM Mg<sup>2+</sup>, 0.4 mM H<sub>2</sub>PO<sub>4</sub>, as well as adequate amounts of the micronutrients) and extra 0.9 g Ca(NO<sub>3</sub>)<sub>2</sub> was added in the solution (5.5 mM  $Ca^{2+}$  and 11 mM  $NO_3^{-}$ ) after the first fruit set.

#### Measurements

Sap flow data were collected between 30 and 31 June for model evaluation and between 06 and 07 July 2014 for model validation on a fully expanded leaf of a well-watered cucumber plant. The leaf was located at the upper canopy, positioned toward southeast and not shaded by other leaves. A heat field deformation sensor (HFD) was installed on the petiole of the leaf to monitor the relative water flow through the petiole (Hanssens et al., 2013, 2014) on these days. A quantum sensor (Li190, Li-Cor, Lincoln, USA) of photosynthetically active radiation (PAR) was installed next to the measured leaf in order to capture the PAR intercepted by the leaf. Data of HFD and the quantum sensor were logged every minute. Average air temperature and relative humidity of 12 min in the greenhouse were recorded by sensors installed 2 m above ground, about 2 m from the measured leaf. Leaf temperatures were measured hourly by an infrared camera (E60, FLIR Systems INC, Boston, USA). Leaf water potential (C52-chambers, WESCOR INC, South Logan., USA) and water content were measured every 2h from 8h00 to 18h00. Since

the measurements of water potential and water content were destructive, they were taken on four leaves comparable (leaf age, position, and orientation in the canopy) to the monitored leaf.

## Input Data

Climatic data recorded on the 6 and 7 of August 2014, representing a sunny and a cloudy day, respectively (**Figure 1**), were used as input data. Moreover, to test the effect of rhythmic fluctuation of climatic conditions on WUE, so called "ideal" sunny and cloudy days were simulated. Variation of temperature and radiation during the ideal days was modeled using sinusoidal functions based on Kimball and Bellamy (1986) light and temperature models. The equation defining the light intensity on ideal days is given by:

$$I(t) = I_{\rm m} + I_a \cos\left(\frac{\pi (t - t_0)}{p} - \pi\right),$$
 (25)

where  $I_{\rm m}$  is the average light intensity during daytime (139 µmol photon m<sup>-2</sup> s<sup>-1</sup> on the cloudy day, 237 µmol photon m<sup>-2</sup> s<sup>-1</sup> on the sunny day),  $I_a$  (µmol photon m<sup>-2</sup> s<sup>-1</sup>) is the amplitude of the oscillation in light intensity (133.435 on the cloudy day, 137.02 on the sunny day), p is the light fluctuation period and  $t_0$  is used to set the initial time point to minimum for the integration. Temperature equations were defined in a similar way

and a constant lag of 30 min (observed from recorded data) was kept between light variation and subsequent temperature change. Parameters of the ideal sunny and cloudy days were chosen to ensure that the integrals of radiation and temperature during the sunny day and the cloudy day were equal to the integrals of radiation and temperature on ideal sunny and cloudy days (**Figure 1**). Using measured data of 06–07/08/2014, a hyperbolic decay function was fitted ( $r^2 = 0.53$ , P < 0.0001) to describe the relationship between relative humidity and temperature:

$$h_{\rm r}\left(t\right) = \frac{1173.613}{T_{\rm a}\left(t\right) - 6.3458},\tag{26}$$

which is valid for  $T_a > 6.3458$ .

Parameters of the sinusoidal light and temperature models were fitted so that the integrals of radiation and temperature during the sunny and cloudy days were equal to the integrals of radiation and temperature recorded on 6 and 7/08/2014, respectively. Moreover, simulations were also performed with different sinusoidal time periods to estimate the effects of fluctuation frequencies on WUE.

## **Parameter Fitting**

The stomata model was parameterized using measurements with the Li6400-XT portable photosynthesis system (Li-Cor, Lincoln,

FIGURE 1 | Climatic data of the cloudy, sunny, ideal cloudy, and ideal sunny days. (A) PPFD recorded on 06-07/08/2014, (B) temperature data of recorded on 06-07/08/2014, (C) PPFD on ideal sunny and cloudy days, (D) ambient temperature on ideal cloudy and sunny days. The integral of total radiation and temperature during the sunny and cloudy days are, respectively, equal to the integral of radiation and temperature during the ideal sunny and cloudy days for a solar period of 2, 1 h, 30 and 15 min.

USA). The leaf was left in darkness for about 30 min, until stomatal conductance was close to zero. Then, PAR was set to 1300  $\mu$ mol photon m<sup>-2</sup> s<sup>-1</sup> and values of stomatal conductance were logged every 5 s until reaching stability. With these data, the time constant  $\alpha_g$  and the initial lag  $r_0$  were estimated using Equation (15). Using data of 30–31 July 2014, the limit light intensity for conductivity PPFD<sub>lim</sub> = 1000  $\mu$ mol photon m<sup>-2</sup> s<sup>-1</sup> and the reference mesophyll water potential  $\psi_{m,r} = -0.9$  MPa were estimated to agree with the observations. The ideal light and temperature model parameters representing the average and the amplitude of light and temperature per oscillation period were fitted using recorded light and temperature data in Excel. The relationship between  $h_r$  and  $T_a$  was fitted using the software Sigmaplot (version 11.0, Systat software GmbH, Erkrath, Germany).

#### Sensitivity Analysis

To test our hypotheses, sensitivity of WUE to the time constant for stomata aperture and closure,  $\alpha_g$ , initial lag for stomatal reaction,  $r_0$ , maximum stomatal conductance (modeled in  $g_1$ ) and mesophyll CO<sub>2</sub> conductance were analyzed. Stomatal behavior parameters were fixed to estimated values for cucumber leaves ( $\alpha_g$ =4.0516 10<sup>-3</sup> s<sup>-1</sup>,  $r_0$  = 2.674 10<sup>-3</sup> mol H<sub>2</sub>O m<sup>-2</sup> s<sup>-1</sup>). Then,  $r_0$ , was changed to 0.0106, 0.0012, and 0.0002 mol H<sub>2</sub>O  $m^{-2} s^{-1}$  and  $\alpha_g$  was changed decreasingly to 0.00682, 0.00338, 0.00134, and 0.00109 s<sup>-1</sup> (values in range of the estimates in Vialet-Chabrand et al. (2013)). In each of these scenarios, WUE was computed per day and per 5 s. The daily WUE was computed as net assimilation integral divided by the transpiration integral in the period from 6:00 a.m. to 20:00 p.m. The maximum stomatal conductance, which should be proportional to stomatal density, increases with  $g_1$  in Equation (16). We changed the value of  $g_1$  from -40 to 90% and analyzed the impact on the daily WUE. Mesophyll CO<sub>2</sub> conductance ( $g_m = 0.3 \text{ mol CO}_2 \text{ m}^{-2} \text{s}^{-1}$ ) was increased from -40 to a 500% to evaluate the effects of  $g_{\rm m}$  on WUE.

"Ideal" light and temperature models (Kimball and Bellamy, 1986) were chosen to represent slow and fast light changing scenarios. Ideal day light intensity was defined with sinusoidal fluctuating functions (day length = 15 h, frequency = 2 h<sup>-1</sup>, 1 h<sup>-1</sup>, 30 and 15 min<sup>-1</sup>).

## RESULTS

The model describes well the decreasing trend of relative water content during daytime for both the sunny day and the cloudy day (**Figure 2**). During daytime, the relative water content (RWC) dropped down to 83% on the sunny day and remained at around 92% during the dark period. The diurnal trend of leaf water potential shows a decreasing trend of water potential during the day. The diurnal course of RWC was well reproduced during the first day (data not shown). On the second day, however, a discrepancy was found between observations and estimation in the morning. Overall, a linear relationship ( $r^2 = 0.54$ , P = 0.0156) was found between observations and simulations. Observed leaf temperature was higher than the simulated values and no linear relationship between observations and simulations was found ( $r^2 = 0.01$ , P = 0.641; data not shown).

Simulations agreed with the observed trend during both the sunny and the cloudy day. Observed raw sap flow data and simulated water inflow in the mesophyll were correlated with  $r^2 = 56\%$ . All fluctuations observed in the sap flow dynamics data were reproduced by the model and the delay observed with respect to irradiance was mimicked, although a discrepancy was observed between simulated and observed sap flow dynamics during the sunny day. As expected, the simulated net assimilation rate, the transpiration rate and stomatal conductance followed the course of the sun (Figures 3A-C). Due to the decrease of  $\psi_{\rm m}$  during daytime, solute accumulation in the leaf increased during daytime and stabilized during the night (Figure 3D). The model showed a decreasing trend of relative water content during daytime due to transpiration in the presence of irradiance and the circadian clock effects on xylem hydraulic conductivity (data not shown).

measured data during a cloudy (first day) and a sunny day (second day). Dots represent measured data of water potential, and dashed lines represent the sap flow raw data and solid lines are simulations from the model. Climatic data are the two days measurement data presented in Figure 1, and all parameter values are defined in Tables 1, 2.

#### TABLE 1 | Input and output variables of the model.

Variable	Description	Туре	Units	Equations	Initial value
$F_i(t)$	Water flux into the mesophyll	Output	mol $H_2O m^{-2} s^{-1}$	(2)	
$k_X(t)$	Hydraulic conductivity between xylem and mesophyll	Output	mol $H_2O m^{-2} s^{-1}MPa^{-1}$	(3)	
k <sub>x,0</sub>	Irradiance dependent component of xylem hydraulic conductance	Input	g H <sub>2</sub> O m <sup>-2</sup> s <sup>-1</sup> MPa <sup>-1</sup>	(4)	
k <sub>x,C</sub>	Oscillation dependent component of xylem hydraulic conductance	Input	g H <sub>2</sub> O m <sup>-2</sup> s <sup>-1</sup> MPa <sup>-1</sup>	(5)	
$\psi_{m}(t)$	Water potential in the mesophyll	Output	MPa	(6)	-0.08
$\psi_{S}(t)$	Osmotic potential in the mesophyll	Output	MPa	(7)	-1.28
$\psi_{\rm p}(t)$	Hydrostatic pressure in the mesophyll	Output	MPa	(8)	1.2
$W_{\sf m}\left(t ight)$	Water content in the mesophyll cell	Output	mol H <sub>2</sub> O m <sup><math>-2</math></sup>	(1)	16
$N_{\rm m}(t)$	Amount of solute in the mesophyll	Output	mol solute m <sup>-2</sup>	(9)	0.121
$F_0(t),$	Efflux from the mesophyll	Output	mol H <sub>2</sub> O m $^{-2}$ s $^{-1}$	(10)	
E(t)	Evapotranspiration rate	Output	mol H <sub>2</sub> O m <sup><math>-2</math></sup> s <sup><math>-1</math></sup>	(10)	
$g_{tw}(t)$	Total conductance to water vapor transport	Output	mol H <sub>2</sub> O m <sup><math>-2</math></sup> s <sup><math>-1</math></sup>	(11)	
δe(t)	Vapor pressure deficit	Input	kPa	(12)	
s(t)	Slope of the curve relating the temperature to the vapor pressure deficit	Input	Pa K <sup>-1</sup>	(13)	
$T_I(t)$	Leaf temperature at time t	Output	К	(14)	295.15
Ta (t)	Air temperature	Input	К	-	
$g_{SW}(t)$	Stomatal conductance to water vapor	Output	mol H <sub>2</sub> O m $^{-2}$ s $^{-1}$	(15)	0.02
$g_{\rm SC}(t)$	Stomatal conductance to CO2	Output	mol CO <sub>2</sub> m <sup>-2</sup> s <sup>-1</sup>	(1.16)	0.0125
$R_{n}(t)$	Net radiation	Input	$J m^{-2} s^{-1}$	Measured	
G(t)	Steady-state target under the current environmental condition	Output	mol CO <sub>2</sub> m <sup><math>-2</math></sup> s <sup><math>-1</math></sup>	(16)	
A(t)	Steady-state net photosynthesis rate	Output	$\mu$ mol CO2 m $^{-2}$ s $^{-1}$	(18, 21, 23, 19, 24)	
C <sub>C</sub> (t)	Chloroplastic CO <sub>2</sub> concentration	Output	$\mu$ mol mol $^{-1}$	(20)	
$h_{\rm r}(t)$	Relative humidity	Input	-	Measured	
J(t)	Rate of electron transport	Output	$\mu$ mol e $-$ m $^{-2}$ s $^{-1}$	(22)	
$I_{inc}(t)$	Amount of incident photosynthetically active irradiance	Input	$\mu$ mol photon m $^{-2}$ s $^{-1}$	Measured

## **Effects of Stomatal Speed on WUE**

Daily WUE was 3.605 and 4.685 mmol  $\text{CO}_2 \text{ mol}^{-1} \text{ H}_2\text{O}$  and on the sunny and cloudy day, respectively. Initial time lag for stomatal response did not lead to an appreciable change of daily WUE (<0.5%, figure not shown). Increasing the time constant for stomatal response slightly increased WUE in all scenarios (**Figure 4**). During the cloudy day, an increase of 1.2% in WUE was reached for an increasing stomatal speed by 60% and a light period of 2 h (**Figure 4A**). The daily WUE increased by 1.46% for the ideal sunny day with a 2 h period of light and temperature fluctuation (**Figure 4B**).

When ambient light drops quickly, stomata with slower opening/closure time need more time to close, and, due to

reduced radiation (**Figures 5A**, **6A**, shaded area), the evaporation rate (**Figures 5D**, **6D**, shaded area) is higher, and the stomatal limitation to net assimilation is lower (**Figures 5B,C**, **6B,C**, shaded area). Therefore, WUE is lower for the slower reacting stomata (**Figures 5E**, **6E**, shaded areas). The impact on WUE depends on climatic conditions on that day. In case of constant light intensity over the day, the stomatal speed did not affect WUE. A higher stomatal speed instantaneously increased WUE by up to 6.25% on cloudy day, depending on light variation (**Figures 5E, 6E**, shaded areas). The model was tested for different light exposure scenarios, including extreme cases when PPFD on sunny days was multiplied by 2, the temperature multiplied by 1.5 and the relative humidity multiplied by 0.6, and for

(A), and different ideal sunny (B) and cloudy days (A) scenarios. Simulations were performed per second over 15 h (from 06:00 a.m. to 9:00 p.m.). The speed of stomatal aperture was varied in a set of 15 values and all climatic data were extracted from the 2 days measurement data presented in **Figure 1** and ideal sunny and cloudy days scenario. The ideal sunny and cloudy days 1 to 3 corresponds to sinusoidal fluctuation frequency equal to  $2 h^{-1}$ ,  $1 h^{-1}$  and  $30 min^{-1}$ . All other parameter values are defined in **Tables 1**, **2**.

different values of boundary layer conductance. Similar results were observed for all scenarios (**Figures 5E, 6E**).

# Effects of Increasing Maximum Stomata Conductance on WUE

An increase of 20% of maximum stomatal conductance lead to a decrease of WUE of up to 8.66% during the sunny day and 8.57% during the cloudy day (**Figure 7**). In fact, increasing the maximum stomatal conductance increased the actual stomatal conductance and therefore transpiration rate. A higher net assimilation rate was also obtained in all cases, but the increased net assimilation did not compensate the water lost, and therefore, the WUE decreased for all stomatal aperture and closure speeds.

# Effects of Higher Mesophyll CO<sub>2</sub> Conductance on WUE

Increasing mesophyll CO<sub>2</sub> conductance increased daily WUE by up to 4.5% on the cloudy day and 5.5% on the sunny day, despite an increase in transpiration rate (1.5%, **Figures 8A,C,D,F**). However, increasing  $g_m$  beyond 0.8 mol m<sup>-2</sup> s<sup>-1</sup>, had only negligible effects on WUE for all stomatal speeds. Combining an increase in stomatal speed and  $g_m$  slightly increased WUE, and increased  $A_{net}$  more than the only effect of  $g_m$ (**Figures 8B,E**).

## Effects of Fluctuating Irradiance on WUE

Using ideal sunny day and ideal cloudy day scenarios, the light period was changed from 2 min 30 s to 2 h. The results show that WUE is maximal when the fluctuation period is around 60 min (**Figure 9**). WUE increased by as much as 70% depending on fluctuation period and total daily radiation.

# DISCUSSION

Speed of stomatal response to environment, stomatal density and mesophyll conductance to  $CO_2$  have been proposed to be important traits of plant to better adapt to drought stress (Merlot et al., 2002; De Lucia et al., 2003; Warren et al., 2003; Büssis et al., 2006; Lawson and Blatt, 2014; Franks et al., 2015). Previous work reported that the speed of stomatal response might be more likely to enhance WUE than stomatal density (Lawson and Blatt, 2014), but their effects were not quantitatively assessed. To overcome the technical difficulties in quantifying the influence of these traits on daily WUE, a model describing the dynamics of WUE controlled by stomatal behavior and mesophyll  $CO_2$  conductance under different climatic conditions was presented.

## **Stomatal Speed**

Although a faster reaction of stomatal conductance can increase the instantaneous WUE by up to 20% (Figures 5E, 6E), it did not improve daily WUE (Figures 4A,B). Fast stomatal opening speed in reaction to light increases carbon gain and water loss through transpiration at the same time. Therefore, it does not significantly increase WUE. The result is not in agreement with Lawson and Blatt (2014) who suggested that fast stomatal response increases both daily carbon gain and WUE. This discrepancy might be due to the fact that Lawson and Blatt (2014) calculated the intrinsic WUE (defined as  $A_{net}/g_{sw}$ ) and ignored the influence of light energy on transpiration. Moreover, Lawson and Blatt (2014) argued that a slow stomatal response creates a stomatal limitation to photosynthesis and inferred that a fast response to light should reduce this limitation. However, the range of stomatal conductance from their measured data is 0.05-0.13 mol m<sup>-2</sup>s<sup>-1</sup>, a range where  $g_{sw}$  limitation would be strongest. In contrast, our  $g_{sw}$  data ranged from 0.15–0.30 mol m<sup>-2</sup>s<sup>-1</sup>,

i.e.,  $g_{sw}$  limitation was much less than in the dataset of Lawson and Blatt (2014). The model should be calibrated to plants with lower maximum  $g_{sw}$ , to quantify the combined effect of  $\alpha_g$  and  $g_1$  on WUE.

## Effect of g1

Medlyn et al. (2011) demonstrated mathematically that the biological interpretation of  $g_1$  is WUE. This interpretation has been further proved by a global dataset showing that  $g_1$  reduces with available water in the soil (Lin et al., 2015). Therefore, it is not surprising that increase of  $g_1$  decreased WUE (**Figure 7A**). It is interesting to identify the traits determining  $g_1$ . According to Equation (16),  $g_0$  and  $g_1$  are the physiological parameters which could increase  $g_{sw}$ . Parameter  $g_0$  represents the  $g_{sw}$  value

in the dark and is normally close to zero (although genotypes in *Arabidopsis* with constantly high  $g_{sw}$  in the dark have been found recently; Costa et al., 2015). Therefore, parameter  $g_1$ should be the factor determining the magnitude of  $g_{sw}$ , which are related to stomatal size and density. This idea can be supported by the recent publication showing that reducing maximal  $g_{sw}$  by stomatal density increases WUE (Franks et al., 2015). Unfortunately,  $g_1$  was not estimated in this publication. Further, study which could show the relationship between  $g_1$  and stomatal density may help us to approach a more mechanistic understanding on  $g_1$ . A minimum decrease of the daily WUE was 5.1% for an increase of  $g_1$  by 20%. This result does not agree with the instantaneous WUE measured by Franks et al. (2015) under steady state conditions. In contrast to Franks et al. (2015),

our results suggest that increasing the maximum stomatal conductance will improve the net assimilation (more than 12.5%), but may not increase WUE. In fact, Franks et al. (2015) estimated a steady state WUE, by letting  $g_{\rm sw}$  and A

stabilize for 45 min, and therefore, did not account for the stomatal behavior under naturally changing environment. Under constant climatic conditions, a similar result was found (data not shown).

**FIGURE 7** | Effect of increasing maximum stomatal conductance on daily water use efficiency.  $g_1$  is a parameter characterizing the maximum stomatal conductance. (A) Daily WUE for different values of  $g_1$  for a cucumber leaf during the recorded sunny and cloudy days. (B) Total daily transpiration rate ( $F_O$ ) and daily net assimilation rate ( $A_{net}$ ) for different values of the maximum stomatal conductance. Simulations were performed per second over 15 h (from 06:00 a.m. to 9:00 p.m.). Values of  $g_1$  = 3.51 was increased from -40 to 90% and each point on the figure is 1 day simulation result. Other climatic data were extracted from the 2 days measurement data presented in **Figure 1** and all other parameter values are summarized in **Tables 1**, **2**.

**FIGURE 8** | Combined effect of increasing mesophyll CO<sub>2</sub> conductance ( $g_m$ ) and stomatal speed ( $\alpha_g$ ) on daily water use efficiency (WUE). (A,D) daily WUE for different values of  $g_m$  and  $\alpha_g$  for a cucumber leaf during the recorded sunny (A) and cloudy (D) days. (B,E) total daily transpiration rate ( $F_O$ ) during the recorded sunny (B) and cloudy (E) days for different values of  $g_m$  and  $\alpha_g$ . (C,F) total daily net assimilation rate ( $A_{net}$ ) during the recorded sunny (C) and cloudy (F) days for different values of  $g_m$  and  $\alpha_g$ . Simulations were performed per second over 15 h (from 06:00 a.m. to 9:00 p.m.). Values of  $g_m = 0.3$  was increased from -40 to 500% and  $\alpha_g$  was varied in a set of 15 values and the figure present daily simulation result. Other climatic data were extracted from the 2 days measurement data presented in Figure 1 and all other parameter values are summarized in Tables 1, 2.

# **Effect of Light Fluctuations**

Increasing oscillation frequency of light and temperature could increase the WUE by up to 70%. The ideal oscillation period for a maximal WUE was found around 50 min. At this oscillation period, the stomatal responses and changes in light intensity may be synchronized in such a way that the light energy is optimally used by the leaf. In fact, stomatal guard cells react in response to changes in environmental conditions. If the light

intensity reaches very fast a high value and drop quickly, then the stomatal aperture, because of the speed of response, may not reach the corresponding maximum target value. Therefore, the plant may not fully make use of the high light intensity due to a higher stomata limitation. This observation might explain results found in the literature. For example, the effects of environmental fluctuations on stomatal behavior were reported as reason for the limited effects of stomatal density (Lawson and Blatt, 2014). However, an increase of 70% in WUE for the same integral of light flux and temperature was unexpected. Further experiments may help to find an optimal light and temperature pattern leading to an optimal WUE for different plant species with different speed of stomatal response.

## Effects of Mesophyll CO<sub>2</sub> Conductance

The model suggested that WUE can be improved by up to 5.5% by increasing mesophyll CO<sub>2</sub>conductance ( $g_m$ ). When  $g_m > 0.8$  mol m<sup>-2</sup> s<sup>-1</sup>, further increase in  $g_m$  did not significantly improve WUE. It might be explained by the fact that the ratio  $A_{\rm net}/g_m$  became very low in comparison with  $C_i$  for  $g_m > 0.8$  so that the chloroplastic CO<sub>2</sub> concentration and  $C_i$  are almost similar.

The model showed an influence of mesophyll  $CO_2$  conductance on E (**Figure 8B**). This could have been caused by the fact that the steady state target of stomatal conductance *G* is calculated from the estimated value of net  $A_{net}$  as modeled by Medlyn et al. (2011), which is a function of mesophyll  $CO_2$  conductance. The model can probably be improved by considering a different stomatal target model, independent of  $A_{net}$ , but depending directly on environmental conditions (radiation, temperature, and vapor pressure deficit or relative humidity).

The model presented in this manuscript considered a fully expanded leaf and all photosynthetic parameters were taken constant during the simulation period. The effect of Rubisco activation and deactivation (Gross et al., 1991), and the age effect on photosynthetic parameters might allow a wider application of the model. Another issue for further development of the model is the canopy WUE, taking into account the effect of leaf age and canopy architecture.

# CONCLUSION

The model presented in this manuscript allowed to quantify the effects of stomatal behavior and mesophyll  $CO_2$  conductance on the WUE of a cucumber leaf. Combining stomatal dynamics with the effects of changing climatic condition on photosynthesis and transpiration rates allows to find that for the case of cucumber leaves that was analyzed, an increase of stomatal speed will not lead to an increase of more than 1.5% of the daily WUE under normal fluctuating light condition. It was also found that increasing maximum stomatal conductance decrease WUE. Increasing mesophyll  $CO_2$  conductance can lead to an increase of daily WUE by up to 5.5%. This suggests that increasing mesophyll  $CO_2$  conductance might be more likely to increase WUE than increasing stomatal density and speed.

# **AUTHOR CONTRIBUTIONS**

DM and TC Developed the model, DM performed all numerical simulations, DM, TC, and HS discussed the data and wrote the paper.
