**Purpose:** Patients with intraventricular tumors are more susceptible to postoperative meningitis (POM) than other intracranial tumors. In this study, we explored the risk factors of POM in lateral ventricular trigone meningiomas (LVTMs).

**Methods:** Clinical features of 64 patients with LVTMs were analyzed. Age, gender, body mass index, medical history, intraoperative blood loss (IBL), intraventricular drainage placement, surgical duration, tumor grade, postoperative tumor cavity hemorrhage, and tumor size were included in univariate and multivariate analyses of POM.

**Results:** Of the 64 patients, 14 patients (21.9%) received diagnosis of POM. The univariate analysis revealed IBL  $\geq 400$  mL (odds ratio [OR], 9.012;  $p = 0.003$ ), tumor size  $\geq 50$  cm<sup>3</sup> (OR, 3.071;  $p = 0.080$ ), and surgical duration  $\geq 5$  h (OR, 2.970;  $p = 0.085$ ) were considered possible risk factors for POM ( $p < 0.10$ ). Tumor size ( $R = 0.514$ ) and surgical duration ( $R = 0.624$ ) were significantly correlated with IBL ( $p < 0.05$ ). In the multivariate analysis, only IBL was found to be an independent risk factor for POM.

**Conclusion:** The IBL  $\geq 400$  mL is independently associated with the increased risk of POM in LVTM patients. Our results demonstrate the importance of controlling IBL for preventing POM, especially in large tumors and long surgeries.

**Keywords:** lateral ventricular trigone meningioma, postoperative meningitis, blood loss, risk factor, cerebral spinal fluid

## INTRODUCTION

Meningioma is the second most common intracranial tumor in adults, with an incidence rate of 1.5–5.5/100,000 (1–5). Whereas the lateral ventricular trigone meningioma (LVTM), which grows in the deep area of cerebral hemisphere, accounts for only 0.39%–2.3% of all meningiomas (6–9). However, LVTMs are often detected in giant tumors with hyper-vascularization due to their unique location (10). Additionally, LVTMs are surrounded by the

cortical centers and fibers associated with speaking, making surgical treatment even more challenging.

Postoperative meningitis (POM) is a challenging problem for all neurosurgeons due to severe complications. Moreover, the complications lengthen the hospital stay and increase the medical costs. Additionally, it can also cause serious neurological dysfunction and even death. Unfortunately, POM is difficult to treat. According to previous reports, the incidence of POM ranges from 0.8%–7% for all craniotomies and 19.8% for intraventricular tumor surgeries (11, 12). Intraventricular meningiomas present a much higher incidence of POM than meningiomas located in other areas (11–13). However, risk factors for POM remain unclear for LVTM surgeries. Therefore, in the current study, we explored the risk factors of POM in LVTM patients ( $n = 64$ ) to bring insight for reducing the incidence of POM.

## MATERIALS AND METHODS

### Patients

We reviewed a total of 2,573 consecutive patients with the diagnosis of intracranial meningioma in the First Hospital of China Medical University from December 2010 to May 2018. Intraventricular meningiomas accounted for 2.8% (71/2,573) of all meningiomas.

**Exclusion Criteria:** Patients with meningiomas in the third or fourth ventricle, lacking preoperative imaging data, and who had not received an operation in the First Hospital of China Medical University were excluded.

Finally, 64 (2.5%) patients with LVTMs were included for the analysis. All of the patients underwent routine preoperative physical, radiological, and laboratory examinations. The study protocol was approved by the institutional review board of the First Hospital of China Medical University. In addition, written informed consent was obtained from each patient to use clinical data for future research.

All patients received 1.0–2.0 g of intravenous ceftriaxone intraoperatively for infection prophylaxis as described previously (14–16). A second dose of ceftriaxone was administered in patients whose operation had lasted more than 3 h (16). A trans-sulcal or transcortical temporal-occipital approach was adopted, depending on the size and location of the tumor. Gross total resection was performed in all the patients (**Figure 1A**). In 13 (20.3%) patients, drainage was left in the ventricular tumor cavity to drain the residual debris and blood after tumor removal (17). The drainage was removed no more than five days after surgery. Pathological diagnoses were reported by the Pathology Department of China Medical University. All of the surgical procedures were performed by neurosurgeons with more than 10 years of experience.

### Postoperative Meningitis (POM)

POM was determined as previously described (18). Briefly, patients with POM presented with the following symptoms and signs: fever  $>38^{\circ}\text{C}$ , headache, meningeal signs. In

addition, each patient had at least one of the following laboratory results: (1) organisms cultured from the cerebral spinal fluid (CSF); (2) elevated white cell count ( $0\text{--}8 \times 10^6/\text{L}$ ), protein level ( $120\text{--}600 \text{ mg/L}$ ), and decreased glucose level ( $2.2\text{--}3.9 \text{ mmol/L}$ ) in the CSF; (3) organisms observed in the CSF smear examination; and (4) positive antigen test in the CSF.

### Data Collection

The clinical data were obtained from our hospital electronic information system. Patient information, including age ( $<50$  vs.  $\geq 50$  years), gender, body mass index (BMI), past medical history (hypertension and diabetes), intraoperative blood loss (IBL), intraventricular drainage placement, surgical duration ( $<5$  h vs.  $\geq 5$  h), tumor grade, postoperative tumor cavity hemorrhage, and tumor size ( $<50 \text{ cm}^3$  vs.  $\geq 50 \text{ cm}^3$ ) were included in univariate and multivariate analyses of POM.

### Statistical Analyses

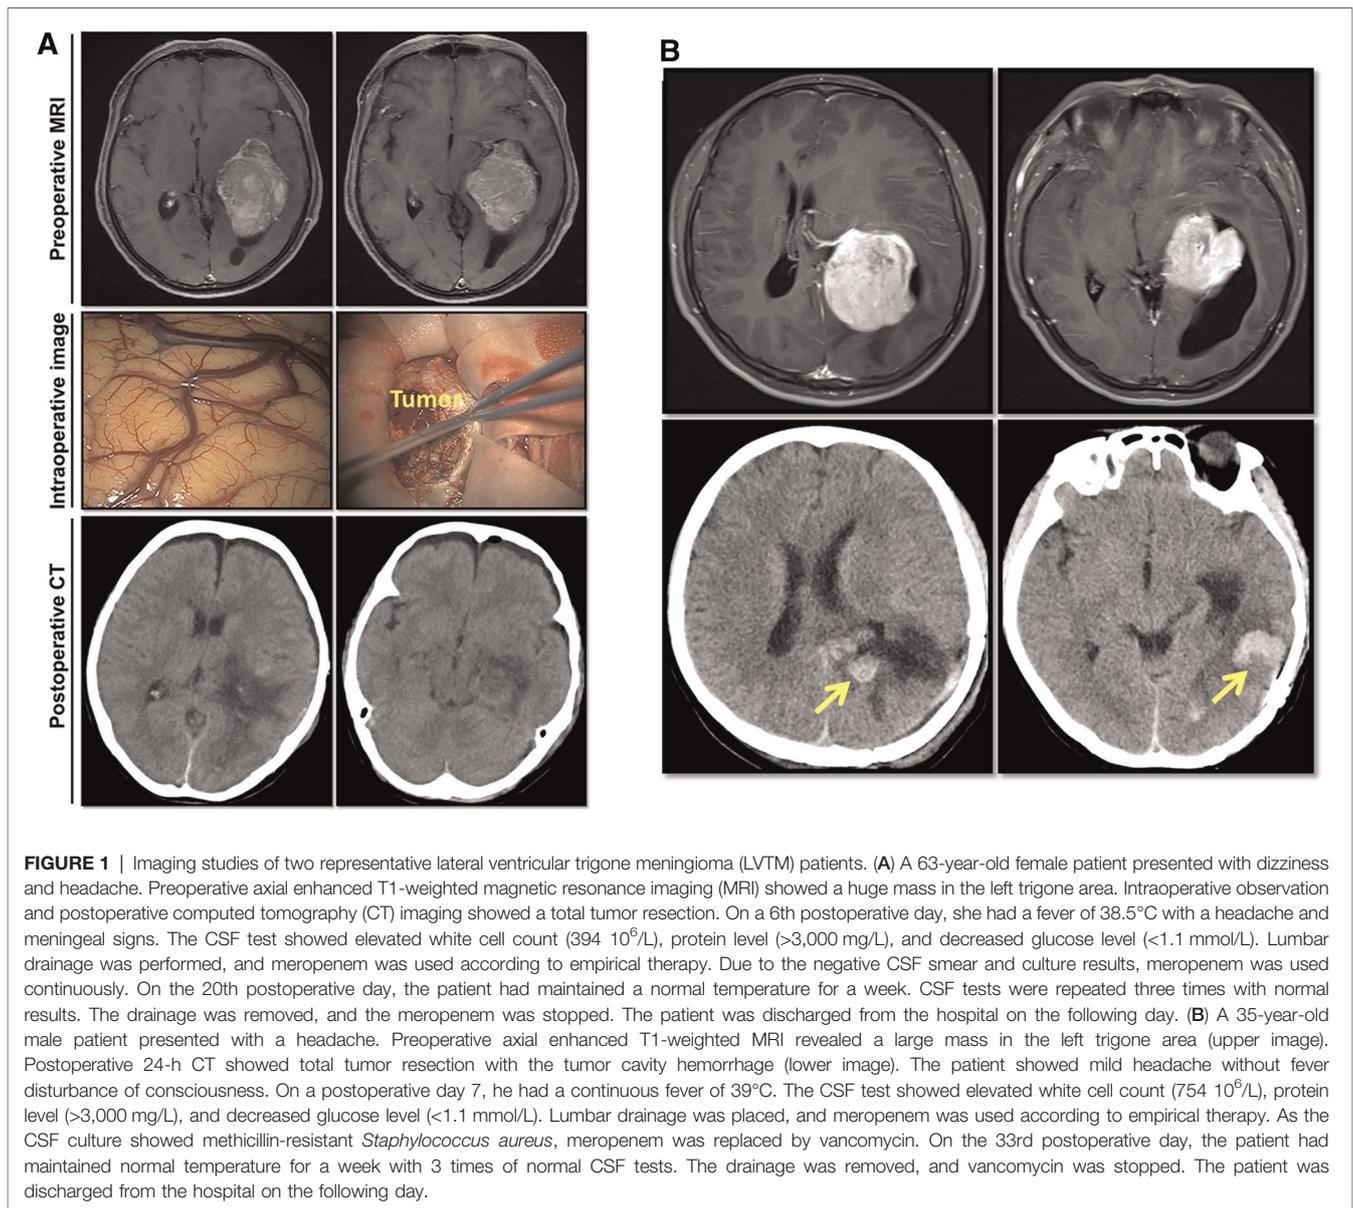

Statistical analyses were performed using SPSS version 26.0 (IBM Corporation). The chi-squared test was conducted, and factors with  $p < 0.10$  were used to input into multivariate logistic regression analysis.  $p < 0.05$  was considered statistically significant.

The study population was divided into two groups for validation analyses depending on the patient's admission time. The first 32 patients from December 2010 to January 2015 were included in group A, while the last 32 patients, from March 2015 to May 2018, were considered group B.

## RESULTS

### Clinical Features of the LVTM Patients

As shown in **Table 1**, among the 64 cases, there were 24 men (37.5%) and 40 women (62.5%). The average age was  $47.39 \pm 13.55$  years (16–72 years). According to the nearest integers of average values, the cutoff values for age, BMI, tumor size, surgical duration, and volume of IBL were determined as 50 years,  $24 \text{ kg/m}^2$ ,  $50 \text{ cm}^3$ , 5 h, and 400 mL, respectively. There were 31 patients (48.4%) with age  $\geq 50$  years and 33 patients (51.6%) with age  $< 50$  years. The average tumor size was  $52.78 \pm 65.09 \text{ cm}^3$  ( $1.9\text{--}301.4 \text{ cm}^3$ ). There were 36 patients (56.2%) with tumors  $< 50 \text{ cm}^3$ , while 28 patients (43.8%) with tumors  $\geq 50 \text{ cm}^3$ . The surgery lasted for an average of  $4.68 \pm 1.88$  h (2–11 h), whereas the average volume of IBL was  $359 \pm 342$  mL (range, 50–1,500 mL). In 18 patients (28.1%) surgery lasted  $\geq 5$  h, while in 46 patients (71.9%) it lasted  $< 5$  h. There were 52 patients (81.2%) with IBL  $< 400$  mL and 12 patients (18.8%) with IBL  $\geq 400$  mL. There were 13 patients (20.3%) who had hypertension and no patients with diabetes. Intraventricular drainage was placed in 13 patients (20.3%). Eight patients had postoperative tumor cavity hemorrhage (12.5%; **Figure 1B**), and two (3.1%) of the patients required secondary surgery to remove the hematoma. Two patients (3.1%) received a ventriculoperitoneal shunt within one year after the

operation. Among the 64 patients tumors, 56 (87.5%) belonged to grade I; seven (10.9%) belonged to grade II, and one (1.6%) belonged to grade III (Table 1) (19). There was no cystic meningioma in the series of cases. Among 14 patients, one patient's CSF smear showed Gram-positive bacteria (7.1%), and another patient's CSF culture showed *Staphylococcus aureus* (7.1%).

### Risk Factors for POM

The potential risk factors of POM are presented in Table 2. The univariate analysis revealed IBL  $\geq 400 \text{ mL}$ , tumor size  $\geq 50 \text{ cm}^3$ , and surgical duration  $\geq 5 \text{ h}$  were considered possible risk factors for POM ( $p < 0.10$ ; Figure 2A). These were included in the multivariate logistic regression analysis. According to the Pearson correlation analysis, tumor size ( $R = 0.514$ ; Figure 2B)

and surgical duration ( $R = 0.624$ ; Figure 2C) were significantly correlated with IBL ( $p < 0.05$ ). However, gender, age, BMI, and history of hypertension did not correlate with POM. Intraventricular drainage placement was not significantly associated with POM in this study.

Furthermore, IBL, tumor size, and surgical duration were analyzed through multivariate analysis. As shown in Table 3, only IBL  $\geq 400 \text{ mL}$  was an independent risk factor for POM ( $p = 0.018$ ; Figure 2D). Our results indicated that larger tumor size and longer surgical duration might cause more IBL, further increasing the risk of POM. Finally, a similar result was obtained in the validation analysis of groups A and B: only IBL  $\geq 400 \text{ mL}$  was an independent risk factor for POM ( $P = 0.049, 0.046$  for groups A and B, respectively).

## Treatment of POM

Patients with POM were treated with lumbar drainage and antibiotics (20). First, lumbar drainage was placed, and meropenem, vancomycin, or both were used as empirical therapy (21, 22). The next course of treatment depended on the results of the CSF tests. Among the 14 patients, nine patients (64.3%) received meropenem only; one (7.1%) received vancomycin only; and four patients (28.6%) received meropenem and vancomycin. The patients were cured within 8–39 days (18.57  $\pm$  8.76 days). However, POM cases average length of postoperative hospital stay was 10 days longer than non-POM cases ( $p = 0.033$ ).

## DISCUSSION

POM is a common postoperative complication of neurosurgery, causing severe consequences (23–25). Previous studies have reported that patients with intraventricular tumors were more susceptible to POM than other intracranial tumors (12, 26, 27). Therefore, identifying the risk factors for POM in LVTM patients carries significant clinical value.

In this study, 64 LVTM patients underwent craniotomy, out of which 14 patients (21.8%) had the diagnosis of POM. Previously, Wang et al. reported a 19.8% incidence of POM, 1.7% incidence of postoperative hematoma evacuation, and 3.3% incidence of postoperative ventriculoperitoneal shunt in out of 121 LVTMs (12). Though they did not analyze the risk factors for POM, their results showed a close relationship between ventricular drainage and postoperative entrapped temporal horn. However, in our study, ventricular drainage was not identified as a risk factor for POM. Besides, ventricular drainage was only used in 20.3% of the patients, which was lower than the report of Wang et al. (87.6%). Nevertheless, the incidence of postoperative complications including meningitis, severe hemorrhage in the operative cavity and hydrocephalus requiring shunting in our series of cases was not significantly different from that in

**TABLE 3 |** The results of multivariate analyses.

	B	Standard deviation	Wald	df	p	Exp(B)	95% CI
Volume of blood loss	1.869	0.793	5.559	1	0.018	6.481	1.371–30.650
Surgical duration	0.420	0.778	0.291	1	0.589	1.522	0.331–6.998
Size of tumor	0.689	0.702	0.996	1	0.326	1.993	0.504–7.883

Wang’s series of cases. In addition, previous studies have reported that ventricular drainage increases the risk of POM (28–31). Thus, ventricular drainage should be used with caution in LVTM surgeries to prevent complications. Intraoperative ultrasound (IoUS) provides great help in neurosurgery, which can increase the chances of total resection and reduce the risk of postoperative bleeding in the surgical cavity. Neurosurgeons can get the real-time information about the anatomical relationship between tumor and its surrounding tissue (32). Therefore, tumors can be removed more precisely with reduced intraoperative blood loss and potentially decreased risk of postoperative meningitis.

We found that IBL  $\geq 400$  mL was an independent risk factor for the POM. This observation was in-concurrence with previous studies reporting the correlation between IBL and POM (33, 34). The large amount of IBL may compromise the patient’s immune system and adversely influence the physiology of local brain tissue. The coagulation pathway might also get activated, leading to the recruitment of inflammatory cells and cytokines. As a result, tissue hypoperfusion and ischemia-reperfusion injury might occur. Further, inflammatory reaction and an ischemia-reperfusion injury increase the vascular permeability damage the integrity of the endothelium, and blood-brain barrier, enhancing the risk of POM (35–38). Massive IBL may decrease the concentration of prophylactic antibiotics in the blood and reduce its preventive effects against infection (39–44). Moreover, massive IBL is associated with allogeneic transfusion. However, the transfusion of red blood cells can contribute to POM by enhancing the inflammatory reaction and suppressing immunity (45–47).

In addition, our results also indicate that large tumor size and long surgical duration were associated with increased IBL. This association further affects the incidence of POM. Large LVTMs are usually hypervascular and fibrous and require long-lasting

operations. Moreover, cystic meningioma is a special kind of meningiomas with a relatively low occurrence of about 3.5% (48). There was no cystic meningioma in our series of cases. However, according to previous study, cystic meningiomas are known to increase the length of surgery and intraoperative blood loss (48). Thus, for cystic meningiomas, surgeons should pay more attention to the risk of postoperative meningitis.

Our results emphasized the importance of controlling intraoperative bleeding. Of note, preoperative embolization, meticulous intraoperative hemostasis, and early tumor devascularization may reduce the IBL and, in turn, decrease the risk of POM (32). However, when a massive IBL occurs, an additional dose of intraoperative antibiotics might be helpful to prevent POM. Importantly, POM significantly prolongs hospital stays, increases medical costs, and affects clinical outcomes. Thus, the prevention of POM may provide significant benefits to patients.

The current study had some limitations. One major limitation was the lack of distinction between bacterial and aseptic meningitis. As a result, they show similar symptoms (new headache, fever, seizures, etc.), CSF test (abnormalities of CSF cell count, glucose, and protein), except CSF culture and smear. However, CSF culture and smear show a low positive rate, which can be reduced by prophylactic antibiotics (49). In this study, all 14 patients with POM showed some improvement and finally recovered after antibiotic therapy, suggesting the potentially beneficial effect of antibiotic therapy.

## CONCLUSION

The IBL  $\geq 400$  mL is independently associated with the increased risk of POM in LVTM patients. Our results

demonstrate the importance of controlling IBL for preventing POM, especially in large tumors and long surgeries.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## AUTHOR CONTRIBUTIONS

All authors contributed to the study conception and design. Material preparation and data collection was performed by TH, SH, LZ and JY, analysis was performed by XH, RW and LL. The first draft of the manuscript was written by XH and all authors commented on previous versions of the manuscript. All authors contributed to the article and approved the submitted version.

## FUNDING

This study was funded by grants from the LiaoNing Revitalization Talents Program (no. XLYC1807253) and ShenYang Science and Technology Innovation Project (no. RC200610).

## ACKNOWLEDGMENTS

We thank Junqi Wu, Department of Clinical Epidemiology, Shengjing Hospital of China Medical University, for assistance in the statistical analyses.
