Exploration of Elite Stilbene Synthase
Alleles for Resveratrol Concentration
in Wild Chinese *Vitis* spp. and *Vitis*
Cultivars. *Front. Plant Sci.* 8:487.
doi: 10.3389/fpls.2017.00487

Resveratrol contributes to a plant's tolerance of various abiotic and biotic stresses and is highly beneficial to human health. A search for elite alleles affecting resveratrol production was undertaken to find useful grapevine germplasm resources. Resveratrol levels in both berry skins and leaves were determined in 95 grapevine accessions (including 50 wild Chinese grapevine accessions and 45 cultivars) during two consecutive years. Resveratrol contents were higher in berry skins than in leaves and in wild Chinese grapevines than in grapevine cultivars. Using genotyping data, 79 simple sequence repeat (SSR) markers linked to 44 stilbene synthase (*STS*) genes were detected in the 95 accessions, identifying 40 SSR markers with higher polymorphisms. Eight SSR marker loci, encompassing 19 alleles, were significantly associated with resveratrol content on ($P < 0.001$), and 5 SSR loci showed repeated associations. Locus Sh5 had four associations: three positive for allele 232 (including leaves in the 2 years) and one negative for allele 236 in four environments. Loci Sh9 and Sh56 for a total of 7 alleles exhibited positive effects in berry skins in the 2 years. In berry skins, locus Sh56 with positive effects was closely linked to *VvSTS27*, and locus Sh77 with negative effects to *VvSTS17*, importantly, the two candidate genes both were located on Chromosome 16. The SSR marker loci and candidate genes identified in this study will provide a useful basis for future molecular breeding for increased production of natural resveratrol and its derivatives.

Keywords: resveratrol, stilbene synthase, elite allele, grape, association analysis, SSR

INTRODUCTION

Resveratrol (*trans*-3, 5, 4'-trihydroxystilbene) is a natural phytoalexin occurring in a limited number of plant species, including *Vitis* spp. (Langcake and Pryce, 1976). Stilbenes in grapevine are very complex, and 18 stilbene derivatives were also identified in two grape samples, including resveratrol and piceid (Flamini et al., 2013). Resveratrol and piceid, in both *cis* and *trans* have been characterized in wine and grape berry (Pezet et al., 1994; Lamuela-Raventos et al., 1995; Romero-Pérez et al., 2001; Vitrac et al., 2005). These compounds are formed by oligomerization of *trans*-resveratrol in grape tissues under stress conditions such as exogenous attack or pathogen infections (Cichewicz et al., 2000; Romero-Pérez et al., 2001). It is interesting to note that *trans*-resveratrol showed either lower or higher concentration in wine and berry using different

determination methods, compared with *trans*-piceid (Lamuella-Raventos et al., 1995; Ribeiro de Lima et al., 1999; Romero-Pérez et al., 2001; Vian et al., 2005; Vitrac et al., 2005; Flamini et al., 2013).

Table grapes and wines are the main food sources of resveratrol. The studies have focused on *trans*-resveratrol due to its various physiological functions in consumers, including antioxidative, anti-tumor, anti-inflammatory activities and reduction of cardiovascular disease and obesity (Jang et al., 1997; Alonso et al., 2002; Frombaum et al., 2012; Konings et al., 2014). The accumulation of resveratrol in plant tissue is induced by exogenous hormone, pathogen attack and UV-C irradiation (Zheng et al., 2009; Shi et al., 2014; Wang et al., 2015, 2016; Yin et al., 2016).

Stilbene synthase (STS), a key enzyme in the biosynthesis pathway of resveratrol, belongs to the polyketide synthase family (Rupprich and Kindl, 1978). Experiments aimed at the generation of transgenic plants with increased resveratrol content or improved resistance to fungal pathogens have focused on inserting foreign STS genes, which were mostly from *Vitis vinifera* (Leckband and Lorz, 1998; Zhu et al., 2004; Serazetdinova et al., 2005; Cheng et al., 2016). Additionally, inserting a foreign STS gene also influenced piceid accumulation in transgenic lines (Ruhmann et al., 2006; Liu et al., 2011; Carlos-Hilario et al., 2015). Recent studies showed that the STS gene family from grapevine included 40 or so members (Parage et al., 2012; Vannozzi et al., 2012; Shi et al., 2014). A very recent report characterized the function of an STS allele (Jiao et al., 2016).

Although the identity and/or function of some members of the STS gene family have been demonstrated, little information is available on how allelic diversities among STS genes contribute to variation in resveratrol accumulation in *Vitis* germplasm. In our previous study, members of the STS gene family showed one of two expression patterns and different expression levels in response to powdery mildew (Shi et al., 2014). Examination of allelic variation and linkage disequilibrium by a candidate gene-based approach would help to decipher the genetic basis of resveratrol biosynthesis. To do this, a representative sample of 95 grapevine accessions were selected, comprising both wild Chinese and cultivated grapevines, both green- and red-skin berries, and both seedless and seeded berries. SSR markers (79 pairs) distributed over the known STS genes from the grapevine PN40024 genotype were designed. Association analysis between STS genes and resveratrol content was performed on this wide collection of wild Chinese grapevines and cultivated European grapevines in order to find the elite alleles responsible for resveratrol accumulation. The results identify grapevine resources that can be used to obtain new grapevine cultivars with high levels of resveratrol in their berries, and can provide useful information for further research on resveratrol biosynthesis.

MATERIALS AND METHODS

Plant Materials and Treatments

Grape accessions, including 50 wild Chinese grapevine species and 45 cultivars from the European species *V. vinifera* or the

American species *V. labrusca* (Table 1), were grown under natural field conditions at the National Grape Germplasm Resources Repository of Zhengzhou Fruit Research Institute, Chinese Academy of Agricultural Sciences. Warm temperate continental climate of Zhengzhou has clear four seasons. The average annual precipitation is about 630 mm and mean temperature is 14.4°C. The details of climatic data were shown in Supplementary Table S1. The experiment vines were planted 9 or 10 years ago in sandy fluvo-aquic soil. And no special cultural practices were taken. All of the vines were in good condition. Grape berries were collected from June to September and leaves were picked at the end of June in 2013 and 2014. Samples were harvested from three grape vines for each accession. For the berries, three grape clusters on each plant were picked, one from the top, middle, and bottom of the canopy, respectively. To ensure that all berries were harvested at their full ripeness, we checked the seeds in the berries every 2 days from June till September. When the seeds completely ripened, the size of berries was no longer increasing, and the red grapes were fully colored, the berries were sampled from that accession. For the leaves, the second or third leaves (depending on healthiness) from the bottom of three different branches with more than 10 leaves were picked in the end of June. Unhealthy berries (cracking, smaller and other underdeveloped fruits) were removed before the samples were quickly frozen in liquid nitrogen and held at -80°C until use.

Determination of *Trans*-resveratrol Content by HPLC Method

Trans-resveratrol levels in berry skins and leaves were measured using HPLC as described by Li et al. (2006) with some modifications, in 95 grapevine accessions in 2013 and 2014. The standard for *trans*-resveratrol was purchased from Sigma-Aldrich (USA). Fruits were peeled and juice was soaked up using filter paper.

Three gram samples were ground to powder using a porcelain mortar and pestle in liquid nitrogen, extracted by 15 mL ethyl acetate in the dark at 25°C for 48 h, and centrifuged at 10,000 r·min⁻¹ for 10 min. The supernatants were transferred into a tube containing 5 mL ethyl acetate, followed by centrifugation at 10,000 r·min⁻¹ for 10 min. All supernatants were evaporated to dryness by Nitrogen blowing instrument (DCY-12S, Qingdao Haike, China) at 40°C. Dried samples were then dissolved in 2 mL of methanol and stored at -80°C. The samples were filtered through a 0.22 μm PTFE membrane filter before resveratrol analysis. Extractable amounts of resveratrol were analyzed using a Waters e2695 HPLC system (USA). Elution was carried out with a mobile phase delivered using a Waters C18 HPLC pump at a flow rate 0.8 mL·min⁻¹. A Waters 2996 UV detector was used at 306 nm. Mean values and standard deviations were obtained from three biological replicates. An HPLC chromatogram of resveratrol was made with a standard solution. The resveratrol content was analyzed by Excel 2003 (Microsoft, USA) and SPSS 17.0 software (IBM, USA).

DNA Isolation and PCR Amplification

Genomic DNA was extracted using Ezup Column Plant Genomic DNA Purification Kit following the manufacturer's protocol

(Sangon Biotech, Shanghai, China). The concentration of the extracted DNA was assessed using a Thermo ND 2000 spectrophotometer (ThermoFisher, USA). Genomic DNA was

adjusted to a final concentration 50 ng/ μ L and was used for PCR amplification. PCR reactions were carried out in a final volume of 20 μ L. Amplification reactions were carried out on a ABI Veriti thermal cycler (USA) using the following cycling profile: 95°C for 5 min, followed by 35 cycles at 95°C for 45 s, 48–56°C for 45 s, and 72°C for 1 min, and a final extension step at 72°C for 10 min. The amplification products were separated through polyacrylamide gel electrophoresis.

Analysis of SSR Markers

Based on predicted *STS* gene sequences in the 12x grapevine PN40024 genome¹ and the gene positions of these 44 *STS* genes (Shi et al., 2014), a total of 79 pairs of SSR primers on chromosomes 10 and 16 were designed using GRAMENE srrtool². Parameter settings were as follows: tetramer for the maximum motif-length group, and 4 for the minimum number of repeats.

Allelic variation was analyzed by calculating the number of alleles (N_a), effective number of alleles (N_e), observed heterozygosity (H_o), and expected heterozygosity (H_e) using Popgene software. Polymorphism information content (PIC) was calculated using PIC-CALC.

¹<http://www.genoscope.cns.fr/externe/GenomeBrowser/Vitis/>

²<http://archive.gramene.org/db/markers/srrtool>

Genetic distance matrices were obtained using SSR data in DPS software³. A phylogenetic tree was constructed by the unweighted pair-group method with arithmetic averages (UPGMA) with MEGA 6.0 software⁴.

Population Structure and Association Analysis

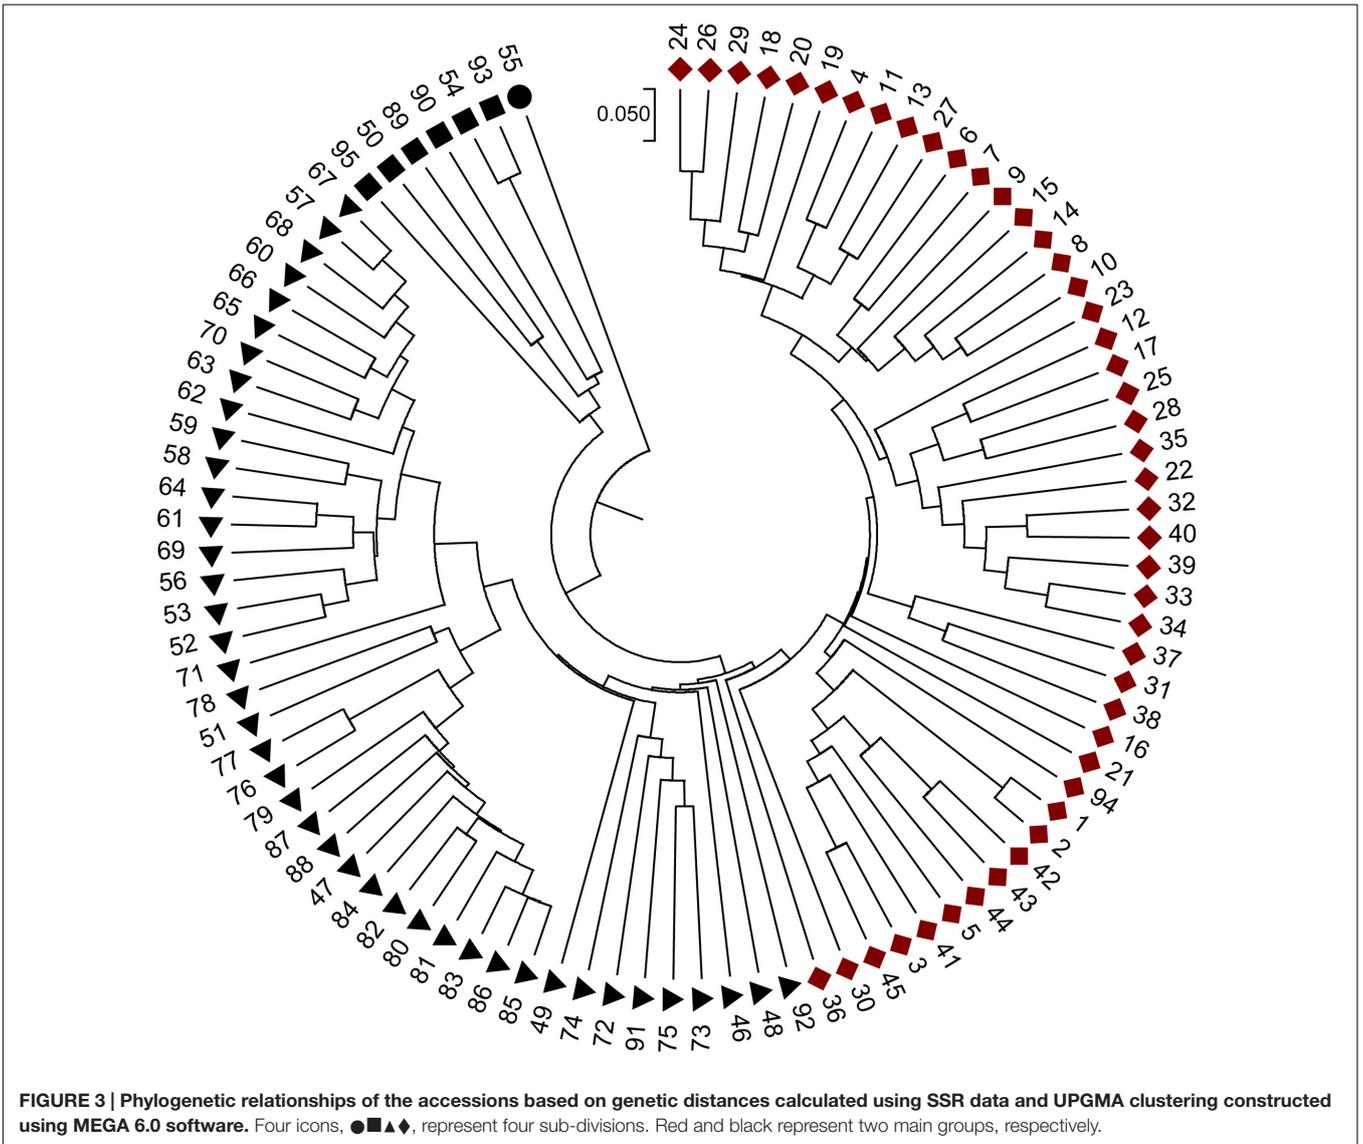

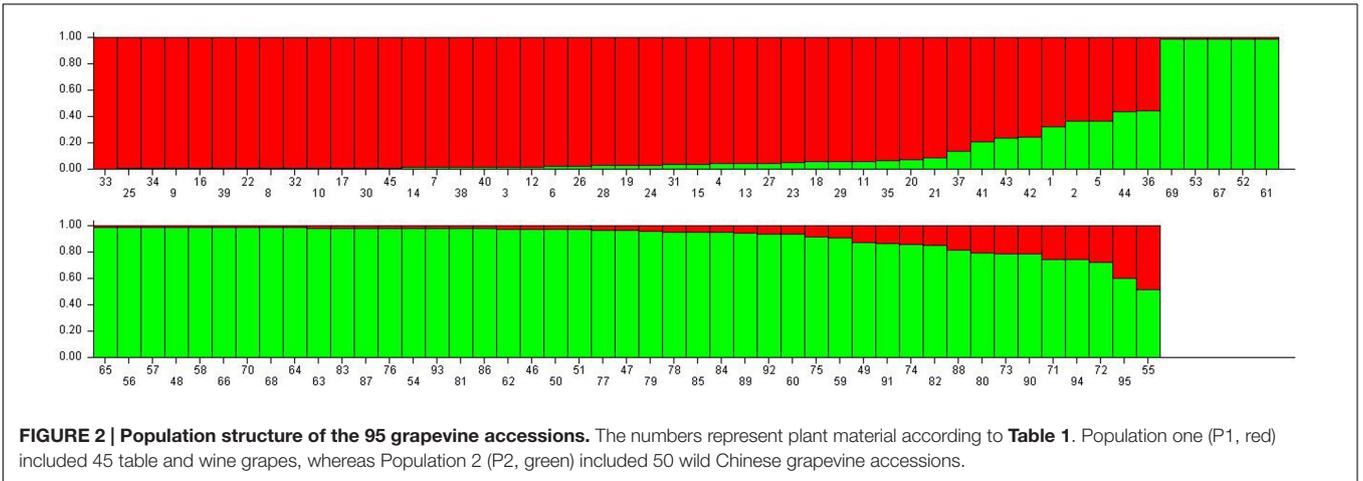

Using 40 *STS*-gene-associated SSR markers, the genetic population structure of the 95 accessions was determined by Structure 2.1⁵. A burn-in phase of 10,000 iterations was followed by 100,000 Monte Carlo Markov Chain iterations. The optimal population number k (from 1 to 10 assumed in this study) was estimated (Evanno et al., 2005). Ten replicates were performed for each cluster, k . When an inflection emerged in the LnP (D) curve, the corresponding k value was adopted as the optimal group number. The values of the estimated membership probability (Q) were calculated to serve as covariates in the association analysis with general linear model (GLM) in Tassel 2.1⁶. Phenotypic effect values of some marker alleles were

evaluated according to null allele as suggested by Brescghello and Mark (2006).

RESULTS

Trans-resveratrol Content

The *trans*-resveratrol levels in skin and in leaf collected from all accessions were determined by HPLC (Figure 1). The *trans*-resveratrol content in berry skins ranged from 0.05 to 67.82 $\mu\text{g}\cdot\text{g}^{-1}$ FW in 2013 and from 0.03 to 68.44 $\mu\text{g}\cdot\text{g}^{-1}$ FW in 2014. For both seasons, the highest levels were from the wild Chinese grapevine *V. adenoclada* accession Shuangxi 03. In leaves, the *trans*-resveratrol content ranged from 0.04 to 10.27 $\mu\text{g}\cdot\text{g}^{-1}$ FW in 2013 and from 0.09 to 11.69 $\mu\text{g}\cdot\text{g}^{-1}$ FW in 2014. The highest levels for both years were in leaves from wild Chinese grapevine *V. amurensis* accession Gaoshan No.2. Resveratrol contents were higher in berry skins than in leaves for each genotype.

Between the 2 years, the variation of resveratrol content was more stable in wild grapevine accessions than that of

cultivated ones. More of the cultivated accessions (51%) showed year-to-year variations of resveratrol content in skin greater than 50%, compared to only 8% of wild grapevine ones, showing such large variations. Similarly, in leaves, 22% of wild accessions and 67% of cultivated ones showed resveratrol content variations greater than 50% (Supplementary Table S2). The results suggested that wild ones retained stable resveratrol biosynthetic capacity.

Polymorphisms of Molecular Markers

Based on the predicted *STS* gene sequences of the 12x grapevine PN40024 genome, 79 SSR primers were designed. These 79 markers were analyzed in the 95 grapevine accessions. Forty SSR markers showed higher polymorphism, and 123 alleles were identified. The PICs of the SSR loci ranged from 0.0206 to 0.6712, with an average of 0.2877 (Supplementary Table S3).

SSR Analysis

When the STRUCTURE software was run using all 95 grapevine accessions, the delta *k* showed a significant peak when *k* = 2; thus the grapevine accessions were divided into

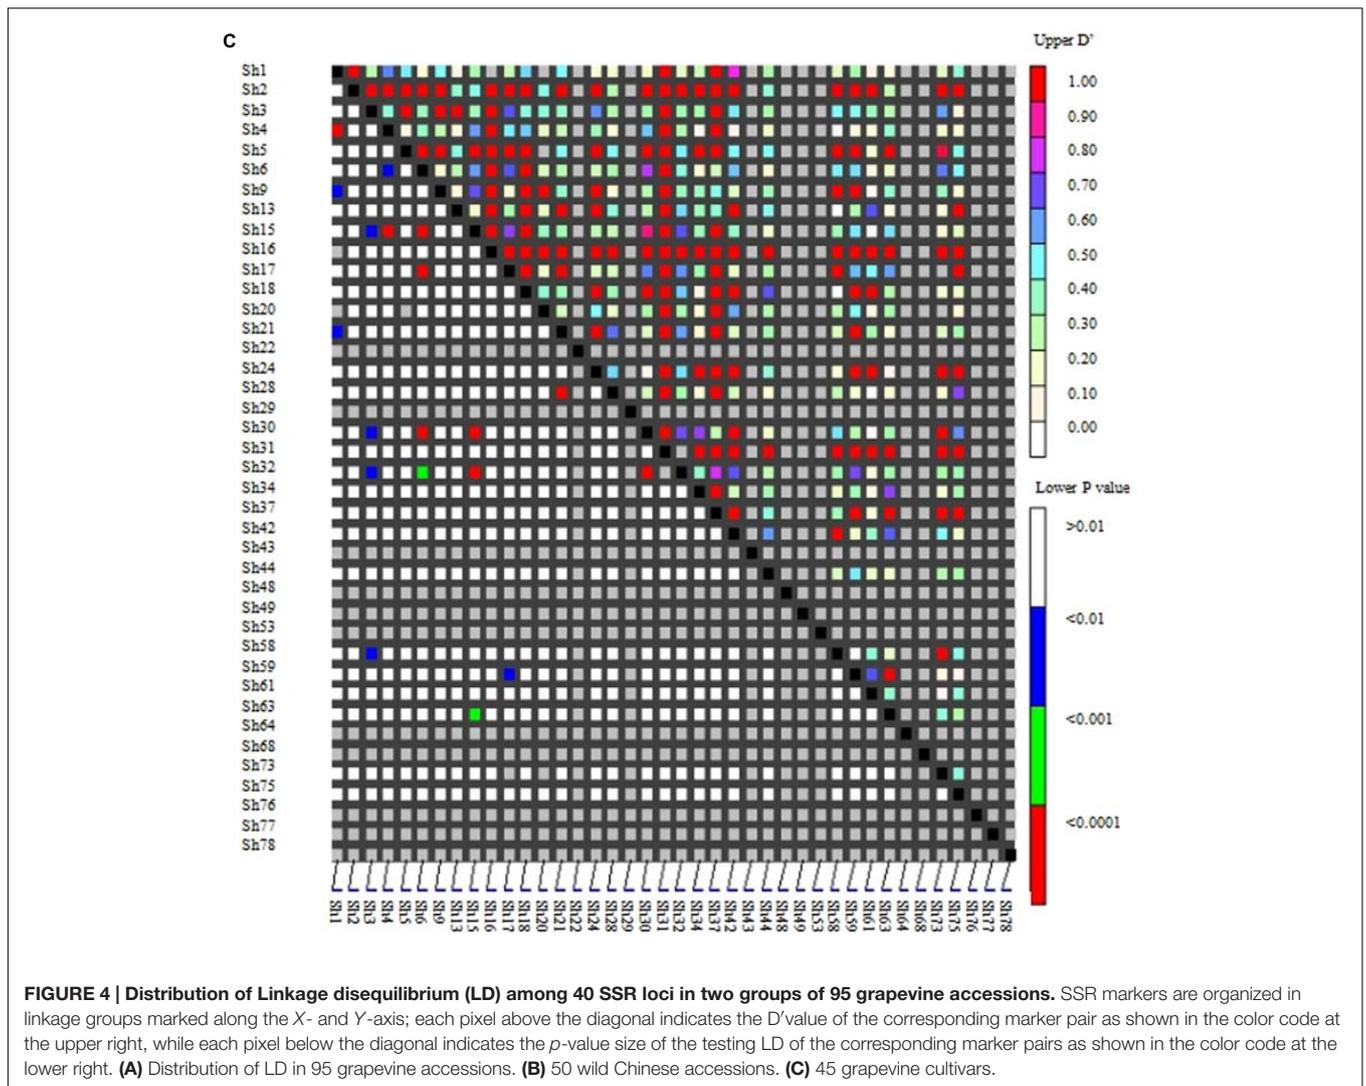

TABLE 2 | The frequency distribution of D' value.

(A) Linkage disequilibrium (LD) for pairwise SSR loci among all 95 grapevine accessions.

Number of LD locus pairs	Frequency distribution of D' (P < 0.001)					Mean of D'
	0–0.2	0.2–0.4	0.4–0.6	0.6–0.8	0.8–1.0	
68 (8.72%)	0	14	32	20	2	0.5329

(B) Comparison of LD values for pairwise SSR loci between *V. vinifera* cultivars and wild Chinese grapes.

Population	Number of LD locus pairs	Frequency distribution of D' (P < 0.001)					Mean of D'
		0–0.2	0.2–0.4	0.4–0.6	0.6–0.8	0.8–1.0	
<i>Vitis</i> cultivars	18 (2.44%)	0	2	6	8	2	0.6046
Wild Chinese grapes	28 (3.59%)	0	0	9	11	8	0.7037

($P < 0.001$) associated with resveratrol content and their explained phenotypic variation (EPV) were all higher than 10% (Table 3). Loci Sh5, Sh21, Sh28, Sh63, and Sh76 were associated with high resveratrol content in the leaves, whereas loci Sh5, Sh9,

Sh56, and Sh77 were associated with high resveratrol in berry skins (Table 4). Moreover, these associations were independent of the year. Locus Sh5 was associated with high resveratrol content in both tissues in both seasons.

TABLE 3 | Marker loci associated with resveratrol content and their explained phenotypic variation (significance at $P < 0.001$).

Trait	Locus	p_Marker	EPV (%)
Leaf in 2013	Sh5	0.00044317	0.1891
	Sh21	0.00034856	0.1916
	Sh28	0.00008824	0.1922
Leaf in 2014	Sh5	0.00080000	0.1429
	Sh63	0.00001241	0.2018
	Sh76	0.00000073	0.2760
Skin in 2013	Sh5	0.00000027	0.3121
	Sh9	0.00098624	0.1939
	Sh56	0.00069694	0.1187
Skin in 2014	Sh77	0.00000003	0.2850
	Sh5	0.00000028	0.3033
	Sh9	0.00050000	0.1800
	Sh56	0.00062219	0.1172
	Sh77	0.00000001	0.2930

The phenotypic effects of the different alleles of the eight loci significantly associated with resveratrol content were evaluated (Table 4). Allele 236 at locus Sh5 produced negative effects four times. On the other hand, allele 232 produced positive effects three times, including in leaves in the 2 years. Loci Sh9 and Sh56, through seven alleles, exhibited only positive effects in berry skins, whereas one allele of locus Sh77 created negative effects in berry skins in the 2 years. The rest of the loci showed negative effects at least once.

The eight loci significantly associated with resveratrol content were mapped to the 12x grapevine PN40024 genome. This revealed that locus Sh56 (location 16506665–16506789 on Chromosome 16) was closely linked to *VvSTS27* (16507444–16503155) and that locus Sh77 (16:366055–16:366171) was closely linked to *VvSTS17* (16372414–16366426) (Table 5). The other six loci were not very closed to known *STS* genes. However, future investigation of predicted genes at these loci may reveal their functions in secondary metabolism.

DISCUSSION

Grapevine is one of the most important fruits in the world. Table grapes are a healthy snack, grape leaves are a staple in some diets, and wine grapes produce a favorite beverage. Resveratrol in both berries and leaves benefit human health, an attribute which has attracted widespread interest. Breeders aim to select and improve the content of resveratrol and other secondary metabolites, such as stilbenes, in grape. Moreover, stilbene concentrations vary depending on multiple factors, including grape cultivar, fungal infection, and climate condition (Jeandet et al., 1995; Mattivi et al., 1995; Ribeiro de Lima et al., 1999). In the present study, the resveratrol contents in 95 accessions were determined by HPLC method in two growing seasons. *Trans*-resveratrol content ranged from 0.03 to 68.44 $\mu\text{g}\cdot\text{g}^{-1}\text{FW}$ in berry skins and from 0.04 to 11.69 $\mu\text{g}\cdot\text{g}^{-1}\text{FW}$ in leaves. A previous study found that resveratrol was significantly higher (1) in berry skin of seeded cultivars than of seedless ones; (2) in berry skin and

seeds in wine grapes than in table grapes; (3) and in red grapes than in green (Li et al., 2006). A recent study reported that an *STS* allele from the wild Chinese grapevine *V. pseudoreticulata* could confer accumulation of stilbenes and resistance against powdery mildew in an *Arabidopsis* heterologous system, whereas

the allele from *V. vinifera* 'Carigane' could not be expressed (Jiao et al., 2016). Together these results demonstrate a wide range of resveratrol content in wild, table and wine grapes, which also suggests the existence of potential genetic variation for resveratrol biosynthesis. Therefore, the use of a wide collection of 95 grapevine accessions in our study lays a foundation for finding elite alleles for resveratrol production.

STS genes encode key enzymes in the last stage of resveratrol biosynthesis. In grapevine, the *STS* gene family contains at least 40 members, although most relevant studies thus far have focused on only one or two *STS* genes from grapevines and peanuts. Overexpression of *STS* genes can improve resistance against a fungal pathogen and other abiotic stresses and increase either resveratrol accumulation (Zhu et al., 2004; Kiselev and Aleynova, 2016), or piceid accumulation (Ruhmann et al., 2006; Liu et al., 2011; Carlos-Hilario et al., 2015). The expression of 32 *STS* genes was analyzed after exposure to UV light, and function of nine *STS* genes of them was characterized (Parage et al., 2012). Our previous findings also showed that about 40 *STS* genes had different expression patterns in different tissues and environments (Shi et al., 2014). Members of the *STS* gene family were analyzed for differences in their molecular structure and transcript accumulation (Vannozzi et al., 2012). In the present study, 40 SSR loci with high polymorphism (an average of 0.2877) were located on Chromosome 16 of the grapevine PN40024 genome, suggesting that Chromosome 16 may be more responsible for resveratrol biosynthesis than *STS* genes on other chromosomes.

Through correlation analysis, all representative samples of the population and the polymorphisms of the SSR markers link an associated locus to several allelic variants. If the corresponding allelic variation tends to phenotypic diversity, it might be selected as optimal allelic variation. In the present study, 8 SSR loci were significantly ($P < 0.001$) associated with resveratrol content, with EPV higher than 10%. Of them, four loci showed repeated associations in four environments. Locus Sh5 associated with high resveratrol content four times, with allele 232 linked three times for positive effects, including in leaves in the 2 years. But allele 236 showed negative effects four times. For resveratrol content in berry skins, loci Sh9 and Sh56, with a combined seven alleles, exhibited positive effects. Recently, many studies using molecular markers have amplified multiple bands, identified relationships, mapped markers to chromosomes, and analyzed the association between molecular markers and agronomic traits (Abdurakhmonov et al., 2008; Jahnke et al., 2011; Lorenzis et al., 2013; Liu et al., 2014; Cai et al., 2016). However, there have not been

many studies on the markers of selected genes (Jin et al., 2016).

As resveratrol is directly catalyzed by STS, correlation between known *STS* alleles, our SSR markers, and resveratrol content were sought. We found eight loci with significant association to resveratrol content in a wide grapevine germplasm collection, while controlling false positives potentially deriving from population structure and multiple testing. Three SSR loci in berry skins with positive effects were mapped onto Chromosome 16. These loci were close to *VvSTS17* or *VvSTS27*. These findings can inform future use of grapevine germplasm resources in breeding for production of resveratrol and its derivatives.

AUTHOR CONTRIBUTIONS

XZ and JS contributed equally to this work. JF, XZ, and JS: conceived and designed the experiments. JS, YY, and YS: performed the experiments and analyzed the data. XZ, JS, and YY: contributed reagents/materials/analysis tools. JF, BT, XY, and JL: provided guidance for the entire study. JS: wrote the manuscript. All authors approved the final manuscript.

FUNDING

This work was supported by the National Natural Science Foundation of China (Grant No. 31201591), Open Project of Key Laboratory of National Genetic Engineering (20150321), Major Project Science and Technology in Henan Province (151100110900), MATS of Henan Province (S2014-11-G02), and Key Scientific Project of College and University of Henan Province (15A210034).

ACKNOWLEDGMENTS

We thank Prof. Chonghuai Liu and Dr. Ying Zhang at Zhengzhou Fruit Research Institute, Chinese Academy of Agricultural Sciences, for great assistance in collecting samples.

SUPPLEMENTARY MATERIAL
