About Frontiers

Frontiers is more than just an open-access publisher of scholarly articles: it is a pioneering approach to the world of academia, radically improving the way scholarly research is managed. The grand vision of Frontiers is a world where all people have an equal opportunity to seek, share and generate knowledge. Frontiers provides immediate and permanent online open access to all its publications, but this alone is not enough to realize our grand goals.

Frontiers Journal Series

The Frontiers Journal Series is a multi-tier and interdisciplinary set of open-access, online journals, promising a paradigm shift from the current review, selection and dissemination processes in academic publishing. All Frontiers journals are driven by researchers for researchers; therefore, they constitute a service to the scholarly community. At the same time, the Frontiers Journal Series operates on a revolutionary invention, the tiered publishing system, initially addressing specific communities of scholars, and gradually climbing up to broader public understanding, thus serving the interests of the lay society, too.

Dedication to Quality

Each Frontiers article is a landmark of the highest quality, thanks to genuinely collaborative interactions between authors and review editors, who include some of the world's best academicians. Research must be certified by peers before entering a stream of knowledge that may eventually reach the public - and shape society; therefore, Frontiers only applies the most rigorous and unbiased reviews. Frontiers revolutionizes research publishing by freely delivering the most outstanding research, evaluated with no bias from both the academic and social point of view. By applying the most advanced information technologies, Frontiers is catapulting scholarly publishing into a new generation.

What are Frontiers Research Topics?

Frontiers Research Topics are very popular trademarks of the Frontiers Journals Series: they are collections of at least ten articles, all centered on a particular subject. With their unique mix of varied contributions from Original Research to Review Articles, Frontiers Research Topics unify the most influential researchers, the latest key findings and historical advances in a hot research area! Find out more on how to host your own Frontiers Research Topic or contribute to one as an author by contacting the Frontiers Editorial Office: frontiersin.org/about/contact

NGS TECHNOLOGIES OF RARE DISEASES DIAGNOSIS

Topic Editors:

María L. Couce, Complejo Hospitalario Universitario de Santiago, Spain

Richard J. Rodenburg, Radboud University Medical Centre, Netherlands

Citation: Couce, M. L., Vioque, E. G., Rodenburg, R. J., eds. (2022). NGS Technologies of Rare Diseases Diagnosis. Lausanne: Frontiers Media SA. doi: 10.3389/978-2-83250-876-3

Table of Contents

- 06 Editorial: NGS Technologies of Rare Diseases Diagnosis**
María L. Couce and Emiliano González-Vioque
- 09 Case Report: Exome Sequencing Identified a Novel Compound Heterozygous Variation in PLOD2 Causing Bruck Syndrome Type 2**
Jing Zhang, Huaying Hu, Weihong Mu, Mei Yu, Wenqi Chen, Dongqing Mi, Kai Yang and Qing Guo
- 16 Case Report: Identification of a Novel ODAD3 Variant in a Patient With Primary Ciliary Dyskinesia**
Rongchun Wang, Danhui Yang, Ting Guo, Cheng Lei, Xu Chen, Xi Kang, Jie Qing and Hong Luo
- 21 Case Report: Co-occurrence of Duchenne Muscular Dystrophy and Frontometaphyseal Dysplasia 1**
Jaewon Kim, Dong-Woo Lee, Ja-Hyun Jang, Myungshin Kim, Jisook Yim and Dae-Hyun Jang
- 27 Clinical Efficiency of Non-invasive Prenatal Screening for Common Trisomies in Low-Risk and Twin Pregnancies**
Yanfei Xu, Pengzhen Jin, Yu Lei, Yeqing Qian, Yuqing Xu, Miaomiao Wang, Jinglei Jin, Yixuan Yin and Minyue Dong
- 36 Whole-Exome Sequencing Reveals a Rare Variant of OTOF Gene Causing Congenital Non-syndromic Hearing Loss Among Large Muslim Families Favoring Consanguinity**
Mohd Fareed, Varun Sharma, Inderpal Singh, Sayeed Ur Rehman, Gurdarshan Singh and Mohammad Afzal
- 48 Case Report: Identification of Novel Variants in ERCC4 and DDB2 Genes in Two Tunisian Patients With Atypical Xeroderma Pigmentosum Phenotype**
Imen Nabouli, Asma Chikhaoui, Houcemeddine Othman, Sahar Elouej, Meriem Jones, Arnaud Lagarde, Meriem Ben Rekaya, Olfa Messaoud, Mohamed Zghal, Valerie Delague, Nicolas Levy, Annachiara De Sandre-Giovannoli, Sonia Abdelhak and Houda Yacoub-Youssef
- 57 High Genetic Heterogeneity in Chinese Patients With Waardenburg Syndrome Revealed by Next-Generation Sequencing**
Sen Zhang, Hongen Xu, Yongan Tian, Danhua Liu, Xinyue Hou, Beiping Zeng, Bei Chen, Huanfei Liu, Ruijun Li, Xiaohua Li, Bin Zuo, Ryan Tang and Wenxue Tang
- 67 Case Report: Exome Sequencing Identified a Novel Frameshift Mutation of α -Actin 1 in a Chinese Family With Macrothrombocytopenia and Mild Bleeding**
Fang-Mei Luo, Liang-Liang Fan, Yue Sheng, Yi Dong and Lv Liu
- 72 Next-Generation Sequencing Analysis of GBA1: The Challenge of Detecting Complex Recombinant Alleles**
Elizabeth G. Woo, Nahid Tayebi and Ellen Sidransky

- 77 ***Characterization With Gene Mutations in Han Chinese Patients With Hypospadias and Function Analysis of a Novel AR Genevariant***
Lifen Chen, Junqi Wang, Wenli Lu, Yuan Xiao, Jihong Ni, Wei Wang, Xiaoyu Ma and Zhiya Dong
- 87 ***Whole-Exome Sequencing Identified CFTR Variants in Two Consanguineous Families in China***
Binyi Yang, Cheng Lei, Danhui Yang, Zhiping Tan, Ting Guo and Hong Luo
- 95 ***A Novel de novo Mutation in EBF3 Associated With Hypotonia, Ataxia, and Delayed Development Syndrome in a Chinese Boy***
Yanru Huang, Libin Mei, Yangdan Wang, Huiming Ye, Xiaomin Ma, Jian Zhang, Meijiao Cai, Ping Li, Yunsheng Ge and Yulin Zhou
- 103 ***Case Report: Identification of a Novel Homozygous Mutation in GPD1 Gene of a Chinese Child With Transient Infantile Hypertriglyceridemia***
Haihua Lin, Youhong Fang, Lin Han, Jie Chen, Jingan Lou and Jindan Yu
- 110 ***Case Report: Diffuse Polymicrogyria Associated With a Novel ADGRG1 Variant***
Fábio Carneiro, Júlia Duarte, Francisco Laranjeira, Sofia Barbosa-Gouveia, Maria-Luz Couce and Maria José Fonseca
- 116 ***Case Report: Clinical Features of a Chinese Boy With Epileptic Seizures and Intellectual Disabilities Who Carries a Truncated NUS1 Variant***
Pingli Zhang, Di Cui, Peiyuan Liao, Xiang Yuan, Nuan Yang, Yuanyuan Zhen, Jing Yang and Qikun Huang
- 124 ***Case Report: Progressive Cholestasis: Severe Phenotype of MEGDEL Syndrome With SATB2-Associated Syndrome***
Yajie Su, Hui Zhang, Huijun Wang, Bingbing Wu, Jiao Yang, Wenhao Zhou and Long Li
- 130 ***Noninvasive Prenatal Screening Based on Second-Trimester Ultrasonographic Soft Markers in Low-Risk Pregnant Women***
Yunyun Liu, Xiaosha Jing, Lingling Xing, Sha Liu, Jianlong Liu, Jing Cheng, Cechuan Deng, Ting Bai, Tianyu Xia, Xiang Wei, Yuan Luo, Quanfang Zhou, Qian Zhu and Hongqian Liu
- 141 ***A Novel SPG7 Gene Pathogenic Variant in a Cypriot Family With Autosomal Recessive Spastic Ataxia***
Christina Votsi, Antonis Ververis, Paschalis Nicolaou, Yiolanda-Panayiota Christou, Kyproula Christodoulou and Eleni Zamba-Papanicolaou
- 151 ***Fetal Congenital Heart Disease Caused by Compound Heterozygous Mutations in the DNAH9 Gene: A Case Report***
Tao Zhang, Hua Yuan, Hongdan Zhu, Yuyi Ying, Jinlong Ding, Haigang Ding, Xiaoliang Shi, Yao He, Haitao Pan and Yongxing Zhong
- 157 ***Clinical Characteristics and Genetic Analysis of a Family With Birt-Hogg-Dubé Syndrome and Congenital Contractural Arachnodactyly***
Jiayong Qiu, Yao Lou, Yingwei Zhu, Min Wang, Huifang Peng, Yingying Hao, Hongwei Jiang and Yimin Mao
- 163 ***Case Report: Novel MFSD8 Variants in a Chinese Family With Neuronal Ceroid Lipofuscinoses 7***
Yimeng Qiao, Yang Gu, Ye Cheng, Yu Su, Nan Lv, Qing Shang and Qinghe Xing

- 169 RNA Analysis and Clinical Characterization of a Novel Splice Variant in the NSD1 Gene Causing Familial Sotos Syndrome**
Olatz Villate, Hiart Maortua, Maria-Isabel Tejada and Isabel Llano-Rivas
- 175 Case Report: Two New Cases of Autosomal-Recessive Hypertrophic Cardiomyopathy Associated With TRIM63-Compound Heterozygous Variant**
Sofiya Andreeva, Olga Chumakova, Elena Karelkina, Viktoriya Lebedeva, Tamara Lubimtseva, Andrey Semenov, Alexey Nikitin, Gleb Speshilov, Alexandra Kozyreva, Polina Sokolnikova, Sergey Zhuk, Yuliya Fomicheva, Olga Moiseeva and Anna Kostareva
- 184 Case Report: Next-Generation Sequencing Identified a Novel Pair of Compound-Heterozygous Mutations of LPL Gene Causing Lipoprotein Lipase Deficiency**
Yakun Li, Man Hu, Lin Han, Lifang Feng, Luhong Yang, Xiaoqian Chen, Tingting Du, Hui Yao and Xiaohong Chen
- 191 Case Report: Successful Management of a 29-Day-Old Infant With Severe Hyperlipidemia From a Novel Homozygous Variant of GPIHBP1 Gene**
Shu Liu, Zhiqing Wang, Xianhua Zheng, Ye Zhang, Sisi Wei, Haimei OuYang, Jinqun Liang, Nuan Chen, Weihong Zeng and Jianhui Jiang
- 199 Case Report: Novel Mutations in the PCCB Gene Causing Late-Onset Propionic Acidemia**
Guang Ji, Yaling Liu, Xueqin Song and Zhenfei Li
- 204 Case Report: Identification of a Novel Heterozygous Missense Mutation in COL4A3 Gene Causing Variable Phenotypes in an Autosomal-Dominant Alport Syndrome Family**
Yanglin Hu, Wei Li, Lulu Tian, Shuai Fu, Yonglong Min, Jia Liu and Fei Xiong
- 213 A Novel Mutation of Transferrin Receptor 2 in a Chinese Pedigree With Type 3 Hemochromatosis: A Case Report**
Shan Tang, Li Bai, Yuan Gao, Wei Hou, Wenyan Song, Hui Liu, Zhongjie Hu, Zhongping Duan, Liaoyun Zhang and Sujun Zheng
- 220 Case Report: Loss-of-Function ABCC9 Genetic Variant Associated With Ventricular Fibrillation**
Anastasia Zaytseva, Tatyana Tulintseva, Yulya Fomicheva, Valeria Mikhailova, Tatiana Treshkur and Anna Kostareva
- 226 Case Report: Two Novel L1CAM Mutations in Two Unrelated Chinese Families With X-Linked Hydrocephalus**
Hang Zhou, Qiuxia Yu, Yingsi Li, Fang Fu, Ru Li, Guilan Chen, Dan Wang, Yan Lu, Xin Yang, Dongzhi Li and Can Liao
- 233 Mutant B3GALT6 in a Multiplex Family: A Dominant Variant Co-Segregated With Moderate Malformations**
Fang Shen, Yongjia Yang, Yu Zheng, Ming Tu, Liu Zhao, Zhenqing Luo, Yuyan Fu and Yimin Zhu
- 241 Novel Variant Expands the Clinical Spectrum of CUX2-Associated Developmental and Epileptic Encephalopathies**
Feng Zhang, Fuwei Li, Fujian Chen, Jinrong Huang, Qiong Luo, Xilong Du, Jiapeng Zhou, Weiyue Gu and Kaishou Xu
- 246 Paternal De Novo Variant of TAOK1 in a Fetus With Structural Brain Abnormalities**
Lihua Yu, Chaoxiang Yang, Ning Shang, Hongke Ding, Juan Zhu, Yuanyuan Zhu, Haowen Tan and Yan Zhang

NGS technologies of rare diseases diagnosis

By Couce ML, González-Vioque E. (2022) Front. Pediatr. 10: 1032359. doi: 10.3389/fped.2022.1032359

Of the estimated 7,000 rare diseases, 80% have a genetic cause (1). Because these diseases can be difficult to recognize based on clinical features alone, genetic testing is critical to help establish diagnosis (2). Genomic sequencing techniques allow the simultaneous analysis of hundreds to thousands of genes in a very short time and at low cost, and offer several strategies to facilitate the diagnosis of patients with suspected genetic disease, including gene panels and clinical exome sequencing (3), whole exome sequencing (WES) (4, 5), and whole genome sequencing (WGS) (6). However, it is becoming increasingly clear that an individual genome cannot be interpreted in isolation (7). WES and WGS data scaling necessitates automation of variant filtering to focus on clinically relevant genomic intervals and/or variants. On the other hand, analytical workflows for rare disease diagnosis involving processing of raw sequencing data, identification of pathogenic variants, and integration of clinical data to achieve robust genetic diagnosis are complex and not fully standardized (8, 9). Assigning pathogenicity to a rare variant identified using a bioinformatic algorithm and establishing a genetic diagnosis can be an extremely challenging process, and may require additional functional studies.

This Special Issue of *Frontiers in Genetics* “NGS Technologies of Rare Diseases Diagnosis” contains 33 studies about prenatal diagnostic technologies, phenotype expansions, added value of gene expression monitoring, and functional studies in the field of rare diseases, particularly those affecting the pediatric population. This collection of articles underscores the recent growth and extensive interest in research on this topic.

Prenatal research studies (Xu et al. (2021), 10) demonstrate the efficacy of cell-free DNA-based noninvasive prenatal screening (NIPS) diagnostic technologies for common trisomies in low-risk and twin pregnancies. However, the authors conclude that NIPS cannot replace invasive prenatal diagnostic techniques, and recommend prenatal diagnosis for fetuses with abnormal ultrasound findings.

Seven original studies have examined how WES can be used to identify genetic variants in rare diseases (Yang et al., Fareed et al., Zhang S et al., Huang et al., Giu et al., Zhang F et al., Yu et al.). The findings of these studies have expanded the variant spectrum of several rare diseases, revealing clearer relationships with clinical phenotypes, improving our understanding of the underlying etiology, and contributing to more rapid genetic diagnosis and subsequent genetic counseling. In their study, Yu et al. examined a fetus with structural brain abnormalities and identified a *de novo*, likely pathogenic variant of *TAOK1* (11). In addition, of the 19 case reports, 16, (Zhang J et al., Nabouli et al., Wang et al., Luo et al., Zhang P et al., Lin et al., Carneiro et al., Andreeva et al., Zhang T et al., Liu et al., Qiao et al., Ji et al., Zhou et al., Li et al., Tang et al., Hu et al.) describe the identification of a new variant, in known genetic diseases. Interestingly, Zaytseva et al. (2022) describe a loss-of-function variant in *ABCC9* that is associated with ventricular fibrillation. And, two of the case reports describe patients with 2 concomitant conditions Su et al. (2021), Kim et al. (2021) describe a case of a 7-year-old boy with two X-linked diseases, Duchenne muscular dystrophy (DMD) and frontometaphyseal dysplasia 1 (FMD1); while Shu et al. report a case of MEGDEL syndrome coinciding with SATB2-associated syndrome. Particularly noteworthy is the case report by Luo et al., which describes a novel frameshift mutation of α -Actin 1 (*ACTN1*) in a Chinese family with macrothrombocytopenia and mild bleeding (NM_001130004: c.398_399insTGCG, p.F134AfsX60). This variant was identified in the proband and his mother, but was absent in other unaffected family members. Western blot revealed that expression of α -actin 1 in the proband was decreased markedly indicating that the novel frameshift mutation may induce non-sense-mediated mRNA decay. These findings not only broaden the spectrum of *ACTN1* variants, but also confirmed diagnosis of inherited macrothrombocytopenia, which may facilitate the management and prognosis of the members of the family in question.

The opinion article by Woo et al. (2021) discusses the inclusion of *GBA1* in many NGS analyses for Parkinson's disease, and the importance of considering the effects of the nearby homologous pseudogene. Recombinant alleles in *GBA1* identified in Gaucher disease and Parkinson's disease patients could be missed by relying on NGS analysis alone without Sanger sequencing validation.

Gene expression monitoring was also addressed in this special issue. Villate et al. (12) contribute a brief report on the importance of performing RNA functional assays in order to determine the clinical significance of intronic variants, and to facilitate genetic counseling and clinical management of patients and their relatives. The authors undertook clinical characterization of a novel splice variant in *NSD1* that causes familial Sotos syndrome. Their findings help highlight the importance of using *in silico* prediction tools to detect

potential alterations in the splicing process. RNA-seq has emerged as a useful tool in the field of rare diseases, enabling the identification of new disease mechanisms and helping us to better understand the information generated by DNA sequencing.

And finally, functional analysis were included in three original studies (13, 14). Chen et al. (2021) characterized gene variants in Han Chinese patients with hypospadias, identifying 1 *de novo* missense variant loci in *AR gene*, and conducted *in vivo* and *in vitro* functional studies that provide molecular evidence that the consequent p.I817N amino acid change may significantly reduce AR transcriptional function, leading to hypospadias. Shen et al. are the first to describe a *B3GALT6*-dominant variant leading to Ehlers–Danlos disease, and their functional experiments confirm that the R295C variant plays a loss-of-function role, while the elongated variant (p.L170fs*268) may exert a dominant-negative effect. Votsi et al. studied a novel *SPG7* pathogenic variant in a Cypriot family with autosomal recessive spastic ataxia, and performed functional studies showing that the variant does not affect RNA or protein expression or protein localization. However, their findings reveal aberrant mitochondrial morphology, suggesting mitochondrial dysfunction and further demonstrating the pathogenicity of the identified variant.

Conclusion

This special issue provides a useful summary of progress made in the field of NGS technologies applied to genetic medicine, particularly in the area of rare diseases. These approaches have helped improve diagnostic capabilities as well as expanding our knowledge of the molecular basis of these diseases, with important clinical and public health implications. Nonetheless, clinical studies with longer follow-up periods will be necessary to establish recommendations to ensure adequate and earlier diagnosis.

Author contributions

MLC and EGV contributed to the design, writing and editing the paper. All authors contributed to the article and approved the submitted version.

Conflict of interest

Report: Exome Sequencing Identified
a Novel Compound Heterozygous
Variation in *PLOD2* Causing Bruck
Syndrome Type 2.
Front. Genet. 12:619948.
doi: 10.3389/fgene.2021.619948

Bruck Syndrome (BRKS) is a rare type of recessive osteogenesis imperfecta (OI) and consists of two subtypes, BRKS1 and BRKS2, which are caused by variations in *FKBP10* and *PLOD2* genes, respectively. In this study, a family that had experienced multiple miscarriages and recurrent fetal skeletal dysplasia was recruited for the purpose of a multiplatform laboratory investigation. Prenatal genetic testing with whole-exome sequencing (WES) identified a compound heterozygous variation in the *PLOD2* gene with two variants, namely c.2038C>T (p.R680*) and c.191_201+3 delATACTGTGAAGGTA (p.Y64Cfs*12). The amino acids affected by the two variants maintained conserved across species. And the result of immunohistochemistry (IHC) indicated that the expression of *PLOD2* protein in the proband's osteochondral tissue was significantly decreased. These findings in our study expanded the variation spectrum of *PLOD2* gene, provided solid evidence for the family's counseling in regard to future pregnancies, strongly supported the application of WES in prenatal diagnosis, and might give insight into the understanding of *PLOD2* function.

Keywords: *PLOD2* gene, Bruck syndrome type 2, osteogenesis imperfecta, whole-exome sequencing, immunohistochemistry detection

INTRODUCTION

Congenital skeletal dysplasia (SD) often displays severe *in utero* manifestations, which provides clues and challenges for prenatal diagnosis (Offiah, 2015; Liu et al., 2019). First, they can provide evidence for the timely formation of management plans; on the other hand, due to the strong clinical heterogeneity of SDs, it is difficult to accurately judge the prognosis by these indeterminate indications alone (Konstantinidou et al., 2009; Offiah, 2015). Under such circumstances, a meticulously designed strategy of genetic detection would help overcome the setbacks in clinical differential diagnosis (Zhou et al., 2018; Yang et al., 2019).

Osteogenesis imperfecta (OI) is a series of congenital metabolic bone disorders and comprises dozens of conditions ranging from early lethality to mild manifestations (Marini, 2013; Liu et al., 2017). OI is mainly characterized by increasing bone fragility, recurrent fracture, and subsequent growth retardation (Forlino and Marini, 2016; Liu et al., 2017). OI patients also share some extraskelatal symptoms, such as blue sclera, hearing deficits, dentinogenesis imperfecta (DI),

and valvular heart disease (Forlino and Marini, 2016). Bruck syndrome types 1 and 2 (BRKS1, MIM #259450; BRKS2, MIM #609220), caused by biallelic pathogenic variants in the *FKBP10* (MIM #607063) and *PLOD2* (MIM #601865) genes, respectively, are two rare subtypes of OI, mainly characterized by congenital joint contractures and pterygia other than the common OI manifestations (Viuen et al., 1989). *PLOD2* encodes lysyl hydroxylase 2 (LH2, EC 1.14.11.4), while *FKBP10* encodes the prolyl cis-trans isomerase FKBP65, the activities of which are required in forming mature crosslinks in bone collagen (Bank et al., 1999; Alanay et al., 2010).

To our knowledge, fewer than 20 studies have reported the BRKS2 cases with respect to defects in *PLOD2* (Mumm et al., 2020). Moreover, the genotype-phenotype correlation of BRKS2 is not fully established, owing to the low amount and relatively clustered distribution of constitutional variations in *PLOD2*, the vague structural and functional delineation of the N-terminal of LH2 protein as well as the strong phenotypic variability of BRKS2 (Tham et al., 2018; Mumm et al., 2020). Furthermore, given the commonality of cell signaling pathways between BRKS2 and multiple types of cancers, the in-depth study of corresponding molecules would benefit scientific and clinical understanding in both fields (Guo et al., 2018; Wang et al., 2020).

Thus, we studied a family having experienced multiple abnormal gestations. Prenatal ultrasonography examination and genetic detections were conducted to identify the cause of fetal skeletal dysplasia in the subject family.

CASE PRESENTATION

A 34-year-old woman was first referred to our Center in February 2015 for having experienced multiple abnormal gestations. At that point she was 8 weeks pregnant.

Based on medical records and her personal dictation, we combed through the couple's complete medical history and illustrated in a pedigree diagram (Figure 1A). They had eight previous pregnancies in total: In August 2005, missed abortion occurred at the eighth gestational week of their first pregnancy. In October 2006, it was diagnosed that the second pregnancy was an ectopic pregnancy on the left fallopian tube, whereupon transabdominal resection of the left fallopian tube was performed. In October 2007, July 2008, August 2010, and December 2012, the couple went through four missed abortions or miscarriages, all of which occurred between 8 and 16 gestational weeks. In November 2013, the fetus of their seventh pregnancy was diagnosed with thickened nuchal translucency (NT), right abdominal fissure and visceral valgus. Induced labor was performed at 15 weeks of gestation.

In 2015, all indicators of their 8th pregnancy during early pregnancy were normal, including serological screening, NIPT (non-invasive prenatal testing) results. However, at 17th week of gestation, ultrasonic examination revealed that the fetus had extremely short limbs and bowing of long bones (Figure 1B). Amniocentesis and subsequent prenatal diagnosis with chromosomal karyotyping and micro array (CMA) were conducted. However, no variation with clinical

FIGURE 1 | The clinical findings in this case: (A) Pedigree diagram of the family with fetal skeletal dysplasia and multiple miscarriages. (B) Ultrasonographic indications of the couple's eighth pregnancy. (C) Ultrasonographic indications of the couple's most recent (ninth) pregnancy.

significance was identified. The fetus was aborted at 20 gestational weeks.

In April 2018, we performed prenatal diagnosis for their most recent pregnancy at the 16th week of gestation. Ultrasonography indicated that bilateral lower limbs of the fetus were shortened, not excluding the presence of bending (**Figure 1C**). Besides regular prenatal genetic testing as described above, whole-exome sequencing was also introduced after induction.

LABORATORY INVESTIGATIONS

Prenatal genetic testing including karyotyping and CMA (with Cytoscan 750k, Thermo Fisher platform) were performed on the last two adverse pregnancies in 2015 and 2018. Both results of those were normal.

Accordingly, whole-exome sequencing was performed on the skin tissue obtained from the aborted fetus of the last pregnancy. In brief, the enrichment of target-region sequences was performed by means of the Sure Select Human Exon Sequence Capture Kit (Agilent, USA). The sequencing libraries were quantified using the DNA Standards and Primer Premix Kit (Kapa Biosystems, USA), massively parallel-sequenced using the XTEN platform and then massively parallel-sequenced again (Illumina, USA). After sequencing and filtering out the low-quality readings, the high-quality readings were compared to the human genome reference sequence [(hg19/GRC h37)]. The GATK software (Genome Analysis TK3.3.0, <https://software.broadinstitute.org/gatk/>) and the Verita Trekker® Variants Detection system (Berry Genomics, China) were used to identify single-nucleotide polymorphisms, insertion and deletions, copy-number variants (CNVs), mitochondrial gene variants, and runs of homozygosity. Subsequently, the Enliven® Variants Annotation Interpretation (Berry Genomics, China) system was used to fulfill the annotation and interpretation progress referring to multiple databases [1000g2015aug_eas (<https://www.internationalgenome.org/>); ExAC_EAS (<http://exac.broadinstitute.org/>); gnomAD_exome_EAS (<http://gnomad.broadinstitute.org/>); HGMD®: Human Gene Mutation Database (Professional Version 2019.4)]. The suspected pathogenic variant was validated by Sanger sequencing through use of ABI 3730 Automated Sequencer (Applied Biosystems). The mutations were identified by sequence alignment with the NCBI Reference Sequence (NG 011537.1) using Chromas 2.33. WES identified a compound heterozygous variation in the *PLOD2* gene consisting of two variants, namely c.2038C>T (p.R680*) and c.191_201+3delATACTGTGAAGGTA (p.Y64Cfs*12) (NM_000935) (**Figure 2A**). Sanger sequencing revealed that the father carried the heterozygous c.2038C>T variant, while the mother carried c.191_201+3del (**Figure 2A**). The former one was reported by Lyu et al. as a pathogenic variant (Lv et al., 2017), while the latter, which would result in a premature truncated protein, was first reported in this study. According to the variant interpretation criteria by ACMG (Richards et al., 2015), it was classified as pathogenic, with the evidence of PVS1, PM2, PM3, and PP4.

The conservatism of all amino acids effected by detected variants was analyzed using MEGA7 (<http://www.megasoftware.net/previousVersions.php>) with default parameters. The results showed that the amino acids Y64 and R680 (i.e., the two variants) maintained evolutionary conservatism among species (**Figure 3A**).

Protein modeling was conducted using SWISS-MODEL (<https://swissmodel.expasy.org/>) and Swiss-Pdb Viewer software (<https://spdbv.vital-it.ch/disclaim.html#>). *PLD2* protein model of wild type (WT)-6fxm.1.A (Seq Identity:59.26%/GMQE: 0.82/QMEAN: -0.67), p.Y64Cfs*12-6fxm.1.A (Seq Identity:57.80%/GMQE: 0.80/QMEAN: -0.78), and p.R680*-6fxm.1.A (Seq Identity:43.59%/GMQE:0.18/QMEAN: -0.87) were shown (**Figure 3B**). According to the results, these two variants would result in premature truncated peptides, which could cause severe damage to protein function. Immunohistochemistry (IHC) (with Anti-*PLD2*/LH2 antibody, ab90088, Abcam, USA) was conducted on the paraffin sections of fetal auricular finger osteochondrocytes of the proband (along with a cartilage tissue sample from an aborted fetus (*PLD2* wild-type) at similar gestational age as normal control). The results indicated that the expression level of *PLD2* protein was significantly decreased in the osteochondral tissues of the proband (**Figure 3C**). The low protein expression of *PLD2* was possibly because c.2038C>T (p.R680*) and c.191_201+3delATACTGTGAAGGTA would be expected to induce non-sensical mediated decay.

DISCUSSION

Recessive forms only account for <10% in OI disorders, yet the list of causative genes has been growing through recent years (Eyre and Weis, 2013). Additionally, with the defects in various proteins involved in bone formation, OIs display a broad range of phenotypic variability (Forlino and Marini, 2016). This promotes the challenge in prenatal diagnosis and management on fetal SDs with similar early manifestations. Therefore, it would appear to be more and more arbitrary to consider the *in utero* limb shortening and bowing of long bones as a collagen-related autosomal dominant condition.

As a rare but typical example of recessive OI, most cases of BRKS are distinguished by congenital joint contractures and pterygia, albeit with several exceptions (Tham et al., 2018; Mumm et al., 2020). Currently, two BRKS subtypes, BRKS1 and BRKS2, with almost identical phenotypes but different pathogenesis are recognized (van der Slot et al., 2003; Alanay et al., 2010). To our knowledge, 25 constitutional mutations in *PLD2* associating with BRKS2-like phenotypes have been detected in fewer than 20 studies, showing significant C-terminal aggregation (**Figure 2B**; **Supplementary Table 1**) (Mumm et al., 2020). In this study, a compound heterozygous variation in the *PLD2* gene with two variants, c.2038C>T and c.191_201+3del, was identified and confirmed. The former one, c.2038C>T, was once reported in BRKS2 patient (Lv et al., 2017); while the latter one, c.191_201+3del, was a novel detected frame-shift variant causing early termination of protein translation. This finding

FIGURE 2 | The genetic variations identified in this case: **(A)** The two variants detected in this fetus and his parents (individual no. corresponding to **Figure 1A**). **(B)** All *PLOD2* variants associating with BRKS2-like phenotype in the literature and in this study, illustrated in diagrams of gene and protein. (In this study, red font represents variants).

expanded the variation spectrum of *PLOD2* gene. Additionally, Guo et al. have determined a 2Å crystal structure of the lysyl hydroxylase (LH) domain corresponding to human *PLOD2* amino acids 548–758, which provided sub-molecular insight into how specific variants affect the structure of LH2 (Guo et al., 2018). The genotype-phenotype correlation of *PLOD2* skeletal dysplasia

is pending further elucidation along with the identification of more variations, particularly at the N-terminal (Leal et al., 2018).

LH2, cloned by Valtavaara et al. (1997), is encoded by *PLOD2* gene, the defect of which is responsible for the onset of BRKS2. LH2 specifically catalyzes the hydroxylation of telopeptide lysyl residues in collagen, which is essential for the

FIGURE 3 | The results of *in silico* analysis and IHC experimentation: **(A)** The conservatism of the two amino acids effected by the two variants. **(B)** The protein models of WT, p.Y64Cfs*12, and p.R680* of *PLOD2* protein model 6fxm.1.A. **(C)** *PLOD2* protein expression in the osteochondrocytes of the proband and control samples, by IHC.

normal crosslinking of bone collagen (Bank et al., 1999; van der Slot et al., 2003). FKBP10, whose deficiency is causative for BRKS1, belongs to a group of proteins termed immunophilins and displays high binding affinity for the immunosuppressant drugs FK506 (Patterson et al., 2000). FKBP10 is thought to function as a collagen chaperone and to assist in collagen folding (Lietman et al., 2014). Subsequently, Chen et al. found that the peptidyl prolyl isomerase activity of FKBP10 positively modulated LH2 enzymatic activity and was critical for the formation of hydroxylysine-aldehyde derived intermolecular collagen crosslinks, which indirectly explained why phenotypes of BRKS1 and BRKS2 were so similar (Chen et al., 2017). LH2 has two splice forms—LH2a (short) and LH2b (long)—resulting from alternative splicing of *PLOD2*, with LH2b containing an additional exon 13A encoding 21 amino acids (Gjaltema and Bank, 2017). The absence of LH2b has great impact on musculoskeletal tissues, particularly bone, as illustrated by

mutations in *PLOD2* (Gjaltema and Bank, 2017). LH2 activity is positively correlated with pyridinoline levels, which indicates its important role in the formation of collagen telopeptide-derived pyridinoline crosslinks (van der Slot et al., 2005; Gjaltema and Bank, 2017). In this study, the result of IHC indicated the extremely low expression of *PLOD2* in cartilage tissue of the proband, which should be the result of the variation he carried. Both mutations c.2038C>T (p.R680*) and c.191_201+3delATACTGTGAAGGTA would be possibly expected to induce nonsense mediated mRNA decay (NMD), whereby the low expression level of *PLOD2* could be responsible for the NMD. Further functional experiments are needed to explore the possible mechanism. However, we failed to detect the mRNA-level expression of *PLOD2* due to the degradation of RNA in the fibroblast sample, which is a flaw in our study and needs to be remedied by subsequent functional studies. From another angle, the protein modeling result revealed that both mutations

possibly caused the peptide chain truncation, which clearly affected the dimerization and maturation process and even the presence of the protein. Besides, the evolutionary conservatism of the amino acids affected by the two variants further supported their pathogenicity. However, further functional experiments are necessary, not only to clarify the effect of each variant on the protein itself but also to understand the role of this effect in the overall process of osteogenic differentiation.

In practical terms, diagnostic report in this study was obtained before the fetal pregnancy entered the perinatal period (after 27⁺⁶ gestational weeks), which was supportive for the application of WES in the field of prenatal diagnosis.

For any future pregnancy of the proband in this study, the recurrent risk of Bruck syndrome 2 condition would be 25%. Given such circumstances, the couple were informed of reproductive options such as prenatal testing and preimplantation genetic diagnosis (PGD). We need to follow up on the outcome of the couple's pregnancy.

CONCLUSION

In summary, this study detected a novel *PLOD2* compound heterozygous variation in a 17-gestation-week fetus with BRKS2 by a multi-platform genetic approach. It clarified the cause of fetal OI in the subject family, provided guidance for any future pregnancy the couple might have and highlighted the value of WES in diagnosis of SD with unclear prenatal indications.

DATA AVAILABILITY STATEMENT

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and

accession number(s) can be found at: <https://www.ncbi.nlm.nih.gov/>, NG 011537.1; <http://www.wwpdb.org/>, NM_000935.

ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Research Ethics Committee of the Shijiazhuang Obstetrics and Gynecology Hospital. The patients/participants provided their written informed consent to participate in this study.

AUTHOR CONTRIBUTIONS

QG designed the overall research strategy and supervised the whole process. JZ recruited the case, performed the prenatal counseling, sampling, and part of the genetic experiments. HH performed the other part of the genetic experiments and data analysis. WM and MY performed IHC. WC conducted protein modeling. DM performed prenatal ultrasonic exam. JZ and HH cooperated in the preparation of this manuscript. All authors contributed to the article and approved the submitted version.

ACKNOWLEDGMENTS

We thank the patients and their families for their participation in this study.

(2021) Case Report: Identification of a
Novel *ODAD3* Variant in a Patient With
Primary Ciliary Dyskinesia.
Front. Genet. 12:652381.
doi: 10.3389/fgene.2021.652381

Background: *ODAD3* encodes a protein of 595 amino acids and contain three highly conserved coiled-coil domains, which is essential for cilia axoneme dynein arm assembly and docking. Primary ciliary dyskinesia (PCD) of *ODAD3* deficiency are rarely reported. Female infertility in PCD related to *ODAD3* variants has not been reported.

Methods: Whole-exome and Sanger sequencing were used to identify the disease-related gene of the patient with PCD in a consanguineous Chinese family. Domain analysis was applied to predict the impact of the variant on *ODAD3* protein.

Results: The 35 year-old female patient exhibited chronic sinusitis, diffuse bronchiectasis, dextrocardia and infertility. We identified a novel homozygous variant in *ODAD3*, c.1166_1169dupAGAC, p.(Leu391Aspfs*105) in the PCD patient by exome sequencing and Sanger sequencing. This frameshift variant was predicted to be disease causing by bioinformatics analysis and was also not presented in the current authorized large genetic databases.

Conclusions: Our study enriches the genetic spectrum and clinical phenotypes of *ODAD3* variants in PCD and provide more evidence for future genetic counseling and gene-targeted therapy for this disease.

Keywords: primary ciliary dyskinesia, *ODAD3*, *CCDC151*, sinusitis, bronchiectasis, dextrocardia, infertility

INTRODUCTION

Primary ciliary dyskinesia (PCD, MIM 244400) is a clinically and genetically heterogeneous motile ciliopathy characterized by recurrent upper and lower respiratory infections, subfertility and laterality defect (Mirra et al., 2017). The estimated prevalence of PCD is 1:10 000 to 1:20 000 live-born children (Afzelius and Stenram, 2006). So far, more than 47 genes associated with cilia structure or function dysfunction have been identified causative for PCD (Wallmeier et al., 2020).

ODAD3 (Outer dynein arm docking complex subunit 3; formerly known as *CCDC151*; coiled-coil domain containing 151) encodes a protein of 595 amino acids which contains three highly conserved coiled-coil domains. This protein was initially recognized as a potential ciliome gene due to its expression in

human ciliary axonemes (Ostrowski et al., 2002) and it is essential for cilia axoneme dynein arm assembly and docking (Hjeij et al., 2014). Up to now, PCD caused by *ODAD3* variants (MIM 616037, CILD30) are rarely reported and female infertility has not been identified in PCD caused by *ODAD3* variants.

In the present study, a novel variant in *ODAD3* was identified in a female PCD patient with infertility from a Chinese consanguineous family.

CASE PRESENTATION

The patient is a 35 year-old female. She was admitted to our hospital because of chronic cough, purulent sputum, nasal congestion for over 30 years and dyspnea for about 5 years. She has been inflicted by recurrent infections of the lower and upper airways since newborn. And he has been married for 10 years but without pregnancy and was diagnosed with infertility. She had no history of drowning, measles, polio, tuberculosis, immunodeficiency, connective tissue disease, etc. Her family members denied any obvious respiratory or other disease history. Physical examination indicated right-side heart sound. High resolution computed tomography of this patient revealed chronic sinusitis (Figure 1A), diffuse bronchiectasis (Figure 1B), situs inversus: heart dextroversion (Figure 1C) and abdominal organs in the reverse location (Figure 1D). Lung function test revealed a moderate to severe mixed (restrictive and obstructive) ventilation dysfunction. Her nasal nitric oxide concentration (nNO) (6 nl/min) was far below the reference nNO cutoff value of PCD (77 nl/min) (Leigh et al., 2013).

METHODS

Ethical Compliance

This study was approved by the Review Board of the Second Xiangya Hospital of Central South University in China. Written informed consent was obtained from the patient.

DNA Extraction and Variant Analysis

We extracted genomic DNA from peripheral blood of the proband and healthy control, using a QIAamp DNA Blood Mini Kit (250) (QIAGEN, Valencia, CA). Then we captured the DNA of the proband with the Agilent SureSelect Human All Exon V5 Kit (Agilent, California, USA) and sequenced on Illumina Hiseq 4000 (Illumina Inc., San Diego, USA).

The valid sequencing reads were aligned to the NCBI human reference genome (GRCh37/hg19) by the Burrows Wheeler Aligner software (Li and Durbin, 2010). ANNOVAR is used to do annotation for Variant Call Format file (Wang et al., 2010). We classified the variants as pathogenic, likely pathogenic and uncertain significance, likely benign, benign according to American College of Medical Genomics (ACMG) guidance (Richards et al., 2015).

We filtered single-nucleotide variants (SNVs) and short insertions and deletions (InDels) as follows (Figure 2): (1) High-frequency (minor allele frequency > 0.01) variants found in 1000 Genomes Project, Exome Sequencing Project (ESP), Genome Aggregation Database (gnomAD) and Novo inhouse Database,

were excluded. (2) Variants within Exonic, splicing sites were included from subsequent analysis. (3) Bioinformatics programs: Mutation Taster, Polyphen2, SIFT, CADD, and LoFtool were used to predict the possible impacts of SNVs. (4) Homozygous variants were retained to be filtered by a PCD-related gene panel including 47 identified genes (**Supplementary Table 1**). Sanger sequencing was performed in the patient to validate the mutation. The location of the mutation was analyzed by SMART program (<http://smart.embl-heidelberg.de>). The DNA samples from the patient's parents were not available. The primer sequences were designed as follows: forward, 5'-ATTCTAAGACCGCTGTGTCCC-3'; reverse, 5' TTGCACAGCAATGTATGGGG-3'.

RESULTS

For the DNA sample of the patient, exome sequencing generated an average of 14.5 Gb data with an ~99% coverage and a depth of >50×. After alignment and frequency filter, 4,373 non-synonymous variants (SNVs and InDels) were further analyzed and 453 variants in exons or in canonical splice sites (splicing junction 10 bp) were further analyzed. Fifteen SNVs and InDels in homozygous state were left and then filtered by the PCD-related gene panel. Finally, only one homozygous variant, *ODAD3*, NC_000019.9:g.11533477_11533480dup, NM_145045.4: c.1166_1169dupAGAC, NP_659482.3: p.(Leu391Aspfs*105), which caused frameshift insertion, passed the filtration.

This variant was in accord with the hereditary mode from consanguineous family (**Figure 3A**) and was validated via Sanger sequencing (**Figures 3B,C**). According to ACMG guidelines (Richards et al., 2015), this variant was classified into pathogenic (meeting criteria of PVS1, PM2, PM3). The location of the variant is within the third coiled-coil domain of the 595-amino-acid *ODAD3* protein (Refseq NP_659482.3) analyzed by SMART program (<http://smart.embl-heidelberg.de>) (**Figure 3D**).

DISCUSSION AND CONCLUSION

This study describes a female with PCD that carried a novel homozygous variant in the *ODAD3* gene. This patient in our study exhibited chronic sinusitis, bronchiectasis, situs inversus, and infertility. Our case enriches the mutation spectrum and clinical phenotypes of *ODAD3* variants in PCD.

PCD is a motile ciliopathy involving multiple organs or system, especially in respiratory tract. Cilia can be classified into two types according their motility: motile cilia with 9+2 or 9+0 microtubule structure and immotile cilia with 9+0 microtubule (Satir and Christensen, 2007). Motile cilia has highly conserved cell structure among different species and extensively exists on airway epithelium, germinal center in fetal period, oviduct and sperm flagella (Bayless et al., 2019). The critical pathogenesis of PCD lies in the abnormality of motile cilia structure or function or ciliogenesis, which accounts for ineffective cilia clearance, abnormal left-right asymmetry and subfertility (Bustamante-Marín and Ostrowski, 2017).

To date, a total of seven likely loss-of-function variants in *ODAD3* have been reported in PCD (**Supplementary Table 2**). The reported *ODAD3* variants including three non-sense variants: p.(Gly309*) (Hjeij et al., 2014); p.(Ser409*) (Hjeij et al., 2014); p.(Glu109*) (Zhang et al., 2019); three frame-shifting variants: p.(Gly56Aspfs*26) (Deng et al., 2020); p.(Lys77Leufs*6) (Mani et al., 2020); p.(His199Argfs*60) (Olm et al., 2019) and one splice site variant: c.244+1G>A (Monies et al., 2019). The only two hitherto reported female patients (10 week and 1 year-old, respectively) did not reach reproductive age. infertility has not been determined in the previously reported patients. However, it means that it was not reported (and probably not even investigated in adult patients) and not that it was not present. Therefore, assessing and reporting infertility in patients affected by PCD is essential, whenever possible. In our study, we detected a novel homozygous variant of *ODAD3*, p.(Leu391Aspfs*105) which was likely to be PCD disease-causing. The patient in our study exhibited typical PCD phenotypes including chronic sinusitis, bronchiectasis, situs inversus and infertility. The frame-shift variant results in an incorrect and premature termination of translation of *ODAD3* protein which may undergo non-sense-mediated decay, indicating a loss of function of *ODAD3* in outer dynein arm (ODA) assembly and docking.

Infertility is more common in males than females in PCD (Wallmeier et al., 2020). The prevalence of infertility among PCD females is unclear, partly due to insufficient awareness of clinicians. A cohort study (Vanaken et al., 2017) among PCD reported 61% (22/36) women are considered infertile related with 13 genes such as *CCDC39*, *CCDC40*, *DNAH5*, which affect motile cilia structure. *CCDC39* and *CCDC40*, similar to *ODAD3*, also contain coiled-coil domains and their defects display disorganization of microtubule doublets and central pair in cilia (Becker-Heck et al., 2011; Merveille et al., 2011). *DNAH5* is the ODA component of motile cilia and its defect lead to ciliary dyskinesia (Hornet et al., 2006). These data indicate that those genes impacting motile cilia structure, may related to female infertility. Our study is the first to report infertility in female PCD patient with *ODAD3* deficiency. The frameshift *ODAD3* variant may lead to ODA defects and then impede the oocytes transportation across the oviduct, which finally results in infertility. As there are currently no way for women to test their potentially PCD-related fertility before trying to conceive, it is necessary for clinicians to pay more attention to fertility status of PCD. Fertility counseling and appropriate assisted reproductive technologies should be included in the standard PCD patient care.

Animal models of deficient *ODAD3* demonstrated phenotypes of ciliary dyskinesia and laterality defects similar to human. *Odad3* in vertebrates is homologous to the *Chlamydomonas* *ODA10* gene which is also associated with cilia outer ODA assembly (Dean and Mitchell, 2013). *ODAD3* is involved in regulating intraflagellar transport (IFT)-dependent dynein arm assembly according to previous research in *drosophila*, zebrafish, and mice (Alsaadi et al., 2014; Hjeij et al., 2014; Jerber et al., 2014). *ODAD3*-knockdown zebrafish had motile ciliary dysfunction in the pronephros and Kupffer's vesicle, and showed abnormal left-right asymmetry (Hjeij et al., 2014). In mice, *Odad3* is expressed

in embryonic nodes and ependymal cells, and deficient *Odad3* may result in ciliary dyskinesia and laterality defects (Jerber et al., 2014). Whether *ODAD3* defect leads to infertility in animal remains unknown and need further research to recapture phenotype in human.

In conclusion, combined clinical profile and sequencing data, we suggest that novel homozygous variant of *ODAD3*, p.(Leu391Aspfs*105), is one of the pathogenic cause of PCD. This is also the first report about female infertility in PCD of *ODAD3* deficiency. Our study enriches the genetic spectrum and clinical phenotypes of *ODAD3* variants in PCD and provides more evidence for future genetic counseling and gene-targeted therapy for this disease.

doi: 10.3389/fped.2021.628190

Herein, we present a rare case of co-occurring Duchenne muscular dystrophy (DMD) and frontometaphyseal dysplasia 1 (FMD1), two different X-linked diseases, in a 7-year-old boy. He presented with proximal muscle weakness and elevated creatine phosphokinase levels. A multiplex ligation-dependent probe amplification study of *DMD* revealed the *de novo* duplications of exons 2–37, thereby confirming the diagnosis of DMD. Initial evaluation revealed atypical features, such as facial dysmorphism, multiple joint contractures, and severe scoliosis, at an early age. However, these were overlooked and were assumed to be atypical manifestations of DMD. Then, the patient's maternal cousin was diagnosed with FMD1 with pathogenic missense variant in *FLNA* (NM_001110556.2: c.3557C>T/p.Ser1186Leu). A family genetic test revealed that the patient and his mother had the same pathogenic variant in *FLNA*. The patient's atypical manifestations were considered symptoms of FMD1. Therefore, if one disease does not fully explain the patient's clinical features, an expanded genetic study is needed to detect coincidental disease.

Keywords: Duchenne muscular dystrophy, frontometaphyseal dysplasia 1, X-linked genetic diseases, *FLNA* gene mutation, genetic disease

INTRODUCTION

Duchenne muscular dystrophy (DMD) is characterized by progressive muscle weakness and atrophy, and it affects ~1 in 3,500–5,000 males (1). DMD is caused by pathogenic variants in *DMD* on chromosome Xp21, and over 2,000 pathogenic variants have been determined. Approximately 55–65% of cases are caused by exon deletions, 30% by single-base variants or small deletions or insertions, and 5–15% by exon duplications (2–5). Individuals with this condition usually experience progressive wasting of the skeletal, respiratory, or cardiac muscles, resulting in death due to cardiac or respiratory compromise (6).

Frontometaphyseal dysplasia 1 (FMD1) is a rare genetic disorder caused by pathogenic variants in *FLNA* on chromosome Xq28 and is characterized by various skeletal development abnormalities. Worldwide, only a few dozen patients have been diagnosed with FMD1 to date. This condition has >10 pathogenic variants, with most being single-base variants (7). Herein, we describe a rare case of co-occurring DMD and FMD1, two different X-linked genetic disorders, coincidentally diagnosed in one patient.

CASE PRESENTATION

A 7-year-old boy visited the neuromuscular disease clinic of our institution with proximal muscle weakness and multiple contractures of the upper and lower limb joints. There was no significant family history. The patient presented with a waddling gait and Gower's sign. However, he could walk independently and go up the stairs with assistance. The manual muscle test showed grade 3/5 for proximal muscles and 4/5 for distal muscles. Whole-spine radiography revealed scoliosis with a Cobb's angle of 25°. According to laboratory tests, the patient's creatine phosphokinase (CPK) level increased to ~10,000 U/L (reference range, <250 U/L). To check for DMD, a multiplex ligation-dependent probe amplification study of *DMD* was conducted using a kit (MRC Holland, the Netherlands) with two probes (P034-A2 and P035-A1). Results revealed duplications of exons 2–37, which is expected to be out-of-frame (Figures 1A,B). Hence, the proband was diagnosed with DMD. The carrier test result of his mother revealed normal *DMD* without any pathogenic variants (Figure 1C).

Based on physical examination, the patient showed facial dysmorphism with hypodontia, prominent supraorbital ridge,

broad and depressed nasal ridge, and micrognathia. Other than muscular dystrophy, various features, such as multiple joint contractures and facial dysmorphism, were atypical manifestations of DMD. The patient received regular steroid and physical therapy. However, multiple joint contractures worsened over time, and 4 years after diagnosis, at 11 years of age, he started using a wheelchair. The patient was subsequently lost to follow-up.

After 3 years, another 13-year-old boy with an appearance similar to that of the current patient visited the neuromuscular disease clinic of our institution due to multiple contractures and facial dysmorphism. Using multigene panel sequencing for skeletal dysplasia, the patient was diagnosed with FMD1 caused by *FLNA* located at chromosome Xq28. The missense *FLNA* variant, which was previously reported as pathogenic variant was identified (NM_001110556.2: c.3557C>T /p.Ser1186Leu) (8, 9). Based on family history, the two children were identified as maternal cousins.

When the DMD patient was 15 years old, we called up the patient and requested him to visit our neuromuscular disease clinic to assess the pathogenic variant of *FLNA*. His joint contractures and scoliosis had worsened

FIGURE 2 | (A) Pedigree of the family. The squares and circles represent male and female family members, respectively. The asterisk indicates people tested for the *FLNA* pathogenic variant. Light gray color represents family members with the FMD1 phenotype. Symbols divided into halves indicate heterozygous carriers of FMD1. Dark gray color represents the co-occurrence of FMD1 and DMD. The arrow indicates the proband. **(B)** Timeline of the clinical presentation and molecular diagnosis of the proband and his family members.

(Cobb's angle increased from 25° to 51°), and he was wheelchair-bound due to progressive weakness, joint contracture, and dyspnea. The strength of both shoulder girdles was graded 2/5; upper limbs, 3/5; proximal lower limbs, 2/5; and distal lower limbs, 3/5, and CPK level was 3,156 U/L.

The patient underwent a Sanger sequencing study for *FLNA*. This study revealed that he had a hemizygous missense variant (NM_001110556.2: c.3557C>T), which is the same variant observed in his cousin. Finally, the patient was diagnosed with FMD1 caused by *FLNA* missense variant (c.3557C>T) inherited from the asymptomatic maternal carrier and, coincidentally, DMD caused by *de novo* DMD exons 2–37 duplications.

Through family testing, we found that the proband's mother, aunt, and female cousin also had the same pathogenic heterozygous variant of the *FLNA*. None of them showed definite phenotype of FMD1 (Figures 2A,B, 3).

Since the patient's cousin had Chiari I malformation and syringomyelia, brain and whole-spine magnetic resonance imaging was conducted and Chiari I malformation was detected. Additionally, head computed tomography scan revealed craniosynostosis similar to his cousin.

DISCUSSION

Herein, we report a rare case of co-occurring DMD caused by DMD exons 2–37 duplications and FMD1 caused by *FLNA* pathogenic variant (NM_001110556.2: c.3557C>T/p.Ser1186Leu) in a patient. The patient presented with atypical DMD characteristics, such as severe scoliosis, joint contractures, facial dysmorphism, Chiari I malformation, and craniosynostosis. Joint contracture is a common complication of DMD; however, in this case, the patient had developed severe joint contracture at an early age (10).

There have been few cases in which DMD alone induced facial dysmorphism. In a previous case, one patient with DMD presented with facial dysmorphism and craniosynostosis. However, only DMD gene-targeted sequencing was conducted, and the presence of other genetic abnormalities was not validated (11). In our case, the presence of multiple contractures and facial dysmorphism, which are not indicative of DMD, was only explained after the diagnosis of FMD1.

This patient presented with two genetic diseases that cause musculoskeletal abnormalities. Hence, whether defective dystrophin and filamin A had interactive or synergic effects was not evaluated in our study but should be considered in the future.

DMD is an X-linked recessive inheritance disorder caused by pathogenic variants in *DMD* that encodes for dystrophin protein, which acts as a connector of the cytoskeleton of muscle fibers and extracellular matrix. These variants help in muscle fiber stabilization during muscle exertion. In the absence of normally functioning dystrophin, progressive muscular damage occurs and regeneration is restricted. Muscle fibers are subsequently transformed into fibrotic or adipose tissues, thus causing pseudohypertrophy (12). In DMD, musculoskeletal complications include progressive muscle degeneration and contracture, resulting in postural compensation or deformities including scoliosis (13). In the later stages, the involvement of cardiac and respiratory muscle becomes apparent. In general, patients require ventilation support during their 20s, and premature death usually occurs during their third or fourth decade of life (14, 15).

FMD1 is a rare genetic disease classified under otopalatodigital syndrome spectrum disorder. It is characterized by skeletal dysplasia, such as multiple joint contractures involving the fingers and/or toes, facial deformity, supraorbital hyperostosis, scoliosis, and sensorineural/conductive hearing loss. The facial features of FMD1 include prominent supraorbital ridge, hypertelorism, and micrognathia (8). In most cases, FMD1

is caused by single-base variants, and all pathogenic variants can maintain the reading frame (9). The *FLNA* comprises 48 exons encoding a 280 kDa filamin A protein. In humans, the filamins are a group of proteins comprising filamins A, B, and C. These proteins are involved in the internal networks of cytoskeleton and filamentous actin rearrangements in the networks in response to mechanical stress. It anchors various transmembrane proteins to the actin cytoskeleton and mediates the signaling processes. Furthermore, filamin A interacts with the glycoprotein-Ib α subunit of the von Willebrand factor receptor, which is associated with cytoskeletal rearrangements, and plays a role in blood vessel and blood clotting (16, 17). Further, filamin C and dystrophin protein were found to have an indirect interaction with each other. However, whether filamin A and dystrophin are correlated or have an interaction with each other is not elucidated (18). Therefore, from a molecular biologic aspect, the presence of these two diseases in one patient is not expected to exert a synergic effect. However, from a clinical aspect, the patient presented with an accelerated deterioration of function, such as gait disturbance, early wheelchair-bound status, severe joint contracture, and scoliosis. If the patient was diagnosed earlier, intensive rehabilitative intervention could have had a positive effect in this case.

TABLE 1 | Pathogenic variants simultaneously found in the X chromosome in patients with DMD.

References	Gender	DMD variant	Combined disease	Combined disease gene variant	Clinical manifestation
Takenaka et al. (20)	Male	Exons 46, 47, 50 deletions (inherited)	Fabry disease (inherited)	α -galactosidase A gene c.409delG	Gait disturbance, weakness, CPK↑
Jiang et al. (21)	Female (skewed X-inactivation)	Exons 30–43 deletions (inherited)	X-linked oculo-facio-cardio-dental syndrome (<i>de novo</i>)	<i>BCOR</i> gene c.1005delC	Muscular hypotonia, weakness, feeding difficulty, CPK↑, congenital anomalies (ASD, cataracts, dental and digital anomalies)
Strmecki et al. (22)	Male	Exons 45–52 deletions (<i>de novo</i>)	Hemophilia A (inherited)	Coagulation factor VIII (<i>F8</i> gene) Inv22 (distal/type I)	Weakness, CPK↑
Varma et al. (23)	Male	Exons 46–52 deletions (<i>de novo</i>)	X-linked myotubular myopathy (inherited)	<i>MTM1</i> gene c.1189dupT (p.Tyr397fs)	Weakness, contractures, poor respiratory effort, facial weakness, feeding difficulty
Kim et al. (current case)	Male	Exons 2–37 duplications (<i>de novo</i>)	Frontometaphyseal dysplasia 1 (inherited)	<i>FLNA</i> gene c.3557C>T (p.Ser1186Leu)	Weakness, gait disturbance, scoliosis, CPK↑, facial dysmorphism, contractures, short stature

CPK, creatine phosphokinase; ASD, atrial septal defect.

The current patient presented with duplications of exons 2–37 in *DMD*, which is an out-of-frame variant, and might have caused DMD (19). In addition, a hemizygous missense variant (NM_001110556.2: c.3557C>T /p.Ser1186Leu) in *FLNA* was previously considered pathogenic, thereby leading to a diagnosis of FMD1.

Until now, there are only a few cases of DMD wherein two or more pathogenic variants occurred simultaneously in the X chromosome. Previous studies have reported Fabry disease (Xq22.1), hemophilia A (Xq28), X-linked myotubular myopathy (Xq28), and oculofaciocardiodental syndrome (Xp11.4) (20–23) (Table 1). *DMD* is the largest human gene known to date, of which one of three pathogenic variants occurs as *de novo*. Hence, in some cases, DMD and other pathogenic variants can coexist in the X chromosome (24).

CONCLUSION

Here we report the co-occurrence of DMD and FMD1 in patient, which has not been previously reported to date. Both diseases showed musculoskeletal involvement and X-linked recessive inheritance. DMD occurred *de novo*, and it was incidentally found that FMD1 was a maternal inheritance. In rare cases, two or more genetic disorders can occur concurrently. Therefore, if one disease does not fully explain the patient's clinical features, an expanded genetic study is required to detect coincidental diseases.

(2021) Clinical Efficiency of
Non-invasive Prenatal Screening
for Common Trisomies in Low-Risk
and Twin Pregnancies.
Front. Genet. 12:661884.
doi: 10.3389/fgene.2021.661884

To evaluate the clinical efficiency of non-invasive prenatal screening (NIPS) for fetal aneuploidies in low-risk and twin pregnancies, patients who received NIPS in a tertiary university hospital were enrolled, and their clinical data, NIPS results and pregnancy outcomes were collected. Patients were divided into singleton and twin pregnancies, and then those with singleton pregnancies were divided into low- and high-risk pregnancies. Sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV) were estimated. Comparisons were made on the clinical efficiency of NIPS between singleton and twin pregnancies, as well as between low- and high-risk pregnancies. Of 66,172 patients enrolled, 59,962 were eligible for analysis. The sensitivity, specificity and NPV were $\geq 99\%$ in singleton and twin pregnancies. The PPVs were 90.4, 56.6, and 13.0% in singleton pregnancies, while 100, 33.3, and 0% in twin pregnancies for trisomy 21 (T21), trisomy 18 (T18) and trisomy 13 (T13), respectively ($P > 0.05$ for all). The PPVs were 97.4 and 90.0% in high-risk pregnancies, while 78.6 and 16.7% in low-risk pregnancies for T21 and T18, respectively ($P < 0.05$ for all). In summary, the performance of NIPS in singleton pregnancies was similar to that in twin pregnancies. NIPS can be recommended for all pregnancies regardless of the risks.

Keywords: non-invasive prenatal screening, twin pregnancy, low-risk pregnancy, trisomy, clinical efficiency

INTRODUCTION

In 1997, Lo et al. found the presence of fetal DNA in maternal plasma (Lo et al., 1997). Then cell-free DNA-based non-invasive prenatal screening (NIPS) has been established to detect fetal aneuploidies (Chiu et al., 2011; Ehrich et al., 2011; Palomaki et al., 2011, 2012; Bianchi et al., 2012; Norton et al., 2012). This technology has been widely used and benefited a lot of women (Chandrasekharan et al., 2014). Previous studies have shown that NIPS has high sensitivity and specificity in detecting common fetal trisomies (trisomies 21, 18, and 13) (Ehrich et al., 2011; Bianchi et al., 2012; Porreco et al., 2014; Gil et al., 2017). A recent meta-analysis estimated that the sensitivity of NIPS was more than 99% for trisomy 21 (T21), and more than 97% for trisomy 18 (T18) and trisomy 13 (T13), with a high specificity of more than 99% for these trisomies, even for low-risk pregnancies

(Rezaei et al., 2019). The positive predictive values (PPV) of NIPS was higher for T21 and T18 than for T13, but PPVs vary in different studies (Chiu et al., 2011; Bianchi et al., 2014; Norton et al., 2015; Petersen et al., 2017; van der Meij et al., 2019). Both the ACMG guideline in 2016 and the updated ACOG guideline in 2020 recommend NIPS as the most sensitive and specific screening for T21, T18 and T13 (Gregg et al., 2016; Rose et al., 2020).

However, most studies focused on the NIPS in singleton and high-risk pregnancies, such as pregnancies of advanced maternal age and high-risk standard screening (Chiu et al., 2011; Palomaki et al., 2011, 2012; Norton et al., 2012). The updated ACOG guideline recommends NIPS be offered to all pregnant women regardless of maternal age or risk. Besides, it suggests NIPS be performed in twin pregnancies, and its performance for T21 was encouraging (Rose et al., 2020). However, the performances of NIPS in low-risk and twin pregnancies were not well understood up to now because of the limited positive cases of aneuploidies, especially the limited positive cases of T18 and T13 in low-risk and twin pregnancies. Meanwhile, few studies have compared the low-risk with the high-risk pregnancies on the detective efficiency of NIPS, and a similar problem exists in singleton and twin pregnancies. Thus, the clinical efficacy research of NIPS in low-risk and twin pregnancies is of great significance for the effective application of NIPS at the present stage.

In the current investigation, 66,172 pregnant women were enrolled in a single-centered tertiary university hospital. The first objective was to evaluate the clinical efficiency of NIPS for fetal T21, T18, and T13 in the overall patients. The second objective was to compare the performance between singleton and twin pregnancies, as well as between high- and low-risk pregnancies. This study will contribute to a more comprehensive understanding of the clinical efficiency of NIPS and reduce unnecessary worries for expanding the scope of application.

MATERIALS AND METHODS

Participants and Data Collection

A retrospective single-centered study was conducted in Women's Hospital, Zhejiang University School of Medicine, and 66,172 pregnant women who received NIPS were enrolled from February 2, 2015, to December 31, 2019. This study was approved by the Ethics Committee of Women's Hospital, Zhejiang University School of Medicine, and all the patients provided their informed consent.

Clinical counseling was provided for all the patients before NIPS was provided. Patients with low-risk NIPS were advised to continue the routine prenatal care, and those with high-risk were advised to receive genetic counseling and invasive prenatal diagnosis. The diagnosis of T21, T18, and T13 depends on the karyotyping and physical examination of the newborn. Pregnancy outcomes of all cases were followed up.

The clinical data included gestational age at sampling, maternal age at the expected date of delivery, fetal numbers, results of standard screening, ultrasonography, NIPS risks, karyotypes and pregnancy outcomes, etc. The standard

screening included the first or second-trimester screening or the combined screening. The first-trimester screening included the measurement of serum biomarkers with or without nuchal translucency (NT). The abnormalities of ultrasound included: (1) micro-anomalies or soft markers, such as increased NT (≥ 2.5 mm), fetal choroid plexus cysts, echogenic intracardiac focus (EIF), nasal bone hypoplasia, nasal bone absence, polyhydramnios, oligohydramnios and single umbilical artery (SUA); (2) structural abnormalities, such as fetal hydrops fetalis, cystic hygroma and urinary tract anomalies. A full-time staff followed up pregnancy outcomes, and the information was obtained by questionnaires or phone calls after delivery.

Study Design

In the primary analysis, sensitivity, specificity, PPV and negative predictive value (NPV) were estimated overall. Patients were divided into two groups: singleton and twin pregnancies, and NIPS performance was compared.

In the secondary analysis, singleton pregnancies were divided into three cohorts based on maternal age, results of standard screening and ultrasonography. In each cohort, patients were further divided into high- and low-risk pregnancies. Those with advanced maternal age, high risk of standard screening and abnormal ultrasonography were incorporated into the high-risk pregnancies, and those without the information above were the low-risk pregnancies. The performance was evaluated and comparisons were made.

NIPS

The DNA extraction, library construction and sequencing were performed according to the protocol of the Human Molecular Genetics Guidelines (Jiang et al., 2012; Chen et al., 2013). Two hundred microliter maternal plasma was used for cell-free fetal DNA extraction by BGISP-300 (BGI, Shenzhen, China) and Nucleic Acid Extraction Kit (BGI, Shenzhen, China). End-repair was performed by adding end-repair enzymes, and PCR was used to amplify DNA. The DNA amplification products were quantified by QubitTM 2.0 (Life Tech, Invitrogen, United States) using QubitTM dsDNA HS Assay Kits (Life Tech, Invitrogen, United States). The volume was calculated according to the concentration of each sample, and samples of the same mass were mixed by pooling. The DNA double strands were thermally denatured after pooling, and then the cyclic buffer and the ligase were added to make DNA circles by the cyclization reaction. DNA circles were used to make DNBs by rolling circle replication (RCR). The concentration of DNBs was quantified by Qubit 2.0 using QubitTM ssDNA Assay Kits (Life Tech, Invitrogen, United States) and the DNBs concentration in the range of 8–40 ng/ μ L was considered as appropriate concentration. The DNBs were loaded onto chips and sequenced on the BGISEQ-500 sequencing platform (BGI, Shenzhen, China). Any sample that failed to meet the quality control criteria (**Supplementary Table 1**) was reported as a detection failure.

The sequence from NGS was compared with the reference sequence map of the human genome, and the percentage of each chromosome was calculated by Illumina Sequencing Analysis

Viewer1.9.1 software. The Z value was used to evaluate the actual disease situation of the samples.

Karyotyping

Amniotic fluid or umbilical cord blood samples were collected. The karyotype was analyzed according to the standard of ISCN (2016) through the process of standardized cell culture, filmmaking and G-banding.

Statistical Analysis

The SPSS statistical software package (version 25.0) was used for statistical analysis. For the analysis of sensitivity, specificity, PPV, NPV and the corresponding 95% confidence intervals (CI), Non-parametric Test of One Sample and the Clopper–Pearson method was used. Chi-square test of Crosstabulation, Pearson Chi-Square or Fisher's Exact Test were used where appropriate. A *P*-value of less than 0.05 was considered to be of statistical significance.

RESULTS

Study Participants

Among 66,172 enrolled patients, 4,716 (7.1%) were excluded because of the drop in follow-up. 1,494 (2.3%) were excluded due to the following situations: (1) missing the data of pregnancy outcomes; (2) missing the data of fetal karyotypes; (3) twin pregnancies but one fetus without the data of pregnancy outcomes or karyotypes; (4) newborns died without karyotypes or physical examinations. 59,962 patients were included for analysis (Figure 1).

Most previous studies focused on the performance of NIPS in high-risk pregnancies. To respond to the updated ACOG guideline in 2020, we focused on low-risk pregnancies. The proportion of high- and low-risk pregnancies varies with the year was shown in Figure 2. High-risk pregnancies had one of the following factors: advanced maternal age, high risk of standard screening, abnormal ultrasonography and personal or family history of aneuploidy. Low-risk pregnancies had none of

FIGURE 2 | The proportion of high- and low-risk pregnancies varies with the year.

the high-risk factors above. There were 30,405 (50.7%) high-risk and 13,731 (22.9%) low-risk patients in all 59,962 patients, respectively. Besides, 15,826 (26.4%) patients could not be grouped because of missing the complete standard screening data, ultrasonography, or information of maternal age.

The clinical characteristics were presented in **Table 1**. The mean maternal age was 32 years old (range 15–60) at delivery, and the mean gestational age was 17⁺ weeks (range 12–37.4) at sampling. In all, 892 (1.5%) patients underwent karyotyping. Among them, 10 were postnatal testing. For the remaining patients, the pregnancy outcomes were based on the physical examinations of the newborns.

Among 59,962 patients, 269 (1 in 223) carried fetuses of aneuploidies that were confirmed by karyotyping. Among them, 215 were T21, 48 were T18 and six were T13, with a prevalence of 1 in 279 for T21, 1 in 1,249 for T18 and 1 in 9,994 for T13, respectively.

Primary Analysis

Overall Performance

Among the 59,962 patients, 213 were true positive (TP), 22 were false positive (FP) and two were false negative (FN) for T21; 48 were TP, 38 were FP and none was FN for T18; six were TP, 45 were FP and none was FN for T13. The estimated sensitivity, specificity, PPV and NPV were listed in **Table 2**.

Performance in Singleton and Twin Pregnancies

Among the 57,563 women with singleton pregnancies, 206 were TP, 22 were FP and two were FN for T21; 47 were TP, 36 were FP and none was FN for T18; six were TP, 40 were FP and none

was FN for T13. Among the 2,399 women with twin pregnancies, seven were TP, none was FP or FN for T21; one was TP, two were FP and none was FN for T18; none was TP, five were FP and none was FN for T13. The detective efficiency and comparisons

between the two groups were listed in **Table 3**. Except for the specificity of T13 ($P = 0.03$), there was no statistical difference ($P > 0.05$ for all).

Secondary Analysis

About 96.0% (57,563 in 59,962) of women were singleton, and 97.0% (261 in 269) of T21, T18 and T13 were detected in singleton pregnancies. Of the three cohorts of maternal age, standard screening and ultrasonography in singleton pregnancies, the detective efficiency was estimated and comparisons were made on the clinical efficiency between low- and high-risk pregnancies (**Table 4**).

*The paired groups could not make comparisons.

The Cohort of Maternal Age

Among the 31,359 patients who were under 35 years old at delivery (low-risk), 101 were TP, 10 were FP and one was FN for T21; 22 were TP, 23 were FP and none was FN for T18; three were TP, 25 were FP and none was FN for T13. Among the 22,324 patients who were 35 years old or older (high-risk), 96 were TP, ten were FP and one was FN for T21; 23 were TP, 12 were FP and none was FN for T18; two were TP, 13 were FP and none was FN for T13. There was no significant difference in detective efficiency between the two groups ($P > 0.05$ for all).

The Cohort of Standard Screening

Among the 14,902 patients who were at low risk of standard screening, 22 were TP, six were FP and one was FN for T21; three were TP, 15 were FP and none was FN for T18; none was TP, ten were FP and none was FN for T13. The incidence was 0.2% (23/14,902) for T21, 0.02% (3/14,902) for T18 and 0% (0/14,902) for T13, respectively. Among the 5,362 patients who were at high risk of standard screening, 38 were TP, one was FP and none was FN for T21; nine were TP, one was FP and none was FN for T18; one was TP, two were FP and none was FN for T13. The incidence was 0.7% (38/5,362) for T21, 0.2% (9/5,362) for T18 and 0.02% (1/5,362) for T13, respectively. The incidence of T21 and T18 was significantly higher in the high-risk than in the low-risk group ($P < 0.01$ for both). Except for the PPV of T21 ($P = 0.02$) and T18 ($P \leq 0.01$), there was no statistical difference ($P > 0.05$) between the two groups.

The Cohort of Ultrasonography

Among the 51,080 patients who had normal ultrasonography (low-risk), 151 were TP, 19 were FP and none was FN for T21; 35 were TP, 35 were FP and none was FN for T18; three were TP, 32 were FP and none was FN for T13. The incidence was 0.3% (151/51,080) for T21, 0.1% (35/51,080) for T18 and 0.01% (3/51,080) for T13, respectively. Among the 2,606 patients who had abnormal ultrasonography (high-risk), 46 were TP, one was FP and two were FN for T21; 11 were TP, none was FP and none was FN for T18; two were TP, six were FP and none was FN for T13. The incidence was 1.8% (48/2,606) for T21, 0.4% (11/2,606) for T18 and 0.1% (2/2,606) for T13, respectively. The incidence of T21, T18 and T13 was higher in the high-risk than in the low-risk group ($P < 0.01$ for T21 and T18; $P = 0.02$ for T13). Except for the NPV of T21 ($P \leq 0.01$), PPV of T18 ($P \leq 0.01$) and specificity of T13 ($P \leq 0.01$), there was no statistical difference ($P > 0.05$) between the two groups.

The comparisons were made between the paired groups on the sensitivity, specificity, PPV and NPV. The P-values (two-sided) were marked if there was a statistical significance; [♂]the cut-off value was < 1/270 for T21 and < 1/350 for T18 in the low-risk group; the cut-off value was ≥ 1/270 for T21 and ≥ 1/350 for T18 in the high-risk group; [‡]patients had no high-risk factors, including maternal age, standard screening, ultrasonography and personal or family history of aneuploidy simultaneously; [§] P < 0.05; [‡]P < 0.01; *the paired groups could not make comparisons.

Performance in the Low-Risk Pregnancies

Among the 13,731 patients without any high-risk factors, 19 were TP, six were FP and none was FN for T21; 3 were TP, 15 were FP and none was FN for T18; none was TP, nine were FP, and none was FN for T13.

False-Negative Cases

There were two false-negative cases of singleton pregnancies. For case 1, the woman was 29 years old with a body mass index (BMI) of 27.3 and a normal karyotype. She had a low-risk standard screening. NIPS was conducted at the gestational age of 13 weeks. The fetal fraction of DNA was unknown. For case 2, the woman was 39 years old with a BMI of 24.8 and a normal karyotype.

NIPS was conducted at the gestational age of 13⁺ weeks. The fetal fraction of DNA was 7%. No other high-risk factors were found before the screening except for the increased NT (3 mm for case 1 and 7.1 mm for case 2). It was confirmed that the karyotype of case 1 was 47, XX, + 21(15)/46, XX(85). Case 2 underwent the prenatal diagnosis because of the abnormal ultrasonography of hydroncus and complete cardiac cushion defect, and the confirmed karyotype was 47, XN, +21.

DISCUSSION

In this retrospectively single-centered study, we found that NIPS had high sensitivity, specificity and NPV for detecting common

fetal trisomies in pregnancies with all risk levels, which was similar to a multicenter prospective study in China (Zhang et al., 2015). The PPV of NIPS was highest for T21 (90.6%), moderate for T18 (55.8%), and relatively low for T13 (11.8%). Our study included singleton and twin pregnancies, as well as pregnancies of all risk levels. We found that the performance of NIPS in singleton pregnancies was similar to that in twin pregnancies. With the higher incidence of T21 and T18 in high-risk pregnancies, the PPV was higher in high-risk than in low-risk pregnancies, but the high sensitivity, specificity and NPV were shown in both high- and low-risk pregnancies. Two false-negative cases of T21 were identified in pregnancies with abnormal ultrasonography, indicating that the pregnancies with abnormal ultrasonography should receive the prenatal diagnosis. The confirmed mosaic T21 indicates that fetal mosaicism is an important cause of false-negative NIPS.

In the current study, the high-risk patients were the main population for NIPS, indicating that NIPS has mainly been applied for or chosen by high-risk pregnant women, and this is inconsistent with the 2020 ACOG guidelines. One reason for this might be that patients who were at high risk would like to choose the NIPS first. The second reason might be the marked increase in pregnant women with advanced maternal age due to the two-child policy in China (Tian et al., 2020). NIPS had a similar performance on sensitivity, specificity, PPV and NPV in different maternal ages in the current observation, and it was consistent with a previous report, but they only analyzed the sensitivity (Dar et al., 2014).

Generally, the incidence of fetal trisomies was higher in the high-risk than in the low-risk pregnancies (Nicolaidis et al., 2012). In our study, the incidence of fetal T21 was higher in the high-risk than in the low-risk standard screening, and the same was found for T18 in standard screening and ultrasonography cohorts. The higher incidence might explain the higher PPV in high-risk pregnancies because the PPV is associated with the number of positive cases in the population (Neufeld-Kaiser et al., 2015; Wang et al., 2015). In our study, the PPVs for T21, T18, and T13 were lower than a multicenter prospective study in China (Zhang et al., 2015), and lower than a national study in the Netherlands in which the PPV was 96% for T21, 98% for T18 and 53% for T13, respectively (van der Meij et al., 2019). The possible reason is that the first study was performed begin 2012 when the enrolled cases were mainly high-risk pregnancies. Therefore, they had a higher incidence of aneuploidies (1/155, 1/663, and 1/5,121 for T21, T18, and T13, respectively) and higher PPVs. The second study had a higher follow-up rate than ours, especially for cases with a high-risk NIPS. While in our cohort, some cases that had a high-risk NIPS rejected karyotyping or were lost to follow-up, and these cases might carry fetal trisomies. Considering those, the incidence of trisomies in our cohort may be lower than it was, so as PPV. Even though the higher PPV in high-risk pregnancies, we could not directly conclude that NIPS performs better in high-risk pregnancies because the ability of the test is determined by the precision of the technology and fetal fractions in the maternal blood rather than the incidence of trisomies in the population (Ashoor et al., 2012; Nicolaidis et al., 2012). Additionally, the high specificity and NPV in each group of the three cohorts as

well as in low-risk pregnancies showed the excellent ability of NIPS in excluding the unaffected pregnancies at any risk levels.

Herein, we proved the high sensitivity of NIPS in singleton and twin pregnancies, which is similar to previous reports (Gil et al., 2015, 2017). Due to the similar performance of NIPS in twin and singleton pregnancies (Fosler et al., 2017; Niemchak et al., 2020), some researchers considered that it could be used as a first-line screening in twin pregnancies (Le Conte et al., 2018; Yu et al., 2019). However, on account of the limited cases of trisomies in twin pregnancies, especially T18 and T13, the performance of NIPS may be unrepresentative and it needs to be further evaluated (Gil et al., 2019).

Two cases of false-negative T21 were identified in pregnancies with abnormal ultrasonography, and it lowered the NPV in this population. These discordant results highlight the irreplaceable status of early ultrasound in prenatal screening strategies (Hui et al., 2017), and NIPS is not a diagnostic test with inevitable false-positive and false-negative results (Allyse and Wick, 2018). More importantly, for those with abnormal ultrasonography, prenatal diagnosis instead of NIPS is essential, which has been issued in a previous study (Beulen et al., 2017), and it has been reported that the rate of pathogenic chromosome abnormalities missed by NIPS in the population of abnormal ultrasonography was 8% (Benachi et al., 2015), which was higher than ours (4%), but we only estimated the common trisomies. Causes of false-negative NIPS include low fetal fraction, which is caused by maternal obesity, multiple gestations causing low fetal fraction per fetus, maternal medical condition or treatment affecting the quality of circulating DNA, certain fetal chromosomal aneuploidies and confined placental mosaicism (Bianchi and Chiu, 2018). In this study, fetal mosaicism was confirmed by the karyotyping, causing the false-negative NIPS of case 1, and a similar finding has been reported in another study (Grati et al., 2014). For case 2, the fetal fraction was 7%, and it was a singleton pregnancy with a BMI of 24.8 and a normal karyotype. Meanwhile, there was no maternal medical condition or treatment during that time. A similar finding has been reported in an obvious study in which placental samples of two false-negative cases of T18 were obtained and both showed low-level confined placental mosaicism of T18 (Zhang et al., 2015). So, confined placental mosaicism may be the cause of false-negative NIPS of case 2.

There are several strengths in this study. Firstly, we assessed the performance of NIPS for common trisomies in a large population with different risk levels. Secondly, we make comparisons of singleton and twin pregnancies and confirmed a similar performance. Thirdly, we make comparisons of low- and high-risk populations in singleton pregnancies, and in which, the analysis was based on a single cohort of maternal age, conventional Down screening, or ultrasonography instead of the combined risk factors (Zhang et al., 2015). This study is the first large-scale retrospective study to assess the performance of NIPS in twin and low-risk pregnancies since the publication of the updated ACOG guideline.

There are also limitations in our study. Firstly, more than 4,400 patients lack information on maternal age, and some did not receive standard and ultrasound screening. So, we could not assess the risk levels of aneuploidy for these patients

accurately. Secondly, we did not enroll cases that had no-call NIPS results and cases that had intrauterine fetal demise or selective termination of pregnancy, but they may be high risk for aneuploidy (Norton et al., 2015). From this point of view, our results may be little different from reality.

CONCLUSION

NIPS has excellent clinical efficiency for common fetal trisomies in the overall patients at different risks, and its performance in singleton pregnancies was similar to that in twin pregnancies. However, NIPS cannot replace the invasive prenatal diagnosis, and fetuses with abnormal ultrasonography should undergo prenatal diagnosis.

Reveals a Rare Variant of *OTOF* Gene
Causing Congenital Non-syndromic
Hearing Loss Among Large Muslim
Families Favoring Consanguinity.
Front. Genet. 12:641925.
doi: 10.3389/fgene.2021.641925

Non-syndromic hearing loss (NSHL) is one of the most frequent auditory deficits in humans characterized by high clinical and genetic heterogeneity. Very few studies have reported the relationship between *OTOF* (Locus: DFNB9) and hereditary hearing loss in India. We aimed to decipher the genetic cause of prelingual NSHL in a large affected Muslim consanguineous families using whole-exome sequencing (WES). The study was performed following the guidelines and regulations of the Indian Council of Medical Research (ICMR), New Delhi. The population was identified from Jammu and Kashmir, the Northernmost part of India. Near about 100 individuals were born deaf-mute in the village of 3,000 inhabitants. A total of 103 individuals (with 52 cases and 51 controls) agreed to participate in this study. Our study revealed a rare non-sense homozygous mutation NC_000002.11:g.2:26702224G>A; NM_001287489.2:c.2122C>T; NP_001274418.1:p.(Arg708*) in the 18th exon of the *OTOF* gene. Our study provides the first insight into this homozygous condition, which has not been previously reported in ExAC, 1,000 Genome and genomAD databases. Furthermore, the variant was confirmed in the population cohort ($n = 103$) using Sanger sequencing. In addition to the pathogenic *OTOF* variant, the WES data also revealed novel and recurrent mutations in *CDH23*, *GJB2*, *MYO15A*, *OTOF*, and *SLC26A4* genes. The rare pathogenic and the novel variants observed in this study have been submitted to the ClinVar database and are publicly available online with the accessions SCV001448680.1, SCV001448682.1 and SCV001448681.1. We conclude that *OTOF*-related NSHL hearing loss is prevalent in the region due to successive inbreeding in its generations. We recommend premarital genetic testing and genetic counseling strategies to minimize and control the disease risk in future generations.

Keywords: hearing disorders, hearing impairment, deaf mutes, autosomal recessive (AR) diseases, cousin marriages, Indian population, Jammu and Kashmir (J and K), genetic counseling

INTRODUCTION

Over 446 million people have disabling hearing loss worldwide. This estimate is projected to accelerate over 630 million by 2,030 and may raise up to 900 million in 2,050 (Olusanya et al., 2019). The global prevalence of prelingual hearing loss is 1 in 500 newborns and is the 4th leading cause of disability among living individuals (Duman and Tekin, 2012). Phenotypically, hereditary hearing loss (HHL) can be classified into syndromic hearing loss (SHL) and non-syndromic hearing loss (NSHL). The NSHL is one of the most frequent sensory deficits in humans characterized by high clinical and genetic heterogeneity. Approximately 90% of NSHL cases from severe to profound congenital deafness exhibit an autosomal-recessive (AR) pattern of inheritance (DFNB forms). The prevalence of prelingual NSHL is approximately 2.7 cases per 1,000 live births (Vona et al., 2015).

Genotype-phenotype correlations help in understanding the mechanistic etiology, progression, and prognosis of the inherited genetic disorder. However, in case of NSHL, the diagnosis becomes more challenging due to high clinical complexity and genetic heterogeneity. The molecular elucidation of such complex disorder with precise genomic approaches can provide genetic origin and functional consequences, which could be better implemented for proper medical investigation, prognostic, and therapeutic targets. To date, a total of 116 NSHL genes have been identified¹. Out of these, 45 genes for autosomal dominant-NSHL (AD-NSHL), 5 genes for X-linked and about 75 genes are linked with AR-NSHL. The product of these genes has multiple roles in maintaining the normal physiology of the inner ear. Mutation in any of these genes may have a deleterious impact, altering the normal hearing physiology (Shearer et al., 1993).

Hearing loss is a severe disorder but grossly neglected in India. According to World Health Organization (2018) data, the prevalence of auditory deficit in the country is over 63 million (about 6.3%) of the total population. The population of India and other South Asian countries provides much complexity due to the admixture of their genomes during evolutionary timescales (Patterson et al., 2012). To discover genetic variations of the heterogenetic disorder in such an ethnic group and/or geographically isolated population may need highly equipped and rigorous diagnostic approaches. Massive parallel sequencing (MPS) or next-generation sequencing (NGS) technologies provide an opportunity to precisely explore the genetic architecture of the disease, which furthermore could be used as a baseline for medical genetic testing (Shearer et al., 2010). Very few studies have reported the relationship between *OTOF* (Locus: DFNB9) and HHL in India.

Here, we employed the whole-exome sequencing (WES) approach to precisely identify the functional pathogenic mutations causing congenital hearing loss from the Muslim population favoring consanguinity.

MATERIALS AND METHODS

Study Population

The cohort was selected from the Doda District of Jammu and Kashmir, North India. Approximate 3,000 residents inhabited this village, belonging to the Muslim community favoring consanguinity in their ancestry. To date, in this village, more than 100 individuals were born deaf-mute; some of them migrated to other states (i.e., Punjab, India) and a few to nearby districts. In our preliminary survey, we identified 74 deaf-mute live and 3 deceased cases. **Figure 1** presents the pedigree and inheritance detail of all 77 cases. Out of 74 deaf-mutes, only 52 cases were agreed to participate in the study. A total of 103 individuals aged 20–60 years (with 52 cases and 51 controls) were recruited for this study. WES was performed in 07 samples with 02 cases (i.e., F7 and G8) and 05 controls (i.e., C4, D5, H9, K11, and M12), while the rest ($n = 96$) were subjected to Sanger sequencing to confirm the candidate pathogenic variant.

Sample Collection, DNA Isolation and Quantification

Blood samples were collected using a 21-gage syringe to draw up to a volume of 5 ml in a vacutainer containing Tris-EDTA. For saliva samples, the participants were provided with collection tubes and were asked to provide a 2.5 ml sample. The participants were instructed to spit into the tube up to the red fill line marked on the tube (approximately 2.5 ml), excluding the froth. DNA was extracted using QIAamp DNA Mini Kit 50 (Cat# 51304, Qiagen). The DNA samples were subjected to QIAxpert for quantifying the amount of DNA and the purity was checked by measuring the 260/280 nm ratio. DNA samples were also subjected to agarose gel electrophoresis and, after passing through DNA quality check (**Supplementary Table 1**), were proceeded for Library Protocol.

Whole-Exome Sequencing and Bioinformatic Analysis

The WES library was prepared using Agilent-Sure Select XT Reagent Kit, Illumina (ILM) platforms. Biotinylated oligonucleotide capture probes (V5 + UTR), also called baits, that was designed for the human exons was provided with the kit and used to enrich the region of interest (whole exome) by hybridization. The workflow involved shearing of DNA, repairing ends, adenylation of 3' ends, followed by adapter ligation. At each step, the products were purified using AMPure beads. The adapter sequence was added onto the ends of DNA fragments to generate paired-end libraries. The resulting adaptor-ligated library was purified, quantified and hybridized with an exome-specific biotinylated capture library. After hybridization, the targeted molecules were captured on streptavidin beads. The resulting enriched DNA library was multiplexed by adding index tags by amplification, followed by purification. Indexed captured library DNA was assessed to check the quality and quantity of the captured libraries. The sequencing was carried out in Illumina HiSeq X10 to generate 2X–150 bp sequence reads at an average 100– sequencing depth. Only those samples

FIGURE 1 | Pedigree and inheritance of deaf-mute syndrome in the families. **(A,B)** are the two large family trees and **(A)** have two sub-family trees expatiated from its first and second generations. The extended family from the first family tree (circled blue) was considered for whole-exome sequencing. The squares and circles represent males and females, respectively, where the cases are presented in red color.

were considered for data processing that surpasses the quality scores (Q30 value) greater than 75% of the sequenced bases. The base quality distribution, base content and the GC content are presented in **Supplementary Figure 1**. The overall alignment

percentage (alignment to GRCh37/hg19) in all the samples was greater than 97% (**Supplementary Table 2**). The average coverage and on-target percentage for the samples was around 99 and 90%, respectively (**Supplementary Table 3**). The distribution

of sequencing depth is shown in **Supplementary Figure 2**. The sequencing reads were processed and analyzed using the BROAD Institute's Genome Analysis Toolkit (GATK-Toolkit) (DePristo et al., 2011) and variant calling was performed using the complete human reference genome (hg19, NCBI release GRCh37).

The bioinformatic pipelines (alignment variant calling and variant annotation) used in our study are shown in **Supplementary Figure 3**. All common polymorphisms with a minor allele frequency (MAF) higher than 0.01 were filtered out using several public databases such as 1,000 genomes database (1000 Genomes Project Consortium et al., 2015), Ensembl GRCh37 genome browser (Zerbino et al., 2018), exome aggregation consortium database (ExAC) (Lek et al., 2016), genome aggregation database (gnomAD) (Karczewski et al., 2020), and database of single nucleotide polymorphisms (dbSNP). The ClinVar database was used to check the previously reported mutations and associated phenotypes. Exclusion of intronic, synonymous, inframe insertions/deletions (InDels) and mutations in untranslated regions whereas the missense, non-sense variations and frameshift InDels located in exons or splice sites were prioritized. The remaining variants were then verified in dbSNP and NCBI databases.

***In silico* Evaluation for the Pathogenicity of Candidate Mutation**

The altered amino acid was checked for its evolutionary conservation across different species, including the primates and mammals using the genome browser of the University of California at Santa Cruz (UCSC) (Kent et al., 2002). *In silico* programs including MutationTaster2 (Schwarz et al., 2014), PolyPhen-2 (Adzhubei et al., 2010) and scale-invariant feature transform (SIFT) (Kumar et al., 2009) were used to predict the possible impact of the detected variants.

Audiometric Characteristics

The pulse tone audiometric (PTA) records of the subjects were noted. The hearing level grades were categorized according to WHO and the National Hearing Test (NHT) guidelines viz., normal (<20 dB), mild (20–40 dB), moderate (41–70 dB), severe (71–90 dB), and profound (>90 dB). The average values of both the ears (left and right) were considered to calculate the hearing threshold levels. The age of the individual was also recorded at the time of audiometry.

Co-segregation Analysis

Whole-exome sequencing (at 100X depth) provides sufficient details for the confirmation of the candidate variant. However, Sanger sequencing has also been performed to re-validate/or reconfirm the mutation identified by targeted NGS. Primers (PXL-A0145439) for exon 18 of the *OTOF* gene (reference sequence NM_001287489.2 and Chr2:26669916-26791779 context region in hg19), were manufactured and supplied by Pxlence². The thermal cycler program was set according to the manufacturer's instructions, using the conditions: initial

incubation 98°C for 2 min, 98°C for 20 sec, followed by 35 cycles at 60°C for 30 s, 72°C for 40 s, final extension 72°C for 10 min and hold at 4°C. PCR products were confirmed using a 1.7% w/v agarose gel electrophoresis. The PCR products were then processed for cycle sequencing/BigDye terminator assay, followed by Sephadex (column-based) purification. Finally, the PCR products were loaded onto DNA Sequencer (SeqStudio Genetic Analyzer).

RESULTS

Identification of a Pathogenic Mutation Using Whole-Exome Sequencing

The variants produced from exome-sequencing are presented in **Supplementary Tables 4–6**. WES analysis generated approximately 72,000 genetic variants (including SNPs, insertions and deletions) in each sample. By applying the narrow down filtering approach, the number of probable causative mutations are presented in **Supplementary Tables 7–9**, respectively. The variant filtering strategy used to find out the most promising causative mutation has been presented in **Figure 2**. The most promising causative variants have been presented in **Supplementary Table 10**. After the removal of duplicates and common mutations, the variants were filtered for rare (<1%), evolutionary conserved and functional homozygous recessive mutations using the online GenIO database (an integrated pipeline based on RefGene, NHLBI-ESP, 1,000 Genomes, dbSNP, ClinVar, COSMIC, gnomAD, OMIM and M-CAP databases) following the American College of Medical Genetics and Genomics and the Association of Molecular Pathology (ACMG-AMP) guidelines (Koile et al., 2018). We observed approximately 03 homozygous and 140 heterozygous mutations (likely to be pathogenic, global MAF <0.01) among the two cases (F7 and G8). After the removal of overlapping variants with controls and considering the conserved in evolution (GERP score >0), we thus identified the disease-causing rare variant NC_000002.11:g.2:26702224G > A; NM_001287489.2:c.2122C > T; NP_001274418.1:p.(Arg708*) (rs80356590) in 18th exon of the *OTOF* gene. This *OTOF* variant is very rare and no homozygous variant previously reported in gnomAD, ExAC, and 1,000 Genome databases; however, few heterozygous cases have been reported in gnomAD. We confirmed the *OTOF* mutation using BAM and VCF files in IGV 2.5.3 software.

The functional consequence (*in silico* validation) of the variant was predicted using Mutation Taster (**Table 1**), which revealed the deleterious consequence homozygous condition by premature terminating the otoferlin protein at 708 amino acid. The substitution of the arginine by a premature stop codon p.(Arg708*) produces a truncated variant of otoferlin remains non-functional in the sensory hair cells, potentially causing profound hearing loss.

In addition to the rare pathogenic *OTOF* variant, the WES data also revealed some novel and rare recurrent genomic mutations in the extended family. The novel variants (not found in ExAC, 1,000 G and gnomAD databases) of

The stop codon insertion by the variant (NM_001287489.2:c.2122C > T) terminates the protein at 708 position (NP_001274418.1:p.Arg708*), causing the loss of various functional domains.

OTOG NM_001292063.2:c.5438T > G; NP_001264198.1:p.(Val1813Gly) and *SLC26A4* NM_000441.2:c.1668T > A NP_000432.1:p.(Tyr556*) and the recurrent variants of *CDH23* NM_022124.6:c.4892C > T NP_071407.4:p.(Ala1631Val), *GJB2* NM_004004.6:c.493C > T NP_003995.2:p.(Arg165Trp), *MYO15A* NM_016239.4:c.5894G > A NP_057323.3:p.(Arg1965His) and others (presented in **Supplementary Table 10**) were observed in heterozygous/or compound heterozygous conditions. The candidate pathogenic (*OTOF*) and the novel variants (*OTOG* and *SLC26A4*) have been submitted to ClinVar database and are publicly available online with the accessions SCV001448680.1, SCV001448682.1, and SCV001448681.1, respectively.

Audiometric and Genotypic Characteristics

All subjects (cases and controls) showed normal clinical features (i.e., no structural and observable phenotypic deformity) other than hearing. The audiometric and genomic characteristics of proband have been presented in **Figure 3**. The normal individuals (control) showed the hearing level in between 0–20 dB at frequencies 0.125, 0.25, 0.5, 1, 2, 3, 4, 6, and 8 kHz. However, the threshold level of deaf-mute subjects falls under a profound (>90 dB) category for the same audio frequencies (**Figure 3A**). The cases F7 (aged 31 years), G8 (aged 25 years) exhibit the characteristics of profound prelingual NSHL. The WES data of cases (F7 and G8) and controls C4 (aged 43 years), D5 (aged 35 years), H9 (aged 60 years), K11 (aged 22 years), and M12 (aged 34 years) have been shown in **Figure 3B**. The cases (F7 and G8) carry a homozygous mutation; among controls, the C4, H9, and M12 possess heterozygous and D5 and K11 are homozygous for the reference allele (carrying no *OTOF* mutation).

Co-segregation Analysis

The family pedigree and *OTOF* segregation with the disease phenotype has been well demonstrated in **Supplementary Figure 4a**. The next generation WES (**Figure 3B**) and Sanger sequencing data (**Supplementary Figure 4B**) provides the evidence for perfect segregation of the *OTOF* variant with the auditory phenotype. The data clearly depicts the autosomal recessive non-syndromic hearing loss (ARNSHL). Further, Sanger sequencing was performed in the remaining 96 samples to reconfirm the mutation pattern of the *OTOF* gene. The genotypic details of the candidate variant of *OTOF* gene for all 103 subjects have been displayed in **Figure 4**. The ancestral lineage of the subjects has a history of consanguineous marriages which determines the existence of the phenotypic spectrum of *OTOF* in the current generation.

DISCUSSION

The results of our study indicate that a non-sense mutation in the *OTOF* gene was terminating the peptide chain and generating a truncated protein variant, which ultimately leads to prelingual neurosensory non-syndromic DFNB9 (OMIM, #601071) hearing loss. The functional evidence of the *OTOF* relationship with DFNB9 impairment has been well established by earlier studies (Roux et al., 2006; Pangršič et al., 2012). The *OTOF*-related NSHL has been previously reported in the populations from India, Pakistan, China, Japan, Altai Republic, Korea, Spain, Turkey, and Iran (Yasunaga et al., 2000; Tekin et al., 2005; Rodríguez-Ballesteros et al., 2008; Choi et al., 2009; Wang et al., 2010; Mahdiah et al., 2012; Ćhurbanov et al., 2016; Kim et al., 2018; Iwasa et al., 2019). In addition to *OTOF*-related deafness, mutations in the autosomal genes like *CDH23*, *Claudin14*, *GJB2*, *GJB6*, *MYO6*, *MYO15A*, *SLC26A4*, *TMC1*, *TMIE*, *TMPRSS3*, *TRIOBP*, *USHIC*, and others are predominant to cause HHL among Indian and Pakistani populations (Yan et al., 2015). It is evident from the previous studies that the mutation spectrum of *GJB2*, *GJB6*, *SLC26A4*, and *TMC1* genes was much common in the ethnic groups of eastern and southern parts of India (Padma et al., 2009; Ganapathy et al., 2014; Adhikary et al., 2015; Singh et al., 2018). In the present study, we have also identified the missense/non-sense heterozygous variants in the *OTOG* p.(Val1813Gly), *SLC26A4* p.(Tyr556*) *CDH23* p.(Ala1631Val), *GJB2* p.(Arg165Trp), and *MYO15A* p.(Arg1965His) genes which are predominant to cause deafness among Indian populations.

Otoferlin is a transmembrane vesicular protein (1997 amino acids in humans) encoded by the *OTOF* gene, spanning in the short arm of chromosome 2 (2p23.3). The otoferlin is expressed in the inner hair cells (IHCs) (Liu et al., 2014) and plays a significant role in neuronal synapse and exocytosis (Shin, 2014). The protein consists of six C2 domains (C2A-F), two Ferlin conserved motifs (Fer-1 and Fer-B) and a transmembrane domain (TMD). Using the Treefam database, Schreiber et al. (2014) the close relationship of otoferlin across different species depicts the domains and motifs that were highly conserved (**Figure 5A**). The functional evidence for the high level of protein

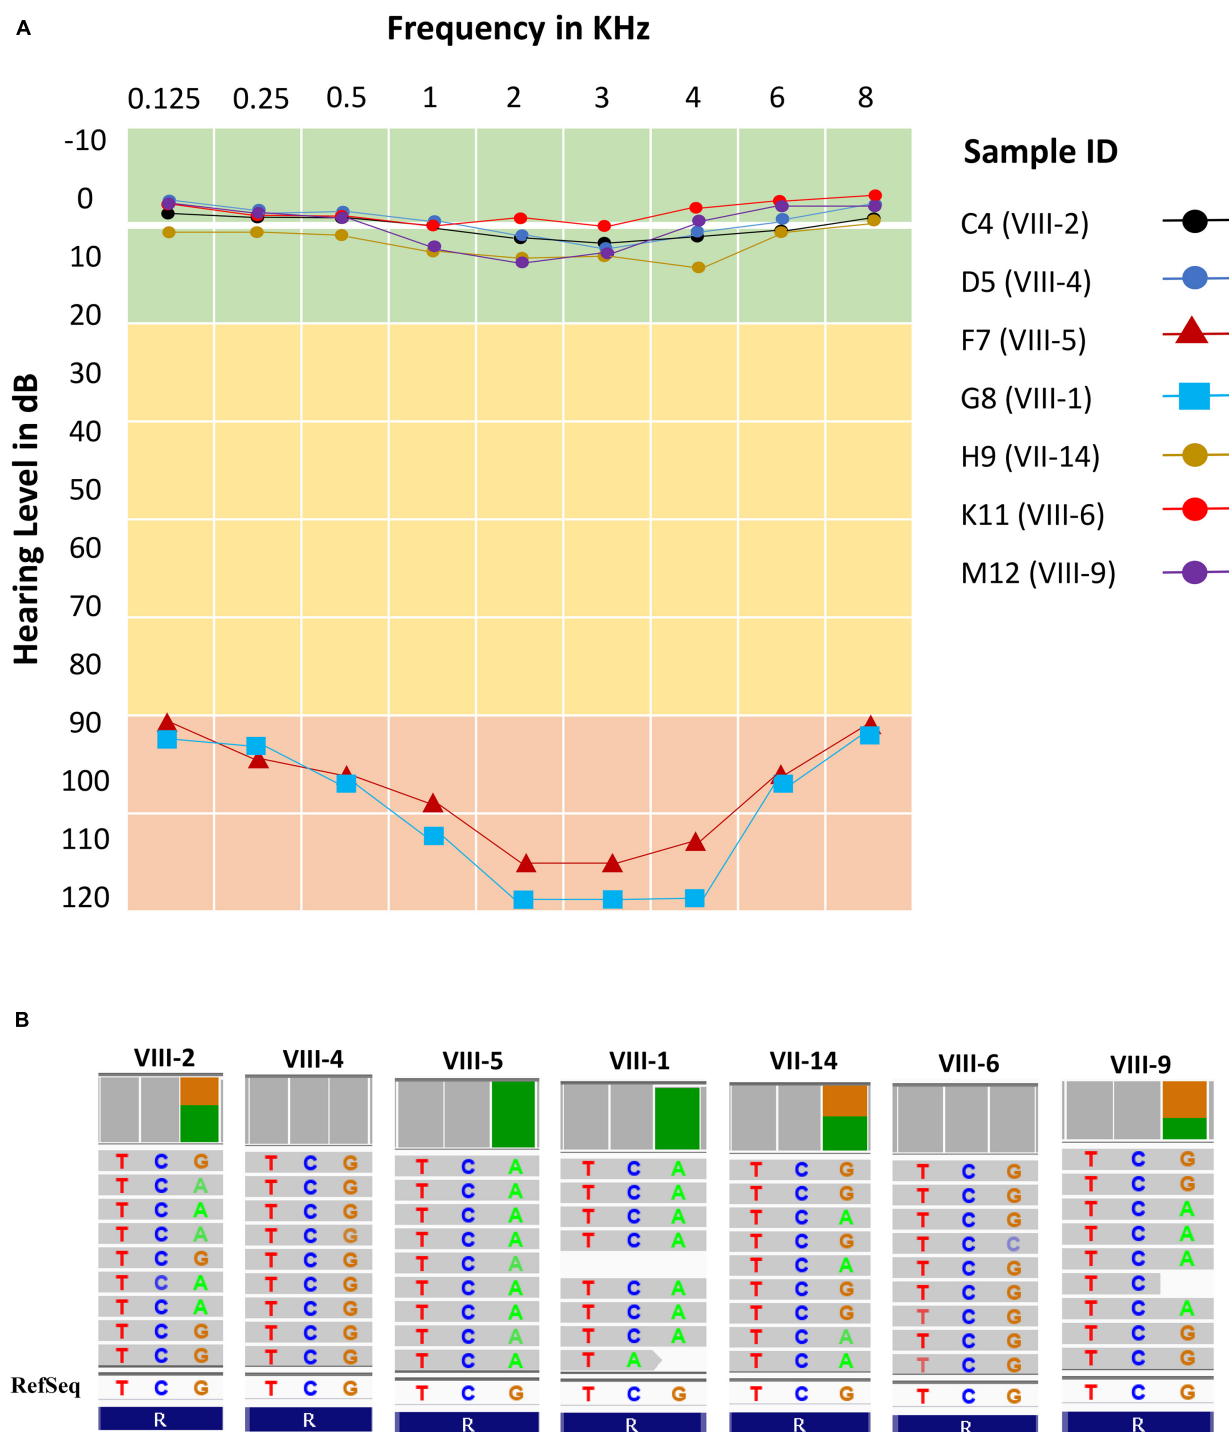

FIGURE 3 | Audiometric characteristics and whole exome data. **(A)** Audiometric data shows five normal hearing subjects (levels between 0 and 10 dB) and two cases (levels > 90 dB) for all frequencies (KHz). **(B)** Whole exome data reflects exactly the phenotypic data with two homozygous cases (F7 and G8), three heterozygous normal (C4, H9, and M12) and two normal with homozygous reference allele (D5 and K11).

conservation at the site of *OTOF* mutation (NP_001274418.1:p.Arg708*) in 8 vertebrates has been displayed in **Figure 5B** and **Supplementary Figure 5a** (using UCSC Genome Browser). The mRNA levels in 20 different tissues reveal the *OTOF* in the brain

is highly expressed (**Supplementary Figure 5b**). The protein-protein interactions of *OTOF* using STRING v11.0 confirm the functional involvement in the neuronal synapse, exocytosis and hearing functions (**Figure 5C**; Szklarczyk et al., 2019).

The non-sense mutations in the *OTOF* gene producing truncated versions of protein causing DFNB9 deafness has been well-established by the researchers using *in vitro* and *in vivo* models in their experiments (Pangršić et al., 2012; Chatterjee et al., 2015; Hams et al., 2017). In the present study, a similar non-sense mutation (NM_001287489.2:c.2122C > T) results in the protein truncation at p.(Arg708*) eventually altering the normal otoferlin physiology. The truncated otoferlin (N-terminus C2A-C) lacking C2D-F and TMD remain unbound with no membrane fusion or exocytosis, which ultimately halts the neurotransmitter release, causing profound hearing loss. Based upon the substantial evidence from *in silico* testing (Table 1) and previously well-established proofs of protein truncation due to different *OTOF* non-sense mutations (Chatterjee et al., 2015; Hams et al., 2017), we propose a schematic model showing the role of otoferlin protein with normal and altered physiology via p.(Arg708*) in the current study (Figure 6). The otoferlin held on synaptic vesicles via TMD and C2 domains interact with the presynaptic membrane via SNAREs to execute exocytosis under Ca^{2+} influx. It is evident from the previous studies that missense mutations in C2B and C2C domains have been linked to hearing loss (Mirghomizadeh et al., 2002; Helfmann et al., 2011). N-terminal domains' role provides structural stability to the protein and C-terminal domains (C2D-F) may play a functionally conserved or redundant role in otoferlin physiology (Chatterjee et al., 2015). Our findings predict the otoferlin synthesis stops at 708 amino acid (between C2C and FerB domains), leading to almost half protein (N-terminal with C2A-C domains) lacking the most conserved and functional part (C2D-F with TMD at C-terminus).

Parental consanguinity has been associated with an increased risk of autosomal recessive disorders (Fareed and Afzal,

2017). The consanguineous marriages with the adverse effects have been previously reported from the Muslim populations of Jammu and Kashmir (Fareed and Afzal, 2014a,b, 2016; Fareed et al., 2017). In the present study, the prevalence of prelingual hearing loss was 1 in 30, considerably higher than the global prevalence (Duman and Tekin, 2012), providing the evident consequence of inbreeding in the population. It might be possible that these groups have settled to the northernmost region of India during the evolutionary time frames and unknowingly have undergone marriages within the groups, which ultimately increased the prevalence of the disorder.

CONCLUSION

The present study evaluated the ARNSHL in a tribal family of the Jammu and Kashmir region. The clinical audiometric evaluation and the information gathered from village representatives suggest the profound prelingual NSHL prevailing in the area. WES categorizes the rare pathogenic mutation in the *OTOF* gene p.(Arg708*), which has been well segregated with the disease. *OTOF* plays a significant role in the neuronal synapse in the IHCs of the cochlea. The pathogenic mutation (NC_000002.11:g.2:26702224G > A) is predicted to result in the lack of the most conserved and functional domains.

The global allele frequency of this *OTOF* variant (rs80356590) is 0.00004284 (source: genomAD), which affirms the extremely rare criteria. However, in the present study population, this globally recognized rare variant of *OTOF* turns into a common one because consanguineous marriages were much prevalent in the region, ultimately increasing the risk of such autosomal

recessive disorder. In summary, our study provides the roadmap and a piece of safeguard advice for clinicians and health care providers to make people familiar with the genetic cause and its increased risk in the context of inbreeding. Identification of such mutations supports better management of such disorders through genetic counseling. Establishing genetic testing facilities will help the appropriate diagnosis and opening new gateways for precision medicine. Familial and premarital screening will help in

controlling the hearing disability in future generations. Further population-wide screening is needed to explore the *OTOF* penetrance and other possible genetic hideouts in NSHL among North Indian populations.

DATA AVAILABILITY STATEMENT

The rare pathogenic and the novel variants observed in this study have been submitted to the ClinVar database and are

publicly available online with the accessions SCV001448680.1, SCV001448682.1, and SCV001448681.1

ETHICS STATEMENT

The studies involving human participants were reviewed and approved by Institutional Ethical Committee (IEC), Jawaharlal Nehru Medical College (JNMC), Aligarh Muslim University, India. The patients/participants provided their written informed consent to participate in this study. All methods were performed following the guidelines and regulations of the Indian Council of Medical Research (ICMR), New Delhi.

AUTHOR CONTRIBUTIONS

MF, VS, IS, SUR, GS, and MA conceived and designed the study. MF analyzed and interpreted the data. MF, VS, SUR, GS, and MA contributed to the drafting and critical review of the manuscript. All authors contributed to the article and approved the submitted version.

ACKNOWLEDGMENTS

We thank the Department of Science and Technology (DST), New Delhi, for financial assistance (File No. DST/INSPIRE/04/2017/001350) to Dr. Mohd Fareed. Special thanks to the Sarpanch (Mr. Mohd Haneef), residents and the participants of the study for their utmost support and cooperation. Thanks to Mr. Shaghaf M. Ansari (Scientist),

Information Technology Division of CSIR-IIIM for his help in downloading the data. Thanks to the IPR committee (CSIR-IIIM/IPR/00284) for reviewing and approving the manuscript.

Xeroderma Pigmentosum (XP) is a rare genetic disorder affecting the nucleotide excision repair system (NER). It is characterized by an extreme sensitivity to sunlight that induces cutaneous disorders such as severe sunburn, freckling and cancers. In Tunisia, six complementation groups have been already identified. However, the genetic etiology remains unknown for several patients. In this study, we investigated clinical characteristics and genetic defects in two families with atypical phenotypes originating from the central region in Tunisia. Clinical investigation revealed mild cutaneous features in two patients who develop multiple skin cancers at later ages, with no neurological disorders. Targeted gene sequencing revealed that they carried novel variants. A homozygous variation in the *ERCC4* gene c.1762G>T, p.V588F, detected in patient XP21. As for patient XP134, he carried two homozygous mutations in the *DDB2* gene c.613T>C, p.C205R and c.618C>A, p.S206R. Structural modeling of the protein predicted the identified *ERCC4* variant to mildly affect protein stability without affecting its functional domains. As for the case of *DDB2* double mutant, the second variation seems to cause a mild effect on the protein structure unlike the first variation which does not seem to have an effect on it. This study contributes to further characterize the mutation spectrum of XP in Tunisian families. Targeted gene sequencing accelerated the identification of rare unexpected genetic defects for diagnostic testing and genetic counseling.

Keywords: xeroderma pigmentosum, NER defects, skin cancer, *ERCC4*/XPF, *DDB2* gene

INTRODUCTION

Consanguinity plays a relevant role in the emergence of rare genetic diseases especially in North Africa and Middle East countries (Romdhane et al., 2012). Xeroderma pigmentosum (XP) is a rare autosomal recessive disorder characterized by predisposition to cutaneous malignancies. Its prevalence is estimated to 1/250.000 in Europe (Kleijer et al., 2008). However, it is more frequent in North Africa and especially in Tunisia (1/10.000) (Zghal et al., 2005). XP displays a wide clinical and genetic heterogeneity. It results from mutations in eight different genes: *XPA* through *XPG*, which encode Nucleotide Excision Repair (NER) genes, and *XPV* that encodes the Translesion Synthesis (TLS) DNA polymerase eta (Kleijer et al., 2008).

XP prognosis was widely improved due to increased knowledge about the frequent forms of the disease in Tunisia as XP-A, XP-C and XP-V (Ben Rekaya et al., 2009, 2014; Messaoud et al., 2010). Recently, thanks to the use of novel technologies such as high throughput sequencing, extremely rare forms are increasingly being identified as XP-D, XP-E, XP-G (Ben Rekaya et al., 2017; Chikhaoui et al., 2019).

The identification of disease-causing mutations in XP patients has an important impact on patient care, as it provides early dermatological follow up to prevent skin cancers and provides genetic counseling for affected family members. However, genetic diagnosis is difficult to carry out for a disease that shows such genetic heterogeneity. In addition, Sanger sequencing for known recurrent mutations that are common in specific geographic area does not always succeed in finding the genetic causes of atypical forms of the disease.

In this study, we describe clinical features and report novel genetic defects using targeted gene sequencing in two patients with particular forms of XP. One associated to XP-F, phenotype which we identify for the first time in the Tunisian population and the other consists of a double homozygous mutation in the *DDB2* gene associated to XP-E form.

Case Presentation

Clinical Presentation

Patient XP21

Patient XP21 is a 56-year-old woman, second child of healthy first-degree consanguineous parents originating from North-West of Tunisia (Figure 1A). When she was 6 years old, she developed achromic maculas on sun-exposed area of her skin. She consulted a doctor at 26, when she developed her first basal cell carcinoma (BCC). XP21 had a normal psychomotor and mental development with no neurological manifestations. In her last consultation at age 56, when this study was conducted, she had developed several actinic keratosis. Her skin was dry and presented hyperpigmented areas. It is important to note that XP21 did not suffer from acute sunburn reaction nor had any photosensitivity manifestations. In addition, she had a short stature, but no microcephaly or neurological disorders suggestive of Cockayne syndrome were observed (Table 1). Only the reported patient and her healthy sister underwent clinical examination in a medical center. As mentioned by the patient, other family members with similar phenotypes

came to our attention during the genetic inquiry about familial history, who presented mainly achromic maculas on their sun exposed area and that's in 2 brothers and one sister (Figure 1A). Unfortunately, they were out of reach as they lived far from medical centers.

Patient XP134

Patient XP134 was a 15-year old girl born from a consanguineous marriage (Figure 1B), with parents originating from the central region of Tunisia. The patient did not show any neurological abnormalities. As she was not protected from UV radiations, she presented an important number of actinic keratosis on sun-exposed areas and numerous squamous cell carcinomas and basal cell carcinomas on the face especially around the nose. She presented few hyperpigmented and hypopigmented patterns macules on her skin (Table 1). We tried to reach XP134's sister who was described as having similar clinical manifestations as pigmentation problems on sun exposed area, but she was out of reach. The proband's parents as well.

Genetic Investigations

Sanger Sequencing for Recurrent Mutations

Genetic pre-screening for recurrent and founder mutations observed in Tunisian XP patients was conducted in both patients XP21 and XP134 using Sanger Sequencing. Firstly, the patients were screened for already known mutations that are recurrent in Tunisian population as: p.Arg228* in *XPA* gene, p.Val548AlafsX25 in *XPC* gene and the deletion g.36847_40771del3925 in *POLH* gene. Secondly, we screened the mutations associated with other mild forms of XP with neurological manifestations as: p.Arg683Gln in the *ERCC2* gene (XP-D phenotype), P.Leu778Pro in *ERCC5* gene (XP-G phenotype) and p.Lys381Argfs*2 mutation in *DDB2* gene (XP-E phenotype). None of these mutations was found.

Therefore, samples underwent targeted gene sequencing to cover other genes of the DNA repair pathways.

Targeted Gene Sequencing Results

Through targeted gene sequencing of 87 genes involved in NER pathway, we identified in patient XP21 a novel homozygous missense variation in *ERCC4*, within exon 8, (NM_005236.2 c.1762G>T p.Val588Phe) (Figure 2A). Bioinformatic prediction tools (SIFT, POLYPHEN, mutation taster...) indicated that this mutation was pathogenic (Table 2). Moreover, through the prediction algorithm of human splicing finder tools, this variation was suggested to create an exonic splicing silencer (ESS) probably altering the splicing process.

Regarding the patient XP134, we found that he carried a double homozygous missense variation in *DDB2* gene in exon 5 (NM_000107.2: c.613T>C p.Cys205Arg) and c.618C>A p.Ser206Arg (rs759622121) (Figure 2B). Both variants were not described in any population database (Exac, GnomAD, 1000 Genomes...) and both are predicted to induce pathogenic effects using several prediction tools (SIFT, POLYPHEN, mutation taster...) (Table 2). Concerning the ACMG classification (Varsome), both variants were classed as of uncertain significance (class 3). Furthermore, this particular genetic profile was not

previously described in any XP patient. Molecular diagnosis was confirmed by Sanger sequencing for each variation.

Molecular Modeling of the Mutant Protein Structures

Modeling XP-F Mutation

The search for a template using BLAST-based approaches was not able to identify an appropriate template. Therefore, we used a fold recognition based approach for such an end. First, we predicted the repartition of the domains of XPF along the sequence. We found that the segment 374–623 matches a hit with a significant E-value of 7.60×10^{-98} corresponding to a helicase insert domain superfamily in accordance with the functional properties of XPF. We then proceeded to model this domain using a threading approach. pGenTHREADER was able to identify several hits with high confidence values. We selected the PDB entry, 1WP9, which corresponds to the crystal structure of *Pyrococcus furiosus* Hef helicase domain (PubMed: 15642269) as a template to construct the model. Our initial attempt to predict the structure led to a

bad quality model consisting of severe distortions of the rigid secondary structure elements. In fact, the RMSD (Root Mean Square Distance) between the template and the model is of 6 Angstroms. When we inspected the model, we found that the problem is caused by the long exposed loops spanning between the alpha-helices of the protein. We, therefore, proceed by trimming the sequences of these loops (**Supplemental Material**) to keep at least 4 amino acids from the C and N termini ends. Such an approach might be capable of preserving the original properties of the exposed surface of the target protein. The Ramachandran plot confirmed a decent quality of the model with 90% of the dihedral angles are in the favored domain and 7% in the allowed region. Even with such a model, we could not be able to explain the effect of the mutation. Therefore, we inspected the possibility that the predicted structure of the helicase insert domain could establish interdomain contacts in the XPF protein. We proceeded first by predicting the residue-residue contact map using RaptorX (Wang et al., 2017). Indeed,

the tool predicted a putative interaction of the helicase insert domain with residues 210-216 (EVVEIHV). According to the protein secondary structure prediction, this segment corresponds to a beta-sheet strand (Drozdetskiy et al., 2015). This region is also flanked by two alpha-helices with 6 and 24 residues. The equivalent aligned segment of the template structure corresponds to two helices of 5 and 24 amino acids flanking a beta stand segment interacting with the helicase insert domain.

Therefore, the structure of XPF was modeled in the presence of the 210-216 segment.

The position of V588 (R138 in the structure) corresponds to an alpha-helix (585-LTFVRQ LEIYR-596) rich in charged and polar amino acids. Residues of this helix are exposed to the solvent with only F589 and L591 making part of the hydrophilic core of the protein. We noticed that in the V588 in the wild type protein forms a hydrophobic cluster of residues with F607, A583, and L580. In the case of V588F mutation causes steric clashes with L580 residue due to its large bulky side chain compared to a valine amino acid in the wild type form (Figure 2C).

Modeling XP-E Mutation

The two mutations, C205R and S206R are located on a beta sheet that forms one of the blades of the WD40 beta-propeller domain. The mutations are close to the protein-DNA interface which are known to rely on electrostatic forces to stabilize the complex. In order to verify if the two mutations can disrupt

the electrostatic properties of the protein-DNA interface, we calculated the pKa for the ionizable side chains at positions 205 and 206 for both the wild type and the mutant forms at physiological pH of 7.4 using PROPKA 3.0 (10.1021/ct100578z). The pKa value of C205 side chain is predicted to be at 8.59. Therefore, this residue is probably deprotonated in the wild type form. Both residues R205 and R206 in the mutant form are positively charged with predicted pKa values of 10.41 and 8.63. To our surprise, the electrostatic potential at the protein DNA interface did not drastically change between the wild type and the mutant forms (Supplementary Data). The R205 ionizable group remains exposed to the central cavity of the WD40 beta-propeller domain. The same configuration is also demonstrated by the side chain of C205 residue in the wild type form. However, for R206, the side chain is bulky compared to S206 amino acid in the wild type form. Its relatively long side chain is unable to interact with the deepest most residues forming the interface of two bladders (Residues V225, V245 and T260) which is not the case for S206 in the wild type form (Figure 2D).

MATERIALS AND METHODS

Patients

This study was conducted according to the principles of the declaration of Helsinki and has obtained the ethical approval (IPT/LR05/ProjectPCI/22/2012/v2) from the institutional review board of Institut Pasteur de Tunis.

The two patients (XP21 and XP134) referred to dermatology department of Charles Nicolle hospital with clinical features suggestive of XP. Written informed consent was obtained for genetic analysis from patients or their parents.

DNA Extraction, Library Construction, Sequencing, and Data Analysis

Genomic DNA was extracted from peripheral blood. Amplicon libraries were prepared from 1,000 ng of genomic DNA from patients. Custom design of DNA repair disorders' panel was performed using SureDesign (Agilent Technologies Inc.), with probes that cover the exons in 87 genes and 15 bp of the surrounding intronic sequences. Library preparation for NGS was done using the Agilent's HaloPlex^{HS} workflow as a target enrichment method. Massively parallel sequencing was performed on an Ion Torrent PGM (Thermo Fisher Scientific).

The data from the sequencing runs were analyzed using the Torrent Suite v4.0.2 analysis pipeline, and aligned using TMAPv.3. The output variant call format (VCF) file was then annotated using the in-house VarAft software version 2.5, which is available online (<http://varaft.eu/index.php>) (Desvignes et al., 2018). Sequence variants were compared with data in Exome Variant Server (<http://evs.gs.washington.edu/EVS/>), 1000 Genomes Project (<http://www.1000genomes.org/>), or GnomAD (<https://gnomad.broadinstitute.org/>), including Exome Aggregation Consortium database (ExAC), Cambridge, MA (<http://exac.broadinstitute.org>). A number of online tools were used to predict the functional impact and pathogenicity of the variants such as MutationTaster (<http://www.mutationtaster.org/>), PolyPhen (<http://genetics.bwh.harvard.edu/pph2/>),

FIGURE 2 | Molecular findings: **(A)** Electropherogram showing the variation in *ERCC4* gene in exon 8 (c.1762 G>T p.V588F) at a homozygous state in the patient XP21. **(B)** Electropherogram showing double variation in *DDB2* gene (c.613 T>C p.C206R and c.618 C>A p.S206R) in exon 5 in XP134 patient. **(C)** Structures of the XPF protein and F588 XPF mutant suggesting a mild distortion in helix domain. **(D)** DNA DDB2 protein interaction for muted DDB2 protein suggestion that R206 affect this process.

TABLE 2 | Prediction scores of the new detected variants in DDB2 and ERCC4 genes.

Gene	Variant	Prediction tools	Score	Significance
DDB2	c.613T>C; p.C205R	Mutation taster	0.99	Disease causing
		Polyphen	1	Probably damaging
		SIFT	2.77	damaging
		M-CAP	0.066	Possibly damaging
		Provean	−6.13	deleterious
		MUpro	−1.40	Decrease stability
DDB2	c.618C>A; p.S206R	Mutation taster	0.99	Disease causing

SIFT (<http://sift.bii.a-star.edu.sg/>), M-CAP (<http://bejerano.stanford.edu/mcap/>), Provean (<http://provean.jcvi.org/index.php>) and MU Pro for protein stability prediction (<http://mupro.proteomics.ics.uci.edu/>).

Sanger Sequencing

The detected variants with a high prediction score of pathogenicity underwent targeted Sanger sequencing for validation using the following primers: **ERCC4F**: 5'GTAAGA TGTCTTCCCTTCGG 3'; **ERCC4R**: 5'CATAAGCAGCATCG TAACGG 3' and **DDB2F**: 5'ATGGAGCAGTCTGAATGTTC 3'; **DDB2R**: 5'CCACTCCTCTAGACAGG3') which cover both variants in DDB2 gene. Direct sequencing was performed using Big Dye terminator technology (ABI 3130), and sequences were analyzed using Bioedit packages. Genomic and protein sequence variants are described following the Human Genome Variations Society Guidelines available at <https://varnomen.hgvs.org/>. *ERCC4* and *DDB2* variants are, respectively, described relative to the transcript reference sequences NM_005236.2 and NM_000107.2. ACMG classification of the variants (Richards et al., 2015) was obtained using Varsome at <https://varsome.com>.

Protein Modeling

The primary structure of XPF endonuclease was deposited in UiprotKB database under the accession Q92889. The sequence consists of 916 amino acids of which only the structure corresponding to segment 834-916 was solved experimentally. To solve the structure of the region containing the mutation we first searched for conserved domains of the entire sequence. The search for the appropriate template to construct the 3D structure of XPF was performed using the pGenTHREADER program. The sequences of the best hits

were then processed and aligned to the target sequence of XPF using 3D-expresso. The resulting alignment was then used to guide the model building process by MODELER (version 9.15). Twenty conformers were generated by the comparative modeling software of which we selected the best model according to the DOPE and the GA341 scores. Finally, the stereochemical quality of the model was assessed by constructing the Ramachandran plot to dress the repartition of the phi/psi angles in the favored, allowed, and non-tolerated dihedral domains.

The XP-E structure was retrieved from the co-crystal complex of PDB code 4E54 (PMID 22822215).

DISCUSSION

XP is a rare autosomal recessive disorder, characterized by ubiquitous defects in the DNA repair system. This disorder is especially characterized by sunburn after brief sun exposure and pigmented macules on sun-exposed skin (Krieger and Berneburg, 2012). Targeted gene panels help to focus on a set of relevant candidate genes within the overlapping phenotypes with similar clinical manifestations, to identify the exact genetic etiology while providing cost and time advantages when compared to classical Sanger sequencing.

About 40% of XP patients do not show sunburn reactions (Bradford et al., 2011). As for XP-E, increased number of freckles in sun-exposed areas seems to be the unique symptom for clinical diagnosis of the disease. These maculae are usually ignored and only the development of primary malignant lesions seems to be the reason leading to clinical consultation. This often results in a late diagnosis of patients with mild XP forms.

We report in the region, the XP-F form which is among the rarest complementation groups of XP. To date, 29 XP-F patients were reported worldwide (Ferri et al., 2020). Most of them are Japanese (Tofuku et al., 2015). XP-F (Omim: #278760) is caused by mutations in *ERCC4* gene. Furthermore, several *ERCC4* mutations were associated to a combined XP/CS phenotype, to XFE progeroid syndrome, Cockayne syndrome, Cerebellar ataxia-dominant phenotype or to Fanconi Anemia disease complementation group Q (Kashiyama et al., 2013; Doi et al., 2018). Although the clinical features of patient XP21 indicated a phenotype of Xeroderma pigmentosum, a moderate form of Fanconi anemia type Q was suspected. This hypothesis was quickly dismissed as patient XP21, and despite her short stature, did not develop internal cancers or neurological disorders. Fertility was not explored as the patient was not married.

The protein XPF consists of 916 amino acids. It forms a heterodimeric complex with ERCC1 and plays the role of structure-specific endonuclease 5' incision during the activation of NER repair system upon UV induced DNA damage (Sijbers et al., 1996; Richards et al., 2015). Twenty-seven variations have been reported thus far in the *ERCC4* gene (Zhou et al., 2017). While most mutations in this gene are located in exon 8, suggesting that it may represent a hotspot mutation site, the variants in this area can lead to different disorders.

Indeed, patient XP21 harbored a novel G to T transversion at position c.1762. In the same exon, other variants as p.R589W give rise to combined XP/CS/FA, Fanconi anemia or mild XP forms. In our study, given the late onset of cutaneous cancer and the lack of associated neurological disorders, we suggest that patient XP21 was affected with a mild XP-F form.

The *ERCC4* endonuclease consists of an N-terminal DNA helicases domain (1-457), a domain containing the nuclease active site (656-813) and a C-terminal containing 2 tandem helix-hairpin-helix (HhH) domain (Manandhar et al., 2015). The previously reported *ERCC4* mutations are widely distributed over the entire length of the protein (Bogliolo et al., 2013; Kashiya et al., 2013; Zhou et al., 2017; Mori et al., 2018). The novel reported variation in this study is located outside the nuclease active site.

The molecular modeling study suggests that the V588F mutation effect is probably caused by the steric clashes between F588 and L580. The latter amino acid belongs to the beta sheet which holds many of the core residues of the helicase insert domain. Of most importance, the 210-216 segment also belongs to this beta-sheet forming the outermost strand. The steric clash between F588 and L580 could cause a local distortion of the beta sheet. While this might not have a significant effect on the interaction of the helicase insert domain with the DNA, the fact that the 210-216 segment is implicated in the interaction network of the central beta sheet, suggests the cooperative functionality established between modeled helicase insert domain and other segments of the protein might be affected by the mutation.

Xeroderma pigmentosum type E (Omicron: # 278740) caused by mutations in the *DDB2* gene. The DDB2 subunit is a component of a complex involved in ubiquitin-mediated proteolysis. Consisting of 427 residues, it plays a major role in DNA-damage recognition (Stoyanova et al., 2009). To date, more than 24 XP-E patients have been reported worldwide (Nichols et al., 1996; Itoh et al., 2000; Vahteristo et al., 2007; Oh et al., 2011; Karagün et al., 2020; Yang et al., 2020) and 17 variations were reported in *DDB2* gene (Yang et al., 2020). None of them is from North African countries except 3 Tunisian patients reported previously by our lab (Ben Rekaya et al., 2017). In this study, we report another novel variation in the Tunisian population emphasizing the complex genetic background of North African population.

It is a double homozygous patient harboring two novel mutations in the same exon of *DDB2* gene, responsible for XP-E, which was never described in XP patients. The emergence of rare autosomal genetic variants is frequent in people with common ethnic origin caused by consanguinity and endogamy. However, the appearance of double variations is an extremely rare event. These double mutations could explain the severe clinical phenotype in XP134 patient.

The DDB2 protein is composed from an N-terminal helix-loop helix segment (101 to 136) followed by a 7-bladed WD40 b propeller domain (residues 137 to 454) (Scrima et al., 2008). It is an ubiquitin ligase component of a multimeric complex involved in the degradation of DNA damage-response proteins

(Liu et al., 2009). The two C205R and S206R variants in XP134 are located on a beta sheet that forms one of the blades of the beta-propeller WD40 domain of the DDB2 protein. Mutations close to the protein-DNA interface are known to delay electrostatic forces to stabilize the complex (Scrima et al., 2008), which could explain the severity of the XP134 phenotype compared to previously described XP-E patients (Ben Rekaya et al., 2017).

Our protein modeling study also suggests that the effect of the C205R mutation is not probably responsible for the clinical phenotype since the mutation preserves both, the number of charges carried by the corresponding residue and the electrostatic potential at the protein-DNA interface. Instead, the S206R mutation might have a significant effect on the protein structure. This could be explained by the fact that the mutation causes the R205 positively charged side chain to be buried inside the hydrophobic core of the protein. Such configuration is highly unstable and could cause the local distortion of the protein at the mutation level, but also could have a more severe consequence on the interaction with the damaged DNA.

CONCLUSION

In this report, we further characterize new XP complementation groups emerging in the Tunisian population and in the region. While the mutational findings have improved the understanding of XP phenotype, it is necessary to continue the molecular investigations for other underdiagnosed patients for whom the discovery of genetic etiology will improve the clinical follow up.

(2021) High Genetic Heterogeneity
in Chinese Patients With
Waardenburg Syndrome Revealed by
Next-Generation Sequencing.
Front. Genet. 12:643546.
doi: 10.3389/fgene.2021.643546

Objective: This study aimed to explore the genetic causes of probands who were diagnosed with Waardenburg syndrome (WS) or congenital sensorineural hearing loss.

Methods: A detailed physical and audiological examinations were carried out to make an accurate diagnosis of 14 patients from seven unrelated families. We performed whole-exome sequencing in probands to detect the potential genetic causes and further validated them by Sanger sequencing in the probands and their family members.

Results: The genetic causes for all 14 patients with WS or congenital sensorineural hearing loss were identified. A total of seven heterozygous variants including c.1459C > T, c.123del, and c.959-409_1173+3402del of *PAX3* gene (NM_181459.4), c.198_262del and c.529_556del of *SOX10* gene (NM_006941.4), and c.731G > A and c.970dup of *MITF* gene (NM_000248.3) were found for the first time. Of these mutations, we had confirmed two (c.1459C > T and c.970dup) are *de novo* by Sanger sequencing of variants in the probands and their parents.

Conclusion: We revealed a total of seven novel mutations in *PAX3*, *SOX10*, and *MITF*, which underlie the pathogenesis of WS. The clinical and genetic characterization of these families with WS elucidated high heterogeneity in Chinese patients with WS. This study expands the database of *PAX3*, *SOX10*, and *MITF* mutations and improves our understanding of the causes of WS.

Keywords: *PAX3*, *SOX10*, *MITF*, Waardenburg syndrome, next-generation sequencing, genetic heterogeneity

INTRODUCTION

Waardenburg syndrome (WS) is a congenital developmental disorder, which is mainly characterized by congenital sensorineural hearing loss (SNHL) and abnormal pigmentation of the iris, hair, and skin (manifests as heterochromia iridis and brilliant blue eyes, a white forelock, and premature graying, and hypopigmented skin) (Read and Newton, 1997). WS has an incidence

rate of approximately 1/42,000 births and is responsible for 2–5% of cases of total congenital deafness (Read and Newton, 1997; Nayak and Isaacson, 2003). Four different types of Waardenburg syndrome (WS I–IV) have been described based on genotypic and phenotypic variations (Read and Newton, 1997; Pingault et al., 2010). WS I is distinguished from WS II by the presence of dystopia canthorum, which is lateral displacement of the inner canthus in each eye; WS III (Klein–Waardenburg syndrome) is similar to WS I except with additional upper limb abnormalities; WS IV (Waardenburg–Shah syndrome) is characterized by general WS features as well as Hirschsprung's disease, a disorder that causes severe blockage of the large intestine. Current research suggests that WS I and WS II are more common than WS III and WS IV (Read and Newton, 1997; Pingault et al., 2010).

Waardenburg syndrome shows a high degree of genetic heterogeneity (Hageman and Delleman, 1977; Read and Newton, 1997; Pingault et al., 2010; Song et al., 2016). Six genes have been linked to this syndrome: paired box 3 (*PAX3*) (Baldwin et al., 1992; Tassabehji et al., 1992; Hoth et al., 1993), melanocyte inducing transcription factor (*MITF*) (Tassabehji et al., 1994), SRY-box transcription factor 10 (*SOX10*) (Pingault et al., 1998; Bondurand et al., 2007), endothelin 3 (*EDN3*) (Edery et al., 1996), endothelin receptor type B (*EDNRB*) (Puffenberger et al., 1994), and snail family transcriptional repressor 2 (*SNAI2*) (Sánchez-Martín et al., 2002). *PAX3* is responsible for WS I and WS III (Baldwin et al., 1992; Tassabehji et al., 1992; Hoth et al., 1993). *SOX10*, *MITF*, and *SNAI2* are associated with WS IV (Tassabehji et al., 1994; Pingault et al., 1998; Sánchez-Martín et al., 2002; Bondurand et al., 2007). *SOX10*, *EDNRB*, and *EDN3* are found to be involved in WS IV (Puffenberger et al., 1994; Edery et al., 1996; Pingault et al., 1998; Bondurand et al., 2007). Although not currently fully understood, all these genes are involved in a complex network in neural crest cells and other derivatives (Read and Newton, 1997; Bondurand et al., 2000; Pingault et al., 2010). The interaction of these genes during the formation and development of melanocytes could be the pathogenesis of WS and other related diseases (Read and Newton, 1997; Bondurand et al., 2000; Pingault et al., 2010).

Diagnosis of WS can be difficult because all features are not present in every patient (Hageman and Delleman, 1977; Newton, 1990; Tamayo et al., 2008; Pingault et al., 2010; Yang et al., 2013). Even within a single family, patients can display different clinical manifestations due to variations in the expressivity of causative genes (Hageman and Delleman, 1977; Newton, 1990; Tamayo et al., 2008; Pingault et al., 2010; Yang et al., 2013). Therefore, genetic testing is an important method for diagnosing this disease and its subtypes (Hageman and Delleman, 1977; Read and Newton, 1997; Pingault et al., 2010; Tang et al., 2015; Song et al., 2016; Wu et al., 2016; Li et al., 2019). To date, ~400 mutations including missense/nonsense mutations, frameshift mutations, insertions/deletions, and copy number variants (CNVs) have been identified in genes associated with WS (The Human Gene Mutation Database¹), with most variants in genes *PAX3*, *SOX10*, and *MITF* (Chen et al., 2010; Pingault et al., 2010; Song et al., 2016). Of these variants, ~100 mutations were identified in

Chinese people. Nevertheless, there are still a number of cases unexplained at the molecular level (Pingault et al., 2010; Song et al., 2016). Discovering novel mutations will lead to a better understanding of the genetic causes of WS pathogenesis.

Recently, next-generation sequencing (NGS) has proven to be a potent tool for the identification of pathogenic mutations related to deafness, which can improve the diagnosis of genetic diseases and the detection of mutations in genes associated with different clinical manifestations (Brownstein et al., 2012; Lin et al., 2012; Tang et al., 2012; Li et al., 2019). In this study, WES was used to identify the possible pathogenic mutations of patients with SNHL or WS. A total of seven novel variants in *PAX3*, *SOX10*, and *MITF* were found, and two of them are *de novo* confirmed by Sanger sequencing of variants in the probands and their parents. Our results show that WS in China has a high degree of genetic heterogeneity and extend the mutational spectrum of WS-related genes.

MATERIALS AND METHODS

Patients

From seven Han Chinese families in the Henan province, 14 patients (Table 1) and nine unaffected family members were recruited for our study and asked to perform audiological and general physical examinations (Figure 1). Furthermore, in family WS04, only WS04-II:1 was recruited because he was adopted and had lost contact with his biological family. Among the seven families, WS01 and WS06 were isolated cases, while the remaining families had multiple affected individuals (Figure 1). Photos and blood were collected after informed consent (Figure 2). This study was conducted according to the Declaration of Helsinki and approved by the institutional review board of the Medical Ethics Committee of The Second Affiliated Hospital of Zhengzhou University (Approval No. 2018008).

Clinical Investigation

All patients (medical history described by parents) received elaborate physical examinations in their hair color and skin pigmentation, joints, skeletomuscular system, digestion, ophthalmology and otology, and intelligence assessment. Patients also underwent audiological examinations, which included auditory steady-state response (ASSR), auditory brainstem response (ABR), and distortion product otoacoustic emission (DPOAE). Additionally, imageological examinations such as computerized tomography (CT) of the temporal bone and magnetic resonance imaging (MRI) were conducted. The characteristics of the patients are summarized in Table 1.

Next-Generation Sequencing-Based Genetic Testing

In this study, WES was applied to identify the potential genetic causes for probands. A standard NGS-based genetic testing, including sample preparation and quantification, library construction, sequencing, and data analyses, was performed as previously described (Pan et al., 2020). Briefly, after library

WS06-II:1	Female	+	–	+	–	–
WS07-I:1	Male	–	–	–	+	–
WS07-II:1	Female	+	+(Unilateral)	–	+	–

construction, the resulting libraries were hybridized to the Agilent SureSelect Human All Exon V7. Then, sequencing was carried out on an Illumina HiSeq 4000 sequencer (Illumina Inc., San Diego, CA, United States) to generate paired-end reads of 150 bp.

Data analyses were divided into bioinformatics analysis and variant interpretation. Under the framework of bcbio-nextgen², we used the Burrows–Wheeler Aligner (BWA) (version 0.7.17-r1188) (Li, 2013) to align the sequencing reads to the human reference genome (GRCh37); GATK Haplotype Caller software (version 4.1.2) (McKenna et al., 2010) to

identify the single nucleotide variants (SNVs) and short indels; DECoN (Fowler et al., 2016) to identify the CNVs; and Vcfanno software (version 0.3.1) (Pedersen et al., 2016) to annotate the VCF files with external database, including Clinvar (Landrum et al., 2018), ExAC (Lek et al., 2016), dbNSFP (Liu et al., 2016), 1,000 Genomes (Auton et al., 2015), and gnomAD (Karczewski et al., 2019). The filtered variants were interpreted following the guidelines of the American College of Medical Genetics and Genomics and the Association for Molecular Pathology (ACMG-AMP) (Richards et al., 2015) and the ClinGen hearing loss expert group’s recommendation on variant interpretation (Oza et al., 2018). Copy number analysis was performed from NGS data using DECoN with

²<https://github.com/bcbio/bcbio-nextgen>

the bam files from the same enrichment panel and sequencing run. Paternity tests were performed on families WS01 and WS06 since the gene tests had shown mutations occurred *de novo*.

Sanger Sequencing

Sanger sequencing was used to confirm the candidate variants detected by NGS and to conduct co-segregation analyses in family members. The specific primers (Table 2) were designed by NCBI Primer-BLAST and synthesized by Sunya Biotech Co., Ltd. (Zhengzhou, China). Conventional PCR was performed for SNVs and short indels detected in families WS01 to WS06. While long-range PCR (LR-PCR) based on nested-PCR and fragments gel-purified were performed for the CNV of patients WS07-I:1 and WS07-II:1. LR-PCR is a traditional approach to obtain CNV breakpoint junction (Woodward et al., 2005; Zhang et al., 2017), for which several primers were designed from both the proximal and the distal breakpoint regions identified, and used in different combinations until an appropriate size product was generated (Supplementary Figure 1). After PCR amplification, purification, and quality control, Sanger sequencing was run in a SeqStudio Genetic Analyzer (Thermo Scientific, United States) with a mixture of PCR products and BigDye™ Terminator v3.1 Cycle Sequencing Kit (Applied Biosystems, Foster City, CA, United States). The sequencing results were analyzed by the SnapGene viewer (Figure 3).

RESULTS

Clinical Findings

A total of 14 patients from seven unrelated families were involved in this study. Before genetic testing, patients WS01-II:1 and WS06-II:1 were primarily diagnosed with SNHL, while the other 12 patients were diagnosed with WS. These diagnoses were made by otorhinolaryngologists based on the manifestation of the typical symptom of WS, such as SNHL, abnormal pigmentation, and the presence or absence of dystopia canthorum, musculoskeletal anomalies, and intestinal aganglionosis. After a genetic diagnosis, further examinations were performed on the patients WS01-II:1 and WS06-II:1. We found that the hair color of WS06-II:1 is gray, which was previously ignored, but nothing new with WS01-II:1.

Among all the patients, heterochromia iridum and deafness were the most frequent features. Ten affected individuals (10/14, 71.4%) had blue iris, of which three were heterochromia iridum; nine patients (9/14, 64.3%) had a profound sensorineural hearing impairment; six (6/14, 42.9%) had dystopia canthorum; one (1/14, 7.1%) had facial freckles; two (2/14, 14.3%) had abnormal pigmentation of hair (Figures 1, 2). Table 1 lists the clinical data of these WS patients.

Members in the same family can have different symptoms. WS03-II:1 and WS03-II:2 are identical twins; one has bilateral blue iris and the other has unilateral. According to his adoptive

FIGURE 3 | Mutation analyses of Chinese Waardenburg syndrome families WS01 to WS07 by sanger sequencing. **(A)** Heterozygous mutation c.1459C > T of *PAX3* in WS01-III:1. **(B)** Heterozygous mutation c.123del of *PAX3* in WS02-I:1, II:3, III:1, and III:2. **(C)** Heterozygous mutation c.198_262del of *SOX10* in WS03-I:2, II:1, and III:2. **(D)** Heterozygous mutation c.529_556del of *SOX10* in WS04-III:1. **(E)** Heterozygous mutation c.731G > A of *MITF* in WS05-III:3, IV:4. **(F)** Heterozygous mutation c.970dup of *MITF* in WS06-II:1. **(G)** Heterozygous mutation c.959-409_1173+3402del of *PAX3* in WS07-I:1, II:1.

father, WS04-II:1 was born with a white forelock that returned to being black (we were unable to collect pictures of the patient with a white forelock). Across four generations, seven members of the family WS05 had unexpectedly brilliant blue eyes without other WS-related symptoms. However, it is impossible to confirm whether they were affected by the same mutation of the proband (WS05-IV:1) since they refused to provide blood samples.

Molecular Etiology

Whole-exome sequencing was performed in probands of these seven families. For each sample, at least 10 Gbp raw data was generated, with more than 82% of bases having a Phred quality score $Q \geq 30$ (Q30), 99% of the clean reads can map to the human reference genome (GRCh37/hg19), and the average sequencing depth of target regions was $100\times$, with 95% of target regions having coverage greater than $20\times$ (**Supplementary Table 1**).

In this study, the genetic causes for all recruited patients had been confirmed, which contain a total of seven mutations in *PAX3*, *SOX10*, and *MITF*, respectively (**Table 3**). To our best knowledge, these mutations, including a nonsense mutation, a missense mutation, a CNV, and four frameshift mutations, have not been reported by previous studies or recorded in any public database. Further analysis by Sanger sequencing of patients and their family members shows that all the variants were present in the affected members and absent in the unaffected ones (**Figure 3**), and variants of probands WS01-II:1 and WS06-II:1 are *de novo*. Pathogenicity analysis of variants was according to the standards and guidelines for interpreting genetic variants proposed by the ACMG-AMP. The mutations and pathogenicity analysis were summarized in **Table 3**.

Genotype–Phenotype Correlation

The phenotypes of WS patients with *PAX3* ($n = 7$), *SOX10* ($n = 4$), and *MITF* ($n = 3$) mutations are compared in **Supplementary Table 2**. Among the WS patients who participated in this study, all patients with *SOX10* mutations have hearing loss, while some patients with *PAX3* (3/7) or *MITF* (2/3) have. Similarly, the symptom of the blue iris could be found in all patients with *SOX10* mutations, while it was found in some patients with *PAX3* (4/7) or *MITF* (2/3) variants. Abnormal hair pigmentation is rare in patients with *PAX3* (0/7), *SOX10* (1/4), and *MITF* (1/3) mutations. Previous reports suggested that freckles could be observed only in Chinese WS II patients with *MITF* mutations (Chen et al., 2010; Sun et al., 2016). Indeed, in this study, we found one WS II patient with *MITF* mutation has freckles. Synophridia is only present in WS I patients with *PAX3* mutations.

DISCUSSION

In this study, we had confirmed seven novel heterozygous variants which are the genetic causes of 14 WS patients from seven unrelated families, including c.1459C > T (nonsense), c.123del (frameshift), and c.959-409_1173+3402del (deletion) of *PAX3* (NM_181459.4), c.198_262del (frameshift) and c.529_556del (frameshift) of *SOX10* (NM_006941.4), and c.731G > A (missense) and c.970dup (frameshift) of *MITF*

(NM_000248.3) (**Table 3**). Among 14 patients, seven each were classified as WS I and WS II, respectively, based on their phenotypes and genotypes, showing that WS I and WS II were two major WS subtypes (Read and Newton, 1997; Pingault et al., 2010). While mutations in *PAX3* were the major causes for WS I (7/7), *SOX10* (4/7), and *MITF* (3/7) were two major causative genes attributable to WS II. Our findings had extended the mutational spectrum of WS-related genes and revealed high genetic heterogeneity in Chinese WS patients (Yang et al., 2013; Sun et al., 2016; Liu et al., 2020).

To explore the genotype–phenotype correlation, we compared the phenotypes between WS patients with *PAX3*, *SOX10*, and *MITF* mutations (**Supplementary Table 2**). Several reports had shown that the clinical features of WS II caused by *SOX10* and *MITF* mutations were indistinguishable, except that freckle was frequent in WS II probands with *MITF* mutation (Chen et al., 2010; Toriello, 2011; Sun et al., 2016). Indeed, in this study, freckle seems to be unique for patients with *MITF* mutations (1/3) but was absent in those with *PAX3* (0/7) or *SOX10* (0/4) mutations. Dystopia canthorum is a rebarbative but crucial clinical feature, because of its value in distinguishing WS I and WS II, but it is not completely applicable for Chinese WS I patients (Sun et al., 2016; Morimoto et al., 2018; Suzuki et al., 2018; Minami et al., 2019). Herein, we had an interesting finding that the synophridia, even though a minor symptom, was only present in WS patients (5/7) but absent in WS II patients (0/7). Our results may have shown the clinical differences between WS II patients with *SOX10* and *MITF* mutations, and between WS II and WS I. However, gene test is as necessary as clinical investigation for the accurate diagnosis and subtype confirmation (Hageman and Delleman, 1977; Read and Newton, 1997; Pingault et al., 2010; Song et al., 2016; Li et al., 2019).

Mutations in *PAX3*, *SOX10*, and *MITF* were the most common genetic causes for WS and responsible for almost all Chinese WS patients (Chen et al., 2010; Wu et al., 2016; Liu et al., 2020). Beyond that, to date, several WS cases associated with mutations in *EDNRB*, *EDN3*, and *SNAI2* had been reported (Sánchez-Martín et al., 2002; Pingault et al., 2010; Xiong et al., 2015; Somashekar et al., 2019), but the situation is a bit different in Chinese. There were two reported cases of WS type I caused by mutations in the *EDNRB* gene (Cheng et al., 2019; Li et al., 2019), which is different from the cases in other races (WS II or IV) (Pingault et al., 2010; Issa et al., 2017). Of the few reports about WS type II being caused by mutations in the *EDN3* gene, there was no Chinese case reported. Only one research group reported *SNAI2* mutations caused WS within two unrelated WS II patients (Sánchez-Martín et al., 2002), which had been questioned recently (Song et al., 2016; Mirhadi et al., 2020). To understand the differences of WS among different races, we need further research on the pathogenesis of WS and more accurate diagnostic means.

The deficiency of melanocytes, the neural crest (NC) derivatives, is common to various WS types (Bondurand et al., 2000; Pingault et al., 2010; Song et al., 2016), which is responsible for the phenotypes of pigmentation defects and hearing loss (Steel and Barkway, 1989). *PAX3* encodes a DNA-binding transcription factor, consisting of a paired box (PD) encoded by exons 2, 3,

TABLE 3 | Gene variants and pathogenicity analysis of patients.

*This mutation was, for the first time, found in humans after being detected and researched by Steingrímsson et al. (1996) in mice, so the criteria "PS3" was given. ACMG-AMP, Association for Molecular Pathology. Reference sequence transcript: *PAX3*: NM_181459.4; *SOX10*: NM_006941.4; and *MITF*: NM_000248.3.

and 4, the homeodomain (HD) by exons 5 and 6, C-terminal transcriptional activation domain by exons 7 and 8 (Read and Newton, 1997; Wildhardt et al., 2013). It is indispensable in the development of somites, skeletal muscle, and the neural crest cells (NCC) and their derivatives like melanocytes. It can cooperate with *SOX10* to regulate the expression of the *MITF* promoter (Pingault et al., 2010). *PAX3*:c.123del and c.959-409_1173+3402del mutations are predicted to activate the nonsense-mediated mRNA decay (NMD) machinery (Khajavi et al., 2006), thereby resulting in haploinsufficiency, which might be the disease-causing mechanism for WS I. *PAX3*:c.1459C > T mutation is located in the exon 10 and could only influence the isoform *PAX3e* (Wang, 2006), which most likely pathogenic mechanism is haploinsufficiency (Barber et al., 1999).

SRY-box transcription factor 10 encodes a transcription factor that contains an HMG (high mobility group) DNA binding domain and a C-terminal transactivation domain (Chan et al., 2003). In the early development of NC, *SOX10* plays an important role in promoting cell survival and maintaining the multipotency of NC stem cells (Kapur, 1999; Kelsh, 2006; Pingault et al., 2010; Stolt and Wegner, 2010). Besides synergy with *PAX3* to regulate the expression of *MITF*, it also can directly regulate the expression of genes important for melanin synthesis, suggesting the importance for melanocyte differentiation (Bondurand et al., 2000; Lee et al., 2000; Potterf et al., 2000; Verastegui et al., 2000; Jiao et al., 2004; Wegner, 2005; Pingault et al., 2010). It is also crucial for the peripheral nervous system like sensory, sympathetic, and enteric ganglia and along nerves (Bondurand et al., 2000; Pingault et al., 2010). *SOX10*: c.198_262del and c.529_556del are located in the HMG domain and predicted to activate the NMD machinery, resulting in haploinsufficiency.

Melanocyte inducing transcription factor, a basic helix-loop-helix leucine zipper (bHLHZip) protein, is the key transcription factor of melanocyte development. The bHLHZip structure binds DNA by basic domain, dimerizes through HLH domain, and is stabilized via the Zip domain (Hodgkinson et al., 1993;

Steingrímsson et al., 1994). The C-terminal of *MITF* contributes to defining the target genes by a serine-rich transcriptional activation domain. Mice with *MITF* mutations show reduced or absent pigmentation, deafness, and small or absent eyes, etc. (Yasumoto et al., 1995; Bertolotto et al., 1998; Steingrímsson et al., 2004; Pingault et al., 2010). *MITF*:c.970dup is a frameshift mutation and predicted to activate the NMD machinery, leading to haploinsufficiency. *MITF*:c.731G > A (p.Gly244Glu) is the genetic cause of III:1 and IV:1 of family WS05 and might be responsible for the other seven affected individuals (**Figure 1**). We had noticed that only one had hearing loss and blue iris while the other eight only had blue iris in this family, although Song et al. (2016) had suggested that nearly 90% of patients with *MITF* have hearing loss. The Gly244Glu mutation of *MITF* was found in humans for the first time, while the mouse model with the same mutation (*MITF*^{Mi-b}) had been found by Steingrímsson et al. (1996). The phenotype of *MITF*^{Mi-b} homozygous animals is mild compared with loss-of-function *mi* alleles. Gly244 would lie at the very beginning of the second helix, close to the protein-DNA interface. The Gly244Glu alteration is at the junction of the loop and helix 2 of the protein. The *MITF*^{Mi-b} protein largely spares dimerization function, while it is defective in its ability to bind DNA. However, the DNA binding function can be partially compensated by a wild-type partner in the dimer, since *MITF*^{Mi-b} is capable of forming TFE3 (Transcription factor E3) heterodimeric complexes which had a stronger DNA binding than the *MITF*^{Mi-b} homodimers. It may explain why the mutation c.731G > A resulting in a less-severe phenotype in the family WS05.

WS has high genetic heterogeneity and highly variable phenotype expressivity (Hageman and Delleman, 1977; Newton, 1990; Read and Newton, 1997; Tamayo et al., 2008; Pingault et al., 2010; Yang et al., 2013; Song et al., 2016), which makes the diagnosis challenging. NGS of numerous genes is allowed in a single test with lower turnaround time, cost, and higher throughput, which makes it ideal for figuring out the exact genetic mechanism (Brownstein et al., 2012;

Tang et al., 2012, 2015). Mutations in *PAX3* are responsible for WS I and WS III in most cases; however, using WES, we had detected a heterozygous nonsense mutation of *PAX3*:c.1459C > T in an SNHL patient (WS01-II:1). To our best knowledge, this is the first mutation found in exon 10 of *PAX3* and results in a premature stop codon, which is very close to the normal ending (487/506) (Boudjadi et al., 2018). We suspect that this is why SNHL is the only symptom of WS01-II:1, even though previous studies argued that there was no correlation between genotype and phenotype of WS caused by *PAX3* mutations (Tassabehji et al., 1995; Boudjadi et al., 2018). Patient WS06-II:1 was also diagnosed with SNHL initially, before being corrected to WS type II after the genetic testing in which a heterozygous *de novo* mutation *MITF*: c.970dup was detected. Besides, the other five families with classic symptoms and clear family histories, these two cases in particular highlight the superiority of NGS in the diagnosis of WS.

In conclusion, the clinical and genetic characteristics of one SNHL patient and six Chinese families of WS had been investigated in this study. Altogether, seven novel pathogenic/likely pathogenic variants in the *PAX3*, *SOX10*, and *MITF* were identified. Our results support that NGS is a useful diagnostic procedure for the diagnosis and subtype differentiation of WS. This report reveals the highly genetic heterogeneity and variable phenotype in Chinese patients with WS and will contribute to a better understanding of the WS by extending the mutational spectrum of WS-related genes.

DATA AVAILABILITY STATEMENT

According to national legislation/guidelines, specifically the Administrative Regulations of the People's Republic of China on Human Genetic Resources (http://www.gov.cn/zhengce/content/2019-06/10/content_5398829.htm, http://english.www.gov.cn/policies/latest_releases/2019/06/10/content_281476708945462.htm), no additional raw data is available at this time. Data of this project can be accessed after an approval application to the Bio-Med Big Data Center, NODE. Sequencing Identified a Novel
Frameshift Mutation of α -Actin 1 in a
Chinese Family With
Macrothrombocytopenia and Mild
Bleeding. *Front. Pediatr.* 9:679279.
doi: 10.3389/fped.2021.679279

Inherited macrothrombocytopenia (IMTP) is a rare disorder characterized by a reduced platelet count and abnormally large platelets. The main clinical symptom of IMTP is mild bleeding in some patients. At present, more than 30 genes have been identified in patients with syndromic and non-syndromic IMTP. In this study, a 3-year-old boy and his mother who presented with mild epistaxis and/or gingival bleeding were diagnosed as having IMTP. We then selected whole sequencing to explore the genetic lesion of the patients. After data filtering and mutation validation, a novel frameshift mutation (NM_001130004: c.398_399insTGCG, p.F134AfsX60) of α -actin 1 (*ACTN1*) was identified in the proband and his mother but absent in other unaffected individuals. Previous studies have proven that mutations in *ACTN1* may lead to IMTP with mild to absent bleeding phenotype. The novel mutation, resulting in a truncated protein in exon 4 of the *ACTN1* gene, was absent in the public database, such as 1000G and genomAD. Further Western blot revealed that the expression of α -actin 1 in the proband was decreased overtly, which indicated that the novel frameshift mutation may induce non-sense-mediated mRNA decay. In summary, this study not only broadened the variants spectrum of *ACTN1* gene, which may contribute to the genetic counseling of IMTP, but also confirmed the diagnosis of IMTP, which may help the management and prognosis for the family members.

Keywords: macrothrombocytopenia, mild bleeding, *ACTN1* mutation, non-sense-mediated mRNA decay, whole-exome sequencing

INTRODUCTION

Inherited macrothrombocytopenia (IMTP) is an important cause of thrombocytopenia, which is defined as a platelet count of $<150 \times 10^9/L$ (1–3). Besides the reduced platelet count, a significant increase in platelet size (>12 fL) is another feature of IMTP (1, 3). As a rare clinical condition, IMTP affects at least 2.7 per 100,000 individuals with mild to absent bleeding phenotype (2, 4). At present, mutations in more than 10 genes including α -actin 1 (*ACTN1*), myosin heavy chain 9 (*MYH9*), tubulin beta class I (*TUBB*), etc. have been identified in non-syndromic IMTP with autosomal

dominant, recessive, and sex-linked patterns (1, 3). In addition, some syndromes are also typically characterized by low platelet counts and severe bleeding tendency, such as Wiskott-Aldrich syndrome, Bernard-Soulier syndrome, Di George syndrome, and so on (5–7). However, because of varying mutations and clinical manifestations, the IMTP shows obvious heterogeneity, which challenges the clear diagnosis of IMTP and leads to the misdiagnosis as immune thrombocytopenic purpura (8).

In this study, we enrolled a 3-year-old boy and his mother with IMTP and mild epistaxis and/or gingival bleeding. The aim of this study was to explore the genetic lesion of the patients with the help of whole-exome sequencing.

CASE PRESENTATION

A family from central south region of China (Hunan province) including seven persons was investigated in this study (Figure 1A). The proband (III-2), a 3-year-old boy, was admitted to our hospital because of mild epistaxis. Blood routine examination of the proband was shown as follows: hemoglobin, 13.0 g/dL; platelet count, $102 \times 10^9/L$; mean platelet volume, 12.9 fL; and platelet distribution width, 18.1 fL. *In vitro* platelet aggregation in response to collagen and ristocetin was normal, but adenosine diphosphate (ADP) was slightly reduced (35%). Medical history survey found that the boy (III-2) has suffered from epistaxis several times with unexplained reason. Further family history investigation revealed that the proband's mother (II-1) and grandfather (I-1) have a history of mild epistaxis and gingival bleeding. Blood routine examination of the proband's mother (II-1) also found the reduced platelets ($111 \times 10^9/L$) count and increased mean platelet volume (12.7 fL) and platelet distribution width (17.7 fL). Peripheral blood smears May-Grünwald Giemsa staining revealed macrothrombocytopenia in the proband and his mother (Figure 1B). No other family members showed abnormal blood routine examination and bleeding diathesis. In addition, 200 unrelated, ethnically matched healthy controls were used as internal controls to exclude single-nucleotide polymorphisms (SNPs) in local individuals. These healthy controls (male/female: 100/100, aged 36.7 ± 8.6 years) lacked IMTP diagnostic features. Each participant underwent thorough examination for clinical diagnosis or exclusion, including general examination such as blood routine examination and peripheral blood smear May-Grünwald Giemsa staining.

We then employed whole-exome sequencing to explore the candidate gene mutation in the proband (III-2). Whole-exome sequencing was conducted at BerryGenomic Institute (Beijing, China) (9). Exomes were captured by Agilent SureSelect Human All Exon V6 kits, and high-throughput sequencing was conducted with an Illumina HiSeq 4000 system. The strategies of data filtering were as follows (9, 10): (a) non-synonymous SNPs or frameshift-causing INDELs with an alternative allele frequency >0.01 in the NHLBI Exome Sequencing Project Exome Variant Server (ESP6500), dbSNP155, the 1000 Genomes Project, the genomAD database, or in-house exome databases of BerryGenomic (2,000 exomes) were excluded; (b) the filtered SNVs and INDELs, predicted by SIFT, Polyphen2, and MutationTaster to be damaging, were remained; (c) the

FIGURE 1 | The clinical data and genetic analysis of the family with IMTP and mild bleeding. **(A)** Pedigree of the family. Black circles/squares are affected; white circles/squares are unaffected; slashed symbol is deceased family member. Arrow indicates the proband. **(B)** Blood smears (May-Grünwald Giemsa staining) revealed macrothrombocytopenia in the proband and his mother. **(C)** Sanger DNA sequencing chromatogram demonstrates the heterozygosity for an *ACTN1* frameshift mutation (NM_001130004: c.398_399insTGCG, p.F134AfsX60) in affected members. **(D)** Western blot analysis of the expression of *ACTN1* in the proband's platelets.

variants belong to pathogenic and likely pathogenic according to American College of Medical Genetics (ACMG) guideline remained (11); (d) cosegregation analysis was conducted in the family.

Whole-exome sequencing yielded 9.98-Gb data. After alignment and single-nucleotide variant calling, 70,145 variants were identified in the proband. Via the aforementioned filtering method and Sanger sequencing validation, a novel frameshift mutation (NM_001130004: c.398_399insTGCG, p.F134AfsX60) of *ACTN1* was identified in the proband and his mother but absent in unaffected individuals (Figure 1C). No other potential pathogenic mutation for macrothrombocytopenia-related phenotype was found (Table 1). Previous studies have proven that mutations in *ACTN1* may lead to IMTP with mild to absent bleeding phenotype (12, 13). The novel mutation, resulting in a truncated protein in exon 4 of the *ACTN1* gene, was absent in the public database such as 1000G and genomAD, as well as

our 200 healthy controls. Bioinformatics programs predicted that this mutation (NM_001130004: c.398_399insTGCG, p.F134AfsX60) was a pathogenic mutation and located in an evolutionarily conserved site of the α -actin 1 protein. According to ACMG guidelines (11), this mutation was pathogenic (PVS1 + PM2 + PM3). We then further extracted total protein from the platelet of the proband and healthy control (II-2). Western Blot indicated that, compared with the healthy controls, the expression of *ACTN1* was decreased by ~49% in the heterozygous carrier (**Figure 1D**). These data suggested that the variant (NM_001130004: c.398_399insTGCG, p.F134AfsX60) of *ACTN1* was a loss-of-function mutation and can lead to non-sense-mediated mRNA decay.

DISCUSSION

The human *ACTN1* gene encoding a member of the actin-crosslinking protein named α -actinin is located on chromosome 14q24.1, and it consists of 21 exons spanning ~3.78 kilobases. α -Actin 1 participates in the organization of the cytoskeleton, thought to be an anchor actin to a variety of intracellular structures and mainly expressed in platelets and megakaryocytes (14). In 2013, six different mutations of *ACTN1* were identified in 13 unrelated families with IMTP, which indicated that *ACTN1* was one of the genetic lesions in IMTP (12). At present, thrombocytopenia caused by pathogenic variants in *ACTN1* gene has been classified to ACTN1-related thrombocytopenia (15). To date, approximately 44 mutations of *ACTN1* have been detected in IMTP patients. Here, we identified a frameshift mutation (NM_001130004: c.398_399insTGCG, p.F134AfsX60) of *ACTN1* in a Chinese family with IMTP. As far as we know, this mutation may be first reported in IMTP patients; our study expanded the variant spectrum of *ACTN1* gene.

The α -actin superfamily consists of four members including ACTN1, ACTN2, ACTN3, and ACTN4, which are responsible for the organization of the cytoskeleton (3, 16). Previous studies have found that *ACTN1* was mainly expressed in platelets and megakaryocytes; the mutated *ACTN1* may lead to a decrease of 50% platelet counts and an increase of 30% in platelet size (12, 17). In our study, the proband and his mother with the novel mutation of *ACTN1* were also presented with macrothrombocytopenia. The novel frameshift mutation (NM_001130004: c.398_399insTGCG, p.F134AfsX60) can lead to the truncation mutation in the N-terminal of ACTN1. According to non-sense-mediated mRNA decay theory (18), the novel mutation may result in the decreased mRNA levels of *ACTN1*. Functional studies further confirmed that the novel mutation may lead to the reduction of *ACTN1* expression, which may affect the organization of the cytoskeleton in platelets and megakaryocytes, finally resulting in macrothrombocytopenia.

Previous studies in Chinese hamster ovary cells revealed that the mutated *ACTN1* may disrupt the normal actin-based cytoskeletal structure (12). The mice with *ACTN1* mutation may present with disorganized actin-based cytoskeleton in megakaryocytes, which may further result in abnormal number and size of platelets (12). In this study, the phenotypes

AD, autosomal dominant; AR, autosomal recessive. The MAF of these mutations was <0.01 in ESP6500, dbSNP155, the 1000 Genomes Project, the genomAD database, and in-house exome databases of BerryGenomic. The bold words represent the genetic mutation which was responsible for this family.

of the novel mutation (NM_001130004: c.398_399insTGCG, p.F134AfsX60) carriers (II-1 and III-2) were consistent with mice model and other reported patients, which further confirmed the pathogenicity of this novel mutation (19, 20).

IMTP can easily be misdiagnosed as immune thrombocytopenic purpura, which may further make problems in therapy and management of patients (8). Hence, precise diagnosis is necessary for IMTP patients, especially for the IMTP patients caused by *ACTN1* mutations. A recent study that involved ~50 *ACTN1* mutation carriers indicated that *ACTN1* mutations lead to a benign form of platelet macrocytosis not always associated with thrombocytopenia (21). Precise diagnosis of *ACTN1*-caused IMTP can provide affected patients and their family members with a good prognosis. In our study, we confirmed the diagnosis of the affected members by whole-exome sequencing and Sanger sequencing, which may aid in the further management and prognosis of the family members. Meanwhile, our study also indicated that whole-exome sequencing combined with Sanger sequencing was an effective method in diagnosis of IMTP.

In summary, by employing whole-exome sequencing, we identified a novel frameshift mutation (NM_001130004: c.398_399insTGCG, p.F134AfsX60) of *ACTN1* in a Chinese family with IMTP and mild epistaxis and/or gingival bleeding. Hence, this study not only broadened the variants spectrum of *ACTN1* gene, which may contribute to the genetic counseling of IMTP, but also confirmed the diagnosis of IMTP, which may help in the management and prognosis of the family members.

Next-Generation Sequencing Analysis of *GBA1*: The Challenge of Detecting Complex Recombinant Alleles

Elizabeth G. Woo, Nahid Tayebi and Ellen Sidransky*

Medical Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD, United States

Keywords: next-generation sequencing, glucocerebrosidase, Gaucher disease, *GBA1*, pseudogene, genotyping

INTRODUCTION

Gaucher disease (GD) is a rare autosomal recessive lysosomal storage disorder caused by pathologic variants in *GBA1*, the gene encoding the enzyme glucocerebrosidase. Deficiency of glucocerebrosidase leads to the accumulation of the substrates glucocerebroside and glucosylsphingosine in macrophages and neuronal cells. Variants in *GBA1* are a significant genetic risk factor for Define- Parkinson disease (PD) (Sidransky et al., 2009). Both patients with GD and heterozygous carriers are at an increased risk of developing PD, although the exact mechanism of this association is not fully understood (Avenali et al., 2020). An estimated 5–20% of patients with PD carry a *GBA1* mutation, although the frequency varies between populations (Gan-Or et al., 2015). The association of *GBA1* variants with this common complex disorder has led to an increasing interest in analyzing *GBA1* in larger cohorts using next-generation sequencing (NGS) methods (Nalls et al., 2014; Gorostidi et al., 2016; Blauwendraat et al., 2018; Stoker et al., 2020). Challenges arise in using NGS for *GBA1* analysis, however, due to the downstream, highly homologous pseudogene.

GBA1 is located in a gene-rich region on chromosome 1q21 that encompasses seven genes and two pseudogenes within an 85-kb region (Winfield et al., 1997). *GBA1* contains 11 exons and 10 introns over a length of 7.6 kb. Located 16 kb downstream is the shorter (5.7 kb), non-processed pseudogene, *GBAP1* (Horowitz et al., 1989). In the coding regions, *GBAP1* is 96% homologous to the functional gene, increasing to around 98% in the region between intron 8 and the 3' UTR. However, *GBAP1* lacks a 55-bp segment in exon 9, which is the major exonic difference between the two sequences (Walley and Harris, 1993; Beutler et al., 1995; Tayebi et al., 1996b). *GBA1* has several *Alu* intronic insertions that are not present in *GBAP1*, indicating that evolutionarily, the gene duplication occurred prior to the integration of the *Alu* sequences (Horowitz et al., 1989). The closest downstream gene, located just beyond *GBAP1* is metaxin (*MTX1*), encoding for part of the mitochondrial outer membrane import complex protein 1, which is transcribed convergently to *GBA1* (Long et al., 1996). *MTX1* also has a pseudogene located in the 16-kb region between *GBA1* and *GBAP1* (Figure 1A). Several hundred mutations have been identified in *GBA1* including missense mutations, deletions, insertions, splice site mutations, and complex recombinant alleles (Hruska et al., 2008).

The presence of these pseudogenes in this region increases the risk for recombination and the generation of complex alleles, particularly due to the close physical proximity and high homology between *GBA1* and *GBAP1* (Chen et al., 1997). Recombinant alleles can arise from both reciprocal and non-reciprocal recombination, resulting in gene fusions, duplications, and gene conversion alleles (Cormand et al., 2000; Tayebi et al., 2003). These genes can serve as a model to demonstrate the effect of unequal pairing and crossover resulting in recombinant alleles in the genome. Identifying complex alleles poses a significant challenge when relying on NGS analysis.

FIGURE 1 | (A) Scaled representation of *GBA1*, *MTX1*, and their highly homologous pseudogenes. *MTXP* lies in the 16 kb region between *GBA1* and *GBAP1*. *MTX1* and *MTXP* are transcribed in the direction opposite to that of *GBA1* and *GBAP1*. **(B)** Example of a reciprocal crossover event, resulting in a (i) gene-pseudogene fusion allele and a (ii) duplicated allele. These recombinant alleles are difficult to detect using next-generation sequencing methods. Sequence reads containing the pseudogene-derived segment (red) of the recombinant alleles may align to the pseudogene instead. This can lead to false negatives and reduce the read depth of *GBA1*. In this example, reads containing the 55 bp deletion from the recombinant alleles may align preferentially to the pseudogene (Adapted in part from Tayebi et al., 2003).

***GBA1* GENOTYPING BY CONVENTIONAL MEANS**

Previously, PCR-based screening techniques were often used targeting specific panels of 7–10 common *GBA1* pathologic variants (Park et al., 2002). These variants were predicted to account for over 90% of mutant alleles among Ashkenazi Jews, a population with a carrier rate of ~1 in 14 (Do et al., 2019). However, relying on such panels can miss other mutant alleles, as demonstrated by a 2019 study that fully sequenced *GBA1* in an Ashkenazi Jewish Parkinson disease patient cohort (Ruskey et al., 2019). Sanger sequencing substantially increased variant detection, even in this group, particularly for the common E326K (p.E365K) variant, known to be present in ~1% of the general population (Lau et al., 1999; Park et al., 2002). This highlights the benefit of sequencing the full *GBA1* gene to detect variants that could be missed using targeted genotyping of selected pathogenic variants. When sequencing *GBA1*, specific primers are required to ensure that functional *GBA1* is being amplified and sequenced rather than the pseudogene (Dandana et al., 2016). For example, primers targeted to the 55-bp pseudogene gap in exon 9 can erroneously misreport patients heterozygous for a recombination in that region as homozygosity for the second allele (Tayebi et al., 1996b).

NEXT-GENERATION SEQUENCING OF *GBA1*

Next-generation sequencing is able to generate vast amounts of sequence data and has been applied to identify variants in *GBA1*. The use of whole-exome and whole-genome sequencing has increased the discovery rate of these variants. For example, a recent large-scale NGS strategy identified 18 novel *GBA1* variants, as well as a rarely reported complex allele likely to be a Dutch founder allele (Zampieri et al., 2017; den Heijer et al., 2020). One Gaucher diagnostics laboratory relying on NGS run by Centogene (Rostock, Germany) provides an on-line list of their identified *GBA1* variants (CentoLSD™), which now includes over 600 different *GBA1* variants with differing predicted clinical significance (<https://www.centogene.com/centolsd.html>). Many NGS protocols have utilized short-read sequencing, which can provide data at a relatively low cost and high accuracy but may be less reliable in cases where there are structural variants and repetitive or highly homologous regions (Mandelker et al., 2016; Mantere et al., 2019). If the functional gene is not specifically amplified during library preparation, reads generated by the pseudogene could align with the functional gene, leading to false-positive results, while reads belonging to the functional gene might align to the pseudogene, reducing

read depth and mapping quality (Claes and De Leeneer, 2014). Long range-PCR (LR-PCR) can help to selectively amplify the functional gene (Tayebi et al., 1996a; Jeong et al., 2011). Even after selectively amplifying the functional gene, challenges still remain in the alignment phase, particularly when recombinant alleles contain regions identical to the pseudogene. In an Illumina short-read NGS method for sequencing *GBA1*, Zampieri et al. initially aligned reads to the whole genome, but missed almost all recombinant alleles, which had aligned preferentially to *GBAP1* (Zampieri et al., 2017). After aligning to *GBA1* rather than the whole genome, they were able to identify recombinant variants that had initially been false negatives, except for the 55-bp deletion mutation. Alignment against the whole genome did not significantly affect the mapping quality and coverage of missense mutations unrelated to recombination. Care should therefore be taken not only in the library preparation, but also in data analysis steps of NGS pipelines to sequence *GBA1*.

The introduction of long-read sequencing technology in recent years addressed some limitations of short-read sequencing (Goodwin et al., 2016). The ability to read longer sequences can help to differentiate highly homologous regions. One such technology is the Oxford Nanopore system, which analyzes a single DNA molecule as it passes through a pore (Logsdon et al., 2020). Resulting disruptions to the current are analyzed in real-time to determine the sequence. This strategy has been applied for the detection of *GBA1* variants using the Oxford Nanopore MinION (Leija-Salazar et al., 2019). The authors were able to detect the 55-bp exonic deletion, but not the more common recombinant allele *RecNciI*. Another study aimed to expand upon this protocol by refining and applying it to the discovery of *GBA1* variants in a PD longitudinal cohort from New Zealand (Graham et al., 2020). They validated the protocol of Leija-Salazar et al. for genotyping *GBA1* and updated the software pipeline, improving accuracy and reducing the computational workload, but were unable to detect any recombinant gene conversion alleles or deletions of >50 bp.

CHALLENGES IN DETECTING RECOMBINANT ALLELES

Accurate and comprehensive NGS analysis of *GBA1* is complicated by complex gene-pseudogene rearrangements and recombination. Recombinant alleles make up a significant proportion of *GBA1* mutations and sites of recombination events have been identified between intron 2 to exon 11 (Hruska et al., 2008). With the high exonic homology between *GBA1* and its pseudogene, there is an increased likelihood of both reciprocal and non-reciprocal recombination (Tayebi et al., 2003). These can result in alleles with multiple exonic point mismatches, such as in *RecNciI*. In this allele, the site of crossover of chromosomal mispairing between gene and pseudogene occurs within intron 9 and continues to the 3'-UTR of the gene, introducing three exon 10 nucleotide mismatches (Latham et al., 1990). Another frequently described reciprocal recombinant allele, *RecTL*, covers the pseudogene sequence from intron 8 or the beginning of exon 9 [Figure 1B(i)] (Zimran and Horowitz, 1994).

Reciprocal crossover can also result in a partial duplication of the gene and pseudogene sequence [Figure 1B(ii)]. The non-reciprocal exchange of homologous sequence, also known as gene conversion, may also occur. One example is an allele that includes only the 55-bp deletion in exon 9. This is a small, converted gene sequence that resembles the pseudogene. Some polymorphic sequences in *GBAP1* (Martinez-Arias et al., 2001) also been observed. Mostly, homologous recombination events occur in regions of high sequence homology between the gene and pseudogene, such as in introns 8 and 9. Several instances of recombination have occurred as a result of crossover between *MTX* and its pseudogene as well (Tayebi et al., 2003). Quantitative real-time PCR and Southern blot analysis have been used to identify fusions and duplications in patients with recombinant *GBA1* alleles (Velayati et al., 2011).

The complexity of *GBA1* gene rearrangements cannot be sufficiently captured using most current NGS methods. Several recent studies using NGS technology without Sanger sequencing validation have not reported the presence of recombinant alleles, including a recent study performed on more than 3,000 PD cases (den Heijer et al., 2020). Thus, it is likely that the results presented may be an underestimation (Zampieri et al., 2017).

NON-CONVENTIONAL INHERITANCE

Gaucher disease is an autosomal recessive disorder that usually results from the inheritance of a mutant allele from each parent. Increasing evidence suggests this may not always be the case, and that there are important exceptions to the traditional Mendelian pattern of inheritance, such as new mutations or uniparental disomy (Nakka et al., 2019). There have been several reported cases of unrelated patients with type 2 GD with *de novo* or germline mutations on the maternal allele (Saranjam et al., 2013; Hagege et al., 2017). Uniparental disomy of chromosome 1 was reported in a proband with concurrent type 3 GD and Charcot-Marie-Tooth disease, who was homozygous for both L444P (p.L483P) in *GBA1* and S78L in *MPZ* (Benko et al., 2008). There have also been cases of patients with all types of GD carrying more than one *GBA1* mutation on the same allele (Hassan et al., 2018). For example, a common mutant allele in Greece and the Balkans includes both H255Q (p.H255Q) and D409H (p.D448H) together in cis (Vithayathil et al., 2009). These examples of non-conventional inheritance underscore the importance of careful and comprehensive examination of entire coding regions for accurate genotyping. This has important implications for diagnostics and establishing genotype-phenotype correlations. Current NGS technology, however, does not always accurately identify all nucleotide changes and recombinant alleles. As a result, NGS is currently limited in its clinical diagnostic capacity for comprehensive *GBA1* screening, and for now, Sanger sequencing should be used for the most accurate genotyping.

DISCUSSION

Next-generation sequencing allows for unbiased simultaneous analysis of many genes. In addition, it makes it more feasible to

analyze specific genes in larger cohorts for the study of common diseases like Parkinson disease. With the inclusion of *GBA1* in many Parkinson disease NGS analyses, it is important to consider the effects of the nearby homologous pseudogene. Recombinant alleles in *GBA1* have been identified in patients with GD and with PD that might be missed when relying on NGS analysis alone without Sanger sequencing validation.

Challenges exist in short-read NGS methods for sequencing highly homologous regions. The shorter reads cannot be mapped uniquely to the reference genome, especially in cases where there are recombinant alleles aligning to the homologous region. A computational custom scaffold-based approach was recently introduced to improve the detection and phasing of targeted complex variants using short reads (Zeng et al., 2020). This method was able to detect a 55-bp deletion in *GBA1* confirmed by Sanger sequencing. In addition, there is evidence to suggest that the choice of polymerase used could be a factor in the accuracy of NGS variant identification. A recent study performed a large-scale screening of *GBA1* based on an NGS protocol and found a significant number of false negatives due to a polymerase-dependent allelic imbalance (den Heijer et al., 2021). After performing a structured assessment of varied PCR conditions, they found that changing the polymerase used led to the resolution of these false negatives. Allele frequency was unaffected by a change in the other conditions. This raises the possibility that current estimates of variant frequency in populations could be underestimates, due to polymerase-dependent false negatives as well.

Long-read NGS has many advantages, one of which is an improved ability to discriminate functional genes such as *GBA1* from their pseudogenes. An additional advantage is the ability to phase mutations and assign haplotypes. It can also detect intronic SNPs. There are still some limitations, including high costs, low throughput, and high per-base error rates. Long-read NGS also

has a limited ability to accurately resolve homopolymers and to detect small insertions and deletions. Importantly, it is still unable to consistently detect recombinant alleles.

The most accurate method for detecting all *GBA1* variants and recombination remains Sanger sequencing. Without validation by Sanger sequencing, the frequencies of *GBA1* variants based on NGS analysis may be underestimated, particularly for complex recombinant alleles. Real-time PCR can also be used to identify recombinant alleles (Velayati et al., 2011). NGS pipelines should be carefully designed in order to capture variants should from the functional gene rather than the pseudogene and attempt to include complex alleles. While long-read sequencing shows promise for increased accuracy of *GBA1* NGS analysis, it is still currently limited in its capacity to recognize recombinant alleles. The shortcomings identified will likely also be pertinent for the analysis of other genes with highly homologous pseudogenes. As sequencing technology continues to rapidly progress, we will likely continue to see improved detection of *GBA1* variants. This has exciting potential for clinical diagnostics and studies of large patient cohorts.

It is estimated that around 10–20% of hypospadias are caused by genetic abnormalities worldwide although the spectrum of associated genes does vary across different ethnicities. The prevalence of hypospadias among the Chinese population has been increasing the last couple of decades. However, the pathogenesis underlying the disease and its associated genetic abnormality remains unclear. Here we performed a genetic analysis of 81 children with karyotype 46, XY and the hypospadias phenotype in order to characterize the genetic components that contribute to the development of hypospadias in Chinese patients. 15 candidate genes, including sex determination genes-SOX9, SRY, NR0B1 (DAX1), NR5A1 (SF1), DHH, sex differentiation genes-AR, SRD5A2, MAMLD1, INSL3, and hypospadias-associated genes-FGF8, FGF10, BMP4, BMP7, ATF3, and MID1 were screened by using next generation sequencing. A total of 18 patients were found to have mutations identified by PCR and sequencing, including 11 cases of SRD5A2 genes, 6 cases of AR genes, and 1 case of MID1 gene, respectively. One novel missense mutation p.I817N was discovered in AR gene. Further molecular analysis found that subcellular localization of the AR_{I817N} was the same as that of wild type AR_{WT} in the absence or presence of hormone. But it led to 50% reduction in AR-induced transcriptional activity in the presence of either the synthetic androgen R1881 or the natural ligand dihydrotestosterone. Our results indicate that SRD5A2 and AR genes are two top candidate genes associated with 46, XY hypospadias in Chinese patients. Further epidemiological and genetic analysis are still needed to further clarify the pathogenesis of hypospadias in Han Chinese patients.

Keywords: hypospadias, gene mutations, AR, SRD5A2, gene function analysis

INTRODUCTION

Hypospadias is one of the most common congenital malformations of the penis (van der Horst and de Wall, 2017; Donaire and Mendez, 2018). It is characterized by a failure of urethral groove closure resulting in an opening on the ventral surface of the penis. The prevalence of hypospadias varies according to ethnical and geographical differences. The reported prevalence in Western countries ranges from 2 to 43 out of 10,000 live births (Springer et al., 2016). In China, the prevalence was

0.7–4.5 from 1996 to 2008, and 5.8 per 10,000 live births in 2010 (Jin et al., 2010), but has increased to 9.3 per 10,000 live births as of 2012 (Li et al., 2012).

Although the exact etiology of hypospadias is unknown, it is agreed upon that environment, endocrine hormones, and genetic factors all play a collective role in the pathogenesis (Carmichael et al., 2012). Environmental factors such as assisted reproductive technology, maternal hypertension during pregnancy, thyroid disease, higher maternal age at delivery, low birth weight, preterm birth, and primiparity have been proposed. Most diagnosed cases of hypospadias are sporadic, but family cluster genetic phenomena do occur (Donaire and Mendez, 2018).

Genetic disruption of male external genital development and urethral growth contribute to 20% of the etiology of hypospadias (Domenice et al., 2000; Gangaher et al., 2016). There are three key pathways in the development of male external genitalia: (a) androgen independent, (b) androgen dependent, and (c) pathways dependent on endocrine and environmental factors (Manson and Carr, 2003). The steroid 5 α -reductase 2 (SRD5A2) and androgen receptor (AR) genes are two androgen dependent genes that were widely evaluated in hypospadias. Among the Chinese population, SRD5A2 and AR dysfunction have been discovered in some patients with hypospadias. The AR is an intracellular transcription factor and plays a crucial role in male sex differentiation. In both sporadic and familial hypospadias, AR gene mutations have been discovered. Hypospadias is one of the major phenotypes of partial androgen insensitivity syndrome (PAIS) (Joodi et al., 2019). To date, over 1,000 mutations have been reported in the AR gene, and it is usually included as one of the top genes in the screening panel test for patients with hypospadias. Moreover, not only are their mutations reported in the coding region of AR, but also SNPs located in the promoter region of AR gene were involved in the development and severity of hypospadias (Geller et al., 2014; Pineyro-Ruiz et al., 2020) however, the functional importance of these mutations remains less known. AR gene mutations also lead to several pathological situations such as androgen insensitivity syndrome (AIS), spinal and bulbar muscular atrophy (SBMA), and prostate cancer (Shukla et al., 2016).

To explore the spectrum of genetic abnormality in Chinese hypospadias patients, we performed next generation sequencing (NGS) on 81 patients with hypospadias targeting 15 candidate genes that could potentially cause hypospadias including (1), sex determination genes: sex determining region of Y chromosome (SRY), SRY-related high mobility group box gene 9 (SOX9), nuclear receptor subfamily 0 group B member 1 (NR0B1), nuclear receptor subfamily 5 group A member 1 (NR5A1), desert hedgehog (DHH) (2), sex differentiation genes: SRAD5, AR, mastermind-like domain-containing protein 1 gene (MAMLD1), Leydig cell insulin-like 3 (INSL3) (3), and hypospadias genes reported by other studies: bone morphogenetic protein gene 4 and 7 (BMP4 and 7), fibroblast growth factor 8 and 10 (FGF8 and 10), activating transcription factor 3 (ATF3), and midline 1 (MID1). Multiple mutations were found in these patients, but not in 50 healthy controls. One of 4 identified AR missense mutations was *de novo* and functional impairment of AR from this mutation was further explored *in vitro*.

MATERIALS AND METHODS

Patients

Patients with external genital malformations who were followed in the Department of Pediatrics at Ruijin Hospital, Shanghai Jiao Tong University School of Medicine from January 2004 to December 2020 were screened initially. 81 cases with karyotype 46, XY and phenotype of hypospadias were identified and included in this study. Those patients who had syndrome related external genital malformations were excluded. Informed written consent was obtained from all patients' parents or their guardians. In addition, 50 boys without external genital malformation were selected as controls for genetic analysis. The study was approved by the Institutional Review Board (Ethics Committee of Shanghai Jiao Tong University School of Medicine).

Clinical Assessment

Clinical assessment of these patients included the child's birth history, family history, maternal history (exogenous sex hormone exposure or intake history during pregnancy), living environment and possible history of exposure to environmental pollutants. Age, gender, body weight, gonadal developmental status, degree of external genital malformation according to the external masculinization score (EMS), and type of hypospadias were recorded. The measurement of penis length and reference value of Chinese men were performed according to the published study by Fu Chao et al. in 2010 (Fu Chao and Xuliang, 2010). The diagnosis of cryptorchidism in these patients was made according to the study performed by Bao et al. (Bao and Zhang, 2012). External Masculinization Score (EMS, range 0–12) (Ahmed et al., 2000) was used to assess the degree of virilization of the external genitalia. The normal male score is 12 and a smaller score indicates a lower virilization degree. An EMS < 7 is considered ambiguous.

Gonadotropin-Releasing Hormone (GnRH) Agonist Testing and Human Chorionic Gonadotropin (hCG) Stimulation Test

GnRH agonist testing was performed in some patients using intravenous administration of a standard dose of GnRH (2 ug/kg Gonadorelin acetate, maximum dose 100 ug). Blood samples were collected at time points 0, 30, 60 and 90 min after stimulation. Normal test was defined as luteinizing hormone (LH) increases about 3–6 times within 30–45 min, and follicle stimulating hormone (FSH) increases by 20–50% after GnRH injection. Serum LH and FSH were measured by immunoradiometric assay (Abbott, Chicago IL). The hCG stimulation test which was used to evaluate the function of testicular synthetic androgens was performed in some patients with a daily injection of hCG (2,000 U) for 3 days. Serum testosterone (T) and dihydrotestosterone (DHT) were measured using a radioimmunoassay kit (Diagnostic Systems Laboratories, Webster, Tex., United States).

DNA Extraction, PCR and Sequencing

Genomic DNA was extracted from the peripheral whole blood using the FlexiGene DNA Kit (Qiagen GmbH, Hilden, Germany), according to the manufacturer's instructions. 15 genes (FGF8, FGF10, BMP4, BMP7, NR5A1, MAMLD1, SRY, SOX-9, NR0B1, DHH, ATF3, INSL3, MID1, SRD5A2, and AR) according to literature search were selected as candidates for polymerase chain reaction (PCR) and sequencing. Primers targeting all exons of these genes were designed using online tool Primer3¹. PCRs were performed in a reaction volume of 50 μ l containing 20 ng template DNA. A 5 μ l aliquot of each PCR was loaded on a 2% agarose gel and visualized by ethidium bromide (Sigma-Aldrich, Beijing, China) staining to confirm the presence of an appropriately sized product. The PCR products were purified using a gel extraction kit (QIAGEN, Mississauga, Ont., Canada) and sequenced in both sense and antisense directions on an Illumina-miseq sequencer (Illumina, United States). DNA fragments were 250–400 bp and the coverage of samples was 80x–3,000x. Positive and negative controls were added to the samples. Sequences generated from all patients were compared with the published reference sequences from the National Center for Biotechnology Information². The mutation was annotated according to HGVS nomenclature³. For identified mutation from NGS, purified PCR products were further sequenced and verified by Sanger sequencing on an ABI 700 sequencer (Applied Biosystems PerkinElmer, Foster City, Calif., United States). The ACMG guidelines (Amendola et al., 2016) were used to classify the mutations into five classifications: pathogenic (P), likely pathogenic (LP), variants of uncertain significance (VUS), likely benign (LB), or benign (B).

Site-Directed Mutagenesis and Construction of AR Expression Vectors

The wild type AR expression plasmid (AR_{WT}) (SC114220) was bought from Origene (Rockville, MD). It served as a template to construct the mutant p.I817N (AR_{I817N}) using the QuikChange II site-directed mutagenesis kit (Agilent Genomics, Santa Clara, CA, United States). The primers were ART2450aF: ccattccactggattaatgctgaagagtagcagtgct and ART2450aR: agcactgtctactcttcagcattaatccagtgatgg. Positive clones were selected and sequenced to confirm the site-directed mutation (Du et al., 2009).

Immunofluorescence Staining

The cultured cells were fixed and then followed by overnight incubation with primary antibody anti-AR (Invitrogen). Sections were washed and then incubated with Cy2-anti-mouse and Cy5 anti-rabbit (Jackson Immuno Research, West Grove, PA). Nuclear staining was performed using 4',6-diamidino-2-phenylindole (DAPI; Molecular Probes, Eugene, OR). Confocal microscopy was performed using a Leica SP2AOBS system (Leica, Wetzlar, Germany) in the Light Microscopy Core Center at the Shanghai Jiao Tong University.

Western Blot

Cells harvested from cultures were homogenized in cell lysis buffer (Cell Signaling Technology, Danvers, MA). Protein concentration determination and immunoblotting were performed as previously described. Briefly, twenty micrograms of protein were separated by SDS-PAGE, transferred to polyvinylidene difluoride membranes and blotted with primary antibodies and secondary antibodies (Cell Signaling Technology, Danvers, MA). Quantification of the image was performed by scanning densitometry and using NIH Image J 1.54 software (National Institutes of Health, Bethesda, MD).

The Transcription Activity Assay

The transactivation activity of the p.I817N mutated AR and wild-type AR were compared in a reporter gene assay as previously described (Du et al., 2009). In brief, Chinese hamster ovary cells (CHO) were transfected with a total of 100 ng DNA per well, consisting of the expression vector (AR_{WT} or AR_{I817N}) and the Cignal reporter plasmid (QIAGEN, Germantown, MD) using transfection reagent Lipofectamine 2000 (Invitrogen, Grand Island, NY, United States). Cells were incubated overnight with dihydrotestosterone (DHT; 0.01–30 nM), methyltrienolone (R1881; 0.001–100 nM), and hydroxyflutamide (OHF; 1–5,000 nM) each in triplicate. For OHF treatment, 0.1 nM of R1881 was added 30 min before the addition of OHF to determine the competition binding. Then cells were lysed and luciferase activity assayed using Victor³ plate reader (PerkinElmer, Waltham, MA).

Statistical Analysis

Statistical analyses were performed using an unpaired, two-tailed *t*-test for comparing between AR_{WT} and AR_{I817N}. The one-way ANOVA was used for comparing cellular responses after R1881 treatment. The clinical data description was not involved in the statistics. Calculations were performed using Graphpad Prism 9 software. Significance was determined using a threshold of *P* = 0.05. All values were reported as mean \pm standard error of the mean (SEM) for three independent experiments.

RESULTS

Clinical Findings of Patients With Hypospadias

All 81 patients diagnosed with hypospadias exhibited other features of external genital malformations at variable degrees as listed in **Table 1**. The age of patients ranged from 3 months to 22.2 years and the average age is 6.1 ± 5.1 years old. According to the location of the urethral meatus, hypospadias was classified into four types. Type I was glandular or coronal, type II was shaft (distal, mid and proximal), type III was scrotal and type IV was perineal. The majority of patients (52/81) were found to have severe types (III and IV). 18 (22.2%) patients were raised as female after birth due to obscure external genitalia, short penis, and poor scrotal development like the labia majora. Except for external genital malformation, some children were also accompanied by other abnormalities, such as being small for their

TABLE 1 | Clinical characteristics of 81 patients diagnosed with hypospadias.

Type of hypospadias	I	II	III	IV	Total
Number of cases (%)	9 (11.1%)	14 (17.3%)	31 (38.3%)	27 (33.3%)	81 (100%)

EMS, external masculinization score; SGA, small-for-gestational age; ASD, atrial septal defect.

gestational age, inguinal hernia, atrial septal defect and breast development during adolescence. A positive family history was found in 2 children, one of whom had a history of hypospadias in both his father and younger brother, and the other had a cousin diagnosed with hypospadias.

Forty-two cases received GnRH stimulation test as a follow up. Seven patients showed high gonadotrophin dysplasia and the remaining cases had normal response. Fifty-two patients underwent the hCG challenge test, and only five patients had a poor response (the T concentration increased less than 3 times of the baseline value after stimulation). Other patients demonstrated a normal testicular response to hCG.

Identification and Characterization of Nucleotide Substitutions

G banding method was used for karyotype analysis and all children have 46, XY chromosomes. 15 candidate genes were selected for the initial screening using Illumina-miseq sequencing according to previous literatures. All mutations detected in the initial screening by NGS were confirmed by traditional Sanger sequencing. A total of 18 patients were found to have mutations, including 11 cases of SRD5A2 genes, 6 cases of AR genes, and 1 case of MID1 gene. According to ACMG guidelines, these mutations were assessed as pathogenic (P) or likely pathogenic (LP) (Table 2). The presence of these mutations was further tested in 50 normal controls to rule out polymorphisms.

Patients With SRD5A2 Gene Mutations

There were 11 cases identified with SRD5A2 mutations. The age of diagnosis ranged from 4-month to 22-years old. The clinical characteristics are listed in Table 3. Among them, 8 patients were seen before puberty (0.3–5.6 years old) and 3 cases were raised as females. There was one case of type II hypospadias that was not accompanied by any other external

genital malformations, 7 cases of type III and 3 cases of type IV. The average EMS of these 9 patients was 4.9. The GnRH test was basically normal, but four children underwent hCG stimulation and were found to have increased T/DHT values. Genetic analysis showed 7 heterozygous mutations (p.R227Q/p.R246Q, p.G203S/p.R227Q, p.Y136Ter/p.R227Q, p.N193S/p.R246P, p.L20P/R227, p.N193S/p.F219Sfs*60, and p.G203S/F219Sfs*60) and 4 homozygous mutations (p.R227Q, p.G203S, p.R246P, p.L20P). 10 of them were reported in the literature. Only p.Y136Ter was a newly identified mutation, where cytosine at position 408 of exon 2 of SRD5A2 gene mutated to adenine causing the stop codon TAA and terminating translation. According to ACMG guidelines, this mutation was assessed as pathogenic (P/PVS1 + PM2 + PM6 + PP3).

Patients With AR Gene Mutations

There were 6 cases with an identified AR gene mutation, the clinical phenotype characteristics are shown in Table 4. Three children were younger (1.6, 0.3, and 5.9 years old) at the diagnosis and the other three had reached adolescence (14.6, 14.3, and 14.2 years old) before seeking medical care. 4 children were born with a female gender due to poorly developed scrotum-like labia. After comprehensive consideration of chromosomal factors, genitalization of the external genitalia, and psychological acceptance of children and parents, 2 patients were changed to male support, and 2 remained in female support. Three cases of hypospadias were type IV, one cases was type III, and the other two were type II. All abnormalities of AR gene were hemizygous mutations (p.R780W, p.I817N, p.R856H, and p.A871V) and included two gross deletions (Exon 5–8 gross deletion, chX 67716101–67724136, and exon 2 gross deletion chX 67643255–67643407). p.I817N was the newly discovered missense mutation and not found in the 50 normal controls. This site was located at the beginning of exon 7 of the AR gene, and

the 245th thymine was mutated to adenine, resulting in the amino acid at position 817 being changed from isoleucine to asparagine. According to ACMG guidelines, this mutation was assessed as likely pathogenic (LP/PS2 + PM1 + PP3 + PP4). Exon 5-8 gross deletion (chX 67716101-67724136) removed 8035bp including the totality of exon 5-8 and exon 2 gross deletion (chX 67643255-67643407) removed 152 bp containing

total exon 2 of AR gene, both were assessed as pathogenic (P/PVS1 + PM2 + PP3 + PP4).

Patients With MID1 Mutations

One patient carried a homozygous mutation in the *MID1* gene, p.P667L, which was located in exon 10 of the *MID1* gene and was the last amino acid encoded by the gene. *MID1* gene mutation

is associated with X-linked Opitz G/BBB syndrome (Fontanella et al., 2008; Preiksaitiene et al., 2015; Maia et al., 2017). The patient with this mutation which was identified in our study only had hypospadias without other symptoms or abnormalities. But according to ACMG guidelines, this mutation was assessed as likely pathogenic (LP/PM1 + PM2 + PP3 + PP4).

Expression and Sub-Cellular Distribution of AR_{I817N}

To determine whether the expression of the AR or the protein stability was affected by this newly identified mutation, site directed mutation was performed using wild type AR gene. An immunoblot was performed after incubation of CHO cell line transiently expressing AR_{WT} or AR_{I817N}, respectively, with different concentrations of R1881 or vehicles for 24 h. The protein expression level of AR_{I817N} appeared to be similar at every R1881 concentration (Figures 1A,B). These data rule out any severe change in protein stability in the absence or presence of ligand.

To investigate whether the p.I817N mutation of AR gene could influence AR expression, we further analyzed the subcellular localization of this mutant in CHO cell line. Cells were transfected with AR_{WT} or AR_{I817N} plasmid DNAs, and the localization of AR protein was examined using confocal microscopy. Both AR_{WT} and AR_{I817N} were predominantly located in the cytoplasm in the absence of hormone (Figures 2A,B,E). In the presence of 1nM R1881 both AR_{WT} and AR_{I817N} were translocated in a similar way to the nucleus and displayed a typical punctuate nuclear distribution (Figures 2C–E).

Transcriptional Activity of AR_{I817N}

The AR_{I817N} mutation is located in the ligand binding domain (LBD) of the AR, which may play a role in coactivator mediated activation of the transcription. Therefore, functional studies were performed to address whether the AR_{I817N} affects the transcription activation potential of AR. The AR_{I817N} or AR_{WT} expression vector was co-transfected with Cignal reporter in luciferase assay. In dose-response curve, the mutated AR showed reduced ability to induce AR-mediated activation of a reporter gene, compared to wild-type AR assessed by the natural ligand DHT or R188. p.I817N caused a 20~46% reduction in activity at doses between 1 and 10 nM DHT or 0.1–100 nM R1881 (Figures 3A,B). In addition, this was further illustrated by using

competitive binding assay with R1881. The mutated AR showed weaker competitive binding than the wild type (Figure 3C). These results suggest that p.I817N mutation leads to a decreased sensitivity of the androgen response.

DISCUSSION

The prevalence of hypospadias is increasing in China (Li et al., 2012). To explore the potential contribution of genetic components in these patients, we screened 81 children with karyotype of 46, XY who had hypospadias using NGS of 15 target genes. 18 out of 81 patients were found to have mutations. The identified genetic abnormalities of the novel missense mutation AR p.I817N were analyzed. It was also noted that 11 mutations in *SRD5A2* gene, 6 mutations in AR gene, and one variant in *MID1* gene in this study were also correlated to abnormal male genital development and hypospadias. The genetic abnormality is 22.2% (18/81) which is higher than reported in the literature which has previously suggested that 10–20% of hypospadias are caused by genetic abnormalities (Carmichael et al., 2012; Kalfa et al., 2019). It supports the hypothesis that hypospadias is a multifactorial disease and is a consequence of combination of both environmental and genetic abnormalities.

Male phenotypic development can be divided into two stages: sex determination and differentiation (Domenice et al., 2000). Genetic mutations in genital differentiation and external genital development can cause hypospadias. Based on previous reports, we have selected 15 genes which are potentially involved in the development of hypospadias. During male sexual development, expression of *SRY* induces a series of gene activation, including its direct downstream gene *SOX9*. They mainly act in the early stage of gender differentiation, and their mutations lead to the development of disorders of sexual development (Harley et al., 2003). *NR5A1* is an important transcription factor in male sexual development and steroid synthesis. *INSL3* regulates the expression of steroidogenic factor-1, which is an important regulator in the development of gonads and adrenal glands (Sadeghian et al., 2005). *NROB1* regulates the early stage of testicular differentiation, and its mutation most often causes adrenal hypoplasia congenita and gonadal dysplasia. *DHH* belongs to Hedgehog secretory signaling molecule family. *DHH* gene mutation can cause 46, XY partial gonadal dysplasia. In this study, 81 patients with hypospadias were screened and

we did not identify any genetic mutations in these six sex determination genes.

Genetic research on hypospadias has focused on identification of causal mutations too. Ethnic variation of genetic contribution of hypospadias has been described in the literature (Beleza-Meireles et al., 2007; van der Zanden et al., 2012). In Chinese patients, mutations or SNPs in *ATF3*, *FGF8*, *FGF10*, *BMP4*, *BMP7*, and *MAMLD1* have been reported. *ATF3* has a regulatory effect on cell growth (Liu et al., 2005; Kalfa et al., 2008). Co-expression and interaction among *FGF8*, *FGF10*, *BMP4*, and *BMP7* participate in the early stage of male genital development (Morgan et al., 2003; Suzuki et al., 2003). *MAMLD1* is a candidate to explore in patients with unexplained 46, XY DSD, as it has been shown to be expressed in fetal Leydig cells around the critical period for sexual development (Chen et al., 2010). The transient knockdown of *MAMLD1* mRNA expression results in significantly reduced testosterone production in mouse Leydig tumor cells and an *NR5A1* target site was found within the *MAMLD1* gene (Ogata et al., 2009). We found *MAMLD1* p.N662S variant in two patients with isolated hypospadias, which were also identified by other hypospadias mutation studies (Kalfa et al., 2012). Based on ACMG guidelines and reference to the ClinVar database, and HGMD databases, the variant was classified into benign (B).

MID1, as a transcriptional regulatory protein, is involved in the development of the mid-segment structure during embryonic

FIGURE 2 | Sub-cellular localization of AR_{WT} and AR_{I871N}. development. Opitz syndrome (OS) is a multiple congenital anomaly disorder that shows a wide spectrum of severity and a highly variable expressivity (OMIM 300000) (Opitz, 1987). In male OS patients, mutations have been found to be scattered throughout the entire length of the *MID1* gene suggesting a loss of function mechanism as the basis of this developmental phenotype (Cox et al., 2000). Hypospadias of all grades was found more commonly in males with *MID1* mutations than in those without (So et al., 2005). The patient in our study carrying *MID1* variant p. P667L only has isolated hypospadias, this loci was assessed as likely pathogenic. Recently *MID1* was found to up-regulate AR protein levels in several prostate cancer cell lines and its expression was negatively regulated by androgen signaling (Kohler et al., 2014). Like the AR gene, *MID1* is expressed in the genital tubercle (GT) in human embryos (Pinson et al., 2004). However, If *MID1* loss-of-function mutations as seen in OS led to decreased AR protein levels in the GT, this may help explain the urogenital anomalies seen in OS (Winter et al., 2016).

The *SRD5A2* gene encoded 5 α -reductase is mainly expressed in male genital and prostate tissues, whose defects cause 46,

FIGURE 3 | Decreased transactivation activity of AR_{I871N} mutation in reporter gene assay. CHO cells transfected with either AR_{WT} or AR_{I871N}, were exposed to DHT (A) or R1881 (B) at the different concentrations. In a competitive binding assay, where R1181 competed with the anti-androgen OHF for AR binding sites, the AR_{I871N} mutation showed slightly weaker binding than the wild type (C). Lower activity of AR_{I871N} was observed when it was compared to the wild-type receptor. The experiments were conducted in triplicate. **P* < 0.05 compared with wild type.

XY DSD due to defects in testosterone metabolism. In this study, 13.6% (11/81) hypospadias is caused by SRD5 mutation, which takes 61.1% (11/18) genetic etiology of hypospadias. A *de novo* mutation p.Y136Ter leads to a stop codon TAA and terminates the translation of SRD5A2 gene. This loci is assessed as pathogenic. The patient carries compound heterozygote p.Y136Ter/p.R227Q and exhibits type II hypospadias, with no external genital malformations except hypospadias. The EMS score was 10 and hCG stimulation tests showed non-response.

So far, more than 1000 cases of mutations with AR defects have been reported in the literature, presenting with a wide variety of phenotypic outcomes. The phenotypes of 46, XY individuals with AR gene mutations are categorized as complete androgen insensitivity syndrome (CAIS) or PAIS, respectively, and the more severe forms belong to disorders of sex determination. They range from a complete male-to-female sex reversal in CAIS patients to variable grades of ambiguous genitalia in PAIS patients. Milder forms of PAIS also include male phenotypes with gynecomastia, decreased fertility, or isolated hypospadias. PAIS could be a consequence of partial defect of AR structure or function caused by defects in AR gene. In this study, 7.4% (6/81) hypospadias was caused by AR mutation, which accounted for 33.3% (6/18) genetic abnormality of hypospadias.

The six mutations of the AR gene were found in 6 patients, of which 3 were previous identified mutation sites (p.R780W, p.R856H, p.A871V). p.I817N was a novel missense mutation. Other two patients have gross deletions of AR gene and both were not reported. All 4 missense mutations were located within the highly conserved carboxy-terminal LBD of the AR gene. The LBD domain consists of 12 contiguous alpha helices, most of which are hydrophobic amino acids that form a hydrophobic pocket which in turn binds the androgen ligand through its hydrophobic interaction. Functional impairment after mutation in this region weakens the binding of androgen to the AR protein in the target cell resulting in a decrease in the activity of androgen. It has been reported that p.A871V mutation was associated with a decrease in the binding affinity between AR and androgen by approximately 56%. p.R856H mutation led to changes in AR tertiary structure, resulting in decreased thermal stability and mutual N/C interactions. Large deletions in AR gene have been reported in patients with CAIS (Li et al., 2011; Doehnert et al., 2015), but in our data, two patients were not complete female phenotype (EMS7 and 1).

The p.I817N mutation identified in our study changed thymine to adenine at position 2450 in the AR gene. It is located in the LBD region of AR and encodes the first amino acid of exon 7, which is involved in the splicing of amino acid chains during transcription and translation. Conservative analysis of 10 mammalian proteins suggested that this region is highly conserved. The concentration of T in the laboratory test was 9.37 ng/ml, and it was 11.95 ng/ml after hCG challenge. It was significantly higher than the serum T level in boys of the same age. This also supports its molecular diagnosis. *In vitro* functional assay was further utilized and revealed that this mutation led to impaired AR transcriptional activity (20~46%), decreased sensitivity for androgen ligand, and was responsible to hypospadias observed in the patient.

To exclude the correlation between the identified mutations and clinical manifestations other than hypospadias, we performed Fisher's exact test which was used to compare the incidences of inguinal hernia, SGA, ASD, and puberty breast development in children with and without candidate genes mutations. There were no statistical differences (*P* > 0.05). This study used a candidate gene strategy, there may be unknown gene variation. We cannot rule out the association of these complications with other gene variations.

In conclusion, genetic involvement of hypospadias was explored in 81 Chinese children using NGS. One *de novo* missense mutation loci was identified in AR and further *in vivo* and *in vitro* functional studies provided the molecular evidence that p.I817N amino acid change could cause significant reduction in AR transcriptional function which led to hypospadias. Our results suggest that genetic mutation is one of many factors contributing to the development of hypospadias in Chinese patients as the mutation was not detected in 78% of our patients, but still our data expand the spectrum of mutations in the SRD5A2 gene and AR gene in patients with hypospadias. Recent studies propose that *in utero* exposure to estrogens found in pesticides used in fruits and vegetables as well as in plastic linings can have an anti-androgenic activity (Donaire and Mendez, 2018). Epidemiological and genetic analysis are still needed to further clarify the pathogenesis of hypospadias in Chinese patients.

Whole-Exome Sequencing Identified
CFTR Variants in Two
Consanguineous Families in China.
Front. Genet. 12:631221.
doi: 10.3389/fgene.2021.631221

Background: Cystic fibrosis (CF) is an autosomal recessive disease caused by genetic variants of the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene. It is a common hereditary disease in Caucasians while rare in the Chinese. Until now, only 87 Chinese patients have been reported with molecular confirmations. The variant spectrum and clinical features of Chinese CF patients are obviously different from those of Caucasians.

Materials and Methods: Whole-exome sequencing was applied to analyze the exome of three individuals who have only the typical CF phenotype in the respiratory system from two consanguineous families. The protein domain and structure analysis were applied to predict the impact of the variants. Sanger sequencing was applied to validate the candidate variants.

Results: A previously reported homozygous variant in *CFTR* (NM_000492.4: c.1000C > T, p.R334W) was identified in proband I. A novel homozygous variant in a polymorphic position (NM_000492.4: c.1409T > A, p.V470E) was identified in two individuals in the family II. The novel *CFTR* variant predicted to be disease-causing is the first, to the best of our knowledge, to be reported in *CFTR*. However, *in vitro* validation is still needed.

Conclusion: Our finding expands the variant spectrum of *CFTR*, reveals clearer clinical phenotype distinction and variant spectrum distinction between Chinese and Caucasian CF patients, and contributes to a more rapid genetic diagnosis and future genetic counseling.

Keywords: cystic fibrosis, *CFTR*, bronchiectasis, Chinese, genetic variants, phenotype

INTRODUCTION

Cystic fibrosis (CF), first reported in 1938, is an inherited autosomal recessive disease involving multiple organs, including the respiratory, digestive, and reproductive systems (Andersen, 1938). Respiratory failure after bronchiectasis and infection is now the main cause of death in CF patients. CF is a common hereditary disease in Caucasians but is rare among Asians, especially the Chinese.

The estimated incidence of the disease in Caucasian population is about 1/3,000, but no more than 100 cases that have been reported in China (Liu et al., 2020). The disease is mainly detected through abnormally high chloride concentrations in sweat and gene sequencing.

Cystic fibrosis is caused by variants of the cystic fibrosis trans-membrane conductance regulator (*CFTR*) gene. *CFTR* is a chloride and bicarbonate transport protein, encoded by the *CFTR* gene located at the long arm of chromosome 7, which has 27 exons. As *CFTR* is mainly expressed in various glandular tissues, the variants can cause abnormal ion transport and secretory function, subsequently leading to bronchiectasis, pancreatic insufficiency, and fertility dysfunction in males (Ratjen et al., 2015). More than 2,000 different variants have been identified in *CFTR*, and the most recent update from the CFTR2 database¹ recorded a total of 442 variants including 360 CF-causing variants. All variants are divided into six classes according to their mechanisms and pathogenicity. The most prevalent variant in Caucasians, p.F508del, was classified in Class II (Ratjen et al., 2015).

Studies have shown that the clinical phenotypes and variant spectrum of CF patients in China and those of the Caucasian population are very different (Guo et al., 2018). There are approximately 90 Chinese CF patients who have been reported up to now. In recent years, however, as the understanding of CF has deepened and the methods of diagnosis have improved, a growing number of CF patients have been diagnosed and reported in China. Here, we used whole-exome sequencing to analyze the exome of three individuals who have only a typical respiratory system CF phenotype, from two consanguineous families, and found *CFTR* variants including a novel variant in a polymorphic position.

MATERIALS AND METHODS

Ethical Compliance

This study was approved by the Review Board of the Second Xiangya Hospital of Central South University in China. Three patients diagnosed with bronchiectasis from two Chinese consanguineous families participated in the study. Written informed consent was obtained from all participants.

Whole-Exome Sequencing and Variants Filtering

Whole-exome sequencing was performed on three individuals from two consanguineous families. Peripheral blood samples (3–5 ml) from proband I in family I; proband IIa and his brother IIb in family II were obtained with informed consent, respectively. The genomic DNA was extracted from peripheral blood cells by DNeasy blood and tissue kit (QIAGEN # 69506). The exomes of the probands were captured by Agilent Sureselect Human All Exons V6 kit (Agilent, California, United States) and sequencing on Illumina HiSeq X-10 platform (Illumina Inc, San Diego, United States). The single-nucleotide variants

(SNVs) and short insertions and deletions (INDELs) were filtered as follow as we describe (**Supplementary Figure 1**): (1) Variants in the 1,000 Genomes Project (1,000G²), NHLBI-ESP project³, and Exome Aggregation Consortium (ExAC⁴) with minor allele frequency (MAF) ≤ 0.01 were included. (2) Intergenic, intronic, and untranslated regions and synonymous variants were excluded from subsequent analyses. (3) Bioinformatics analyses (Sift, Polyphen-2, Mutationtaster, MutationAssessor) were used for the remaining variants. (4) The remaining data were filtered by bronchiectasis-related diseases, which include primary ciliary dyskinesia (PCD), cystic fibrosis, and primary immunodeficiency. (5) Runs of homozygosity (ROH) analysis was also performed due to the fact that all probands came from consanguineous families. The ROH analysis was based on the data from whole-exome sequencing data using the Automap algorithm (Quinodoz et al., 2021).

Variant Validation With Sanger Sequencing

Sanger sequencing was used to validate the candidate variants found in whole-exome sequencing. Primers for PCR amplification of fragments with individual variants were designed by Primer Premier 5 software (Premier Biosoft, Palo Alto, CA, United States). The sequences of the primers are listed in **Supplementary Table 1**.

RESULTS

Clinical Summary

Family 1

Proband I was a 14-year-old girl whose parents are consanguineous (**Figure 1**). She had suffered from recurrent coughing and expectoration for 2 years and came to our clinic for 1 day due to acute hemoptysis. Physical examination showed moist rales in both lower lungs. CT (computed tomography) showed inflammation in bilateral maxillary sinus, ethmoid sinus, and sphenoid sinus, bronchiectasis in both lungs, and calcification of the liver (**Figure 2A**). Her nasal nitric oxide concentration (nNO) was 74 parts per billion (ppb). The pulmonary function test indicated that she had severe mixed pulmonary ventilation dysfunction (FEV1% predicted: 48.0%, FEV1/FVC: 80.5%), and the bronchial dilation test was negative. The sputum culture showed infection with *Pseudomonas aeruginosa*. After hemostasis, antibiotic, and expectorant treatment, her symptoms were relieved, and the patient was discharged.

Family 2

Proband IIa was a 17-year-old teenager whose parents are also consanguineous (**Figure 1**). He had been coughing and expectoration repeatedly for 6 years and experiencing

FIGURE 1 | Pedigree of two families with *CFTR* variants. Circles refer to females. Squares refer to male subjects. Solid symbols refer to affected subjects. Crossed-out symbols refer to subjects who have passed away. The arrows indicate the probands.

FIGURE 2 | High resolution computed tomography reveals signs of bronchiectasis in all probands [(A), proband I; (B), proband IIa; (C), patient IIb].

shortness of breath for 1 year, and he was admitted to the Respiratory Intensive Care Unit due to suddenly worsening symptoms. Physical examination revealed a barrel chest, some moist rales, and finger clubbing. Arterial blood gas analysis suggested hypercapnic acidosis. Chest radiography suggested bronchiectasis and infection. Color Doppler echocardiography showed mild mitral regurgitation. CT showed chronic inflammation of bilateral maxillary sinuses, an undeveloped sphenoid sinus, and left frontal sinus, along with diffuse bronchiectasis with patchy infection foci (**Figure 2B**). His nasal nitric oxide concentration (nNO) was 159 ppb. The patient was given ventilator and phlegm treatment. The sputum culture was positive for *Pseudomonas aeruginosa*. The cough and expectoration have not improved significantly after changing antibiotics several times. After sputum aspiration under fiberoptic bronchoscopy, the patient's coughing and expectoration decreased, and his condition improved significantly. Soon after, the patient was discharged from the hospital.

IIb is the 5-year-old brother of IIa. His nitric oxide concentration (nNO) was 113 ppb. He had no symptoms except for digital clubbing and the CT suggested sinusitis, bronchiectasis, and calcification of the liver (**Figure 2C**).

Whole-Exome Sequencing Identified Two Variants in *CFTR*

The whole-exome sequencing was performed on three individuals, and the results were listed in **Supplementary Table 2**. Notably, 14.24, 7.09, and 7.25 Gb sequencing data were generated, and more than 99% of the targeted regions were covered, with a depth of more than 10×. Non-synonymous variants occurring in exons or splice sites (splicing junction 10 bp) were selected and analyzed after alignment. After the selection of rare variations (minor allele frequency <1%) related to bronchiectasis, one homozygous variant of cystic fibrosis transmembrane conductance regulator (*CFTR*) was identified in each

FIGURE 3 | Exon structure of the *CFTR* gene. Domain structure of the CFTR protein. The positions of variant c.1000C > T, p.R334W, and c.1409T > A, p.V470E. TMD, transmembrane domain; NBD, nucleotide binding domain; RD, regulatory (R) domain.

FIGURE 4 | The CFTR protein tertiary structure was predicted by Swiss-model software. Different structures caused by amino acid changes are shown in position 470 of CFTR.

family. The results of our ROH analysis confirmed the homozygous region in chromosome 7 contains the variants of *CFTR*. The detailed results of ROH analysis are shown in **Supplementary Figure 2**.

A homozygous variant of *CFTR*, c.1000C > T, p.R334W, which had been reported to be disease-causing, was found in proband I (Sheppard et al., 1993).

A novel variant of *CFTR*, c.1409T > A, p.V470E was found in proband IIa and IIb. It hadn't been reported before and hadn't been recorded on the Cystic Fibrosis Mutation Database⁵. The novel variant was predicted to be deleterious by SIFT and the CADD (CADD PHRED score = 24.8). Located at the exon 11, the variant may affect the function of the nucleotide binding domains 1 (NBD1) domain after translation (**Figure 3**). Swiss model was also used to predict the protein tertiary structure, the amino acid change from valine to glutamic acid might affect the stability of the helix (**Figure 4**).

⁵<http://www.genet.sickkids.on.ca>

Sanger Sequencing for Variant Validation of *CFTR*

Sanger sequencing was used to validate the candidate variants identified by whole-exome sequencing, and segregation analyses were performed in both family members. Homozygous variant c.1000C > T, p.R334W in proband I and homozygous variant c.1409T > A, p.V470E in proband IIa and IIb were validated by Sanger sequencing. Sanger sequencing also confirmed that the healthy parents of the probands were all heterozygotes in corresponding positions (**Figure 5**).

DISCUSSION

In this study, whole-exome sequencing was performed to identify 2 variants in *CFTR* in 2 families. The parents of patients in both families are heterozygously married and are close relatives. A novel homozygous variant (c.1409T > A, p.V470E) was found in both patients in family II. It was located in the NBD1 domain

of CFTR and may disturb the structure and function of ATP binding. Another reported homozygous variant (c.1000C > T, p.R334W) found in patient I was considered to be the cause of her respiratory disease.

The novel variant c.1409T > A, p.V470E in exon 11, which may affect the function of the NBD1 domain after translation, was not present in the current Cystic Fibrosis Mutation Database or the Human Gene Mutation Database⁶. Notably, this position is a polymorphic position of M470V (c.1408G > A) variants

and is related to bronchiectasis and chronic pancreatitis by affecting structural stability of NBD1 and intrinsic chloride channel activity when it is combined with other variants (Lee et al., 2003; Yang et al., 2018). The V470 allele can reduce the activity of the CFTR protein chloride channel, which might help to reduce the disease damage and decrease the rate of diarrhea, primary sclerosing cholangitis, and prostate cancer (Henckaerts et al., 2009; Qiao et al., 2008). M470 allele is significantly associated with an increasing risk of chronic pancreatitis in both Asian and Caucasian populations (Zhou et al., 2020), which also contributes to a low birth rate through the congenital bilateral

FIGURE 6 | Sequence alignment of mammalian CFTR proteins. The R334 is located in a highly conserved amino acid, and the V470 is located at a variant position according to the MutationTaster.

absence of the vas deferens (CBAVD) (Kosova et al., 2010). The variants in sequence among different races and species well reflect the natural selection during human evolution (Maria Ciminelli et al., 2011; **Figure 6**). The functional difference and species evolution caused by the polymorphic variants at this site also indicate that the variant V470E at this site has a high possibility of affecting the function of CFTR and causing disease. Both patients in family II have the typical cystic fibrosis clinical phenotype, and brother IIb, with no infection or symptoms, still had significant CT imaging findings of bronchiectasis and digital clubbing. This suggested a possible relationship between the variant and cystic fibrosis. According to ACMG guidelines, the novel variant was classified as the variant of uncertain significance (VUS), meeting the following criteria from the ACMG guidelines: PM2, PP1, PP3, and PP4 (Richards et al., 2015). Nevertheless, the phenotype-genotype association is hard to define completely because of the small sample size. *In vitro* validation is still in need for confirmation of this variant's role in cystic fibrosis.

The variant found in proband I was a reported variant c.1000C > T, p.R334W, present in the common Caucasian CFTR mutation-screening panels (Gasparini et al., 1991). According to the database of CFTR2, there are 429 recorded data of alleles in this position, and only 40% of patients suffered from pancreatic insufficiency. Like most patients with this site variant, proband I showed no symptoms other than respiratory symptoms such as bronchiectasis and sinusitis. This variant is located in the eighth exon and the sixth transmembrane region, which is close to the gate situated between amino acid residues 337 and 344 (Beck et al., 2008; Gao and Hwang, 2015; **Figure 4**). Because it only affects the conductivity of the channel that decreases the flow of ions, the phenotype of patients is often comparably less severe. The variant was defined as a mild variant (Class IV) based on the pathogenic mechanism and severity of bronchus and pancreas (Ratjen et al., 2015).

The survival rate of CF patients has been greatly improved with the rapid development of treatments. The CFTR potentiator, ivacaftor, the first drug approved to be used in CF patients, is now approved to be used in many class III and class IV variants. Ivacaftor is also effective for the most common pathogenic variant, p.F508del, when combined with corrector lumacaftor. However, patient I in our study has the class IV variant R334W and is not a target of ivacaftor. New research showed that phosphodiesterase (PDE) inhibitors RPL554 (Verona Pharma) can elevate intracellular cAMP in R334W Fisher rat thyroid (FRT) cells. This finding supports the therapeutic potential of RPL554 for CF patients with class III/IV variants including R334W (Turner et al., 2020). In addition, gene and molecular therapy for some mutations is also a research hot spot. At present, the main difficulty is to find a suitable vector (Ratjen et al., 2015).

Cystic fibrosis is the most common and potentially fatal genetic disease in Caucasians, though it is rare in China. Here, we reviewed the 90 cases of Chinese CF patients with DNA sequencing (**Supplementary Table 3**). Like the previous review, only a few patients had pancreas insufficiency and CBVAD, and most patients have been diagnosed with bronchiectasis and lung infections (Shen et al., 2016). According to the results of a sputum culture, chronic infection of *Pseudomonas aeruginosa* was found in 62% of patients. Compared with the low prevalence of ABPA in CF patients in Europe, more than 25% of Chinese CF patients met the criteria for ABPA. Sweat testing has always been the gold standard for CF diagnosis; however, it has only been carried out in hospitals in some large cities. Only 66 of 90 cases had the data of sweat conductivity test. Different from the most common pathogenic variants p.F508del in Europe and America, c.2909G > A (p.G970D) was the most common pathogenic variant in China among all the variants. Research has shown that the CFTR variant spectrum of CF patients in China is different from that in Caucasians in Europe and America since some variants, such as c.1766 + 5G > T, only occur in Chinese people (Xu et al., 2017). It is necessary for us to establish

a variant database of Chinese CF patients since most variants in Chinese CF patients have not been present in the common Caucasian *CFTR* mutation-screening panels. For patients with atypical clinical symptoms, it is difficult to make a clear diagnosis at an early stage without sweat tests or genetic testing, explaining the low diagnosis rate of CF in China. In the last decade, the number of reports of cystic fibrosis patients in China has increased significantly, and more cystic fibrosis patients and data will be discovered and reported in the future, after awareness and diagnosis techniques of the disease are improved.

CONCLUSION

Our study used whole-exome sequencing to identify two homozygous variants of *CFTR*, including a novel variant (c.1409T > A, p.V470E) and a reported variant (c.1000C > T, p.R334W), in three individuals from two consanguineous families. The existence of the novel variant (c.1409T > A, p.V470E), which has never been reported, implies the association between the polymorphism of the site and the disease and indicates its changes in human evolution. In addition, our findings in the patient with variant c.1000C > T, p.R334W are the same as that of previous studies that showed that the phenotype identified by this variant is less severe. Although the current functional test and drug experiment for these variants have not achieved decisive results, we do think that they are necessary. Our review of Chinese CF patients also suggests that doctors should pay more attention to the atypical symptoms of Chinese CF patients. Our result expands the variant spectrum of *CFTR* and contributes to a more rapid genetic diagnosis and future genetic counseling.

Objective: Global developmental delay has markedly high phenotypic and genetic heterogeneity, and is a great challenge for clinical diagnosis. Hypotonia, ataxia, and delayed development syndrome (HADDs), first reported in 2017, is one type of global developmental delay. The aim of the present study was to investigate the genetic etiology of a Chinese boy with global developmental delay.

Methods: We combined clinical and imaging phenotyping with trio whole-exome sequencing and Sanger sequencing to the patient and his clinically unaffected parents. A luciferase reporter and immunofluorescence were performed to detect the effect of mutation on transcriptional activity and subcellular localization.

Results: The patient presented with several previously unreported symptoms in the patients with HADDs, including hemangiomas, mild hearing abnormalities and tracheomalacia. A novel *EBF3* c.589A > G missense mutation (p.Asn197Asp, p.N197D) was identified in the patient but not in his parents. By constructing the plasmid and transfecting HEK293T cells, *EBF3*-N197D mutant showed impaired activation of luciferase reporter expression of the p21 promoter, and the mutant affected its entry into the nucleus.

Conclusion: To the best of our knowledge, this is the first report of *EBF3* pathogenic mutation which associated with HADDs in the Chinese population. Our results expand the phenotypes and pathogenic mutation spectrum of HADDs, thus potentially facilitating the clinical diagnosis and genetic counseling of HADDs patients.

Keywords: hypotonia, ataxia, delayed development syndrome, *EBF3*, pathogenic mutation, trio whole-exome sequencing, c.589A > G

INTRODUCTION

Global developmental delay refers to a significant retardation of a child's growth and development relative to its peers (Shevell et al., 2003). It affects cognitive or thinking skills, motor skills, social and emotional, language, and vision.¹ Different individuals present with different levels of severity, thus deterring its clinical diagnosis. The etiology of global developmental delay includes exogenous and genetic (non-metabolic or metabolic) factors (Papavasiliou et al., 2000; Michelson et al., 2011). Advancements in modern biotechnology and genetic testing technology have facilitated

the diagnosis of children with global developmental delay (Srouf and Shevell, 2014). Whole-exome sequencing (WES), whole-genome sequencing (WGS), and genome-wide microarrays have facilitated the identification of several candidate genes associated with developmental delays.

Herein, we curated data from one family, which included a boy with global developmental delay, born to non-consanguineous parents with a normal phenotype. The patient presented with motor delay, mental retardation, language delay, fontanelle closure delay, hypotonia, funnel chest, cryptorchidism, hemangioma, and febrile seizures. No obvious microdeletion or microduplication was detected using genome-wide microarray analysis (Affymetrix CytoScan 750K). A novel *EBF3* gene c.589A > G missense mutation was detected in the patient via Trio-WES but not in the parents. To our knowledge, there are no more than 20 cases, who had *de novo* variants in *EBF3* and a distinct neurodevelopmental syndrome, reported worldwide since the disease first reported in 2017 (Chao et al., 2017; Harms et al., 2017; Slevin et al., 2017). Besides, this is the first report about HADDs from China.

MATERIALS AND METHODS

Genomic DNA Extraction and Genome-Wide Copy Number Variation Analysis

Genomic DNA was extracted from peripheral blood leucocytes of the proband and his parents using the QIAamp Blood Mini Kit (QIAGEN, Hilden, Germany) following manufacturer protocol. CMA-SNP array analysis of the proband's DNA was performed using the Affymetrix® CytoScan™ 750K Array (Affymetrix, Santa Clara, CA, United States) following the manufacturer's recommended protocols. When all quality control tests were passed, we analyzed deletions of ≥ 50 kb (marker ≥ 20 kb), repeats of ≥ 100 kb (marker ≥ 20 kb), and homozygous chromosomal fragments of > 5 Mb.

Whole-Exome Sequencing and Bioinformatics Analysis

The genomic DNA of the proband and his parents was digested using segmentase (BGI, Shenzhen, China) into 100–500-bp fragments. Thereafter, 280–320-bp-long fragments were subjected to enrichment, blunting, A-tailing, and adapter ligation, followed by PCR amplification for library preparation. The DNA library thus generated was used to capture and collect DNA from the target exons and adjacent splice sites, using the BGI V4 probe (58.7M). Finally, the MGISEQ-2000 sequencing platform (MGI, Shenzhen, China) was used for PE100 + 100 sequencing. The quality control indicator for the sequencing data was an average effective sequencing depth of $\geq 100\times$ for the target region, where 95% of the sites had an average depth of $20\times$.

After the quality control analysis of the raw data, reads were aligned with the UCSC hg19 human reference genome, using

BWA to eliminate duplicates. GATK was used to calibrate SNV and INDEL base quality scores and genotype analysis.

Validation by Sanger Sequencing

One pair primers (*EBF3*-7F: CGAAAGTCGCAGCTATTATCAT; *EBF3*-7R: TTAGACTTGATGAATCTGGCATAC) were designed using Oligo 6 to amplify the candidate regions of the mutation in *EBF3* gene (NM_001005463.2) identified by WES. Then, forward and reverse Sanger sequencing were performed using ABI PRISM 3730 gene analyzer (Applied Biosystems, California, United States).

Cell Culture

HEK293T cell line (ATCC, Rockville, MD, United States) was cultured in DMEM medium (GIBCO, Invitrogen Corporation, NY, United States) containing penicillin (final concentration of 100 U/ml, Sigma, St. Louis, MO, United States), streptomycin (final concentration of 100 μ g/ml, Sigma, St. Louis, MO, United States) and 10% fetal bovine serum (FBS, Hyclone, Logan, UT, United States).

Expression Analysis

To characterize the effects of the *EBF3* mutation at the cellular level, transient cell transfections were performed in HEK293T cell line with WT or mutated *EBF3* mRNA expressed as fusions to the C-terminus of Flag (pcDNA-Flag-C, Invitrogen Corporation, NY, United States). Mutation was introduced via site-directed mutagenesis (QuickMutation™ Site-Directed Mutagenesis Kit, Beytime, Shanghai, China) with the forward primer 5'-CTAGGATCCATTACAACACAGTCAGCACT-3' and the reverse primer 5'-ATTGAATTCTCTTCTGTTTCATGCCGTAG-3'. All of the inserts were systematically verified by sequencing. The transfection was performed by incubating 2 μ g of fusion protein construct using Lipofectamine 3,000 (Thermo Fisher Scientific, Pittsburgh, PA, United States) according to the manufacturer's instructions.

Firefly Luciferase Reporter Gene Assay Kit (Beytime, Shanghai, China) was used to detect the transcriptional activity of *EBF3*-WT and *EBF3*-N197D.

Immunofluorescence was used to detect the subcellular localization and captured by Laser Scanning Confocal Microscopy (Zeiss LSM, Zeiss, Germany).

The scraped cells were transferred to a 1.5 mL precooled microcentrifuge tube with 1 mL precooled PBS. Centrifuge at 4°C, collect cells at 1,000 g for 3 min, remove supernatant as possible with pipet, add 200 μ l precooled Buffer A for every 20 μ l compacted cell volume (add 1 μ l DTT, 10 μ l PMSF, and 1 μ l protease inhibitor for every 1 mL Buffer A before use). The maximum rotational speed vortex vibrates violently for 15 s, and it is placed on ice for 10–15 min. Add 11 μ l precooled Buffer B, swirl vigorously for 15 s at maximum rotating speed, and place on ice for 1 min. The solution was centrifuged at 4°C for 14,000 g for 5 min. At this time, it could be seen that the solution was divided into three layers: The lowest transparent layer, on which was white nucleus precipitate, and then the supernatant. The supernatant is transferred to another clean micro-centrifuge

tube precooled as soon as possible and placed on ice to obtain cytoplasmic protein. The supernatant is packed and stored at -80°C to avoid repeated freeze-thaw. Insert the tip of a SPAR into the bottom of the centrifuge tube, suck out the bottom liquid and discard it. Add $100\ \mu\text{L}$ of precooled Buffer C to the centrifuge precipitates (add $1\ \mu\text{L}$ of DTT, $10\ \mu\text{L}$ of PMSF, and $1\ \mu\text{L}$ of protease inhibitor for every $1\ \text{mL}$ of Buffer C before use). The maximum rotating speed of the vortex vibrated violently for $10\ \text{s}$, and the vortex was placed in an ice bath in a shaker for $40\ \text{min}$, $150\ \text{times/min}$, and then vibrated again for $30\ \text{s}$. The supernatant was centrifuged at 4°C for $14,000\ \text{g}$ for $5\ \text{min}$ and transferred into a clean micro-centrifuge tube precooled as soon as possible to obtain nuclear protein. The supernatant was packed and stored at -80°C to avoid repeated freeze-thaw. At last, the nucleoplasmic distribution of *EBF3*-WT and *EBF3*-N197D was detected by Western blot (Mini-PROTEAN Tetra,® Bio-Rad, United States).

Primary antibodies used were anti-Flag antibody (ab205606), anti-GAPDH antibody (ab8245), Anti-LaminA antibody (ab108595), Goat Anti-Rabbit IgG H&L (HRP) (ab6721), Rabbit Anti-Mouse IgG H&L (HRP) (ab6728), which were purchased from Abcam Company (Abcam, Cambridge, United Kingdom).

RESULTS

The Clinical Phenotypes and Imaging Examination Results of the Patient

The proband, a Chinese boy, was referred to the genetic counseling clinic of our hospital owing to global developmental delay. The patient was the first child and first birth, born through cesarean delivery at 39 weeks. All examinations during pregnancy were normal. The proband's birth length was $48\ \text{cm}$ (3rd–10th centile); birth weight was $3.2\ \text{kg}$ (25th–50th centile); head circumference was $34\ \text{cm}$ (25th–50th centile); chest circumference was $32\ \text{cm}$; abdominal circumference was $29\ \text{cm}$. He presented with labored breathing, hypotonia, micropenis, microscrotum, palpable testis in the right inguinal canal, and impalpable left testis. Color ultrasound imaging of the patient's bilateral scrotum, testes, and epididymis at birth elucidated an undescended testis in the left abdominal cavity, and a high mobility of the right testis with minor testicular hydrocele. Significant hypotonia was detected at 5 months. The patient could lift his head only at 10 months and underwent orchiopexy at 10 months. The first febrile seizure occurred at 1 year 2 months of age. The patient is now 1 year 6 months of age, his height is $78\ \text{cm}$ ($\leq 1\ \text{SD}$) and weight is $9.5\ \text{kg}$ ($\leq 1\ \text{SD}$). He was unsteady when sitting unassisted; could not climb, and could not say dad or mom; had an unclosed fontanelle; presented late teething; and exhibited slight orbital hypertelorism, high nasal bridge, broad nasal tip, deep philtrum, downturned mouth, and myopathic facies (stiff facial expressions) (Figure 1A). He also presented with pectus excavatum (Figure 1B), motor delay, intellectual disability, hemangiomas (in the palm of the left hand, Figure 1C), tracheomalacia, and feeding difficulties.

Brain MRI at 5 months (Figures 1D,E) revealed T2 hyperintensity in the bilateral anterior limbs of the internal capsule, suggesting potentially delayed myelination. Furthermore, enlargement of the bilateral lateral ventricles and lateral apertures, mega cisterna magna, bilateral mastoid, and middle ear effusions were observed. Brainstem auditory evoked potentials at 1 year 4 months of age showed prolonged latency of waves I, III, and V, and intervals and amplitudes were normal, suggested damage to the brain stem. No obvious abnormality was found in EEG.

Analysis of the proband's karyotype from peripheral blood lymphocytes ($400\text{--}500\ \text{kb}$) did not reveal any abnormality. The proband's parents, who were non-consanguineous marriage, had normal clinical assessment, no exposure to toxic or harmful substances during pregnancy, and no family history of genetic diseases.

Genome-Wide Copy Number Variation Analysis

No obvious microdeletion or microduplication was found.

Identification of Candidate Mutations by Whole-Exome Sequencing

High-quality data were obtained through WES. The data of the proband, father, and mother were of 15.5 , 14.4 , and $15.8\ \text{Gb}$, the coverage of the target region was 99.78 , 99.62 , and 99.82% , and the average sequencing depth was 119 , 131 , and 144 reads, respectively. The percentage of the target region with an average sequencing depth of > 10 reads accounted for 98.02 , 95.06 , and 96.11% , respectively. After filtering variants according to the following criteria: (1) frequency $< 1\%$ according to the dbSNP, 1000 Genomes Project, ESP6500, and ExAC database; (2) protein-alteration or on canonical splice-sites; (3) homozygous, heterozygous, or *de novo* mutations; and (4) sequence variants interpreted in accordance with the guidelines of the American College of Medical Genetics and Genomics, and harmful variants were screened in accordance with the proband's phenotype; an *EBF3* heterozygous mutation was detected in the proband but not in his parents.

Validation via Sanger Sequencing

Sanger sequencing was performed to validate this heterozygous mutation in the proband, and the mutation was not observed in the parents' DNA isolated from peripheral blood lymphocytes (Figure 2A). The *EBF3* c.589A $>$ G mutation was characterized by a substitution of Asn197 in CDS to Asp (p. Asn197Asp, p.N197D).

There is no record of this variant in the dbSNP, 1000 Genomes Project, ESP6500, and ExAC database. p.N197D is located in a highly conserved domain (Figure 2B). Multiple online software, including PolyPhen-2, SIFT, mutationtaster, and revel, predicted that this variant was pathogenic. Based on the ACMG guidelines for interpreting sequence variants, this variant was classified as a likely pathogenic variant. Specific evidences of pathogenicity for this variant includes:

FIGURE 1 | The appearance and MRI results of the patients. **(A)** The patient has an unclosed fontanelle, slight orbital hypertelorism, high nasal bridge, broad nasal tip, deep philtrum, and downturned mouth. **(B)** The patient has pectus excavatum. **(C)** The hemangiomas are in the palm of the left hand. **(D,E)** Brain MRI shows insignificant T2 hyperintensity at the bilateral anterior limbs of the internal capsule, enlargement of the bilateral lateral ventricles and lateral apertures.

FIGURE 2 | Sanger sequencing data and conservation of the amino acid residues around the mutation sites. **(A)** Sanger sequencing shows a heterozygous mutation of c.589A > G in *EBF3* is present in the proband, whereas both of the parents are wild-type for this variant. **(B)** The box shows the change is located at the conserved leucine residues. The mutated amino acid is highly conserved in 8 species.

(1) PS2, *de novo* (both maternity and paternity confirmed) in a patient with the disease and no family history; (2) PM2, absent from controls (or at extremely low frequency

if recessive) in Exome Sequencing Project, 1000 Genomes Project, or Exome Aggregation Consortium; (3) PP3, multiple lines of computational evidence support a deleterious effect on

FIGURE 3 | Transcriptional activity of EBF3-N197D mutant in transfected cells. The transcriptional activity of p21 promoter in EBF3-N197D mutant was decreased. Results were mean \pm SD for three individual experiments which, for each condition, were performed in triplicate. ** $p < 0.01$.

the gene or gene product (conservation, evolutionary, splicing impact, etc.).

The Effects of the EBF3 Mutation at the Cellular Level

To test the transcriptional activity of p21 in EBF3-N197D, HEK293T cells were co-transfected with the p21 report plasmid and Flag-EBF3-WT or Flag-EBF3-N197D, and the luciferase signal was detected. Results were mean \pm SD for three individual experiments which, for each condition, were performed in triplicate. In agreement with other studies (Jin et al., 2014; Harms et al., 2017), EBF3-N197D mutant showed impaired activation of luciferase reporter expression of the p21 promoter (Figure 3). In order to detect the effect of p.N197D mutant on protein localization, HEK293T cells were transfected with Flag-EBF3-WT or Flag-EBF3-N197D, and the localization of Flag-EBF3-WT and Flag-EBF3-N197D in HEK293T cells were detected by western blot assay and immunofluorescence assay. As shown in Figure 4, in contrast to the WT, the distribution of p.N197D mutant in nucleus was significantly reduced ($p < 0.05$, $p < 0.01$) (Figures 4A,B), and the mutant aggregated in the cytoplasm (Figures 4A,C) and affected its entry into the nucleus (Figure 4D).

DISCUSSION

EBF3, which encodes the early B-cell factor 3, is located in the q26 locus on chromosome 10 (Zardo et al., 2002). The protein is a highly conserved member of the Collier/Olf/EBF (COE) family of transcription factors, and is involved in neuronal differentiation, maturation, and migration. It is a necessary component in the development of the central nervous system (CNS) (Wang et al., 2004; Yamazaki et al., 2004). EBF3 contains a DNA-binding domain (DBD) with a unique zinc-finger-like conformation, an Ig-like/plexins/transcription factors (IPT/TIG) domain, an atypical helix-loop-helix (HLH) domain, and a C-terminal transactivation domain (TAD) (Figure 5A; Liberg et al., 2002; Siponen et al., 2010). Structural damage to the DBD potentially decreases the EBF1-like activity of EBF3 owing to haploinsufficiency (the DBD of EBF1 and EBF3 are highly homologous) (Feldhaus et al., 1992; Lukin et al., 2011). Furthermore, EBF3 mutations potentially lead to the formation of abnormal EBF3-EBF2 heterodimers (EBF2 and EBF3 are highly homologous) (Sleven et al., 2017). EBF3 p.Arg163Leu and p.Pro177Leu can partially damage the DBD, thus reducing its ability to bind to DNA, while also reducing the transcriptional activity of wild-type EBF3 through dominant negative effects (Lukin et al., 2011; Sleven et al., 2017). However, nonsense variants are predicted to undergo nonsense-mediated mRNA decay *in vivo* (Harms et al., 2017; Sleven et al., 2017). Therefore, EBF3 mutations may exert their effects through loss of function or dominant negative regulatory mechanisms (Lukin et al., 2011; Chao et al., 2017; Sleven et al., 2017).

Upon validation via trio whole-exome sequencing and Sanger sequencing, we report a novel heterozygous missense mutation, c.589A > G, in EBF3 in a boy with global developmental delay. JSMOL simulation of the EBF3 protein structure (Figure 5B) revealed Asn197 is located proximal to the DNA. Asn is a polar, uncharged amino acid, whereas Asp is a polar, negatively charged amino acid. Therefore, p.Asn197Asp can not only partially damage the DBD, but also affect the ability of EBF3 to recognize DNA, thereby decreasing its DNA-binding ability. Harms et al. (2017) reported that changes in p.Arg209Trp potentially alter Asn197 and reduce the binding affinity between Asn197 and DNA, thereby altering EBF3-mediated genetic regulation, inducing the downregulation of wild type EBF3, and eventually leading to a series of pathological conditions. The p.Asn197Asp mutation reported herein may directly affect the DNA-binding ability of this protein. In this study, the pathogenicity of the mutation was confirmed by cellular model. p.Lys193Asn, a variation closer to Asn197 (Figure 5C), reported by Sleven et al. (2017), could damage the electrostatic network of interactions with the DNA phosphate backbone and the carbonyl oxygen of Ser65, and activate Cd79a transcription. The p.Asn197Asp mutation might also disrupt the electrostatic network. Our study showed that EBF3-N197D mutant impaired activation of luciferase reporter expression of the p21 promoter (Figure 3) which was consistent with previous studies (Jin et al., 2014; Harms et al., 2017). Besides, the mutant was significantly reduced in nucleus while increased in the cytoplasm which affected its entry into the nucleus (Figure 4). These data suggest

FIGURE 4 | The localization of Flag-EBF3-WT and Flag-EBF3-N197D in HEK293T cells. The distribution of p.N197D mutant was significantly reduced in the nucleus (A,B), and increased in the cytoplasm (A,C) and affected its entry into the nucleus (D). Results were mean \pm SD for three individual experiments which, for each condition, were performed in triplicate. ** $p < 0.01$.

that the decreased affinity between ASN197 and DNA may lead to the reduced nuclear presence of EBF3, thus leading to the decreased expression of reporter genes.

Thus far, 33 mutations of *EBF3* have been reported worldwide, all of which are *de novo* mutations, including missense, frameshift, and nonsense mutations and splice variants (Chao et al., 2017; Harms et al., 2017; Slevin et al., 2017). Its functional heterozygous deletion is associated with developmental defects in the nervous system, eventually leading to hypotonia, ataxia, and delayed development syndrome (HADDs, OMIM #617330) (Chao et al., 2017; Harms et al., 2017; Slevin et al., 2017; Tanaka et al., 2017). HADDs follows an autosomal dominant inheritance. We compared the clinical phenotypes of patients with HADDs previously reported. The common phenotypes shared by these patients include motor delay, hypotonia, intellectual disability, and retardation in language acquisition. Besides the typical HADDs symptoms, our patient presented with an unclosed

fontanelle, delayed teething, minimal facial expressions, high nasal bridge, broad nasal tip, deep philtrum, downturned mouth, feeding difficulties, cryptorchidism, micropenis, and pectus excavatum, consistent with the variable symptoms of HADDs, thus providing novel evidence for this syndrome. Furthermore, our patient did not present with ataxia, probably because he was too young for ataxia to be manifested. Although most previously reported patients with HADDs presented with ataxia, this symptom was observed only at a later stage (Lukin et al., 2011; Chao et al., 2017; Harms et al., 2017; Slevin et al., 2017; Tanaka et al., 2017). Moreover, Harms reported that ataxia was absent in a boy aged 1 year 11 months and a 25-year-old female (Harms et al., 2017). The present patient further presented several unusual symptoms including hemangioma, mild hearing abnormalities, and tracheomalacia, which have not been reported. *Ebf3*-deficient mice reportedly died of respiratory failure due to diaphragmatic relaxation dysfunction within

FIGURE 5 | Schematic representations of EBF3 structure. **(A)** The EBF3 protein consists of a DNA-binding domain with special zinc knuckle, an Ig-like/plexins/transcription factors domain, an atypical HLH domain, and a C-terminal transactivation domain. The mutant amino acid identified in this study is shown in black arrow. **(B,C)** Close up of DNA-binding interactions of the variant (generated with JSmol). The protein is shown in gray, and the DNA is shown in orange. Asn197 is interacted with DNA. Asn197 is close to Lys193 which participated in the electrostatic network of interactions with the DNA phosphate backbone and the carbonyl oxygen of Ser65.

12 h postpartum (Jin et al., 2014). In the present patient, tracheomalacia may have been caused by hypotonia. However, it remains unclear whether tracheomalacia, and mild hearing abnormalities were truly associated with this condition.

CONCLUSION

We found a novel heterozygous *EBF3* mutation with Trio-WES in a Chinese boy with HADDs. By constructing the plasmid and transfecting HEK293T cells, *EBF3*-N197D mutant showed impaired activation of luciferase reporter expression of the p21 promoter, and the mutant was significantly reduced in nucleus while increased in the cytoplasm which affected its entry into the nucleus. Thus, this mutation was most likely the pathogenic mutation for this individual. This syndrome is yet to be reported in Asia. To the best of our knowledge, this study is the first to report hemangiomas, tracheomalacia, and mild hearing abnormalities in HADDs caused by an *EBF3* mutation. However, only a few cases have been reported and further assessments of a larger number of patients are required to determine whether these symptoms are associated with HADDs.

This study further validated the association between *EBF3* pathogenic mutations and HADDs. It provides key information regarding the pathogenic mutation spectrum of HADDs, which will facilitate the clinical diagnosis and genetic counseling of patients with HADDs. More case studies are needed to clarify genotype-phenotype interactions in HADDs.

doi: 10.3389/fgene.2021.726116

Transient infantile hypertriglyceridemia is a rare autosomal recessive disorder characterized by hypertriglyceridemia, hypohepatia, hepatomegaly, hepatic steatosis and fibrosis in infancy. Mutations in *GPD1* gene are considered the causative factor but the underlying mechanism of this disorder is still enigmatic. To date, only 24 different *GPD1* mutations have been reported in the literature worldwide with transient infantile hypertriglyceridemia or relevant conditions. Here we report a Chinese girl who developed hepatomegaly hepatic steatosis, elevated transaminase and hypertriglyceridemia from the age of 4 months. A novel homozygous variant c.454C>T (p.Q152*) was found in *GPD1* gene by next-generation sequencing. This patient is the 3rd Asian reported with transient infantile hypertriglyceridemia. We summarized the clinical presentations of transient infantile hypertriglyceridemia and also expanded the spectrum of disease-causing mutations in *GPD1*.

Keywords: glycerol-3-phosphate dehydrogenase 1, transient infantile hypertriglyceridemia, hepatomegaly, hypohepatia, hepatic steatosis, next-generation sequencing

INTRODUCTION

Transient infantile hypertriglyceridemia (HTGTI; OMIM#614480) is a rare disorder with an autosomal recessive pattern of inheritance. Most patients with HTGTI present with transient hypertriglyceridemia, elevated transaminases, early-onset hepatomegaly, persistent fatty liver and hepatic fibrosis. Rare phenotypes include fasting hypoglycemia, kidney disease, obesity, insulin resistance, dermal abnormalities and short stature (Dionisi-Vici et al., 2016; Li et al., 2017). This condition has been considered to be caused by mutations in the *GPD1* gene (OMIM#138420) which encodes the intracellular isomer of glycerol-3-phosphate dehydrogenase 1 (GPD1). A total of 31 mutations in the *GPD1* gene have been reported in Human Gene Mutation Database (HGMD) (Stenson et al., 2017), of which only 24 mutations have been described with HTGTI or associated phenotypes worldwide (Basel-Vanagaite et al., 2012; Joshi et al., 2014; Di Resta et al., 2015; Dionisi-Vici et al., 2016; Dron et al., 2017, 2020; Li et al., 2017, 2018; D'erasmo et al., 2019; Matarazzo et al., 2020). Herein we report a Chinese girl with a hitherto unreported homozygous variant of the *GPD1* gene, who presented with elevated transaminases, massive hepatomegaly, hepatic steatosis and hypertriglyceridemia from the age of 4 months.

CASE PRESENTATION

The patient is a 4-year-old Chinese girl born via cesarean section without remarkable complications. Her weight at birth was 3.15 kg (50th percentile) and her height was 50 cm (50th percentile). Her parents were both healthy and non-consanguineous. Her older brother was physically healthy (**Figure 1A**). The patient has no relevant family history of the disease. No liver dysfunction, hyperlipidemia, or hepatic steatosis has been found in the patient's parents or brother.

The patient suffered from bronchopneumonia at the age of 4 months and 5 days. During this period, liver dysfunction was noticed. After recovering from bronchopneumonia, the patient was referred to our hospital for further examination and treatment due to persistent elevations in liver transaminase. At her physical examination at the age of 4 months, her weight was 5.8 kg (6th percentile) and her height was 61.2 cm (17th percentile). She presented with marked hepatomegaly but splenomegaly. She showed normal growth and psychomotor development. In laboratorial examinations, her results of liver function tests were abnormal. Her alanine aminotransferase

(ALT, 107 U/L, reference range (r.r): 0–60 U/L), aspartate aminotransferase (AST, 186 U/L, r.r: 0–60 U/L), γ -glutamyl transpeptidase (γ -GT, 265 U/L, r.r: 0–50 U/L) and total bile acids (18.2 μ mol/L, r.r: 0–10 μ mol/L) were highly elevated. Blood lipid test also showed elevated triglycerides (TG, 4.39 mmol/L, r.r < 1.7 mmol/L). The levels of total cholesterol, lipoprotein, bilirubin, coagulation test and albumin were within normal limits. Further workups including routine blood test, blood glucose, electrolytes, serum ammonia, lactic acid levels, fatty acids, ceruloplasmin, serological markers for viruses (cytomegalovirus, Epstein-Barr virus, hepatitis virus), toxoplasmosis, thyroid function, creatinine, uric acid, autoimmune serology and immunoglobulin levels, all of which showed normal results. B-mode ultrasound of the liver showed diffuse hepatomegaly with increased echogenicity (**Figure 1B**). Contrast-enhanced abdominal CT suggested significant hepatomegaly with fatty changes (**Figure 1C**). No splenomegaly was observed. The results of echocardiogram showed atrial septal interruption (Φ 0.31 cm). No abnormalities were observed in electrocardiogram (ECG), chest radiographs, portal vein and inferior vena cava

FIGURE 1 | Clinical features and genetic sequencing data of the patient. **(A)** The pedigree of the family. **(B)** B-mode ultrasound demonstrated diffuse hyperechogenicity of the liver with a fine granular pattern. **(C)** Contrast-enhanced CT scan of abdomen shows a significantly enlarged liver with fatty change. **(D)** Sanger sequencing shows that the patient harbored homozygous mutations (c.454C>T, p.Q152*) in exon 6. The patient's parents and brother were all heterozygous for this mutation.

ultrasonography. Liver biopsy was recommended but her parents refused.

After administering compound glycyrrhizin tablets (half tablet per day) (Each tablet contains 25 mg glycyrrhizin, 35 mg monoammonium glycyrrhizinate, 25 mg aminoacetic acid and 25 mg methionine; Minophagen Pharmaceutical Co., Ltd., Japan) for 3 months, her transaminase levels decreased but remained above normal (ALT, 85 U/L; AST, 127 U/L; γ -GT, 258 U/L.). At 3.5 years old, her TG and transaminases were at normal levels and her abdominal ultrasound showed that her liver was smaller in size than before. At the age of 4, her weight was 13 kg (3rd percentile) and her height was 94 cm (3rd percentile). Except for short stature, no other symptoms were presented.

GENETIC ANALYSIS

The patient was suspected with hereditary metabolic liver disease due to a combination of elevated liver transaminases, hypertriglyceridemia and hepatomegaly. Peripheral blood samples of the patient, her parents and her brother were collected and sent to Running Gene Inc. (Beijing, China) for next-generation sequencing (NGS). DNA samples were extracted using the QIAamp DNA Blood Midi Kit (Qiagen, Hilden, Germany) and quantified using Nanodrop spectral analysis (Thermo Fischer Scientific, Inc., Waltham, MA). The patient's genomic DNA was fragmented into 200–300 bp for sequencing library generation by KAPA Library Preparation Kit (#KR0453, Kapa Biosystems, Wilmington, MA). Pooled libraries were screened by the customized xGen Inherited-Diseases-Panel Probe. The captured libraries were sequenced by the Illumina HiSeq2500 Analyzers (Illumina, San Diego, CA). Single-nucleotide variants and indels were called and filtered based on multiple databases [ExAC (Lek et al., 2016), gnomAD (Karczewski et al., 2020), 1kGenome (Genomes Project et al., 2015), ESP6000 (Fu et al., 2013), ClinVar (Landrum and Kattman, 2018), and HGMD]. Candidate variants were classified according to the American College of Medical Genetics and

Genomics (ACMG) guidelines (Richards et al., 2015). Suspected pathogenic variants were then verified in the proband and her parents by Sanger sequencing.

A pair of homozygous non-sense variant c.454C>T (p.Q152*) was identified in the *GPD1* gene (NM_001257199). The mutated variants of the proband were inherited from her parents, in fact, the same variant was also found in heterozygosis in her parents and her brother, consistent with the pattern of recessive inheritance (Figure 1D). This variant, which has not been recorded in any public databases, is novel. Variant c.454C>T altered codon for Glu152 to a termination codon, which may produce a truncated protein or lead to non-sense-mediated mRNA decay (PVS1). This variant is located in N-terminal NAD-dependent glycerol-3-phosphate dehydrogenase (Figure 2) (PM1) and absent from controls (ExAC, gnomAD, 1kGenome, ESP6000) (PM2). Multiple software predicted the variant as deleterious [MutationTaster2 (Schwarz et al., 2014), 1,000, disease causing; Ba+Del_addAF (Feng, 2017), 0.625 > cutoff = 0.069, deleterious; CADD (Rentzsch et al., 2019), 35 > 15, damaging; fathmmMKL-inherited (Shihab et al., 2013), 0.927 > 0.5, damaging.] (PP3). Thus, c.454C>T (p.Q152*) is classified as a pathogenic variant (PVS1+PM1+PM2+PP3), according to the ACMG guidelines.

DISCUSSION

GPD1 mutation related to HTGTI was first discovered by Basel-Vanagaite et al. in 10 family members of four highly consanguine Israeli Arab families carrying c.361-1G>C (Basel-Vanagaite et al., 2012). Subsequently, nine articles described extra 30 mutations of *GPD1* gene associated with HTGTI, chylomicronemia syndrome, Brugada syndrome or low HDL cholesterol, respectively. Only six articles worldwide described complete clinical presentation and genetic data of 18 patients with HTGTI or relevant phenotypes, and we summarized them with our current patient (Table 1). The mean age of onset was about 10 months, with a median age of 5 months. The gender

ratio (male to female) is 1.375 (11:8). Common clinical features of *GPD1*-associated patients are hepatic steatosis (100%, 19/19), hepatomegaly (100%, 18/18), hypertriglyceridemia (95%, 18/19), and hypohepatia (elevated liver transaminases) (95%, 18/19). Other phenotypes, including splenomegaly (4/11), fibrosis (6/19), short stature (6/19), vomiting (4/19), elevated total bile acids (4/19), and failure to thrive (3/19), are also involved. The affected individuals tended to vomit and fail to thrive as the first symptoms, but more than half of cases were asymptomatic. A third of patients had a liver biopsy, showing steatosis with varying degrees of fibrosis. Our patient has characteristics of *GPD1* deficiency includes early-onset, elevated ALT and γ -GT levels, hypertriglyceridemia, fatty liver and mild failure to thrive. The clinical manifestations were similar to the 18 patients described in the previous articles (Basel-Vanagaite et al., 2012; Joshi et al., 2014; Dionisi-Vici et al., 2016; Li et al., 2017, 2018; Matarazzo et al., 2020). Although phenotypic studies of *GPD1* mutations have focused on dyslipidemia and secondary hepatic metabolic disorders, the clinical features of patients reported by Dionisi-Vici et al. were slightly different from other reported cases. One patient had recurrent fasting hypoglycemia; the second presented with severe liver disease with intrahepatic cholestasis involving the kidney. A patient with rare phenotypes (obesity, insulin resistance, pimple, acanthosis nigricans, hypertrichosis and short stature) was also reported (Li et al., 2017). Based on the available case reports, the severity of the clinical phenotype of *GPD1* mutation-associated HTGTI is independent of the type and location of the mutation site.

Although hypertriglyceridemia is a significant risk factor for coronary disease, acute pancreatitis and metabolic syndrome (Cullen, 2000; Athyros et al., 2002; Hopkins et al., 2005), all affected individuals had a relatively good medium-term prognosis. According to follow-up data from patients with *GPD1* mutations, in most patients, the TG and liver enzyme indices normalize with age and no specific treatment is required. Furthermore, no clinical evidence of coronary disease or pancreatitis has been reported, nor in the oldest patients (Basel-Vanagaite et al., 2012). Therefore, liver transplant is not recommended for patients with HTGTI. Lipid-lowering drugs are not routinely used because TG levels can be ameliorated without particular treatment. That proves the diagnosis of *GPD1* deficiency is of great significance for the management of the patients. Although no conclusions can be drawn about the risks in adulthood or long-term prognosis, sufficient attention must be given to HTGTI patients during long-term follow-up. Assessment of the growth and development and screening for abnormal indicators such as liver transaminases, total cholesterol, TG, abdominal ultrasound are recommended at follow-up visits.

Located on chromosome 12q13.12, *GPD1* gene encodes glycerol-3-phosphate dehydrogenase 1, a member of the NAD-dependent GPD family. *GPD1* is a protein of 37.5 kD size that catalyzes the invertible conversion of dihydroxyacetone phosphate (DHAP) and nicotinic adenine dinucleotide (NADH) to glycerol-3-phosphate (G3P) and NAD⁺ in the cytoplasm, working in the metabolism of carbohydrate and lipid (Menaya et al., 1995; Ou et al., 2006; Basel-Vanagaite et al., 2012). Along with *GPD2* (mitochondrial), *GPD1* (cytosolic) also forms

a glycerol phosphate shuttle which plays an important role in the transport of reducing equivalents from the cytosol to mitochondria, resulting in the reoxidation of NADH formed from glycolysis and the regeneration of NAD⁺ in the brain and skeletal muscle.

A total of 31 mutations of *GPD1* were reported in HGMD, including 24 mutations associated with HTGTI or relative phenotypes. Of these 24 mutations, only 11 mutations are disease-causing (DM) and 13 are possibly disease-causing (DM?). Including our current novel variant, only four non-sense have been reported in *GPD1* and they are all classified as DM. However, the underlying mechanism of HTGTI caused by *GPD1* mutations is still unknown. Only a few theories have been hypothesized and studied. Since the availability of G3P has been considered as a regulatory factor of TG synthesis, it has been suggested that *GPD1* mutations may cause an increase in the amount of hepatic G3P available for TG synthesis by limiting the conversion of G3P to DHAP, consequently leading to elevated TG (Basel-Vanagaite et al., 2012). Intriguingly, as the conversion is from DHAP to G3P under physiological conditions, it is also possible that DHAP may not be converted to G3P due to the lack of *GPD1*, resulting in a relative surplus of DHAP and a decrease in G3P. This theory has been demonstrated in a mouse model of *GPD1* deficiency (Macdonald and Marshall, 2000). DHAP can be acylated firstly then reduced to 1-acyl-sn-G3P. The acyl DHAP pathway also plays a significant role in the synthesis of glycerides in the liver (Athenstaedt and Daum, 2000; Zheng and Zou, 2001). The pathogenesis of fatty liver in HTGTI patients may be caused by excessive DHAP acylation. *GPD1* mutations lead to increased TG synthesis in the liver, decreased output from the liver, increased inflow of fatty acids into the liver, and impaired hepatic beta-oxidation causing non-alcoholic hepatic steatosis (NASH) (Dionisi-Vici et al., 2016). In two of the studies, *in vitro* functional studies using cell experiments confirmed the pathogenicity of the c.361-1G>C, c.220-2A>G and c.820G>A mutations (Basel-Vanagaite et al., 2012; Li et al., 2017). Only one of the affected individuals described in the above studies has an overweight body mass index, which refutes the role of obesity in the pathophysiology of the development of hepatic steatosis in these individuals. The pathogenesis of each symptom in *GPD1*-associated HTGTI requires more clinical and basic medical research to be explored.

In summary, this study reported a Chinese HTGTI patient and also expanded the spectrum of disease-causing mutations in *GPD1* gene. In future clinical diagnosis, *GPD1* deficiency should be considered if hypertriglyceridemia, elevated liver enzymes, hepatomegaly, hepatic steatosis and fibrosis are present in early infancy. When the cause cannot be determined by traditional clinical examination, NGS is a promising approach to help clinical diagnosis and guide clinical management.

DATA AVAILABILITY STATEMENT

The original contributions presented in the study are included in the article/supplementary materials, further inquiries can be directed to the corresponding author. Genetic sequencing data are available in Sequence Read Archive (SRA) by PRJNA747113.

ETHICS STATEMENT

This study was reviewed and approved by the Research Ethics Committee of The Children's Hospital, Zhejiang University School of Medicine (2020-IRB-166, November 16, 2020). Written informed consent was obtained from the patient's parents for the investigation and publication of this article.

AUTHOR CONTRIBUTIONS

HL analyzed and interpreted the patient data and drafted the manuscript. JC and JL were responsible for guiding the diagnosis

and treatment of the patient. LH analyzed sequencing data, produced figures, and made a significant contribution to the manuscript. YF contributed to gathering patient data and was a major contributor in writing the manuscript. HL and LH reviewed the final manuscript. All authors read and approved the final manuscript.

ACKNOWLEDGMENTS

We thank the patient's family for their cooperation. We are also grateful for the warm helps from physicians, nurses, and technicians who supported us.

Diffuse Polymicrogyria Associated
With a Novel *ADGRG1* Variant.
Front. Pediatr. 9:728077.
doi: 10.3389/fped.2021.728077

Pathogenic variants of the *ADGRG1* gene are associated with bilateral frontoparietal polymicrogyria, defined radiologically by polymicrogyria with an anterior-posterior gradient, pontine and cerebellar hypoplasia and patchy white matter abnormalities. We report a novel homozygous *ADGRG1* variant with atypical features. The patient presented at 8 months of age with motor delay, esotropia, hypotonia with hyporeflexia and subsequently developed refractory epilepsy. At the last assessment, aged 12 years, head control, sitting and language were not acquired. Magnetic resonance imaging revealed diffuse polymicrogyria with relative sparing of the anterior temporal lobes, without an anterior-posterior gradient, diffuse hypomyelination and pontine and cerebellar hypoplasia. A panel targeting brain morphogenesis defects yielded an unreported homozygous *ADGRG1* nonsense variant (dbSNP rs746634404), present in the heterozygous state in both parents. We report a novel *ADGRG1* variant associated with diffuse polymicrogyria without an identifiable anterior-posterior gradient, diffuse hypomyelination and a severe motor and cognitive phenotype. Our case highlights the phenotypic diversity of *ADGRG1* pathogenic variants and the clinico-anatomical overlap between recognized polymicrogyria syndromes.

Keywords: *ADGRG1*, bilateral generalized polymicrogyria, *GPR56*, polymicrogyria, bilateral frontoparietal polymicrogyria, case report

INTRODUCTION

Polymicrogyria (PMG) is a cortical malformation characterized by supernumerary, small gyri with abnormal cortical lamination. PMG syndromes are markedly heterogeneous in etiology and phenotype, including infectious or vascular causes as well as genetically defined multiple congenital anomaly syndromes or inborn errors of metabolism. PMG can also occur in isolation (unilateral or bilateral PMG syndromes), frequently with a genetic etiology (1). Bilateral PMG syndromes are further categorized according to the topographical distribution of the abnormal gyral pattern into bilateral frontoparietal (BFPP), bilateral generalized (BGP), bilateral perisylvian, bilateral posterior or bilateral parasagittal PMG (1).

Autosomal recessive pathogenic variants of *GPR56* or *ADGRG1* (OMIM*604110; henceforth designated as *ADGRG1*), a member of the family of G protein-coupled receptors (GPCRs), were found to be specifically associated with BFPP (2, 3). BFPP is radiologically defined by the presence of PMG with an anterior to posterior gradient, bilateral patchy white matter signal changes and brainstem and cerebellar hypoplasia or dysplasia (3). The clinical phenotype consists of early onset hypotonia with subsequent motor and cognitive developmental delay, seizures and eye abnormalities (strabismus and/or nystagmus) (3). We herein report a novel *ADGRG1* variant causing a generalized PMG pattern and a severe clinical phenotype.

CASE PRESENTATION

The proband is a 12-year-old male, the second-child of consanguineous parents (first degree cousins). The family history is relevant for learning disabilities and motor delay in a paternal aunt and learning disabilities in a paternal uncle. Notably, the patient's older brother by 9 years has no history of developmental delay or learning difficulties.

Gestation and birth were uneventful and in the post-natal period the patient only presented neonatal jaundice (maximal bilirubin dosing 12.4 mg/dL) treated with phototherapy.

Global development was reportedly normal until 6 months of age, when hypotonia and failure to achieve motor milestones were first noticed and the patient was referred to our Child Neurology outpatient clinic (**Figure 1**). On first assessment, at 8 months of age, the general examination showed mild dysmorphic features (almond eyes, long philtrum and low-set ears) without other relevant findings. Neurological examination revealed bilateral alternating esotropia and predominantly upper limb and axial hypotonia with diminished reflexes. We found a significant delay in psychomotor development, cephalic control was not present and the patient was unable to sit. There was poor social interaction, only few vocalizations and no hand manipulation. The initial magnetic resonance imaging (MRI) at 9 months revealed diffuse polymicrogyria without an identifiable anterior-posterior gradient, diffuse hypomyelination, thin corpus callosum, supratentorial ventriculomegaly and pontine and cerebellar hypoplasia, affecting both cerebellar vermis and hemispheres. There were no abnormalities on the electroencephalogram (EEG). The patient underwent an evaluation for chromosomal abnormalities, fragile-X mutation, imprinting disorders, mitochondrial DNA and ATPase 6 mutations, comprehensive blood, urine and cerebrospinal fluid (CSF) metabolic screening and muscle biopsy with assessment of respiratory chain enzymatic activity, which were all normal. There was no evidence of systemic disease on echocardiogram, liver, renal and spleen ultrasounds.

At 14 months, the patient developed focal seizures with impaired consciousness (behavioral arrest and eye deviation) initially responsive to valproate. The EEG showed predominantly frontal spikes and spike-waves, within a normal background.

The patient progressed very slowly and was able to maintain cephalic control and an unaided sitting position at 21 months. He

was able to maintain eye contact, smile and produce elementary sounds, but language was not present.

At 2.5 years, however, there was significant motor and cognitive regression with loss of cephalic control and unsupported sitting ability and poorer interaction. Simultaneously, a gradual worsening of epilepsy was observed, with the appearance of multiple seizure types including epileptic spasms, atonic, myoclonic and tonic-clonic bilateral seizures. The EEG showed slow background activity with multifocal, anterior or centro-parietal predominant, spikes and spike-waves. The patient was subsequently treated with several anti-epileptics including vigabatrin, levetiracetam, topiramate, clonazepam, and perampanel, with partial control of seizures, but without significant motor and cognitive improvement. Serial neurological examinations consistently showed bilateral alternating esotropia, horizontal nystagmus and flaccid tetraparesis, without pyramidal or cerebellar signs. Visual and auditory evoked-potentials revealed prolonged conduction times bilaterally. Repeat MRI at 11 years of age (**Figure 2**) was globally consistent with the above-mentioned features.

Genetic analysis with a next-generation sequencing panel targeting brain morphogenesis defects yielded a homozygous *ADGRG1* nonsense variant (rs746634404), caused by a nucleotide change [(NM_001145771.2: c.1504C>T) (NP_005673.3: p.Arg502Ter)] in exon 12. This variant is not present homozygously in GnomAD. Segregation analysis through Sanger sequencing confirmed the presence of the variant in the homozygous state in the patient and revealed that both parents were heterozygous carriers (**Figure 3A**). The variant is located in the seven-transmembrane (7TM) domain of the *ADGRG1* protein, which binds to a heterotrimeric G-protein complex and initiates downstream signaling (**Figures 3B,C**). The reported allele is rare in the population [GnomAD frequency: $f = 0.0000119$; European (Non-Finnish): $f = 0.00000881$]. *In silico* analysis was performed using two different algorithms to predict the pathogenicity of the variant. DANN (4) (Deleterious Annotation of genetic variants using Neural Networks) is a pathogenicity scoring methodology based on neural networks, with values ranging from 0 to 1 (where 1 represents variants predicted to be most damaging). MutationTaster (5) employs a Bayes classifier to predict the disease potential of an alteration, based on evolutionary conservation, splice-site, mRNA, protein and regulatory features. The reported variant was predicted as “damaging” by DANN (DANN score: 0.9983) and as “disease causing” by MutationTaster. Finally, the level of evidence of pathogenicity was classified as “very strong” according to American College of Medical Genetics criteria (6), as the nonsense variant was identified in a gene for which loss-of-function is a known mechanism of disease.

DISCUSSION

We report a novel *ADGRG1* truncating variant, presenting with atypically diffuse PMG and hypomyelination and a severe clinical phenotype.

At the time of publication, *ADGRG1* pathogenic variants have been described in a total of 77 patients from 47 pedigrees and 34 different corresponding variants (2, 3, 7–20). In all reported cases, *ADGRG1* variants were associated with a typical anatomical

BFPP distribution, i.e., either a restricted frontoparietal PMG or an anterior-posterior gradient of cortical malformation. However, in our case a gradient of involvement was not identified. Complete or near-complete involvement of the entire cerebral cortex without any region of maximal involvement or any gradient of severity is the hallmark of BGP (21, 22). Relative sparing of the interhemispheric or temporal gyri has been described occasionally and is present in our patient. Considering other associated imaging features, patchy white matter signal changes or white matter volume reduction are most commonly associated with BFPP while more diffuse white matter involvement is present in more than 50% of BGP patients (22). The most distinguishing feature, however, is the presence of brainstem and cerebellar involvement in BFPP, also identified in our patient, and typically absent in BGP. Therefore, we believe that the anatomical distribution of cortical and non-cortical dysgenesis in our case mostly conforms to a severe and diffuse form of the BFPP syndrome.

Clinically, BFPP presents as a pseudomyopathic pattern, with hypotonia developing in the first year of life and occasionally being identified at birth (13). This initial clinical phenotype and imaging pattern is frequently suggestive of congenital muscular dystrophies of the “cobblestone complex” (13). The initial course of disease in our patient mimicked this pattern, but similarly to previously reported cases the muscle biopsy was normal and thus channeled the investigation away from this group of diseases. Following the pseudomyopathic presentation, the clinical course of BFPP is also considerably homogeneous in the cases reported in literature. **Table 1** describes the frequency of clinical features associated with BFPP described in the reported cases.

Cognitive and motor delay are universal features, although their severity is variable between cases. While the majority of patients (79.3%) had severe cognitive impairment with language restricted to only a few words, motor impairment was reportedly milder. Indeed, most patients (81.6%) were able to walk, either with or without support, although gait is frequently described as “unsteady” or ataxic. Gait acquisition was delayed in almost all cases (13, 20). On the other hand, there was a total of nine cases without gait acquisition, originating from six different variants in seven pedigrees, of which five variants were either frameshift or nonsense (14, 20). In our case, also a nonsense variant, motor impairment was abnormally severe, since the patient was unable to walk, sit or achieve cephalic control. To our knowledge, there are only two reports sharing this severe

FIGURE 3 | (A) Sanger sequencing chromatograms of the patient and parents. The patient is a homozygous carrier of the nonsense variant c.1504C>T. The variant was present in the heterozygous state in both parents. **(B,C)** Schematic of the ADGRG1 protein, showcasing the novel variant in the 7TM domain of the protein (p.Arg502*). 7TM, 7 transmembrane domain; GAIN, GPCR-Autoproteolysis-INDucing domain; GPS, GPCR proteolysis site motif; PLL, Pentraxin/Laminin/neurexin/sex-hormone-binding-globulin-Like domain.

phenotype. One is curiously of a Portuguese patient described by Santos-Silva et al. though the two cases do not share the same variant (14). The other report, by Cauley et al. describes a family with severe motor and cognitive delay, where the typical imaging phenotype of BFPP was present in association with Joubert-like features (7). The patients were found to have an additional

pathogenic variant in *KIAA0556* by exome sequencing, with both variants interacting to create a more severe and complex phenotype. Pyramidal signs and ataxia are also common (75.9 and 92.6%), although pyramidal signs were absent in our patient and ataxia was impossible to ascertain due to the severity of motor impairment. Other common clinical manifestations in

TABLE 1 | Clinical features of reported BFPP cases (2, 3, 8–20).

Clinical feature	n (%)
Motor impairment	
Able to walk	40 (81.6)
Age at walking in years, median (IQR)	3.5 (3.0)
Unable to walk	9 (18.4)

BFPP and present in this case are epilepsy (88.2% of patients described in the literature, being drug-refractory in 60% of those) and oculomotor dysfunction (92.1% of reported cases, most commonly strabismus). In short, the clinical picture present in our case is in accordance to BFPP, although the severity of motor impairment is atypical.

Could this severe phenotype be more in line with BGP? In the study by Leventer et al. (22), BGP patients were more likely to present with global developmental delay, intellectual disability, spastic quadriplegia, seizure onset at younger age, and hearing

and cortical visual impairment, when compared to other PMG syndromes. Interestingly, the reported severity of cognitive and motor delay was also variable, with mild impairment in some cases, although severe phenotypes similar to our patient were reported (21). Thus, there seems to be considerable clinical overlap between BFPP and BGP in both the type and severity of clinical manifestations.

Several hypotheses can be proposed to explain the atypical clinical features in our case. First, they may result from the unique molecular characteristics of the gene product associated with the pathogenic variant. Physiologically, the ADGRG1 protein is a GPCR that binds extracellular matrix proteins (most notably collagen type III) and undergoes agonist-induced conformational changes. This, in turn, promotes release of the α subunit of the heterotrimeric G-protein complex from the 7TM domain of ADGRG1 and initiates downstream signaling via interaction with various cytosolic effector proteins. Even though other pathogenic variants of the surrounding 7TM region (such as the L487P, E496K, and R565W variants) do not present this particular phenotype (8, 12, 18), it is possible that subtle variations in the mutated protein impair different downstream signaling cascades, thereby resulting in varied phenotypic expressions. In our particular case, the severity of the clinical phenotype can also be interpreted in the context of an epileptic encephalopathy since there was motor and cognitive regression occurring simultaneously with epilepsy decompensation. Another hypothesis is the co-existence of additional pathogenic variants of genes involved in brain morphogenesis, as highlighted by the recent report from Cauley et al.

CONCLUSIONS

We report a novel *ADGRG1* truncating variant associated with generalized PMG without an anterior-posterior gradient, diffuse hypomyelination and a severe motor phenotype. Clinical and radiological features of BFPP were also present, highlighting the clinical-anatomical overlap between recognized PMG syndromes and the phenotypic diversity of *ADGRG1* pathogenic variants.

The mental retardation-55 with seizures (MRD55) is a rare genetic disease characterized by developmental delay, intellectual disability, language delay and multiple types of epileptic seizures. It is caused by pathogenic variants of the *NUS1* gene, which encodes Nogo-B receptor (NgBR), a necessary subunit for the glycosylation reactions in mammals. To date, 25 disease-causing mutations of *NUS1* have been reported, which are responsible for various diseases, including dystonia, Parkinson's disease, developmental and epileptic encephalopathy as well as congenital disorder of glycosylation. In addition, only 9 of these mutations were reported with detailed clinical features. There are no reports about Chinese cases with MRD55. In this study, a novel, *de novo* pathogenic variant of *NUS1* (c.51_54delTCTG, p.L18Tfs*31) was identified in a Chinese patient with intellectual disability and epileptic seizures. This pathogenic variant resulted in truncated NgBR proteins, which might be the cause of the clinical features of the patient. Oxcarbazepine was an effective treatment for improving speech and movement of the patient, who consequently presented with no seizure. With this novel pathogenic variant found in *NUS1*, we expand the genotype spectrum of MRD55 and provide valuable insights into the potential genotype-phenotype correlation.

Keywords: whole-exome sequencing, *NUS1*, epilepsy, MRD55, ID

INTRODUCTION

The mental retardation-55 with seizures (MRD55, OMIM 617831) is a rare genetic disease characterized by developmental delay, intellectual disability, language delay and multiple types of epileptic seizures (1). It is caused by pathogenic variants of the *NUS1* gene, which encodes Nogo-B receptor (NgBR) (2). NgBR is a conserved subunit of the dehydrololichyl diphosphate synthase (DDS) complex, which promotes cisprenyltransferase (cis-PTase) activity and is necessary for the glycosylation reactions in mammals (3). To date, 25 disease-causing mutations of *NUS1* have been reported (according to the Human Mutation Database), nine of which were reported with detailed clinical phenotypes. These nine pathogenic variants, however, are associated with four various diseases, including dystonia (4), Parkinson's disease (5, 6), developmental and epileptic encephalopathy (1, 6–8), and congenital disorder of glycosylation (3). Thus, it seems that different pathogenic variants cause distinct diseases. In addition, cases with genotypes and detailed clinical

features are limited. Additional cases are needed for a better understanding of the relationship between MRD55 and the associated pathogenic variants.

Here, we report the clinical and molecular characterization of the first Chinese MRD55 patient, who displayed intellectual disability and epileptic seizures, and had a novel, *de novo* pathogenic variant of *NUS1* (c.51_54delTCTG, p.L18Tfs*31). With this novel pathogenic variant found in *NUS1*, we expanded the genotype spectrum of MRD55.

METHODS

Case Presentation

Our patient was the first child to non-consanguineous, healthy parents. He was born full-term *via* cesarean delivery, G1P1, with no asphyxia. The birth parameters included weight 3.0 kg ($Z = -0.925$), length 50.0 cm ($Z = 0.004$), and head circumference (HC) 38.0 cm ($Z = 1.299$). There was no abnormality in the perinatal period, and neither of his parents had a related family history. He could roll over, sit, call his parents and walk independently at the ages of 3, 6, 12, and 16 months, respectively. When the patient was 3 years old, he presented with unstable standing, involuntary movement of the limbs, abnormal posture and dance-like movements when he was emotionally agitated or fatigued. During this period, the patient was conscious and occasionally experienced sudden falls or involuntary squatting, with no binocular upward gaze, perioral bruising, or limb stiffness. The whole duration lasted approximately several seconds to several hours, which could be relieved spontaneously after the patient rested. The results of brain magnetic resonance imaging (MRI) were normal whereas video electroencephalogram (EEG) revealed slow and spiny-slow waves in the bilateral frontopolar, frontal, and anterior temporal regions during the sleeping period. The diagnosis of epilepsy was confirmed, and he was treated with Depakine (6 mg/kg/day) for a month. The treatment was not effective, and the patient continued to have seizures and unsteady standing in a variable frequency. The patient gradually developed occasional instability in the walking gait. He did not have any malformations or autistic feature but presented with a moderate intellectual disability at the age of 4 years and 7 months. The scores of full-scale intelligence quotient (FIQ), performance intelligence quotient (PIQ) and verbal intelligence quotient (VIQ) were 48, 47, and 61, respectively, as tested by Korean-Wechsler Preschool and Primary Scale of Intelligence (K-WPPSI). He was not given any treatment this time. At the age of 6 years, the patient suffered convulsions. The symptoms included unconsciousness, rolled-up left eye, stiff upper limbs and cyanotic lips. The duration of each convulsion was ~5 min, and the patient was admitted to the hospital for “paroxysmal dyskinesias.” The following abnormalities were detected in the video EEG: paroxysmal hypertonic 2–3 Hz slow waves interspersed with spikes were found in each conductor, especially in the frontal region. No other abnormality was identified from the blood or urine test, metabolic profiling analyses (amino-acid and acyl-arnitine profiles) or MRI scans (cervical, thoracic and lumbar spine). The patient was treated with madopar (2.1 mg/kg/day,

Q12h) for a month, but did not improve. He still walked unsteadily and sometimes stood unsteadily. The treatment was discontinued. After 15 months, when the patient was 7 years and 3 months old, convulsions occurred during the quiet sleep. The symptoms were similar to those described before. Physical examination was performed, and the results were all normal except for the video EEG. The background activity was slow, with slow wave emitted in the left frontopolar during sleep. Meantime, the Gesell developmental scales were performed, and the results indicated a developmental stage of 2 years old. The patient was given oxcarbazepine (40 mg/kg/d) and sensory integration training. The treatment was effective, and the patient consequently did not have seizures. His speech and movement improved. However, he still presented with an unsteady walking gait, slow and slurred communication and poor numeracy. He was unable to add or subtract within ten digits of recognizable numbers. Additionally, his logic and comprehension were poor.

Genetic Analysis

The peripheral blood of the patient was collected and sent to Running Gene Inc. (Beijing, China) for whole-exome sequencing (WES) to identify the causal gene. Briefly, DNA was isolated and fragmented to build a DNA library by using the KAPA Library Preparation Kit (Illumina, Inc., USA). Then, the library was sequenced using an Illumina HiSeq X10 platform (Illumina, San Diego, USA) using a 150-bp paired-end reads according to the standard manual. The sequencing data was filtered and aligned with the human reference genome (GRCh37/hg19) by using the BWA Aligner (<http://bio-bwa.sourceforge.net/>). and variants were annotated by ANNOVAR (annovar.openbioinformatics.org/en/latest/). The candidate causal genes thereby discovered were then confirmed *via* Sanger sequencing.

RESULTS

A novel variant c.51_54delTCTG (p.L18Tfs*31) of *NUS1* (NM_138459.3) was identified in the patient *via* WES analysis (**Figure 1A**). This *de novo* (PS2) heterozygous deletion in exon 1 introduces a premature terminator and results in a truncated protein with 31 miscoded amino acids (**Figure 1B**). The truncated protein consists of 18 correctly encoded amino acids, constituting part of the transmembrane domain 1 (TM1). Other functional domains (TM2, TM3, the *cis*-IPTase domain and the RXG motif) are expected to be deleted, resulting in the loss of function (PVS1). This variant is absent from the controls (1000 Genomes, ExAC, gnomAD, and CNGB) (PM2). Thus, variant c.51_54delTCTG is classified as a pathogenic variant of *NUS1* according to the standard of American College of Medical Genetics (9), and was predicted to cause MRD55. No other pathogenic variant was identified in genes that may be associated with the developmental delay and epileptic encephalopathy of our patient.

FIGURE 1 | (A) *De novo* heterozygous variants of c.51_54delTCTG in the patient. **(B)** Scheme of the reported disease-causing mutations of *NUS1*. The transmembrane (TM) 1 (AA 1-23), TM2 (AA 35-56) and TM3 (AA 117-135) domains are colored in cyan. The *cis*-IPTase domain (AA 136-293) is colored in blue. The RXG motif (AA 290-292), which is crucial for the prenyltransferase activity, is colored in orange. The 31 miscoded amino acids of the truncated protein are colored in magenta. The pathogenic variant reported in this study is colored in red and those reported with detailed clinical features are colored in gray. **(C)** Alignment of the *NUS1* proteins of various species. Residues G102 and R290 (indicated in blue boxes) are highly conserved.

PVS1, null variant (non-sense, frameshift, canonical ± 1 or 2 splice sites, initiation codon, single or multi-exon deletion) in a gene where loss of function (LOF) is a known mechanism of disease; PS2, de novo (both maternity and paternity confirmed) in a patient with the disease and no family history; PM2, absent from controls (or at extremely low frequency if recessive) in Exome Sequencing Project, 1000 Genomes or ExAC; PP1, Co-segregation with disease in multiple affected family members in a gene definitively known to cause the disease; PP3, Multiple lines of computational evidence support a deleterious effect on the gene or gene product; MRD55, mental retardation-55 with seizures; CDG1AA, congenital disorder of glycosylation type 1aa; ID, intellectual disability; N/A Not available, Not assessed; Het, Heterozygous; Hom, Homozygous.

DISCUSSION

MRD55 is a rare congenital disease characterized by developmental delay, intellectual disability, language delay

and multiple types of seizures (1). It was first reported in three unrelated patients, who presented with onset of myoclonic seizures and carried heterozygous, *de novo* pathogenic variants of the *NUS1* gene (1). The diagnostic criterion for this disorder

FIGURE 2 | The crystal structure of the human NgBR/DHDDS complex (PDB code: 6W2L). Shown are the cartoon representation of the wildtype NgBR/DHDDS structure and the G102, R290 mutants. The DHDDS and NgBR subunits of the heterodimer are colored in wheat and light blue, respectively. Residues G102, R290 and their pathogenic variants D102, H290 are shown in green sticks. D34, S133, E209, P238, L240, V241, L242, F253, E288, E293 and two IPEs are shown in sticks and highlighted in cyan (DHDDS subunit) and yellow (NgBR subunit). The water molecules of DHDDS and NgBR are colored in orange and light blue, respectively. The metal ion Mg^{2+} is colored in pink. All the structural figures were generated using PyMOL (<http://www.pymol.org>).

were established. Considering the epileptic seizures, moderate intellectual disability and the identified pathogenic *NUS1* variant, the patient was diagnosed with MRD55.

NUS1 encodes Nogo-B receptor, which consists of 293 amino acids and regulates cis-PTase activity (3). It interacts with the dehydrololichyl diphosphate synthase complex subunit (DHDDS), forming a biological functional heteromer (the DDS complex). DDS is essential for the biosynthesis of dolichol monophosphate (Dol-P), which is utilized as a sugar carrier during protein glycosylation in the endoplasmic reticulum (ER) (3, 10–12). Therefore, the protein encoded by pathogenic *NUS1* variants might lack the proper function, and thus the regulation of protein glycosylation is disrupted and disease ensue.

To date, 25 disease-causing mutations of *NUS1* have been reported (Figure 1B), nine of which are described with detailed clinical phenotypes (Table 1) (1, 3–8). It is interesting that ten pathogenic variants, including the one reported in our study, are responsible for four different diseases, including dystonia, Parkinson's disease, CDG1AA and MRD55. Phenotypes are diverse, patients present with seizures (13/16), intellectual disability (ID, 12/16), language delay (5/16), developmental delay (6/16), ataxia (10/16), scoliosis (4/16) and hypotonia (3/16). Autism and dysmorphic features are rare, which are only found in one MRD55 (1) and two CDG1AA patients (3), respectively. All the *NUS1* pathogenic variants carried by MRD55 patients are truncated variants (frameshift, splicing and exon deletion), suggested to cause MRD55 features *via* a mechanism of haploinsufficiency (1). Two heterozygous variants have been detected in patients with Parkinson's disease. One had the splicing-site variant c.691+4dupA, which generates an aberrant spliced mRNA, leading to a significant reduction in the *NUS1* level (5). The other one carries the frameshift variant c.22_23insA, which is barely expressed in human embryonic kidney (HEK) cells 293 cells, indicating a similar reduction in *NUS1* level (6). In the patients with dystonia and CDG1AA, the missense variants p.G102D (heterozygous) and p.R290H (homozygous) were observed, respectively. G102 and R290 are phylogenetically highly conserved (Figure 1C), and their substitutions are expected to impair the function of *NUS1*.

G102 is located on the β -sheet of the *NUS1* protein, directly binding to residues L240 and L242, as shown in the crystal structure of the human NgBR/DHDDS complex (Figure 2, the right side). The substitution of G102 with D102 forms an interaction between D102 and S133. Additionally, the side chain of D102 highly repels residues P238, V241 and F253, and thus the protein structure of the protein destroyed, impairing the protein function.

R290 is located on the contact surface of the NgBR/DHDDS complex. The coordination sphere of R290 includes residues from NgBR (E288 and K293), residues from DHDDS (D34 and E209), two IPEs, and three water molecules (Figure 2, the left side). When residue R290 is substituted, its interactions with E209, E288 and the three water molecules are lost. One of the three water molecules mediates and interaction between R290 and Mg^{2+} . The interaction between residues R290 (NgBR) and E209 (DHDDS) contributes to the formation of the heterodimer. Therefore, the substitution of R290 with H290 has a great

impact on the structure and function of the protein complex. In addition, the pathogenic variant p.R290H is homozygous, which is expected to cause a more dramatic reduction in NgBR activity, resulting in more severe clinical symptoms.

It is noteworthy that a heterozygous *NUS1* frameshift variant has been identified in 5 familial patients with different clinical features (6). Three patients had ID and absent seizures, and could be diagnosed with typical MRD55. One patient only presented with clonic seizures, and another one displayed Parkinsonism without epilepsy. Why these five patients presented with distinct phenotypes is unknown. We can only speculate that *NUS1* pathogenic variants as well as epigenetic, and/or environmental factors interact with each other to produce the specific phenotypes.

The number of cases with the *NUS1* pathogenic variants is still too low to draw a genotype/phenotype correlation, especially given that the *NUS1* pathogenic variants can cause different diseases. The molecular mechanisms underlying the effects of the *NUS1* pathogenic variants in patients who presented with different diseases are unknown. Additional cases and functional studies are needed for a better understanding of *NUS1* gene and related diseases.

CONCLUSION

In this study, we reported a Chinese MRD55 patient with detailed clinical phenotypes. The *de novo* variant of *NUS1* identified by WES was novel and was concluded to be responsible for the clinical presentation of the patient. With this novel pathogenic variant found in *NUS1*, we expanded the genotype spectrum associated with the MRD55 phenotype and provided the potential for a better understanding of the relationship between this rare disease and the pathogenic variants.

DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation, to any qualified researcher.

ETHICS STATEMENT

The studies involving human participants were reviewed and approved by The Ethics Committee of Shandong University Qilu Hospital (Qingdao). Written informed consent was obtained from the individual(s), and minor(s)' legal guardian/next of kin, for the publication of any potentially identifiable images or data included in this article.

AUTHOR CONTRIBUTIONS

PZ, JY, and QH cared for the patient, collected the clinical data of the patient and drafted the clinical portion of the manuscript. DC analyzed the results of WES and wrote the extra part of the manuscript. XY applied the clinical tests on patients. PL assisted the clinical test and recorded the clinical information. YZ and NY

summarized characteristics of reported cases. PZ, DC, JY, and QH finally revised the manuscript. All authors read and approved the submitted version.

FUNDING

This study was supported by Shandong Provincial Natural Science Foundation Project (ZR2020MH196). The funding

bodies had no roles in the design of the study, the collection, analysis, or interpretation of the data, or writing the manuscript.

ACKNOWLEDGMENTS

We thank all colleagues in our department for their clinical assist. We thank Running Gene Inc. for their technical support.

MEGDEL syndrome and SATB2-associated syndrome (SAS) are both rare congenital disorders with poor prognoses caused by gene mutations. We present the case of a 2-day-old girl with an unexplained abnormal liver function, feeding problem, and dystonia. Using next-generation sequencing, we identified two novel mutations in *SERAC1* and a mutation in *SATB2*. Now, she is 15 months old and has the characteristics of SAS, such as downslanting palpebral fissures and delayed primary dentition. Besides the typical phenotypes of MEGDEL syndrome, such as hypertonia, failure to thrive, deafness, and motor regression, she has progressive cholestasis and is prone to high serum lactate after rehabilitation training and hypoglycemia with low ketone under starving conditions. These phenotypes substantially differ from the transient liver function abnormalities and hypoglycemia reported in the literature.

Keywords: MEGDEL syndrome, SATB2-associated syndrome, phenotype, next-generation sequencing, follow-up

INTRODUCTION

MEGDEL syndrome (3-methylglutaconic acidemia, deafness, encephalopathy, and Leigh-like syndrome) is a rare specific mitochondrial disorder due to mutations in the *SERAC1* gene (NM_032861), which is an autosomal recessive inherited disorder (1). The *SERAC1* gene encodes for a phosphatidylglycerol remodeler that is essential for mitochondrial functions and intracellular cholesterol trafficking (2). The SATB2-associated syndrome (SAS) is a recently described syndrome caused by mutation of *SATB2* gene (NM_015265). It's an autosomal dominantly inherited disorder which characterized by developmental delay with absent or limited speech, behavioral problems, dysmorphic features, and craniofacial abnormalities, including palatal and dental abnormalities (3).

We describe a rare disease progression and a severe phenotype of progressive cholestasis of a girl from birth to 15 months, who was compound heterozygous for *SERAC1* of MEGDEL syndrome and had a mutation in *SATB2* of SATB2-associated syndrome.

CASE DESCRIPTION

A female infant was born at 38+ 5/7 weeks gestational age to a 38-year-old mother who had gestational anemia, which was supplemented with oral iron, and gestational diabetes, which

was controlled with diet. The mother has a healthy 6-year-old girl but also had a spontaneous abortion and an artificial abortion due

to embryo death. The mother's brother had a history of epilepsy and had passed away.

The infant's birth weight, head circumference, and length were 2,830 g (10–25th percentile), 33 cm (25–50th percentile), and 48 cm (10–25th percentile), respectively, with a normal Apgar score. However, she had mild blepharoptosis and there was a 3 cm cleft palate from the palate to the uvula. On day of life (DOL) 2, the infant vomited milk twice accompanied by weakness in sucking. A few hours later, she went into convulsions that involved rowing movements of the limbs. Her blood glucose was 0.7 mmol/L and blood gas analysis revealed anion gap metabolic acidosis (24.69 mmol/L). After providing glucose (8 mg/kg/min) and phenobarbital (10 mg/kg) injection treatment, the convulsions did not occur again, but she became somnolent, developed an unexplained abnormal liver function, and an aggravating increase in serum lactate (16.4 mmol/L). The infant was immediately transferred to our tertiary neonatal intensive care unit (NICU) center on DOL 3 for further newborn care.

The infant's serum lactate was normal on DOL 4 after giving intravenous fluids and nasogastric feeding. Blood glucose was

normal on DOL 6 without intravenous fluids. The problems during hospitalization were poor neonatal sucking, reduced movements, and unexplained elevated liver enzymes (gamma-glutamyltransferase (GGT) 1,373 mmol/L, total bile acids (TBA) 58.2 μ mol/L, aspartate aminotransferase (AST) 132 U/L, prothrombin time (PT) 46.1s, albumin 26.57 g/L) with normal stool color and abdominal ultrasound. In addition, magnetic resonance imaging (MRI) showed high signals on T2 and FLAIR, where the lenticular nucleus was swollen on both sides. There were multiple hyperintensity patches on the dorsal side of the brainstem and posterior limb of the internal capsule near the anterior and posterior horns of the right lateral ventricle (**Figure 1**). Evoked otoacoustic emission test was not passed on both ears.

Blood tandem mass spectrometry (MS/MS) showed an increase in tyrosine 227.85 μ M (25–225 μ M). Urine gas chromatography-mass spectrometry (GC/MS) showed an increase in oxalate 57.78 (0–33), 3-methylglutaconic aciduria 4.35 (0–1), and 3-(4-hydroxyphenyl) lactic acid 1122.49 (0–20). Next-generation sequencing and Sanger sequencing detected two compound heterozygotes of *SERAC1*

(c.1502-1G>C (likely pathogenic) from the maternal side, c.227-228dupAT (pathogenic) from the paternal side) and a *de novo* variant of *SATB2* (c.1166G>A) (likely pathogenic) (**Figure 2**). The quality control of WES data analysis and procedure of variant annotation refers to pipeline version 2 of Children's Hospital of Fudan University (4). We classified the pathogenicity of the identified variants according to the ACMG guideline, the details showed in (**Supplementary Table 1**).

On DOL 17, the infant was discharged from hospital with a nasogastric tube. After symptomatic treatment, the high GGT at admission had dropped to 264 mmol/L and the PT returned to normal (16.2 s). She experienced slow weight gain and increasing TBA, which was unmanageable by drugs after discharge. When she was 3 months old, there was a continuous mild increase in methionine (Met) for 2 months. After providing Met-free formula milk, the level of Met reduced to normal, and her motor development improved. When she was 12 months old, she had a high fever of 39°C. Afterward, her gross and fine motor regressed to the level of 5 months. Now, she is 15 months old with four primary teeth and has completed a cleft palate repair surgery in order to improve her nutritional status. When she was discharged

from the hospital in the first time, the GGT were maintained between 430 and 470 mmol/L, the AST were maintained between 62 and 87 U/L and albumin were maintained between 31.4 and 36.9 g/L. In addition, PT (15.1 s) and international normalized ratio (1.31) was slightly elevated at 12 months of age. Only bile acids were continuously increasing. Because she had normal stool color, normal skin color, and normal abdominal ultrasound, we excluded the extrahepatic biliary atresia and choledochal cyst and did not perform liver biopsy. She is susceptible to higher serum lactate after rehabilitation training and hypoglycemia with low ketone under starving conditions (Table 1).

DISCUSSION

When a newborn demonstrates an unexplained feeding problem and a high anion gap metabolic acidosis, doctors will change the direction of diagnosis and treatment to inherited metabolic diseases, especially because in this case, the infant had dystonia, an abnormal MRI, and increased liver enzymes and serum lactate. Even though the MS/MS presented an increased level of 3-methylglutaconic aciduria, we still cannot present a diagnosis because of the various phenotypes present in the neonatal period.

The infant carries two variants of *SERAC1* (c.1502-1G>C from the maternal side, c.227-228dupAT from the paternal side), neither of which have been reported before (<http://www.hgmd.cf.ac.uk>). She has the typical phenotypes of 3-methylglutaconic acidemia, deafness, and Leigh-like syndrome (present with bilateral basal ganglia lesions on brain MRI) (5). She still has progressive cholestasis and is susceptible to high serum lactate after rehabilitation training and hypoglycemia with low ketone under starving conditions. These phenotypes are substantially

different from the transient liver function abnormalities and hypoglycemia reported in the literature (6).

As we know, *SERAC1* encodes for a phosphatidylglycerol remodeler that is essential for mitochondrial functions and intracellular cholesterol trafficking. Although there is no medicine that can completely treat the disease. When the diagnosis is clear, we should give *baclofen* (10 mg, bid), *trihexyphenidyl hydrochloride* (2 mg, bid) to improve her hypertonia and *coenzyme Q10* (30 mg/d), *L-carnitine* (1 g, bid), *vitamin B1* (100 mg/d), and *vitamin E* (100 mg/d) to improve mitochondrial functions. Due to the influence of pandemic of COVID-19, she didn't go to the hospital in time and was not treated until 5 months after birth. But her parents thought there was not obvious effect after treatment and did not adhere to the standard treatment. Here, we try to explain its function through the metabolic pathways (Figure 3). On one hand, mutations in *SERAC1* cause leucine degradation barriers, which, in turn, cause an increase of 3-methylglutaconic aciduria; on the other hand, under glucose deficiency or starvation, fatty acids are oxidized in the liver to produce ketone bodies as energy for the brain. In the process of amino acid metabolism, fatty acid metabolism, and glycolysis, mitochondria are required to participate in the key production of Acetyl-CoA (7). Therefore, low ketone hypoglycemia not only occurs when fatty acid metabolism is abnormal (8) but also when mitochondrial function is abnormal. In the cholesterol metabolism pathway, impaired *SERAC1* activity leads to deficiency of PG36:1 and increases free cholesterol (9), which is the main substance for the synthesis of bile acids.

Many syndromes have the phenotype of developmental delay. We were unable to complete the intelligence test because of the patient's deafness and we could not distinguish whether the

delayed psychomotor development was caused by mutations in *SERAC1* or *SATB2* or a combination of the two genes. However, the characteristics of downslanting palpebral fissures, cleft palate, and delayed primary dentition are consistent with phenotypes of SAS because *SATB2* is expressed in upper-layer neurons, neural crest progenitors of the jaw, osteoblasts, odontoblasts, and other dental progenitor cells (10). We listed the phenotypes of the two diseases in **Supplementary Table 2**.

Strengths and Limitations

We followed-up the case for 15 months and presented a complete process of disease development. These findings extended the phenotype spectrum of the two diseases and provided new insights into such rare diseases. Although medicine of muscle relaxant and antioxidant play roles in symptomatic treatment, the child was not given timely and standardized treatment, which might aggravate her delayed motor development. In addition, MEGDEL syndrome has the phenotype of cholestasis, but we cannot determine whether it is a severe phenotype of MEGDEL syndrome or the superposition of the two rare syndromes.

CONCLUSION

We identified two novel variants of *SERAC1* and a *de novo* variant of *SATB2* in a newborn. The case showed typical and specific phenotypes of these two rare diseases, especially the progressive cholestasis and high serum lactate after rehabilitation training and hypoglycemia with low ketone under starving conditions. The article presented a serious phenotype and disease progression, and summarized the metabolic pathways of abnormal indicators in the infant. We hope to enlighten our pediatric colleagues by providing more information on such rare diseases.

Background: We aimed to assess the clinical application of noninvasive prenatal screening (NIPS) based on second-trimester ultrasonographic soft markers (USMs) in low-risk pregnant women.

Methods: Data of pregnant women between April 2015 and December 2019 were retrospectively analyzed. Pregnant women [age at expected date of confinement (EDC) of <35 years; low risks for trisomy 21 (T21) and trisomy 18 (T18) based on maternal serum screening; presenting second-trimester USMs (7 types)] who successfully underwent NIPS and had available follow-up information were included in our study. Cases with positive NIPS results were prenatally diagnosed. All patients were followed up for 6 months to 2 years after NIPS, and their clinical outcomes were obtained. Subgroup analyses were performed according to the different USMs.

Results: NIPS suggested that among a total of 10,023 cases, 37 (0.37%) were at high risk of aneuploidy, including 4 T21, 6 trisomy 13 (T13), and 27 sex chromosome abnormalities (SCA). Ten cases with aneuploidy (0.10%) were confirmed by prenatal diagnosis, consisting of two T21 and eight SCA. The eight fetuses with SCA consisted of one monosomy X, two XXY, one XXXY, one XXX, one XYY, and two mosaicisms. T21 was detected in one fetus with absent or hypoplastic nasal bone and one fetus with echogenic intracardiac focus (EICF). SCA was detected in five fetuses with EICF, two fetuses with multiple soft markers, and one fetus with echogenic bowel. The positive rate of chromosomal aneuploidy was significantly higher in fetuses with absent or hypoplastic nasal bone (6.25 vs. 0.10%, $p = 0.017$), echogenic bowel (3.7 vs. 0.10%, $p = 0.029$), and multiple soft markers (0.678 vs. 0.10%, $p = 0.045$) than in the total fetuses. The positive predictive values (PPVs) of NIPS in these three groups were 100%, 50%, and 100%, respectively. EICF accounted for 93.25% (9,346/10,023) of the study population, whereas the PPV of NIPS was only 20%.

Conclusion: NIPS is an advanced screening test for low-risk pregnant women. In the 10,023 pregnant women sampled, SCA were more common than autosomal trisomy, and

EICF was the most frequent USM but the least predictive aneuploidy. Further aneuploidy evaluation is suggested for low-risk pregnant women whose ultrasound indicates absent or hypoplastic nasal bone, echogenic bowel, or multiple soft markers. NIPS can serve as a second-line complementary screening for these women.

Keywords: noninvasive prenatal screening, ultrasonographic soft markers, trisomy 21 (Down syndrome), sex chromosome abnormality, positive predictive value, aneuploidy

INTRODUCTION

With the rapid development of ultrasound technology for application in the first and second trimesters, an increasing number of small ultrasound markers have been discovered, that is, ultrasonographic soft markers (USMs). USMs have a special ultrasonic feature; some USMs disappear naturally in later pregnancy stages or after delivery, whereas others may persist even after birth. USMs are closely associated with fetal chromosomal abnormalities and adverse pregnancy outcomes. The association between nuchal translucency thickness and Down syndrome was first reported in the 1980s (Benacerraf et al., 1985). Since then, diverse ultrasound anomalies have been reported to be associated with trisomy 21 (T21) (Nyberg and Souter, 2001), such as echogenic intracardiac focus (EICF), absent or hypoplastic nasal bone, and mild pyelectasis. Nevertheless, several studies have shown that USMs increase the incidence of invasive prenatal puncture surgery (Ahman et al., 2014). Lee et al. (2007) also found that the detection and interpretation of USMs were correlated to an increase in maternal anxiety and unnecessary amniocentesis.

Moreover, in the relevant laws, regulations, norms, or corresponding guidelines of China, there are currently no clear provisions on how to handle USMs. Article 17 of the Law of the People's Republic of China on Maternal and Infant Health Care (revised on August 30, 2018 and effective as of August 30, 2018) stipulates that if doctors find or suspect fetal abnormalities after prenatal examination, prenatal diagnosis should be made for pregnant women. Article 20 of the Measures for the Implementation of Law of the Peoples Republic of China on Maternal and Infant Health Care (promulgated on June 20, 2001) stipulates that if a fetus is abnormal or has suspicious malformations, doctors should make a prenatal diagnosis; however, USMs do not necessarily indicate fetal abnormalities or malformations. To further confirm aneuploidy, most Chinese doctors refer to the consensus issued by the American College of Obstetricians and Gynecologists (ACOG) (American College of Obstetricians and Gynecologists' Committee on Practice Bulletins-Obstetrics et al., 2020) and the Society for Maternal-Fetal Medicine (SMFM) (Prabhu et al., 2021). ACOG Practice Bulletin 226 (American College of Obstetricians and Gynecologists' Committee on Practice Bulletins-Obstetrics et al., 2020) states that if aneuploidy testing shows a low-risk result, then no further risk assessment is needed for fetus exhibiting particular USMs such as EICF, choroid plexus cyst, mild pyelectasis, or short femur length. The Society for Maternal-Fetal Medicine (SMFM) (Prabhu et al., 2021) also suggests that fetuses with negative maternal serum screening

results for EICF, echogenic bowel, and shortened long bones need no further aneuploidy evaluation. However, only few studies have examined the applicability of these two guidelines for pregnant women in China and the residual risks of NIPS in these women.

Currently, maternal serum screening and NIPS are the major prenatal screening programs for evaluating the risk of aneuploidy. Lo et al. (1997) reported the presence of circulating cell-free fetal DNA (cffDNA) in maternal plasma and serum, which has been rapidly and widely used for prenatal screening owing to its high sensitivity and high positive predictive value (PPV). However, the traditional maternal serum screening method cannot assess the risk of sex chromosome aneuploidy (SCA). Except for Turner syndrome, in which structural anomalies are easily observed, the clinical features of other types of SCA are often undetectable in prenatal ultrasound examinations. Unless SCA is detected by invasive prenatal diagnosis, most fetuses with SCA are not diagnosed until birth or puberty. NIPS *via* massive parallel sequencing enables the detection of fetal SCA. Therefore, NIPS can simultaneously detect the risk of trisomy and SCA.

For the identification of birth defects and for health and economic considerations, prenatal screening methods are applied in China, including maternal serum screening, NIPS, and ultrasound examination. Prenatal screening is usually performed in the following order: first-trimester ultrasound (to detect nuchal translucency, NT), first-trimester serum screening, second-trimester serum screening, and second-trimester ultrasound. According to the relevant regulations in China, NIPS is recommended for pregnant women at intermediate risk based on maternal serum screening. These women are subjected to NIPS at relatively late pregnancy weeks. In contrast, some pregnant women choose NIPS for direct evaluation of fetal aneuploidy after understanding the difference between maternal serum screening and NIPS; these women undergo NIPS at relatively early gestational weeks. Prenatal diagnosis is recommended for pregnant women at high risk based on maternal serum screening and high risk of NIPS, as well as those with advanced age at delivery and an indication of abnormal fetal structure in ultrasound examination.

Previous studies have shown that NIPS has a good ability in detecting aneuploidy, including T21 and SCA, in high-risk populations (Bianchi et al., 2014; Garshasbi et al., 2020). However, the application of NIPS for detecting fetal aneuploidy has not been extensively studied in pregnant women at low risk based on maternal serum screening and follow-up ultrasound indicating USMs. Therefore, we retrospectively reviewed the data of pregnant women who underwent maternal serum screening and NIPS in the Prenatal

Diagnosis Center of West China Second University Hospital of Sichuan University. Pregnant women who had low risk for T21 or trisomy 18 (T18) based on maternal serum screening and second-trimester ultrasound and successfully underwent NIPS were included in our study.

The aims of the present study were (1) to assess the clinical application of NIPS in the second trimester in a retrospective cohort of pregnant women with USMs and at low risk for common chromosomal abnormalities according to maternal serum screening; (2) to determine the USMs possessing a strong predictive value in the study population; and (3) to determine the feasibility of recommending the screening method that we designed in clinical genetic counseling from the perspective of health economics.

MATERIALS AND METHODS

Study Population

We retrospectively analyzed the data of pregnant women who underwent maternal serum screening, NIPS, and prenatal diagnosis at the Prenatal Diagnosis Center of West China Second University Hospital of Sichuan University, Chengdu, Sichuan Province, China from April 2015 to December 2019. The inclusion criteria were as follows: (1) age at the expected date of confinement (EDC) of less than 35 years; (2) low risk for T21 and T18 based on maternal serum screening; (3) indication of USMs according to second-trimester ultrasound; and (4) NIPS case. The exclusion criteria were as follows: (1) no NIPS results, including failure during cell-free DNA (cfDNA) extraction and low fetal fraction; (2) no clinical pregnancy outcome, including termination of pregnancy, miscarriage, high-risk NIPS cases who declined further prenatal diagnosis, and cases lost to follow-up.

Pretest counseling was performed by trained clinical geneticists. All patients signed an informed consent form for genetic investigation. The test results were used for research with informed consent from the patients or legal guardians.

MATERNAL SERUM SCREENING

This procedure was described in our previous study (Deng et al., 2019; Bai et al., 2021). Risks of fetal T21 and T18 were obtained based on maternal serum screening, and patients were divided into three groups: the low-risk, intermediate-risk, and high-risk groups. A risk value of <1 in 1,000 indicated low risk for T21, and a risk value of <1 in 1,000 suggested low risk for T18. The risk value of the intermediate-risk group was 1/271–1/1,000 for T21 and 1/351–1/1,000 for T18. The risk value of the high-risk group was $\geq 1/270$ for T21 and $\geq 1/350$ for T18.

First-Trimester and Second-Trimester Ultrasound Examination

First-trimester ultrasound examination for NT and second-trimester ultrasound examination for fetal anomalies were performed in the Department of Diagnostic Ultrasound of

West China Second University Hospital, Sichuan University, and other allied hospitals or affiliated hospitals that have medical business cooperation with West China Second Hospital of Sichuan University, following the guidelines of the International Society of Ultrasound in Obstetrics and Gynecology (Salomon et al., 2011). The diagnosis of second-trimester USMs was confirmed by a second experienced ultrasonographer. The following seven types of second-trimester USMs were included in this study: EICF, mild pyelectasis (dilatation of the renal pelvis ≥ 4 mm), single umbilical artery, mild ventriculomegaly (10 mm and <12 mm), absent or hypoplastic nasal bone (absent or <2.5 mm), echogenic bowel, and short femur length (Z-score, -2 to -4).

Noninvasive Prenatal Screening

Peripheral blood (8–10 ml) was collected from each pregnant woman and then placed into Cell-free BCT tubes (Streck Inc., Omaha, NE, United States). The upper plasma was isolated from the blood samples after being centrifuged twice within 72 h. Fifty microliters of cfDNA was isolated from 1,200 μ l of plasma using a DNA extraction kit (Hangzhou Berry Gene Diagnostic Technology Co., Ltd., Hangzhou, China) according to the manufacturer's instruction. The obtained DNA concentration ranged from 0.05 ng/ μ l to 0.6 ng/ μ l. Next, 20 μ l of cfDNA libraries was constructed by end filling and adapter ligation, and qPCR analysis was performed to verify whether the concentration and quality of cfDNA libraries were satisfactory. The cfDNA libraries were subjected to massive parallel sequencing using the NextSeq CN500 high-throughput sequencing kit (Illumina) on a NextSeq CN500 platform (Illumina), generating approximately 5 million raw data with 36-bp reads (Liu et al., 2021).

Sequencing reads were uniquely mapped to the hg19 human reference genome. The Z-score values of the 24 chromosomes were further calculated using normalized chromosome representation and GC correction (Liu et al., 2021). The fetal autosomal trisomy status was determined based on Z-scores (normal range, $-3 < Z < 3$). A high risk of NIPS was defined as a Z-score of greater than 3 for chromosome 21, 18, or 13. A Z-score value of chromosome 21, 18, or 13 ranging from -3 to 3 indicated a low risk of NIPS. The method for calculating the Z-score value of chromosomes X and Y was described in our previous study (Bai et al., 2021).

All participants were given an NIPS test report on the estimated fetal risk of T21, T18, and trisomy 13 (T13) and a supplementary report if a high risk of SCA was suspected. The test was considered a failure if unqualified total cfDNA concentration was obtained twice or if the fetal fraction was twice calculated to be $<4\%$.

Invasive Prenatal Diagnosis

For pregnant women at high risk of NIPS, clinical counselling was offered by clinical geneticists, and further invasive prenatal diagnosis to determine chromosomal abnormalities was recommended.

Amniocentesis or cordocentesis was performed in the late second trimester or early third trimester, and chromosomal

FIGURE 1 | EDC, expected date of confinement; USM, ultrasonographic soft markers; NIPS, noninvasive prenatal screening; TOP, termination of pregnancy.

microarray analysis (CMA), copy number variation sequencing (CNV-Seq), or karyotyping was conducted to detect fetal aneuploidy and other fetal chromosome abnormalities, in accordance with previously published studies (Wang et al., 2018; Deng et al., 2019; Hu et al., 2021). Furthermore, all samples were subjected to quantitative fluorescence polymerase chain reaction (QF-PCR) for chromosomes 21, 18, 13, X, and Y, and if the short tandem repeat markers were abnormal, enumeration was performed by fluorescence *in situ* hybridization.

The pregnant women were subjected to clinical follow-up assessments *via* telephone communication and review of medical records from 6 months to 2 years after undergoing NIPS. We also collected data on circumstances before birth, including prenatal diagnosis results, situations of high-risk NIPS cases who declined further prenatal diagnosis, and developmental details diagnosed by pediatricians after birth.

Statistical Analysis

SPSS Statistics software version 19.0 (SPSS Inc., Chicago, IL, United States) was used for statistical analysis. Comparisons

between groups were determined using chi-square test or Fisher's exact test. Statistical significance was set at $p < 0.05$.

RESULTS

Study Participants

This was a retrospective study. A total of 143,067 pregnant women underwent NIPS at our hospital between April 2015 and December 2019. A total of 10,023 pregnant women who met the inclusion criteria were included, and retrospective analysis was performed. The study flow diagram is shown in **Figure 1**.

The maternal age ranged from 16 to 34 years. The median maternal weight was 58.80 kg (range, 37–97 kg), and the median maternal height was 159.00 cm (range, 140–177 cm). The study population predominantly originated from China. A total of 99.60% (9,983/10,023) of the pregnancies were singleton pregnancies, and 1.14% (114/10,023) of the pregnant women conceived with assisted reproductive technology (without Pre-implantation Genetic Testing for Aneuploidy). The demographic

TABLE 1 | Demographic characteristics of the 10,023 patients.

Characteristic	N (%)
Mean maternal age (range), years	26.75 (16–34)
<35 years	10,023 (100%)
Median maternal weight (range), kg	58.80 (37–97)

ART, assisted reproductive technology.

characteristics of the pregnant women included in this study are shown in **Table 1**.

EICF was the most common USM present in 9,346 cases (93.25%), followed by multiple soft markers in 295 cases (2.94%) and mild pyelectasis in 166 cases (1.66%).

Numerical Abnormality of Chromosomes in the Fetus

The overall prevalence of high risk of chromosomal aneuploidy (NIPS-positive results) in the fetuses was 0.37% (37/10,023). Among the 37 cases, 10 fetuses (27.03%) had a high risk of autosomal trisomy, including 4 fetuses at high risk of T21 and 6 fetuses at high risk of T13, and 27 fetuses (72.97%) had a high risk of SCA.

Finally, two cases were confirmed to have T21, and eight fetuses were diagnosed with SCA *via* invasive prenatal diagnosis. As shown in **Table 2**, among the eight fetuses with SCA, one had monosomy X, two had XXY, one had XXXY, one had XXX, one had XYY, and two had mosaicisms. SCA was detected in two pregnant women with multiple soft markers. Among fetuses with EICF, one T21 and five SCA cases were detected. One T21 case was detected in a fetus with absent or hypoplastic nasal bone, and one SCA was detected in a fetus with echogenic bowel. The other 27 cases showed false-positive results for NIPS, as confirmed by prenatal diagnosis. These cases consisted of 2 fetuses at high risk

of NIPS for T21, 6 at high-risk of NIPS for T13, and 19 at high-risk of NIPS for SCA. A false-positive NIPS result for chromosomal aneuploidy was detected in 24 fetuses with EICF, one fetus with mild pyelectasis, one fetus with mild ventriculomegaly, and 1 fetus with echogenic bowel.

Clinical Test Results for NIPS in the Study Population

All NIPS-positive cases were confirmed by prenatal diagnosis and then followed up. No false-negative results were observed in any of the NIPS-negative cases. Thus, the rate of false-negative results for NIPS for T21, T18, T13, and SCA was 0% in this study. The sensitivity, specificity, positive predictive value (PPV), and negative predictive value of NIPS, respectively, were as follows: for T21: 100% (95% CI: 19.79–100%), 99.98% (95% CI: 99.92–99.99%), 50.00% (95% CI: 9.19–90.81%), 100% (95% CI: 99.95–100%); for SCA: 100% (95% CI: 59.77–100%), 99.81% (95% CI: 99.70–99.88%), 29.63% (95% CI: 14.50–50.34%), and 100% (95% CI: 99.95–100%). Among the cases with high risk for T13 as detected by NIPS, there were no true positive cases, resulting in a very low PPV. The clinical test performance of NIPS is outlined in **Table 3**.

Characteristics of Aneuploidy Among Fetuses With Ultrasonographic Soft Markers

In the study population, the rates of true-positive results for T21 and SCA as confirmed by prenatal diagnosis were 0.02% and 0.08%, respectively. The rate of true-positive results for chromosomal aneuploidy was significantly higher in fetuses with absent or hypoplastic nasal bone (6.25% vs. 0.10%, $p = 0.017$), echogenic bowel (3.7% vs. 0.10%, $p = 0.029$), and multiple soft markers (0.678% vs. 0.10%, $p = 0.045$) than in the total fetuses.

In the multiple soft markers and absent or hypoplastic nasal bone groups, NIPS had a PPV of 100% for aneuploidy, and this value reached 50% in the echogenic bowel group. EICF was the most common and abundant USM, accounting for 93.25% (9,346/10,023) of the study population. In contrast, NIPS had

only 20% PPV and 80% false-positive rate in the EICF group. No positive cases were found in the mild and mild ventriculomegaly groups. The results are listed in **Table 4**.

Among the 10 clinically confirmed aneuploidy cases, two pregnant women had a history of spontaneous abortion. Six pregnant women (60%) were selected for prenatal diagnosis with CNV-Seq after positive results for NIPS was obtained. The Z-scores of NIPS were >5 in confirmed T21 cases, and the Z-scores of X chromosomes were >7 in confirmed Klinefelter syndrome cases. The two pregnant women whose fetus were prenatally diagnosed with mosaicism chose to give birth. The detailed clinical information is presented in **Table 5**.

accounting for 97.66% of the total NIPS-negative population. There were 234 abnormal cases, accounting for 2.34% of the total NIPS-negative population, among which the fetus with height less than the standard value 2 SD, with weight less than the standard value 2SD, or both, accounted for 1.08% of the total birth population. Preterm births at less than 37 gestational weeks accounted for 0.39%, followed by congenital heart disease. Fetuses delivered by pregnant women with negative NIPS results were evaluated by senior pediatricians, and they reported no T21, T18, T13, SCA, or related abnormalities during neonatal examination and follow-up of this study population.

Clinical Follow-Up Outcomes of Noninvasive Prenatal Screening-Negative Cases

The pregnancy outcomes of NIPS-negative pregnant women and fetuses are shown in **Table 6**. There were 9,752 normal fetuses,

DISCUSSION

USMs are of great importance in clinical practice. They are often transient and nonpathological, but may indicate an increased risk of underlying fetal aneuploidy (Hu et al., 2021). In fact, USMs can

increase the detection rate of malformations by 4% (Boyd et al., 1998). However, the detection of USMs cause stress in pregnant women, and the depressive symptoms may persist until delivery (Ahman et al., 2010; Nevay et al., 2016). Previous studies have shown that USMs, such as EICF, thickened nuchal fold, and mild pyelectasis were commonly repeated in subsequent pregnancies, providing deeper insights into the genetic predisposition and recurrence of USMs (Ginsberg et al., 2017). In particular, the interpretation of abnormal results and clinical genetic consultation in pregnant women who have had USMs and undergone NIPS may also cause confusion for them and the clinicians. When ACOG and SMFM guidelines are used for genetic counseling, the residual risk in pregnant women in China must be elucidated. Moreover, large-scale studies of the clinical application of NIPS in pregnant women at low risk based on maternal serum screening and second-trimester ultrasound are required. Thus, we designed this study to explore the potential application of NIPS for USM-based detection of fetal aneuploidy in low-risk pregnant women, as well as to formulate a feasible strategy for aneuploidy detection.

The positive rate of aneuploidy was 0.1% (range: 0.064%–6.25%), which suggests a residual risk for aneuploidy of approximately 0.1% in our study population if no further aneuploidy evaluation is conducted. The positive rate of aneuploidy was lower than that reported in previous studies (Norton et al., 2015; Garshasbi et al., 2020; Margiotti et al., 2020). Selection bias might be attributable to this difference. There were several other possible reasons: (1) In our study, we selected patients with age at EDC of <35 years and those with low risk for T21 and T18 based on maternal serum screening, leading to a reduction in the overall background aneuploidy risk in this

study population. (2) Several pregnant women whose age at EDC was close to but did not reach 35 years as well as several pregnant women whose maternal serum screening results were very close to the cutoff value may have been more inclined to opt for prenatal diagnosis directly. (3) In the second trimester, T18 and T13 are more likely to show structural abnormalities than T21, and the group of pregnant women who preferred prenatal diagnosis were excluded from our study population.

The mean gestational age in our study was 24 weeks, with a range of 14–28 weeks, and there were differences in the routine timings of NIPS, which is usually performed in the late first trimester or early second trimester (van der Meij et al., 2019). Detailed sonographic anatomical scanning is usually performed at 22–25 weeks of gestation in China. Our study population was pregnant women who underwent NIPS after second-trimester ultrasound examination; thus, the mean gestational age was the second trimester of pregnancy. Previous studies showed that the percentage of fetal fraction significantly increased with increasing gestational age (Hou et al., 2019). Therefore, the detection results of NIPS were credible.

In our study, the sensitivity of NIPS for both T21 and SCA reached 100%, and the specificity was >99.7%. Compared with direct prenatal diagnosis, NIPS delays the diagnosis of aneuploidy, but it can effectively screen fetal aneuploidy. No false-negative cases were found in our study after long-term follow-up (false-negative rate: 0). In addition, false-positive results are a serious issue in NIPS. In our study, 27 false-positive cases were identified. Considering that the cfDNA sample used for NIPS was derived from placenta, and not fetal DNA, the main cause of these false-positive results may be confined placental mosaicism. Other possible causes include

vanishing twin syndrome, maternal copy number variants, cancer, previous organ or bone marrow transplantation, medical conditions, or treatment affecting the quality of circulating DNA (Snyder et al., 2015; Bianchi and Chiu, 2018).

In the absence or hypoplastic nasal bone group, a case of T21 was confirmed, with a positive rate of 6.25% (1/16). The highest incidence of T21 was found in fetuses with absent or hypoplastic nasal bone, followed by that in fetuses with EICF. In our study, the PPV of NIPS for T21 was 100% in fetuses in the absent or hypoplastic nasal bone group, which was consistent with the data reported by Du et al. (2018). A previous study has also reported absent or hypoplastic nasal bone as one of the most prominent USMs in the second trimester (Agathokleous et al., 2013).

Isolated EICF was the most common USM in our study. The true-positive rates of T21 and SCA in the EICF group were much lower than those in the other groups. Only one T21 and five SCA cases were confirmed by prenatal diagnosis. This was consistent with previous findings (Agathokleous et al., 2013) that EICF had low positive likelihood ratio values for T21. According to ACOG (Committee on Practice Bulletins-Obstetrics; Committee on Genetics; Society for Maternal-Fetal Medicine. 2020) and SMFM (Prabhu et al., 2021), if isolated EICF is detected, no further risk assessment is needed in pregnant women at low risk based on maternal serum screening. Furthermore, NIPS is a good option for evaluating fetal aneuploidy if the mother demands further aneuploidy assessment. In our total study population, the aneuploidy positive rate and PPV of NIPS were reanalyzed after removing the EICF group, which increased the values to 0.59% and 50%, respectively.

However, large-scale studies focusing on the correlations between the prevalence of SCAs and USM in fetuses in low-risk populations have rarely been published in the literature. In our study, the highest incidence of SCAs was found in fetuses with echogenic bowel (3.7%), followed by those with multiple soft markers (0.68%). In previous studies, echogenic bowel was associated with fetal aneuploidy, congenital infections (mainly congenital CMV infection), structural anomalies (D'Amico et al., 2021; Ronin et al., 2017), the incidence of intrauterine growth restriction and intrauterine fetal demise (Mailath-Pokorny et al., 2012), and Zellweger syndrome (Aydemir et al., 2014). In previous studies, multiple soft markers were associated with a high incidence of chromosomal abnormalities (Wang et al., 2018; Hu et al., 2021). Our study found that the PPV of NIPS and the positive rate of SCAs in multiple soft marker groups were higher than those in the total population.

According to previous studies, Z-scores are considered to be correlated with NIPS accuracy (Tian et al., 2018; Zheng et al., 2020). In the current study, the Z-scores of NIPS were >5 for T21, and the Z-scores of X chromosomes were >7 for Klinefelter syndrome. Thus, in clinical genetic counseling with ultrasound, in addition to different types of USMs, we can also focus on the Z-scores of NIPS. Hu et al. (2021) and Wang et al. (2018) showed a correlation between the presence of USMs and the risk of pathogenic copy number variations (pCNVs), particularly in short femur length and multiple soft markers. Furthermore, prenatal diagnosis is recommended for detecting pCNVs in pregnant women with USMs and NIPS positivity. Chromosomal microarray analysis and CNV-Seq are also applicable to these cases.

In follow-up, we found that 17.78% (8/45) of women with positive NIPS results rejected further aneuploidy evaluation. Moreover, in pregnant women with negative results for NIPS, the preterm birth rate was 0.39%, and the proportion of infants with height or weight less than the standard value -2 SD was 1.08% of the overall population. The genetic disorders thalassemia and favism were also identified. Although NIPS can identify fetuses with abnormal chromosome numbers, it is not useful for detecting several monogenic diseases and autosomal recessive genetic disorders. Therefore, pregnant women with a family history of relevant genetic disorders should be fully informed of the scope and limitations of NIPS during genetic counseling.

The large sample size was a considerable strength of our study. Moreover, we performed subgroup analyses of different types of USMs and conducted an in-depth investigation of the applicability of NIPS in fetuses with different types of USMs in a low-risk population. Our findings offer more comprehensive genetic counseling for clinicians when facing a certain type of USMs.

However, our study also had several limitations. First, the distribution of the different types of fetal USMs varied considerably. The number of absent or hypoplastic nasal bone and short femur length cases was relatively small, which might have led to selection bias. Second, the karyotype results remained unknown for cases who had positive results for NIPS but rejected further aneuploidy evaluation, as well as for those who had termination of pregnancy and miscarriage, which might have caused bias in data analysis. Third, the gestational weeks at the time of second-trimester ultrasound were not recorded, and thus we could not incorporate this variable in our analysis.

CONCLUSION

Our study suggests that NIPS is an advanced screening test for pregnant women with age at EDC younger than 35 years, a low risk of maternal serum screening, and second-trimester USMs. In our study population, SCA was more common than autosomal trisomy, whereas EICF was the most frequent USM, but the least predictive of aneuploidy. If second-trimester ultrasound indicates absent or hypoplastic nasal bone, echogenic bowel, or multiple USMs, further aneuploidy evaluation is recommended, and NIPS can be used as a viable second-line complementary screening method.

SPG7 Gene Pathogenic Variant in a
Cypriot Family With Autosomal
Recessive Spastic Ataxia.
Front. Genet. 12:812640.
doi: 10.3389/fgene.2021.812640

The *SPG7* gene encodes the paraplegin protein, an inner mitochondrial membrane—localized protease. It was initially linked to pure and complicated hereditary spastic paraplegia with cerebellar atrophy, and now represents a frequent cause of undiagnosed cerebellar ataxia and spastic ataxia. We hereby report the molecular characterization and the clinical features of a large Cypriot family with five affected individuals presenting with spastic ataxia in an autosomal recessive transmission mode, due to a novel *SPG7* homozygous missense variant. Detailed clinical histories of the patients were obtained, followed by neurological and neurophysiological examinations. Whole exome sequencing (WES) of the proband, *in silico* gene panel analysis, variant filtering and family segregation analysis of the candidate variants with Sanger sequencing were performed. RNA and protein expression as well as *in vitro* protein localization studies and mitochondria morphology evaluation were carried out towards functional characterization of the identified variant. The patients presented with typical spastic ataxia features while some intrafamilial phenotypic variation was noted. WES analysis revealed a novel homozygous missense variant in the *SPG7* gene (c.1763C > T, p. Thr588Met), characterized as pathogenic by more than 20 *in silico* prediction tools. Functional studies showed that the variant does not affect neither the RNA or protein expression, nor the protein localization. However, aberrant mitochondrial morphology has been observed thus indicating mitochondrial dysfunction and further demonstrating the pathogenicity of the identified variant. Our study is the first report of an *SPG7* pathogenic variant in the Cypriot population and broadens the spectrum of *SPG7* pathogenic variants.

Keywords: Cypriot family, novel missense variant, paraplegin, spastic ataxia, *SPG7* gene

INTRODUCTION

Hereditary cerebellar ataxias (HCA) and hereditary spastic paraplegias (HSP) comprise two groups of genetically and clinically heterogeneous disorders with more than 70 genes and loci reported for each group (Parodi et al., 2018). Pure and complex clinical forms for both groups as well as a considerable overlap have been described (Tesson et al., 2015; Bereznayakova and Dupre, 2018). Recent advancements in genetic diagnosis such as the use of next generation sequencing (NGS), enabled the association of new genes with

FIGURE 1 | Identification of the *SPG7* novel variant. **(A)** Family pedigree with segregation analysis (WT, wild-type, M, mutant). The arrow indicates the proband. **(B)** Sanger sequencing electropherograms. Unaffected carrier = II:1, affected = III:4 and control = non-related healthy individual. **(C)** Conservation of identified variant. The DNA sequence of the *SPG7* gene region encompassing the identified variant (c.1763C > T; p.Thr588Met) is highly conserved in various mammals.

these disorders and added to the phenotypic expansion of known genes. Therefore, the existing overlap has been strengthened and the new concept of spastic ataxia (SA) spectrum has been defined (Parodi et al., 2018).

Several genes initially classified as HSP or HCA have now been considered as SA genes. The *SPG7* gene with more than 100 reported pathogenic variants, was initially linked to pure and complicated HSP with cerebellar atrophy, and now represents a frequent cause of undiagnosed cerebellar ataxia and SA (Lallemant-Dudek and Durr, 2020). It encodes the paraplegin protein, a member of the ATPases AAA family that is located in the inner mitochondrial membrane and is implicated in other mitochondrial proteins processing (Wedding et al., 2014). Functional studies aiming at understanding the pathogenetic mechanisms of identified variants have linked the protein to mtDNA homeostasis (Wedding et al., 2014).

We hereby describe the genetic investigation of a large Cypriot family with five affected individuals presenting with SA. Whole exome sequencing enabled the identification of a novel homozygous missense variant in the *SPG7* gene. We also

provide detailed clinical descriptions of all affected individuals and highlight some intrafamilial phenotypic variation.

MATERIALS AND METHODS

Samples

A four-generation family with 24 members and five patients (two males, three females) in two generations (**Figure 1A**) was included in the study. The grandparents originate from the same village; however, no relationship has been reported. Detailed clinical histories were obtained from all patients and they were subjected to neurological and neurophysiological evaluation by the CING neurologists. Brain MRI has been performed only at the early stages of the disease for three patients (III:4, IV:5, and IV:7). Blood samples were obtained from individuals II:1, II:2, II:5, III:1, III:2, III:3, III:4, III:5, III:7, III:8, III:9, IV:1, IV:2, IV:5, IV:6, IV:7, and IV:8. DNA was extracted from all available samples using standard salting out procedures.

Ethics Statement

This study has been approved by the Cyprus National Bioethics Committee (EEBK/EII/2013/09 and EEBK/EII/2013/28). Written informed consent was obtained from all study participants. Written informed consent was obtained from the individuals for the publication of any potentially identifiable images or data included in this article.

Molecular Analyses

Whole Exome Sequencing and Variant Filtering

WES was carried out on the proband as described previously (Votsi et al., 2014), followed by variant filtering: a preliminary filtering excluding variants with a minor allele frequency < 0.05 in 1,000 genomes, ExAC (Exome Aggregation Consortium) and EVS (Exome Variant Server) control databases was initially performed. Further *in silico* analysis focused on a gene panel encompassing HCA and HSP genes. Filtering criteria such as the expected genotype (homozygous/heterozygous), the coverage (>20x), the percentage of the alternative allele (>30%), the severity and the effect prediction according to Sift, Condel and Polyphen tools, were applied in order to prioritize the most significant variants to be further investigated for family segregation, with Sanger sequencing. Pathogenicity prediction was performed for a single novel pathogenic variant cosegregating with the disease in the family. Twenty one additional *in silico* tools or algorithms (including the widely used CADD, PROVEAN, Mutation Taster, DANN and other) provided by the VarCards database (Li et al., 2018) were used.

Sanger Sequencing

Primers amplifying the sequence encompassing the selected novel candidate variant, were designed by us. Amplification products were sequenced in both directions using the Big Dye Terminator v1.1 Cycle Sequencing kit [Applied Biosystems (ABI), California, United States]. Sequence traces were automatically compared with the normal region sequences as listed in the GenBank database using the Seqscape software (ABI).

Cell Lines

Lymphoblastoid cell lines (LCLs) were previously established using the standard Epstein Barr virus (EBV) infection procedure, for a couple of patients and independent control individuals after informed consent. They were cultured in RPMI 1640 medium (Biosera, Nuaille, France), supplemented with 10% FBS (ThermoFisher, Massachusetts, United States), and 50 U/ml of Penicillin/Streptomycin (Biosera).

Human SH-SY5Y were cultured in Dulbecco's Modified Eagle's medium (Biosera) supplemented with 10% FBS, 2 mM Glutamine (ThermoFisher), 50 U/ml Penicillin and 50 mg/ml Streptomycin.

All cell lines were kept at 37°C in 5% CO₂.

RNA Analysis

Total RNA was extracted from patients and independent control individuals LCLs, using the RNeasy Mini Kit (Qiagen, Hilden, Germany). cDNA was synthesized using the Protoscript First Strand cDNA Synthesis Kit (New England Biolabs, Ipswich, MA, United States). The synthesized strands were used as substrates

for RNA expression studies and cloning of the *SPG7* gene. Three independent real-time PCR experiments of three technical replicates for each sample, using TaqMan probes for the *SPG7* (Hs00275795_m1) and two housekeeping genes [*GAPDH* (Hs99999905_m1) and *B2M* (Hs00187842_m1)] were performed using the QuantStudio 7 Flex instrument (ABI). The QuantStudio Real-Time PCR software was used for data analysis and the Student's *t*-test was used for the statistical analysis of the independent experiments derived values. A *p*-value < 0.05 was set as a threshold for statistical significance.

Plasmid Construction and Cell Transfection

The cDNA samples of a control individual and the proband were used as templates in order to amplify the wild-type (WT) and mutant *SPG7* ORFs, respectively. Appropriate primers sets containing specific restriction sites in order to insert the amplified fragments into the p-EGFP-N1 vector were designed by us and are available upon request. Sanger sequencing was employed in order to confirm that all plasmid constructs have been free of any new nucleotide changes in the *SPG7* cDNA. SH-SY5Y cell lines were then transfected with these constructs with the use of Lipofectamine 3000 (ThermoFisher) following the manufacturer's instructions. Cells were harvested 48 h after transfection for protein extraction.

Protein Analysis

In order to perform expression studies, protein was extracted from the patients' and controls' LCLs as well as the transfected SH-SY5Y cells as described previously (Ververis et al., 2020). After running in an SDS-PAGE polyacrylamide gel, proteins were transferred to Hybond-P hydrophobic polyvinylidene difluoride (PVDF) membranes (Millipore, Germany). Membranes were blocked for 3 h (LCLs) or 1 h (SH-SY5Y) in 5% non-fat dry milk in phosphate buffered saline (PBS)/Tween, at room temperature, followed by overnight incubation at 4°C with the primary antibodies for the protein of interest and a housekeeping control [rabbit anti-SPG7 (Sigma Aldrich Taufkirchen, Germany)/1:6,500 for LCLs, rabbit anti-GFP (Proteintech, Illinois, United States)/1:5,000 for SH-SY5Y, mouse anti-β-ACTIN (Sigma-Aldrich)/1:4,000 for LCLs, mouse anti-vinculin (7F9) (Santa Cruz Biotechnology, Heidelberg, Germany)/1:1,000 for SH-SY5Y]. The next day membranes were washed 3 × 10 min in PBS/Tween and incubated with the appropriate secondary antibodies for 1 hour. Three washes followed and proteins signals were visualised using the LumiSensor Chemiluminescent HRP Substrate Kit (Genscript, New Jersey, United States), in a UVP BioSpectrum Imaging System (UVP, California, United States). Three independent experiments were carried out for each case. The ImageJ 1.51j8 software was used for data analysis.

Immunofluorescence

SH-SY5Y cells were grown on coverslips. After 24 h they were transiently transfected with the pEGFP-N1 *SPG7*^{WT} and mutant constructs with the use of Lipofectamine 3000 (ThermoFisher) following the manufacturer's instructions. After 48 h, cells were fixed for 10 min at RT with 4% w/v paraformaldehyde in PBS, permeabilised with Methanol for 10 min at -20°C and quenched

TABLE 1 | Clinical features of the patients.

Patient	III:1	III:4	IV:2	IV:5	IV:7

for 10 min at RT with 50 mM NH₄Cl in PBS. Cell mitochondria were stained using the AIF antibody (Cell Signaling Technology, Leiden, Netherlands) and nuclei using Hoechst 33342 (ThermoFisher). Coverslips were mounted with Dako Fluorescent Mounting Medium (Agilent, California, United States). Images were captured with a Zeiss fluorescent microscope using the Axiovision software. Colocalization index was quantified by Manders' coefficient using Coloc2 plugin for ImageJ, and two-tailed *t* test was used to assess the *p* value. Mitochondrial morphology parameters were assessed with the use of a macro titled “mitochondrial morphology,” developed by the Chu Lab for ImageJ as previously described (Dagda et al., 2009). One-way ANOVA analysis was conducted for the statistical evaluation of the mitochondrial morphology parameters.

RESULTS

Clinical Picture

The proband (III:4) developed balance difficulties during secondary school (16 years old) and by the age of 31 he presented spastic paraparesis. His elder sister (III:1) had a disease onset much later at 46, whereas the younger son of their cousin (IV:7) had an early onset, at 17. The two affected cousins (IV:2 and IV:5) had an onset between 23–25. All patients initially presented with gait unsteadiness and impaired balance

which gradually deteriorated. They developed spasticity in the lower limbs, ataxic spastic gait and lower limb proximal weakness (Table 1). Dysarthria, bilateral nystagmus, dysmetria and dysdiadochokinesia, as well as bilateral extensor plantar reflex and clonus were observed in all patients. Progressive external ophthalmoplegia (PEO), pes cavus foot deformity, urinary incontinence and upper limbs weakness at advanced stage with facial weakness, double vision and mild neuropathy were also observed in some of the patients (Table 1). Patient III:1 also suffers from abdominal pains and gastrointestinal hemorrhages for many years, but most probably these derive from a non-neurological disease. Electrophysiological evaluation of the patients with nerve conduction studies revealed sensory-motor axon neuropathy in two patients (III:1, IV:5). Somatosensory evoked potentials examinations were within normal limits in the majority of the patients. Bilateral optic pathway dysfunction in patients III:4 and IV:7 has been indicated at advanced stages of the disease through visual evoked potentials examination. Brain MRI at the early stages of the disease (performed on three patients) revealed cerebellar atrophy. Muscle biopsy performed on the proband at the early stages of the disease, revealed a normal mitochondria number and structure. Overall, the progression of the disease was slow and the patients became wheel-chair bound on average 20 years after the disease onset. The first clinical impression had been recessive cerebellar ataxia with spasticity and more recently it has been redefined to SA.

Genetic Analysis

A total of 71,696,896 reads, an average coverage of $>20\times$ for 92% of the target regions and 43,500 variants were identified through WES of the proband. After initial exclusion of variants with a minor allele frequency >0.05 in public databases, further analysis considering the HSP/HCA genes panel, enabled a significant reduction of the candidate variants to nine (Supplementary Table S1). Further evaluation considering the genotype, the variant consequence and severity, resulted in the identification of the single homozygous missense variant c.1763C > T, p.Thr588Met in the *SPG7* gene (Figure 1B), which has been also confirmed with family segregation analysis. Nucleotide and protein position of the reported variant are based on RefSeq accession numbers NM_003119.2 and NP_003110.1. This is a novel variant neither registered in gnomAD (gnomad.broadinstitute.org/), ExAC, 1,000 genomes, the ClinVar nor the LOVD databases. It has been also excluded from more than 200 control Cypriot chromosomes using Sanger sequencing. This variant results in the replacement of a neutral by a hydrophobic amino acid, and is located in the conserved peptidase M41 domain (Figure 1C) where many other missense pathogenic variants have been described. It is predicted to affect the protein function causing deleterious

consequences. High pathogenicity scores thus enabling the characterizations “deleterious” or “damaging” which denote the most severe possible effects, resulted from 20 prediction algorithms or tools which are based either on single or diverse annotation methods. These included the Sift (0.001), the Provean (−4.94), the CADD (34), the DANN (0.999), the MutationTaster (1.0), the FATHMM (−1.72), the LRT (0.0), and other scores.

RNA and Protein Expression Studies

In addition to the pathogenicity prediction results for the novel *SPG7* c.1763C > T variant, we investigated a possible effect on the RNA and protein expression. To compare the expression of *SPG7*^{WT} and *SPG7*^{T588M}, RNA and protein extracts derived from two available patients and three control individuals LCLs were used. qRT-PCR lead to the observation of similar expression levels between the patients and controls (Figure 2) thus excluding any effect of the variant on the RNA expression levels in this tissue. Western blot analysis using an anti-*SPG7* antibody also did not indicate a significant difference between patient and control (Figure 3A). To further investigate if this was a tissue specific result we also performed protein expression studies using an

FIGURE 4 | Intracellular localization of SPG7^{WT}-GFP and SPG7^{T588M}-GFP and mitochondrial morphology assessment. **(A)** SPG7^{T588M}-GFP retains colocalization with mitochondria, in similar fashion with SPG7^{WT}-GFP. Green color represents the SPG7-GFP, red color represents mitochondria and blue color represents the nuclei. Scale bars are 10 μm . **(B)** Graph displaying Manders' coefficient quantification (fraction SPG7^{WT}-GFP or SPG7^{T588M}-GFP colocalizing with AIF, and vice versa) calculated from at least 20 fluorescence microscopy images for each isoform. Error bars are given by the SD and $n > 30$ for each condition. **(C)** Graphs displaying morphological characteristics of mitochondria: size, elongation, interconnectivity and number, in WT (SPG7^{WT}-GFP) and mutant (SPG7^{T588M}-GFP) transfected SH-SY5Y cells as well as in untransfected cells, calculated from at least 20 fluorescence microscopy images for each condition. Error bars are given by the SEM and $n > 30$ cells for each condition (* refers to $p < 0.05$, ** to $p < 0.01$, and *** to $p < 0.001$ statistical significance, while ns corresponds to non-significant for the comparisons shown).

in vitro model, the human derived neuroblastoma SH-SY5Y cell lines that had been transfected with the p-EGFP-N1 constructs expressing *SPG7*^{WT} and *SPG7*^{T588M}. Similar to the LCLs, western blot analysis using an anti-GFP antibody (thus detecting only the exogenous *SPG7*), did not indicate any significant difference between the expression of the mutant and the WT *SPG7* in these cells (Figure 3B).

Protein Localization and Mitochondrial Morphology

We also performed immunofluorescence experiments using the transfected SH-SY5Y cells, in order to investigate the localization of the *SPG7*^{WT} and *SPG7*^{T588M} proteins and assess the mitochondrial morphology of mutant and WT cells by evaluating four well documented parameters (Dagda et al., 2009; Wiemerslage and Lee, 2016). The resulting data showed that the mutant protein retains its localization to mitochondria similar to the WT (Figures 4A,B), thus indicating that possibly the novel variant does not affect protein localization. Regarding mitochondrial morphology, it has been observed that mitochondria in mutant cells were smaller and less elongated with a low degree of interconnectivity (Figures 4A,C), which are typical signs of a dysfunctional mitochondrial network. In contrast, mitochondria in WT cells were longer, elongated and interconnected ($p < 0.05$; Figures 4A,C), indicating a healthy mitochondrial network. Furthermore, the mitochondria mean number of mutant cells (Figure 4C) was significantly higher compared to the WT, and that accompanied by a smaller mitochondrial size indicates mitochondrial fragmentation.

DISCUSSION

We hereby describe the clinical picture and the genetic investigation of a large Cypriot family with SA. Before the advent of WES, the family had been extensively studied and excluded in the past (more than 15 years ago) for linkage to HCA genes and loci (guided from the first clinical impression and that period relevant literature), as well as pathogenic variants previously reported in the Cypriot population (Nicolaou et al., 2008; Zamba-Papanicolaou et al., 2009; Votsi et al., 2014).

It is widely accepted that the advent of NGS strategies, including the targeted sequencing panels, the WES and the whole-genome sequencing (WGS), improved dramatically the genetic diagnosis of clinically and genetically heterogeneous diseases such as the HCAs and HSP. NGS has also enabled the identification of many novel genes and variants (Coutelier et al., 2018; Elert-Dobkowska et al., 2019; Krygier and Mazurkiewicz-Beldzińska, 2021; Sahin and Saat, 2021). Through a WES approach followed by *in silico* targeted gene analysis, the present study describes the first identification of a pathogenic variant in the *SPG7* gene in the Cypriot population. The successful efficacy of this approach in the study of HCAs and HSPs has been well documented (Coutelier et al., 2018; Sahin and Saat, 2021; Saputra and Kumar, 2021). Compared to other diagnostic approaches such as the classic Sanger sequencing based on phenotype-oriented gene prioritization, or even the NGS gene

targeted panel sequencing, the exome targeted capture has several advantages. Gene prioritization based on phenotypic presumptions is abolished, and there is no need to redesign a panel in case new HCA or HSP genes are published. Moreover, in the context of the HCA and HSP heterogeneity, a broader range of genes must be allowed to be tested, including genes linked with other types of transmission or other neurological diseases which have overlapping features with HCA or HSP. This approach captures variants in genes associated with various transmission modes or variants that would not be identified by a typical HCA or HSP panel. However, it might be more expensive than a targeted panel analysis with a relatively lower coverage provided. The major limitation of both the targeted panel and WES compared to the WGS approach, which provides longer reads, has been their inability to detect repeat expansions, deep intronic variants or CNVs (Coutelier et al., 2018; Krygier and Mazurkiewicz-Beldzińska, 2021; Saputra and Kumar, 2021). Therefore, for undiagnosed patients excluded from small scale variants through gene panel analysis or WES, the use of WGS could be a promising option. Thus far, WGS has contributed to discovering ataxia (Cortese et al., 2019) and other disease novel tandem repeat expansions (Bahlo et al., 2018; Kim et al., 2019) and is expected to identify additional new ataxia-causative expansions in the future. Further advances in NGS techniques and bioinformatics analysis are promising towards better detecting pathogenic variants and expansions even from the analysis of short-read data.

Pathogenic variants in the *SPG7* gene had been initially linked to pure and complicated HSP, whereas lately they have been considered as frequent causes of undiagnosed cerebellar ataxia and SA cases. In the United Kingdom, *SPG7* variants have been reported as the fourth more common cause of the genetic ataxias in general and the second of the recessive ataxias (Hewamadduma et al., 2018). A variety of variants including several missense, frameshift, nonsense, small insertions, deletions, duplications, macro deletions and splice site variants have been described. More recently, a deep intronic heterozygous cryptic splice variant has been reported to cause SA in combination with a heterozygous missense variant, thus suggesting the re-examination of existing cases characterized as dominant *SPG7* variants (Verdura et al., 2020).

The core clinical presentation of the Cypriot family patients is similar to other described cases. The majority of their features correspond to >50% of the worldwide described cases (Hewamadduma et al., 2018). However, within the family some phenotypic differences were observed, with the age of onset being the most significant. It has been reported that the localization of a mutation in relation to the different functional domains of the protein affects the age of onset. More specifically, homozygous mutations in the M41 peptidase domain have been correlated to an earlier disease onset compared to mutations in a non-functionally assigned domain (Hewamadduma et al., 2018). This novel missense *SPG7* c.1763C > T variant is located within the M41 domain, and is associated with a variable age of disease onset (ranging from 16–46 years). Patient III:1 had a very later age of onset compared to the other patients, and the two males had an earlier onset compared to the other females. Moreover, only patient III:1 presents with respiratory difficulties and dysphagia, as well as a more severe cerebellar dysarthria. Additional symptoms which are

not common for all the patients such as optic atrophy, sensory deficit, pes cavus deformity, facial weakness, double vision, peripheral neuropathy and urinary incontinence have been recorded. Moreover, PEO is present in 3/5 patients, and it has been referred as one of the rare findings in the majority of described *SPG7* cohorts (Hewamadduma et al., 2018; Verdura et al., 2020). To our knowledge, similar phenotypic differences in patients sharing an identical *SPG7* pathogenic variant, have been observed, mostly between different families and more rarely between members of the same family (Van Gassen et al., 2012; Hewamadduma et al., 2018). Such differential phenotypic expression could be attributed to the contribution of other genetic, epigenetic or environmental factors.

The identified novel *SPG7* variant has been predicted to cause deleterious consequences with almost all the prediction tools. There are many possible effects of a missense variant including protein folding, stability and flexibility alterations, binding processes prevention, subcellular localization and expression alterations. One or a combination of such effects might cause an abnormal protein function (Zhang et al., 2012). To investigate the possible expression and subcellular localization alterations, we employed the patient/control derived LCLs (only for expression) and the *in vitro* model neuroblastoma SH-SY5Y cell lines. The SH-SY5Y cell lines is a well-established model that has been used for the investigation of various neurodegenerative disorders, including ataxia and spastic paraplegia types (Bolinches-Amoros et al., 2014; Wagner et al., 2019; Morani et al., 2020). However, to our knowledge, this is the first time that they are employed for the study of an *SPG7* relevant disease. Furthermore, there are no other reports for the investigation of the effect of missense *SPG7* variants in LCLs. There are limited reports for differential expression in other cells, in most of which a missense variant was in compound heterozygosity with another type of variant and therefore its contribution (if any) was not clear. Increased RNA and protein expression was observed in muscle cells of a group of patients carrying *SPG7* compound heterozygous variants (nonsense and missense) (Pfeffer et al., 2014). Increased protein expression was also identified in olfactory neurosphere-derived cells, isolated from patients carrying the common missense p.Ala510Val variant in compound heterozygosity with other variants (Wali et al., 2020), whereas decreased protein expression was identified in fibroblasts of a patient heterozygous for a missense variant and a deep intronic cryptic splice variant (Verdura et al., 2020). Another study reported paraplegin accumulation in post-mortem cerebellar and cerebral cortex neurites of a patient homozygous for the common p.Ala510Val variant; however, it was not clear whether this observation was due to the protein overexpression or mislocalization (Thal et al., 2015). Our experimental data indicate that the reported variant does not affect the expression of either the RNA or the protein in both tested cell lines. Localization of the mutant protein remains unaffected as well.

Aberrant mitochondrial morphology representing an unhealthy mitochondrial network has been detected in cells expressing *SPG7*^{T588M}, thus indicating mitochondrial dysfunction and further supporting the predicted pathogenicity of the reported variant. Similar mitochondrial morphology, accompanied by additional types of mitochondrial dysfunction that have been associated with neurodegeneration (including decreased mitochondrial membrane potential, reduced

mitochondrial mass, reduced oxidative phosphorylation, reduced ATP content, diminished cellular proliferation and increased mitochondrial oxidative stress) were identified in the olfactory neurosphere-derived cells mentioned above (Wali et al., 2020). Mitochondria defects associated with neurodegeneration have also been described through studies in other cell and animal models lacking paraplegin (Atorino et al., 2003; Ferreira et al., 2004; Pareek et al., 2018). In contrast, increased mitochondrial mass and enhanced networks which are referred as typical for a mitochondrial disorder, have been identified in fibroblasts of patients carrying compound heterozygous variants (with at least one of the two being nonsense in the three patients) (Pfeffer et al., 2014).

Based on our findings, we hypothesize that the currently reported *SPG7* variant consequences on the tested cell lines mitochondrial network, are not relevant with protein expression alterations or mislocalization. Other mechanism(s) such as the protein folding, stability and flexibility changes, and protein interaction alterations or a combination of these, might affect protein's normal function, thus leading to the observed dysfunctional mitochondrial network and perhaps to other dysfunction(s) that remain unknown.

In conclusion, our study is the first report of an *SPG7* pathogenic variant in the Cypriot population. It is a novel variant that broadens the spectrum of *SPG7* pathogenic variants and evidently causes mitochondrial dysfunction. It also provides detailed clinical features of the patients, thus indicating intrafamilial differences, and enabling comparisons with other reported cases. Our findings also further support the usefulness of WES followed by *in silico* targeted gene analysis as a powerful diagnostic tool in the study of clinically and genetically heterogeneous diseases such as the HCAs and HSPs, as well as the suitability of the SH-SY5Y cells for the functional investigation of *SPG7* variants.

DATA AVAILABILITY STATEMENT

The datasets for this article are not publicly available due to concerns regarding participant/patient anonymity. Requests to access the datasets should be directed to the corresponding author.

ETHICS STATEMENT

The studies involving human participants were reviewed and approved by The Cyprus National Bioethics Committee. The patients/participants provided their written informed consent to participate in this study.

AUTHOR CONTRIBUTIONS

CV and KC designed and conceived the study; Experimental studies, data acquisition, data analysis and interpretation were

carried out by CV (molecular analysis and part of functional analysis) and AV (functional analysis); CV drafted the manuscript; AV, YC, and KC revised the manuscript; PN and KC contributed in data interpretation; YC and EZ-P performed the clinical characterization; KC supervised the study; All authors read and approved the final manuscript.

FUNDING

This work was partly supported by Norway grants and the Cyprus Institute of Neurology and Genetics.

Background: Fetal congenital heart disease (CHD) is the most common congenital defect, with an incidence of 0.6–0.8%, accounting for 30–50% of infant congenital disease deaths. The pathogenesis of CHD is still unclear, so an active and effective prenatal diagnosis is very important for the prevention and control of CHD. Herein, a Chinese CHD patient with rare compound heterozygous mutations in the *DNAH9* gene was reported, and the 3D structure and functional changes of *DNAH9* protein were predicted.

Case presentation: A 23-year-old pregnant woman came to our hospital for prenatal diagnosis at 27 weeks of gestation. Both she and her partner were unaffected. Fetal CHD was detected by ultrasound screening. Copy number variation sequencing (CNV-seq) revealed an 81 kb deletion at chr17p12 (11,486,795–11,568,385), including exons 1–15 of *DNAH9* gene, which plays a key role in cardiac development. Then, whole exome sequencing (WES) was used and identified a nonsense mutation (c.10975C>T) in *DNAH9*, which resulted in the mutation of amino acid 3,659 from glutamine to termination. The 3D mutant protein structures were predicted using SWISS-MODEL and showed structural changes from functional β -sheet and α -helix to termination, respectively.

Conclusion: We describe a case of fetal CHD caused by *DNAH9* mutations and provide an effective diagnostic technique for identifying intragenic deletions. This diagnostic process can be implicated in prenatal diagnosis of CHD.

Keywords: congenital heart disease, *DNAH9* gene, copy number variation sequencing, whole exome sequencing, 3D structure

INTRODUCTION

Congenital heart diseases (CHD) are the most common birth defects, which can severely affect human health, accounting for 2–8% of newborn children (Hoffman et al., 2004; Lambrechts et al., 2005). The clinical manifestations and severity of CHD are widely variable. Mild cases, such as some small ventricular septal defects, can self-close after birth. Severe cases, such as most instances of tetralogy of Fallot (TOF), seriously affect the function and structure of the heart, with a high mortality. CHD is often accompanied by multiple organ malformations, which is one of the main causes of neonatal death (Pediatric Cardiac Genomics Consortium et al., 2013; Egbe et al., 2014). Traditional thought is that CHD is the combined result of environmental and genetic factors, in which environmental factors are dominant (Kalisch-Smith et al., 2020). However, with the development of technologies, it has been found that the incidence of CHD is significantly higher in monozygotic twins, or when patients have family history of CHD or consanguinity. A variety of chromosomal aberrations is often associated with different types of CHD. It is now highly suggested that genetic factors play an important role in the pathogenesis of CHD (Van der Bom et al., 2011). In particular, the invention and application of chromosome microarray technology (CMA) and high-throughput sequencing technology provide a strong basis for elucidating the extremely important role of genetic factors in the occurrence of CHD (Charron et al., 2010; Rehm, 2013; Aburawi et al., 2015).

Monogenic inherited disease refers to disease caused by a single gene abnormality, also known as Mendelian genetic disease. Monogenic disease can be divided into autosomal dominant or recessive, X-chromosome dominant or recessive genetic diseases. The incidence rate of any individual monogenic disease is not high, but the overall incidence rate of all monogenic diseases combined is 4–5%. This kind of genetic disease can also be seen in various CHD, which can be an isolated CHD phenotype (such as in *GATA4* and *NKX2.5* gene mutations (Winston et al., 2012)) or a part of complex syndrome, such as Noonan syndrome or Holt-Oram syndrome.

DNAH9 gene associated primary ciliary dyskinesia 40 is characterized by chronic respiratory tract infection, visceral translocation and infertility (Fassad et al., 2018; Loges et al., 2018). Most of the patients with primary ciliary dyskinesia have congenital respiratory diseases. From early childhood, patients will have repeated respiratory infections. However, the respiratory compromise of primary ciliary dyskinesia type 40 is relatively light, and usually does not develop into serious lung disease. About 50% of patients with primary ciliary dyskinesia have mirror image inversion of internal organs, and some patients have been reported to have severe congenital heart malformations.

In this study, we reported the case of a Chinese fetal proband, who presented with fetal CHD by ultrasound screening. Copy number variation sequencing (CNV-seq) revealed an 81 kb deletion at chr17p12, including a deletion of exons 1–15 in *DNAH9*. Then, whole exome sequencing (WES) revealed a nonsense mutation (c.10975C>T) in *DNAH9* on the other

FIGURE 1 | The fetus with congenital heart disease. Ultrasound scans of the fetus showed abnormal heart development, a single ventricle, pulmonary artery stenosis and situs inversus.

allele. This base mutation resulted in the codon of amino acid 3,659 from glutamine to termination. To predict the changes of 3D protein structure, we used SWISS-MODEL and PyMO and revealed these two mutations changed functional β -sheet and α -helix structures, respectively.

MATERIALS AND METHODS

Sample Collection

The study was approved by the institutional ethics committee of Shaoxing Maternity and Child Health Care Hospital. The family members had signed informed consent documents. Parental consent was obtained for collecting the prenatal fetal cord venous blood at 27 weeks of pregnancy. Peripheral blood samples also were collected from proband's parents.

Copy-Number Variation Sequencing and Whole Exome Sequencing

Genomic DNA was extracted from the proband and parental blood using a DNEasy Blood and Tissue Kit (Qiagen, Hilden, Germany) according to the manufacturer's procedures, respectively. For WES, the genomic DNA of the proband was enriched for coding exons using Agilent SureSelect Low Input Reagent Kit and sequenced on Illumina HiSeq X Ten platform. The sequencing data captured 99.75% of coding regions across 35,519,957 bp length of 25,701 genes in total. The average sequence depth is 180.347X and 97.87% of targeted regions

FIGURE 2 | The loss of heterozygosity at 17p12 in the proband and the mother were detected by CNV-seq. **(A)** Copy number of chromosome 17 in the proband by sequencing. **(B)** Copy number of chromosome 17 in the proband's mother by sequencing. The chr17:11,486,795–11,568,385 and chr17:11,486,795–11,565,741 showed in **(A)** and **(B)** were regions of deletion in the proband and her mother, respectively.

with average depth >20X. For CNV-seq, the genomic DNA was fragmented using Hieff NGS® Fast-Pace™ DNA Fragmentation Reagent and prepared for the PCR-free library by Hieff NGS® Complete Adapter Kit for Illumina®.

Data Analysis

The AfterQC (Chen et al., 2017) was used to evaluate the sequencing quality of the original sequencing data, and the low quality and contaminated reads were removed. After data were aligned to human reference hg19 by BWA software (Li and Durbin, 2010), the single nucleotide variants (SNV) and indels in genome were called by using the GATK software (McKenna et al., 2010). Then, we used 1000 Genomes database (1000 human genome dataset), Genome AD (Genome Aggregation Database dataset) 2.1.1, and ExAC (The Exome Aggregation Consortium dataset) to screen the SNV and indels and the OMIM, HGMD, and Clinvar databases to filter the reported mutations. dbNSFP database was used to predict the pathogenicity of missense mutation and splice mutation. All mutation sites were classified by ACMG genetic variation classification criteria and guidelines. Finally, Sanger sequencing method was used to verify all possible pathogenic sites.

Protein Structure Prediction

The protein sequence with 4,486 amino acid residues of *DNAH9* was download from NCBI (NP_001363.2). The wild-type and mutant-type 3D structure of the *DNAH9* protein was predicted

using SWISS-MODEL web server (<https://swissmodel.expasy.org/>) (Waterhouse et al., 2018). The best model was selected based on QMEANDisCo global score. The final predicted structure was visualized using PyMOL program (<https://pymol.org/>).

RESULTS

Clinical Features

At 31 weeks of gestation, the parents were fully informed of severe fetal deformity and the significance of the compound *DNAH9* mutations. The parents strongly requested the induction of labor. With the approvement of the institutional ethics committee of Shaoxing Maternity and Child Health Care Hospital, the pregnancy was terminated for fetal anomalies. The parents and other families were in normal physical condition, without any family history of genetic diseases. Prior to the proband, her mother had two histories of adverse pregnancies: 1) At 26 weeks of gestation, pregnancy was terminated due to the discovery of fetal single chamber heart and 2) at the third month of another pregnancy, spontaneous abortion occurred. Her mother's menstruation was irregular in the period of 30–40 days.

There was no early pregnancy reaction, no exposure to poison or radioactive substances, and no history of folic acid supplementation in early pregnancy. At 9 weeks of gestation, her mother came to our hospital for ultrasound examination and

found the normal gestational sac and gestational age. At 15 weeks of gestation, her mother came to our hospital for routine prenatal examination and found the normal physical condition, low risk value of non-invasive prenatal testing (NIPT), and normal range of OGTT. However, at 27 weeks of gestation, the result of ultrasound examination showed fetal cardiac abnormalities include single ventricle, pulmonary artery stenosis and visceral inversion (**Figure 1**). More detailed tests were carried out 2 days later and confirmed that the proband had no ventricular septal structure. CDFI showed mild left atrioventricular regurgitation. Because of the continuous histories of adverse pregnancy outcomes, the parents hoped to clarify the genetic factors and guide the next birth.

Molecular Analysis

Using CNV-seq, we identified an 81 kb deletion at chr17p12 (11,486,795–11,568,385) in the fetus (**Figure 2A**). This deletion region includes 1–15 exons of the *DNAH9* gene. After verified in her parents by CNV-seq, it is found that the mother had a 79 kb deletion at chr17p12 (11,486,795–11,565,741) (**Figure 2B**). The result implied the deletion at chr17p12 of the fetus was inherited from her mother. Moreover, we also performed the WES in the fetus and revealed another mutation at c.10975C>T (p.Q3659*) in the exon 57 of *DNAH9* gene (**Figure 3A**). Subsequently, sanger sequencing was used to verify this nonsense mutation in all family members and showed c.10975C>T *DNAH9* mutation

was inherited from her father (**Figure 3B**). According to the American College of Medical Genetics and Genomics (ACMG) guidelines (Richards et al., 2015), both the 81 kb deletion at chr17p12 and c.10975C>T in *DNAH9* gene were predicted to be pathogenic mutations because of the evidence chain (PVS1+PM2+PP3).

Effect of Mutations on Protein Structures

We used SWISS-MODEL web server (Waterhouse et al., 2018) to predict changes of DNAH9 protein structures when there were mutations in the sequence (Figure 4A). The deletion of 1–15 exons in *DNAH9* gene will alter the 3D structure on β -sheet (Figure 4B), while the c.10975C>T (p.Q3659*) mutation will change the 3D structure from α -helix to termination (Figure 4C). The combination of these structural changes would alter the conformation of the DNAH9 protein and affect the protein stability and binding facility.

DISCUSSION

Fetal CHD has become the most important birth defect type in China, accounting for the majority neonatal non-infectious diseases. However, the accuracy rate of prenatal diagnosis was only 36% by investigating 309 participants with CHD, including post-natal and fetal termination (Friedberg et al., 2009). The prenatal diagnosis rate of left ventricular outflow tract obstruction, transposition of great arteries and anomalous pulmonary venous drainage was the lowest. The traditional technology, ultrasound is the most effective non-invasive way of diagnosing CHD in fetal cases. However, because of the small meridian of the fetal heart, complex blood circulation, difficulties of capturing the fetal variable blood flow and the limitation of ultrasound itself, not all fetal CHD can be diagnosed by ultrasound in the prenatal setting. Although MRI can overcome shortcomings of the small field of vision and poor contrast of soft-tissue, the malformations of CHD patients are sometimes not limited to the heart. Additionally, many CHDs are accompanied by genetic changes, including chromosome aberration, single gene genetic defects, multi gene genetic defects and so on. Therefore, it is of great and urgent practical significance to make early and accurate prenatal genetic diagnosis of CHD in fetal cases by using next-generation sequencing technology.

Previous studies have proved that CMA is an effective tool to detect fetal genomic imbalances, including abnormalities of chromosome number and copy number variations (Xia et al., 2018). However, the price of CMA is relatively expensive. Copy number variation sequencing (CNV-seq), is a technology by using next-generation sequencing technology, can detect CNVs with high resolution in the whole genome. Compared with CMA, it can increase different sequencing depth to obtain more accurate information, and has the advantages of more flexible, fast, accurate and low operation cost (Duan et al., 2013). Moreover, CNV-seq technology has been applied to the genetic diagnosis of fetal CHD, recently (Zhu et al., 2016). In our study, we found that the proband had a loss of heterozygosity of 81 kb at 17p12 (11,486,795–11,568,385) by high-resolution CNV-seq. This deletion was within *DNAH9* gene. Then the parent's samples were verified by CNV-seq, and found her mother was a carrier of this deletion.

The loss of heterozygosity in *DNAH9* alone should not cause CHD. To search for other potential genetic defects, WES and sanger sequencing of the proband and the parents were

further performed and found one heterozygous nonsense mutation of *DNAH9* gene (c.10975C>T) in the proband inherited from her father. This mutation resulted in termination of translation at amino acid 3,659. With additional clinical evaluation, these two mutations meet ACMG criteria for classification as pathogenic of *DNAH9* mutations in this case.

In summary, through the combined application of high-throughput sequencing technologies (CNV-seq and WES), we established a probable cause of the couple's poor pregnancy outcomes. The proband had compound heterozygous mutations, the deletion of 81 kb at 17p12 (11,486,795–11,568,385) and *DNAH9* c.10975C>T (p.Q3659*), inherited from each carrier parent. In addition, our results showed that the combination of CNV-seq and WES is an effective approach to prenatal diagnosis.

DATA AVAILABILITY STATEMENT

The datasets for this article are not publicly available due to concerns regarding participant/patient anonymity. Requests to access the datasets should be directed to the corresponding authors.

ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Institutional Ethics Committee of Shaoxing Maternity and Child Health Care Hospital. Written informed consent to participate in this study was provided by the participants' legal guardian/next of kin.

AUTHOR CONTRIBUTIONS

TZ and YZ conceived and designed the experiments. HP performed the experiments, HY, YH, XS and HZ contributed new materials, YY, JD and HD analyzed the data and wrote the paper. All authors read and improved the manuscript.

Clinical Characteristics and Genetic
Analysis of a Family With Birt-Hogg-
Dubé Syndrome and Congenital
Contractural Arachnodactyly.
Front. Genet. 12:768342.
doi: 10.3389/fgene.2021.768342

Background: Birt-Hogg-Dubé (BHD) syndrome and congenital contractural arachnodactyly (CCA) or Beals-Hecht syndrome are clinically rare autosomal dominant genetic diseases. In this study, we describe an extremely rare family with BHD syndrome and CCA.

Objective: To investigate the clinical and genetic characteristics of a family with BHD syndrome and CCA.

Methods: We describe the clinical characteristics, family history, and clinical manifestations of the patient's family members. The patient underwent a blood test, computed tomography (CT) of the chest, color Doppler ultrasound of the abdomen and heart, and digital radiography of the hands. Whole exome sequencing was performed on his family members.

Results: Two years ago, the male proband developed chest tightness and shortness of breath that was accompanied by an irritating cough as well as repeated (four times) spontaneous pneumothorax. The chest CT indicated spontaneous pneumothorax on the right side and cyst and bullae in both lungs. He had no kidney tumors or skin lesions. His son had a history of pulmonary bullae and experienced spontaneous pneumothorax twice. The proband, his mother, and his son were all born with a hand deformity. The sequencing results demonstrated that both the proband and his son had heterozygous variations of the folliculin (FLCN) gene c.1015C > T (p. Gln339Ter) and fibrillin-2 (FBN2) gene c.3485G > A (p. Cys1162Tyr), which are associated with BHD syndrome and CCA, respectively.

Abbreviations: ACMG, American College of Medical Genetics and Genomics; ANCA, Anti-Neutrophil Cytoplasmic Antibodies; BHD syndrome, Birt-Hogg-Dubé Syndrome; BHS, Beals Hecht Syndrome; CCA, Congenital contractural arachnodactyly; CT, Computed Tomography; DR, Digital Radiography; FLCN, Folliculin; FBN2, Fibrillin two gene; HGMD, The Human Gene Mutation Database; MFS, Marfan syndrome; OMIM, Online Mendelian Inheritance in Man; UTR, Untranslated Region; WES, Whole Exome Sequencing.

Conclusion: For patients with chest tightness, shortness of breath, recurrent spontaneous pneumothorax, and congenital hand deformity without inducement, genetic testing should be carried out as soon as possible to make a clear diagnosis, which can then guide treatment and genetic counseling.

Keywords: birt-hogg-dubé syndrome, congenital contractural arachnodactyly, FLCN, FBN2, whole exome sequencing

INTRODUCTION

Birt-Hogg-Dubé (BHD) syndrome is a rare autosomal dominant genetic disease. Folliculin (FLCN), located on chromosome 17p11.2, is its causative gene. Its common features include multiple fibrofolliculoma, bullae (spontaneous pneumothorax), and kidney tumors (Black et al., 2020). Phenotypically, this condition is highly variable. Even in the same family, affected individuals may exhibit any combination of skin, lung, or kidney manifestations of varying severities (Daccord et al., 2020). Regardless, spontaneous pneumothorax is usually the first manifestation of BHD syndrome (Johannesma et al., 2015), maybe the only one (Xing et al., 2017). In FLCN mutation carriers, skin manifestations usually appear in the fourth decade and gradually increase and become more obvious with age (Iwabuchi et al., 2018). Compared to lung cysts/pneumothorax, the renal manifestations of BHD syndrome occur later (Pavlovich et al., 2005).

Congenital contractural arachnodactyly (CCA) or Beals-Hecht syndrome is a rare autosomal dominant connective tissue disease; it is associated with the disease-causing fibrillin-2 (FBN2) gene. The main clinical features of CCA are spider fingers (toes), flexion fingers, major joint contractures, scoliosis, pectus excavatum, and helix shrinkage (Aivaz et al., 2015). In this paper, we report an extremely rare family with BHD syndrome and CCA.

MATERIALS AND METHODS

Clinical Characteristics of the Family

We describe the clinical characteristics, family, and clinical manifestations of the patient's family members. Family history: the patient's parents were married but not intermarried, and both were deceased. The father had no history of symptomatic pneumothorax or hand malformations, while the mother had congenital hand malformations and no history of symptomatic pneumothorax. The patient had two brothers (one has three daughters, one has one son and one daughter) and one sister, and none of these people had no history of symptomatic pneumothorax or hand malformations. The second brother had hemiplegia, and the sister died of cerebral infarction at the age of 40. The patient's unmarried son had congenital hand malformations, a history of bullae, and spontaneous pneumothorax twice in the local hospital. His son's condition improved after drainage, and he was physically fit. While the patient denied a history of other familial

diseases, his family is considered to have a familial hereditary disease, possibly BHD syndrome.

Blood tests, computed tomography (CT) of the chest, color Doppler ultrasound of the abdomen and heart, rheumatism-related indicators, and digital radiography (DR) of the hands were performed on the patient's family. Blood samples from the patient and his son were sent to the Henan Rare Disease Research Center for genetic sequencing.

The study was approved by the hospital ethics committee (2021-03-B024), and the family members signed informed consent forms.

Whole Exome Sequencing (WES)

With their full notification and informed consent, 3 ml of peripheral blood from the patient and his son was drawn and sent to a third-party company for WES. First, the DNA was fragmented, and the library prepared. Then, the Agilent V6 probe was used to hybridize and capture the DNA from the entire exome as well as part of the untranslated region. Finally, the high-throughput sequencing platform was used to detect mutations. Pathogenic genes of single-gene genetic diseases that had been identified in the Online Mendelian Inheritance in Man (June 2019) were analyzed. Please refer to the American College of Medical Genetics and Genomics (ACMG) for standards and guidelines on the interpretation of genetic variations and their grades. Separate clinical analyses of different samples were performed, including clinical symptom matching and disease recommendations.

RESULTS

A Rare Family's Characteristics

In the past 2 years, a 55-year-old male patient had chest tightness, shortness of breath, and an irritating cough without obvious triggers. He was repeatedly admitted to the hospital for spontaneous pneumothorax (four times in total).

Physical examination: body temperature, heart rate, and blood pressure were stable, except for shortness of breath. No abnormal findings on skin or mucous membranes upon examination. Weak breathing sounds in the right lung and thick breathing sounds in the left lung. No dry or wet rales were heard. Upon percussion, the right lung made drum-like sounds, while the left lung was voiceless. The heart and abdominal examinations found no abnormalities, but the fingers had bilateral deformities and asymmetries, along with incomplete extension. The patient

FIGURE 1 | Clinical characteristics of the patient and family members. **(A):** Computed tomography of the patient's chest indicated spontaneous pneumothorax on the right side and cyst and bullae in both lungs. **(B):** Digital radiography in both patient's hands revealed changes in both hands and wrists, suggesting degenerative changes or chronic inflammatory lesions. **(C):** The patient's hands. **(D):** The hands of the patient's son.

had a history of hypertension for over a month, and his blood pressure was as high as 180/120 mmHg. His blood pressure was lowered via oral administration of amlodipine besylate, valsartan, and bisoprolol fumarate, and it was controllable. The patient had no bad habits of tobacco or alcohol.

Patient's blood tests: blood routine, liver and kidney function, and rheumatism-related indicators (including antinuclear antibody profile, anti-neutrophil cytoplasmic-related antibodies, rheumatoid factor, and high-sensitivity C-reactive protein) were normal.

Chest CT revealed: spontaneous pneumothorax on the right side and cyst and bullae in both lungs (**Figure 1A**). A thoracic surgeon was consulted and asked to provide closed thoracic drainage to promote lung recruitment. The DR in both hands indicated changes in both the hands and wrists, suggesting degenerative changes or chronic inflammatory lesions (**Figure 1B**). Both the patient and his son had a history of hand deformities and pulmonary bullae formation (see **Figures 1C,D**, respectively, for photographs of the patient's and his son's hands). No abnormalities were found with the abdominal and cardiac color Doppler ultrasounds. No manifestations of kidney tumors or skin lesions. Pulmonary function test was not performed due to pneumothorax and bullae.

Following treatment, part of the patient's lung re-expanded, the pneumothorax improved, and air bubbles were still visible in the closed thoracic drainage bottle after the chest tube was intermittently clamped. He was transferred to thoracic surgery for thoracoscopic right lung volume reduction, pleural adhesion cauterization, and pleural fixation. His postoperative recovery was good. No spontaneous pneumothorax recurred during regular telephone and Outpatient follow-up.

Family WES Results

The WES results revealed that the proband and the son had heterozygous variants of the *FLCN* gene c.1015C > T (p. Gln339Ter) and *FBN2* gene c.3485G > A (p. Cys1162Tyr) (**Figure 2**). A heterozygous nonsense mutation was detected in the exon region of the *FLCN* gene c.1015C > T, resulting in an amino acid change: p. Gln339Ter. The mutation site is reported as a pathogenic variant in the Human Gene Mutation Database (HGMD) but is not included in the ClinVar database. Using the ACMG guidelines, the variant was judged to be pathogenic (PVS1 + PM2 + PP5). A heterozygous missense mutation was also found in the exon region of the *FBN2* gene c.3485G > A, resulting in an amino acid change: p. Cys1162Tyr. This mutation is not included in either the HGMD Professional database or the ClinVar database. However, according to the ACMG guidelines, the variant was judged to be potentially pathogenic (PM1 + PM2 + PM5 + PP3).

The *FLCN*-gene-associated disease is BHD syndrome, an autosomal dominant genetic disease. The proband and son are consistent with the phenotype of this disease. The *FBN2* gene-associated disease is CCA, an autosomal dominant genetic disease. The proband, mother, and son are phenotypically consistent with this disease (see **Figure 3** for the genealogical tree). Consequently, the final diagnosis was BHD syndrome and CCA.

DISCUSSION

In this study, we report for the first time an extremely rare family with BHD syndrome and CCA. This combination has not been reported in China or abroad until now. Compared to Caucasians,

FIGURE 2 | Family whole exome sequencing results. FLCN gene c.1015C > T (p. Gln339Ter) mutation sequencing results in the proband (2a, heterozygous mutation) and his son (2b, heterozygous mutation). FBN2 gene c.3485G > A (p. Cys1162Tyr) mutation sequencing results in the proband (2c, heterozygous mutation) and his son (2d, heterozygous mutation).

FIGURE 3 | The genealogical tree of Birt-Hogg-Dubé syndrome and congenital contractural arachnodactyly. Blue indicates the patient. The proband (4), his son (15), and his mother (2) all have BHDS and CCA.

Asians with BHD syndrome have a lower incidence of skin and kidney manifestations but a higher rate of pneumothorax recurrence (Park et al., 2017). Indeed, the risk of pneumothorax in BHD patients is 50 times higher than the

general population (Kennedy et al., 2016). Pulmonary cysts, multiple and bilateral, occur in 80–100% of patients with BHD syndrome, and 76% of them have pneumothorax. BHD syndrome is one of the most common causes of familial spontaneous

pneumothorax (Liu et al., 2020). Thus, a family history of pneumothorax is an important clue that suggests a BHD diagnosis (Gupta et al., 2016). The pulmonary manifestations of BHD syndrome need to be distinguished from other diffuse cystic lung diseases, such as lymphangioleiomyomatosis, Langerhans cell histiocytosis, and lymphocytic interstitial pneumonia (Cui et al., 2016). Unlike other cystic lung diseases, BHD disease does not cause progressive lung function loss or chronic respiratory insufficiency (Liu et al., 2020). According to the literature, the prevalence of renal involvement in BHD patients ranges from 6.5 to 34% (Kunogi et al., 2010). Furuya et al. (Furuya et al., 2016) found that 25.8% of BHD patients have renal damage, especially renal cell carcinoma, the most common histology in chromophobe renal cell carcinoma (43.6%), and all patients with renal involvement also have lung cysts. Kidney cancer is the most serious manifestation of BHD syndrome.

The skin manifestations of BHD syndrome include fibrofolliculoma, trichodiscoma, and perifollicular fibroma. These three types are papules that are between 2 and 4 mm, flesh-colored or light gray-white, and smooth dome-shaped. They are commonly found on the face, neck, and trunk (Aivaz et al., 2015). The most common skin manifestation of BHD syndrome is fibrofolliculoma, where their numbers can range from two to more than 100. Fibrofolliculoma is rare and unique to BHD syndrome and can be diagnosed using needle biopsies (Tong et al., 2018). This patient's family currently has no skin or kidney manifestations, but they require regular review and follow-ups.

The diagnosis of BHD disease needs to be combined with family history and clinical and/or skin histopathological criteria. Its management mainly includes early pleurodesis in the case of pneumothorax, regular kidney imaging for tumor detection, and diagnostic tests to find BHD syndrome among the patient's relatives (Gupta et al., 2016). For patients diagnosed with BHD syndrome, follow-ups should be initiated, with special attention to the condition of the kidneys. Currently, pneumothorax is usually treated symptomatically, and electrocoagulation, laser, and curettage are generally used for treating skin lesions.

In this family, both the proband and his son had recurrent spontaneous pneumothorax. First, we must be alert to the possibility of familial pneumothorax. After a clear diagnosis, kidney tumors and skin lesions should be ruled out. If corresponding symptoms occur, seek medical attention in time. It is recommended to screen the genetic locus in members of the subject's blood-related family, establish a follow-up plan for carriers as soon as possible, and conduct genetic counseling in situations involving fertility. At present, this disease has no special treatment and should be tracked via regular follow-ups.

The main clinical features of CCA are spider finger (toe), flexion finger, major joint contracture, scoliosis, pectus excavatum, and helix shrinkage (Xu et al., 2020). Marfan syndrome (MFS) is a rare autosomal dominant multi-system disease, and it is manifested via bone, eye, skin, and cardiovascular symptoms (Verstraeten et al., 2016). CCA and MFS have many common clinical features, including the so-called Marfan-like appearance, which consists of a tall, slender, and weak appearance as well as skeletal features that include spider fingers, bipedal deformities, pectus excavatum, and kyphosis

(Inbar-Feigenberg et al., 2014). However, most patients with CCA have helix shrinkage, flexion contracture, and muscle hypoplasia (Lavillaureix et al., 2017). MFS and CCA are two similar syndromes that are caused by mutations in genes *FBN1* and *FBN2*, respectively (Frédéric et al., 2009). They are difficult to distinguish based on clinical symptoms alone (Gupta et al., 2004); the best way to differentiate them is via genetic testing.

The clinical manifestations of CCA patients are different, involving the heart, bones, lens, and other parts, requiring individualized treatment for the patients. Flexion contractures of the large joints of the extremities often do not require targeted treatment, while hand joint contractures can loosen joints and skin grafts to improve appearance and function. Kyphosis and scoliosis deformity can be corrected by surgery if it affects life. Severe heart deformities often require early surgical treatment, and regular follow-up monitoring is required for non-severe ones (Yin et al., 2020). The proband, mother, and son in this family all have congenital hand deformities with mild symptoms and do not affect normal functions. Since the mother of the proband also has hand deformities, and because the mother is deceased, it is recommended to send samples from the maternal relatives of the proband for screening at this site and establish a follow-up plan for carriers as soon as possible. Genetic counseling when there is a need for fertility.

CONCLUSION

WES is currently the gold standard for diagnosing these two familial genetic diseases. For patients with chest tightness, shortness of breath, recurrent spontaneous pneumothorax, and congenital hand deformity without inducement, genetic sequencing should be carried out as soon as possible to make a clear diagnosis, which can guide treatment and genetic counseling. Lifelong follow-up after the diagnosis is made to control the patient's progress in time and reduce complications.

Declarations

Ethical Approval and Consent to participate The study was approved by the hospital ethics committee (2021-03-B024), and the family members signed informed consent forms.

Consent for publication Subject agrees.

Report: Novel MFSD8 Variants in a
Chinese Family With Neuronal Ceroid
Lipofuscinoses 7.
Front. Genet. 13:807515.
doi: 10.3389/fgene.2022.807515

Neuronal ceroid lipofuscinoses (NCLs) are among the most common progressive encephalopathies of childhood. Neuronal ceroid lipofuscinosis 7 (CLN7), one of the late infantile-onset NCLs, is an autosomal recessive disorder caused by mutations in the *MFSD8* gene on chromosome 4q28. Almost all reported mutations of *MFSD8* in CLN7 patients were SNVs. However, we report a 4-year-old boy with CLN7 harboring compound heterozygous mutations in the *MFSD8* gene, including one novel two-nucleotide deletion c.136_137delAT (p. M46Vfs*22) and one whole gene deletion of *MFSD8* confirmed by Sanger sequencing, genomic quantitative PCR and CNV-seq. Therefore, for nonconsanguineous CLN7 patients with homozygous mutations in the *MFSD8* gene, genetic counseling staff should focus on the possibility of whole gene deletion. This is one case report describing a whole gene deletion in a Chinese patient with CLN7, suggesting the diagnosis of CLN7 should be based on clinical suspicion and genetic testing.

Keywords: neuronal ceroid lipofuscinoses, CLN7, MFSD8, whole gene deletion, mutation

INTRODUCTION

Neuronal ceroid lipofuscinoses (NCLs), among the most common progressive encephalopathies of childhood, with ages of onset ranging from birth to adulthood (Williams et al., 2006; Jalanko and Braulke, 2009), are a clinically and genetically heterogeneous group of neurodegenerative disorders (Schulz et al., 2013; Zare-Abdollahi et al., 2019). NCLs are ultrastructurally characterized by the intracellular accumulation of autofluorescent lipopigment storage material in different patterns (Goebel and Wisniewski, 2004). Patients developing such disorders may suffer from cognitive impairment (HP:0100543), motor deterioration (HP:0002333), progressive visual loss (HP:0000529), and uncontrolled seizures (HP:0001250) (Goebel and Wisniewski, 2004; Mole et al., 2005). NCLs are historically classified into four major subtypes based on the age of onset: infantile, late infantile, juvenile, and adult (Butz et al., 2020). To date, thirteen causal genes have been identified in different subtypes (Kohan et al., 2011; Chartier et al., 2021). One gene can be involved in different clinical forms, and conversely, one clinical form can be due to different genes (Mole et al., 2019).

Neuronal ceroid lipofuscinosis 7 (CLN7; OMIM: 610951) is an autosomal recessive disorder caused by mutations in the *MFSD8* gene on chromosome 4q28 (Kousi et al., 2009). *MFSD8* (NP_001358525) encodes a 518-amino acid integral lysosomal transmembrane protein that includes twelve membrane-spanning domains with cytosolic N- and C-terminal domains (Siintola et al., 2007). More than 40 different *MFSD8* mutations, including missense, nonsense or Indel mutations,

have been detected, causing an accumulation of cellular glycoproteins and lipoproteins, ultimately resulting in cellular degeneration and the occurrence of CLN7 (McBride et al., 2018).

To date, next-generation sequencing (NGS), which enables fast and cost-effective generation of genome-scale sequence data with exquisite resolution and accuracy, has been increasingly used as a diagnostic tool in the clinic (Xuan et al., 2013; Sawyer et al., 2016). Technologies including target NGS panel (Panel), clinical exome sequencing (CES), whole exome sequencing (WES), CNV-seq and whole genome sequencing (WGS) have greatly improved the diagnosis rate for inherited diseases (Xue et al., 2015; Monlong et al., 2018).

We report one case of a 4-year-old boy with CLN7 who presented with global developmental delay (GDD) (HP:0001263), sleeping disturbance (HP:0002360), and ataxia (HP:0001251) with no ocular abnormalities (HP:0000478) and who harbored novel compound heterozygous mutations in *MFSD8* (c.136_137delAT, p. M46Vfs*22, inherited from the mother and one whole gene deletion, inherited from the father). This is the first report of two severe *MFSD8* trans-mutations associated with CLN7 in a Chinese family.

METHODS AND MATERIALS

Subjects and Clinical Assessment

Four members of a nonconsanguineous Chinese family with one individual affected by GDD were recruited for this study. Magnetic resonance imaging (MRI) and the 24-h video electroencephalogram (EEG) were performed on the proband and an additional three non-affected family members. The Psychiatric Class B scale and the Sign-significant relations were used to assess the developmental characteristics of the proband. After obtaining written informed consent, peripheral venous blood samples were collected from the four family members. A statement of informed consent was obtained from the parents of all subjects under the age of 18 after full explanation of the procedure. The research protocol was reviewed and approved by the ethics committee of Henan Children's Hospital in accordance with the Declaration of Helsinki.

Whole Exome Sequencing and CNV-seq

Total genomic DNA was extracted from peripheral blood with the QIAamp® DNA Blood Mini Kit (QIAGEN, Hilden, Germany) according to the manufacturer's protocol. A NanoDrop spectrophotometer was used to measure DNA purity and concentration. The method of WES and CNV-seq was previously described (Gao et al., 2019).

For WES-seq, DNA libraries were prepared using xGen Exome Research Panel v1.0 (Integrated DNA Technologies, Inc., Coralville, IA, United States) according to manufacturer's protocol. Sequencing was performed on Illumina HiSeq2500 platform to a mean per-sample depth of 100×. After sequencing, the reads were mapped to the hg19 human reference genome using Burrows-Wheeler Aligner and variants were called using the Genome Analysis Toolkit (GATK).

SAMtools and Pindel were subjected to call SNVs and Indels, respectively. The variants with minor allele frequency >1% in dbSNP, NHLBI exome sequencing project (ESP1), ExAC database, the 1,000 genomes project database, and 200 in-house controls were removed. The pathogenicity of the variants was predicted using the Sorting Intolerant From Tolerant (SIFT), Polymorphism Phenotyping v2 (PolyPhen-2), Combined Annotation Dependent Depletion (CADD) and Mutation Taster. Each variant identified in a known neurodevelopmental disease gene as selected from OMIM (4 August 2021) could be considered as potential disease-causing variants according to the guidelines of the American College of Medical Genetics and Genomics (ACMG). Possible pathogenic genes were identified based on heredity models, deleterious variants and clinical phenotypes.

For CNV-seq, more than 1 µg genomic DNA was broken into 200–300 bp fragments for library preparation and sequenced on the Illumina HiSeq 2,500 (Illumina, San Diego, United States). Raw data were analyzed by fastp v0.18.1 software, and clean data were then subjected to human reference genome (hg19) analysis using BWA. After PCR duplications were removed by Picard MarkDuplicates, the mixture-hidden Markov model (*m*-HMM) approach was applied to estimate the window-based copy number change points and copy number states. An in-house pipeline was used to map and call CNVs larger than 100 kb. Candidate CNVs were annotated by analyzing the genes contained in the CNVs and the CNV intervals themselves with the databases Decipher v11.8, ClinVar, ClinGen, and OMIM. Then the candidate CNVs were filtered with normal frequency databases DGV v107 and ISCA. Interpretation of constitutional CNV was based on annotation information and frequency database (less than 0.5%) according to ACMG as reported previously.

Sanger Sequencing

The candidate disease-causing variants were confirmed by Sanger sequencing. Amplification was performed using the following primers: 5'-GTTCTAGGGATTGGTTGCACA -3' (forward) and 5'-TGCTGTCATCAAGTAGAGCATG-3' (reverse). Parent and sibling samples, where available, were also analyzed by Sanger sequencing to determine if the origin of the variant was paternal, maternal, or *de novo*.

Genomic Quantitative PCR

Deletions in *MFSD8* were validated by qPCR using ABI Quant Studio six Flex (Thermo Fisher). We designed two pairs of primers within the *MFSD8* gene (**Supplementary Table S1**). qPCR was carried out in a total volume of 10 µL containing 5 µL of TB Green® Premix Ex Taq™ (Tli RNaseH Plus) (TaKaRa Biotechnology, Dalian, China), 0.2 µL ROX Reference Dye II, 0.4 µM of each primer and 20 ng of genomic DNA. All samples were run in triplicate. Thermal cycling conditions were 95°C for 30 s, followed by 40 cycles at 95°C for 5 s and 60°C for 30 s. The *ALB* gene was selected as the control amplicon. The dosage of each amplicon relative to *ALB* and normalized to the mother's DNA was determined using the $2^{-\Delta\Delta C_t}$ method.

FIGURE 1 | Brain MRI of the proband. Widened cerebellum sulci. Axial T2-weighted FLAIR image (A,B). Abnormal signals of white matter near the posterior horn of bilateral lateral ventricles. Axial T2-weighted FLAIR images (C,D). Widened bilateral cerebral hemispheres sulci. Axial T2-weighted FLAIR image (E,F). Widened bilateral cerebral hemispheres and cerebellar sulci. Sagittal T1-weighted images (G,H).

RESULTS

Case Description

The proband, a 4-year-old boy, was born after an uneventful pregnancy and delivery, with nonconsanguineous marriage of his parents. He was born at the gestation period of 36 weeks plus 5 days with a birth weight of 3,500 g. The patient suffered jaundice approximately 1 month after birth and received blue light radiation and oral medication. He presented some phenotypes, such as cognitive impairment, motor deterioration, expressive language delay (HP:0002474), sleeping disturbance, and ataxia (HP:0001251), with no ocular abnormalities. His lower limbs were prone to involuntary tremors and he would fall when tired or frightened. On physical and neurological examinations at admission, he had a weight of 18.3 kg, a height of 105 cm, and a head circumference of 49.5 cm. The MRI of the brain showed bilateral widening of the cerebral hemispheres and cerebellar sulci and abnormal white matter signals in the posterior horns of both sides of the ventricle (Figure 1). The 24-h video EEG showed abnormal activity: widespread sharp waves, sharp slow waves, and pointed slow wave emission. Slow waves were discharged from the tip of his right forehead during sleep. According to the Psychiatric Class B scale, at the age of four, his exercise and social adaptation were equivalent to 12 months, and his intelligence was equivalent to only 11 months. The development score showed the mental index (MI) < 44 points and the developmental quotient (DQ) < 44 points. The Sign-significant relation (S-S) also indicated

language developmental delay. Due to these clinical and laboratory findings, he was diagnosed with GDD.

Genetic Analyses

The average coverage for exome sequencing of the proband was approximately 100×, and the mean sequencing depth of the deletion region (chr4:128846736–128976763) at 4q28.2 was 46×, respectively. After a step-by-step bioinformatics analysis containing base calling, variant annotation, and biological function prediction, only a novel homozygous mutation in *MFSD8* (NM_001371596.2: c.136_137delAT, p. M46Vfs*22) was identified as being responsible for the boy's phenotype. The AT deletion caused a frameshift mutation with a change in amino acids from 46 to 68 and introduced a new terminating TAA codon at position 69. According to ACMG guidelines, the c.136_137delAT (p. M46Vfs*22) variant is classified as “likely pathogenic (LP)” (one PVS1: LOF mutation + one PM2: the frequency of all normal population databases is less than 0.0005). Sanger sequencing revealed that the mother was a heterozygous c.136_137delAT carrier and that the father was a non-carrier (Figure 2). These data support the view that one mutation was inherited from the mother and another was *de novo*. To further investigate whether the proband's GDD phenotype was related to the deletion of the paternal genome, we performed qPCR using primers to amplify exon 11—intron 11 (F1R1) and exon 12 (F2R2) of *MFSD8* (NM_001371596.2). Deletions were validated in the proband and his father. Furthermore, we conducted CNV-seq and detected a deletion of approximately 130 kb (chr4:128846736–128976763) at 4q28.2 and confirmed that the identified deletion was paternal,

indicating that both the father and proband were heterozygous for the whole *MFSD8* deletion (**Figure 2**). As far as we know, the identified ~130 kb deletion is not present in our homemade exome database, which contains 200 samples, or in public databases. In addition, according to the ACMG guidelines for sequence variants, the deletion was classified as “pathogenic”. All of the above results indicated that the compound heterozygous variants were very likely to be the genetic cause of the proband’s GDD phenotype.

DISCUSSION

GDD is an underdiagnosed condition, likely due to its heterogeneous etiology, presentation, and course (Vasudevan and Suri, 2017; Belanger and Caron, 2018). CLN7 is initially diagnosed as GDD and remains a devastating pediatric disease for which there are currently no cures (McBride et al., 2018; Kohlschütter et al., 2019). Although treatments may be useful to slow or even halt disease progression, few therapies are unlikely to reverse the disease (Specchio et al., 2021). In this work, we identified a 4-year-old boy with CLN7 harboring compound heterozygous mutations in *MFSD8* (c.136_137delAT and one whole gene deletion).

The etiology of CLN7 was due to mutations in the *MFSD8* gene. As a member of the major facilitator superfamily of active transport proteins, the *MFSD8* protein posits transport solutes across the lysosomal membrane to aid in the digestion and clearance of cellular biomolecules, although the exact function of *MFSD8* remains elusive (Sharifi et al., 2010). Human Gene Mutation

database (HGMD), indicates that more than 40 mutations have been reported in association with CLN7, among which 30 mutations are nonsense or missense, five mutations are splicing, while six are small indel mutations. Because CLN7 exhibits a variable spectrum of clinical manifestations and the genetic variants may have different effects on the presence and function of the *MFSD8*, the explanation for the phenotypic variability most likely resides in the genotype of the patients. Non-functional variants result in severe clinical features of CLN7 while dysfunctional variants with residual activity may result in a markedly attenuated presentation. To the best of our knowledge, our case is the first report describing an ~130 kb deletion at 4q28.2 in a Chinese patient with CLN7. The deleted region contained *MFSD8* and *ABHD18* genes (**Figure 3**). Despite the ubiquitous expression of *ABHD18*, the characteristics and function of *ABHD18* are still unknown. *MFSD8* is the causative gene of CLN7, which supports the conclusion that the severe phenotype seen in this patient was attributable to biallelic null variants leading to non-production of *MFSD8*. This finding will give us a better understanding of the pathogenicity of *MFSD8* and provide new insight into how *MFSD8* works and functions to cause CLN7.

MFSD8 plays an important role during growth and development, not only in humans but also in other animals. In fact, animals such as Japanese macaques and mice with mutations in the *MFSD8* gene had similar symptoms to humans with *MFSD8* mutations. Japanese macaques with a homozygous frameshift mutation in the *MFSD8* gene (*MFSD8*^{-/-}) display progressive neurological deficits, including visual impairment, tremors, incoordination, ataxia and impaired balance (McBride et al., 2018). Homozygous *MFSD8* (tm1a/tm1a)

mice biochemically resembled human CLN7 patients, showing signs of the accumulation of autofluorescent material in the brain and peripheral tissues (Damme et al., 2014).

NCLs are characterized by decreased cognitive impairment, motor deterioration, progressive visual loss, and uncontrolled seizures (Mole et al., 2005). Our case carried two severe trans-mutations (one frameshift deletion and one whole gene deletion) without ocular abnormalities, which provides more evidence for the genotype-phenotype model in which a combination of a severe and mild variant cause nonsyndromic macular dystrophy with central cone involvement, and two severe mutations cause variant late-infantile neuronal ceroid lipofuscinosis (Roosing et al., 2015).

Autosomal recessive disorders such as CLN7 have been associated with homozygous or compound heterozygous mutations. In our report, no definite diagnosis could be given to the 4-year-old boy with GDD until WES was conducted. Initially, when focusing only on the c.136_137delAT (p. M46Vfs*22), the two-nucleotide deletion was thought to be homozygous, which seemed to fit the recessive inheritance pattern in consanguineous families. However, this conclusion was determined to be incorrect when the deletions were verified by qPCR. This uncommon compound heterozygous mutation composed of one two-nucleotide deletion inherited from the mother and one large mutation inherited from the father reminds us of the important role of WES accompanied by CNV-seq in clinical diagnosis. With the correct explanation for causing CLN7, appropriate medical genetic counseling can be given to this family. Therefore, for patients exhibiting homozygous mutations in *MFSD8*, medical staff should focus on the whole *MFSD8* gene deletion.

In summary, the clinical manifestation of movement disorders in patients with CLN7 has not been fully elucidated. Here, whole *MFSD8* gene deletion has been found to underlie CLN7. The uncommon compound heterozygous *MFSD8* mutations in this family show further heterogeneity of CLN7 at the DNA level. The increasing recognition of different mutations may provide insight into the unknown mechanisms involved in the development of CLN7.

DATA AVAILABILITY STATEMENT

Background: Sotos syndrome is an autosomal dominant disorder characterized by overgrowth, macrocephaly, distinctive facial features and learning disabilities. Haploinsufficiency of the nuclear receptor SET domain-containing protein 1 (*NSD1*) gene located on chromosome 5q35 is the major cause of the syndrome. This syndrome shares characteristics with other overgrowth syndromes, which can complicate the differential diagnosis.

Methods: Genomic DNA was extracted from peripheral blood samples of members of the same family and targeted exome analysis was performed. *In silico* study of the variant found by next-generation sequencing was used to predict disruption/creation of splice sites and the identification of potential cryptic splice sites. RNA was extracted from peripheral blood samples of patients and functional analyses were performed to confirm the pathogenicity.

Results: We found a novel c.6463 + 5G>A heterozygous *NSD1* gene pathogenic variant in a son and his father. Molecular analyses revealed that part of the intron 22 of *NSD1* is retained due to the destruction of the splicing donor site, causing the appearance of a premature stop codon in the *NSD1* protein.

Conclusions: Our findings underline the importance of performing RNA functional assays in order to determine the clinical significance of intronic variants, and contribute to the genetic counseling and clinical management of patients and their relatives. Our work also highlights the relevance of using *in silico* prediction tools to detect a potential alteration in the splicing process.

Keywords: next-generation sequencing, *NSD1*, Sotos syndrome, molecular analysis, RNA, splicing mutation

INTRODUCTION

Sotos syndrome (OMIM #117550) is a rare autosomal dominant disorder characterized by overgrowth (increased height, macrosomia, and macrocephaly), characteristic facial features and learning and intellectual disabilities (1). Other associated clinical features include scoliosis, seizures, renal and cardiac anomalies (2, 3).

Sotos Syndrome is caused by heterozygous pathogenic variants in the nuclear receptor SET domain-containing protein 1 (*NSD1*) gene located on 5q35. *NSD1* encodes a histone methyltransferase that catalyzes the transfer of methyl groups to lysine residues of histone tails (4). The overall prevalence of this syndrome is estimated at 1 in 14,000 (5). More than 95% of the cases arise from *de novo* mutations and familial cases of Sotos syndrome account for about 5% of the diagnoses (6–8).

This syndrome shares characteristics with other overgrowth syndromes, which can complicate the differential diagnosis. The greatest phenotypic overlap is between Sotos and Weaver syndromes (5, 6). The clinical features of post-natal overgrowth, advanced bone age, and intellectual disability particularly in the context of mild facial dysmorphism can make it difficult to distinguish between these syndromes (6).

Targeted exome sequencing has become a powerful and useful method to diagnose patients with suspected overgrowth disorders (9). After performing next generation sequencing (NGS) studies, different novel variants of uncertain significance (VUS) can be detected in the studied patients so it is crucial to characterize their biological impact and determine their pathogenicity. In the case of variants that have been shown by bioinformatics programs to alter the splicing process, functional approaches such as RT-PCR analysis of patient-derived RNA or minigene splicing assays can be used to assess the effect of these variants on mRNA splicing (10, 11). The relevance of reclassification of splice variants classified as VUS lies in the fact that the patient needs to follow precise medical management, in accordance with the international guidelines (12, 13).

In this study, we report one novel intronic *NSD1* variant in two members of the same family. Clinical, familial and molecular data, together with our experimental RNA functional assays, have provided a pathogenicity characterization of the *NSD1* variant.

MATERIALS AND METHODS

Patients

A Spanish boy and his father were recruited. This study was conducted in full accordance with the World Medical Association Declaration of Helsinki (version 2008) and the additional requirements. Informed consent approved by the clinical ethical committee of Cruces University Hospital (Spain) was obtained prior to genetic testing.

Next Generation Sequencing Studies and Sanger Validation

Genomic DNA was extracted from peripheral blood and targeted exome analysis was performed in the Institute of Genomic Medicine (IMEGEN, Valencia, Spain). The analysis of the genes

associated with overgrowth syndromes included: *AKT1*, *APC2*, *CDC45*, *CDC6*, *CDKN1C*, *CDT1*, *DICER1*, *DIS3L2*, *DNMT3A*, *EED*, *EZH2*, *FBN1*, *GMNN*, *GPC3*, *GPC4*, *H19*, *HERC1*, *IGF2*, *MCM5*, *MYO5A*, *NFIX*, *NSD1*, *OFD1*, *ORC1*, *ORC4*, *ORC6*, *PIK3CA*, *PTEN*, *RNF135*, *SETD2* and *SUZ12*. For this purpose, the exonic regions of interest were captured using the kit xGen Exome Panel v1.0 (IDT) and pair-end libraries were generated. Ultrasequencing was performed on the NextSeq 500 sequencing system platform (Illumina). Bioinformatics analysis of the data was done using Data Genomics Exon Pipeline software (version v1). Subsequently, the results were interpreted and prioritized. Changes with a number of readings >20 and with a frequency greater than 30% were considered variants. The variants detected were analyzed in four different databases (Exome Aggregation Consortium, 1000 Genomes, Human Gene Mutation Database and Exome Variant Server) and *in silico* prediction programs (SIFT, Polyphen-2, and MutationTaster-2). Conventional Sanger sequencing in genomic DNA validated candidate variant. Primers used were NSD1gF 5'-ACCCATTGCCACGGAAGAAA-3' and NSD1gR 5'-CAC CGCTGTCCCATTTCTTCA-3'.

Splicing *in silico* Analyses

In silico study of the variant found by NGS was used to predict disruption/creation of splice sites and the identification of potential cryptic splice sites. The following online programs were used: NNsplice (http://www.fruitfly.org/seq_tools/splice.html) and Human Splicing Finder (<http://www.umd.be/HSF/>).

RT-PCR and cDNA Analysis

cDNA was obtained using Superscript RT II enzyme (Invitrogen, Carlsbad, CA, USA) from 500 ng of total RNA extracted from peripheral blood in a volume of 20 µl. cDNA was amplified and sequenced to identify potential splicing variants. Primers used for cDNA amplification and identification of splice variants were: NSD1cF 5'-CCAAAGAATCAACCCATTGC-3' and NSD1cR 5'-GATTGCTCTGCCAGGTGAGT-3'. Primers for new splice variant sequencing were: NSD1svF 5'-AGCAGGTTGATGCCA AAATC-3' and NSD1svR 5'-CTCTGCCAGGTGAGTGCTT-3'.

RESULTS

Patients

The proband was a 3-year-old male patient being the second child of a non-consanguineous Spanish couple. He presented with plagiocephaly, asymmetric facies, high palate with decreased posterior palatal movement and uvula slightly deviated to the left. Prominent chin and prominent forehead were also present. Ear pinnae were well implanted. Chest and abdomen did not show alterations and no scoliosis was observed. Size was 111.5 cm (>p99 +3.3 SDS), height 23 kg (p99, +2.3 SDS) and head circumference 54 cm (>p99, +2.5 DS). Full limbs, symmetrical, with large hands and feet and thumbs of the four extremities wide (Figure 1A). Smooth skin, no spots, no asymmetric overgrowths and no alterations of subcutaneous tissue were noticed. Psychomotor development considered within normality except for delayed speech, language articulation problems, with

FIGURE 1 | Physical characteristics of the patients and confirmation of the *NSD1* gene variant. **(A)** Photographs of the two patients showing large hands in both of them and macrocephaly, facial asymmetry and tall height in the father. **(B)** Electropherogram of the genomic sequence obtained by Sanger sequencing confirming the *NSD1* variant identified by targeted exome sequencing in the patients. The control did not present the variant.

communicative intention. No seizures. Features were shared with his 43-year-old father presenting with tall stature (184 cm, p84 +1.02 SDS), macrocephaly, facial asymmetry (**Figure 1A**) and velopalatine insufficiency. Intelligence was normal-low and he had no seizures. Paternal grandfather, deceased, seemed to present with macrocephaly and facial features similar to the father.

Targeted Exome Analysis

Father's DNA was used for Next Generation Sequencing studies. In total 94.8% of the region of interest (coding region of the selected genes) was covered at least 20X. A heterozygous change was detected in intron 22 of the *NSD1* gene c.6463 + 5G>A (NM_022455.4). This change was not previously described and it was considered a variant of uncertain significance. In total 100% of the region of interest of the *NSD1* gene was covered with a depth greater than 20X. The coding region of this gene was covered with an average depth of 93.4X. The presence of this variant was validated in the father and his son by Sanger Sequencing (**Figure 1B**) and was not identified in the healthy sister of the proband.

In silico Analyses

The Human Splicing Finder program predicted an alteration of the donor site indicating a probable disruption of splicing in intron 22. The NNSplice program predicted that the score for the

donor splice site changes from a high value of 0.80 in the wild type sequence to a low value of 0.23 in the mutated sequence indicating that the donor consensus sequence is weakened. The next donor splice site in the mutated sequence in the intron 22 was predicted to be 120 bp far from the first one indicating that the variant could induce the retention of part of the intron (**Figure 2A**).

Molecular Characterization of the New Variant

To perform the functional studies, RNA samples were obtained from the father, the son and two healthy controls. *NSD1* transcripts were first analyzed by PCR in two controls. Only one band corresponding to the size of the normal transcript was observed and it was confirmed by sequencing (**Figure 2B**). Subsequently, the same study was performed on cDNA obtained from RNA from the father and the son and the results showed two bands, the band corresponding to the normal transcript and an additional one 120 bp longer than the normal one (**Figure 2B**). The two bands obtained in each case were sequenced. Sequencing confirmed that 120 bp of the intron were retained as predicted by *in silico* analysis. The retention of 120 bp has a potential impact on the protein as a premature stop codon is produced and a PHD finger and a C5HCH domain are affected in the mutated protein (**Figure 3**). This alteration confirms the pathogenicity of the variant.

DISCUSSION

In this study, we have combined molecular, clinical and functional analysis of two patients of the same family suspected of having an overgrowth syndrome. Our main aim was to contribute to the molecular and clinical classification of the variant of uncertain significance detected in *NSD1*.

The variant found in *NSD1* by targeted exome sequencing was mapped in the position +5 of the intron 22. It is well known that the GT dinucleotide at the 5' end of an intron (positions

+ 1 and + 2) is highly conserved in human genes (> 98%) and critical for RNA splicing (14). These alterations are nearly systematically classified as pathogenic or probably pathogenic. In the position +5 of the 5' splice sites the guanine is the most frequently nucleotide found, reaching 78% conservation among over 180,000 human 5' splice sites (14) and it has been shown that disease-associated alterations are very often detected at this nucleotide (15). The variants at this position are usually classified as VUS so functional studies are required to determine their pathogenicity. Our results support the relevant role of intronic position + 5 in normal splicing and agree with previous studies showing that this position seems particularly prone to aberrant splicing when altered (10, 16). Moreover, we observed a good concordance between *in silico* programs used to predict splicing alterations and the results of the molecular assays for this variant located at the + 5 position.

To identify more disease causing variants in overgrowth syndromes there is a need to extend the studies to intronic variants. Due to the size of intronic regions, identifying deep intronic variants that affect splicing is challenging. The recent applications of whole-genome sequencing (WGS) to clinical screening studies enable the investigation of non-coding variation and identification of pathogenic deep intronic variants that lie >100 bp away from the nearest canonical splice sites (17).

In the Human Gene Mutation Database Professional 2020.4, 564 mutations have been reported in *NSD1*, 461 of them associated to Sotos Syndrome. The c.6463 + 5G>A variant is not reported in HGMD and our patients are the first ones described with this change. It is worthy to note that 24 splice variants are described as responsible for Sotos Syndrome phenotype and only one of them is mapped in position +5 of the splice site (18). This could suggest that functional studies are not being performed on variants at positions other than +1 and +2, which are necessary to confirm the diagnosis and provide correct genetic counseling. Of the 24 splice variants described in HGMD, 21 of them affect positions +1, +2, -1 and -2. The Human Splicing Finder program predicts in these variants an alteration of the donor or acceptor site depending on the position, indicating that most probably

affect the splicing process. The variant previously described at position +5, c.4378 + 5G>C, according to bioinformatics analysis causes an alteration of the wild type donor site, most probably affecting splicing. There is also a splice variant described at position -5, c.6152-5T>G, and it is predicted to alter the wild type acceptor site, most probably affecting splicing. The last variant described that is not in the canonical positions is found at position +33, c.3796 + 33A>T, and in this case, the Human Splicing Finder prediction considers no significant impact on splicing signals. The NSD family members, consisting of NSD1, NSD2 and NSD3 are methyltransferases implicated in multiple diseases (19). We have shown that the variant found in *NSD1* has a potential impact on the protein causing a shortening and affecting C5HCH and PHD finger domains due to the appearance of a premature stop codon. NSD1 binds upstream of the bone morphogenetic protein 4 promoter, enforces H3K36 methylation levels within this region, and thus promotes bone morphogenetic protein 4 transcription (20). It has been shown that the PHD5-C5HCH domains of the NSD1 protein might have chromatin targeting ability and that Sotos syndrome mutations within these domains seem to alter the normal function of NSD1 (19). This would confirm the pathogenicity of the variant present in the two patients.

CONCLUSIONS

Our findings underline the importance of performing RNA splicing assays in order to determine the clinical significance of intronic variants, and contribute to the genetic counseling and clinical management of patients and their relatives. Our work also contributes to highlight the relevance of using *in silico* prediction tools to detect a potential alteration in the splicing process.

Hypertrophic cardiomyopathy (HCM) is one of the most common hereditary diseases, and it is associated with fatal complications. The clinical heterogeneity of HCM requires risk prediction models to identify patients at a high risk of adverse events. Most HCM cases are caused by mutations in genes encoding sarcomere proteins. However, HCM is associated with rare genetic variants with limited data about its clinical course and prognosis, and existing risk prediction models are not validated for such patients' cohorts. *TRIM63* is one of the rare genes recently described as a cause of HCM with autosomal-recessive inheritance. Herein, we present two cases of HCM associated with *TRIM63*-compound heterozygous variants in young male sportsmen. They demonstrated progressively marked hypertrophy, advanced diastolic dysfunction, a significant degree of fibrosis detected by magnetic resonance imaging, and clear indications for implantable cardioverter-defibrillator. One of the cases includes the first description of *TRIM63*-HCM with extreme hypertrophy. The presented cases are discussed in light of molecular consequences that might underlie cardiac and muscle phenotype in patients with mutations of *TRIM63*, the master regulator of striated muscle mass.

Keywords: hypertrophic cardiomyopathy, *TRIM63*, MuRF1, compound heterozygote, extreme hypertrophy, diastolic dysfunction

INTRODUCTION

Hypertrophic cardiomyopathy (HCM) is the most common cardiovascular hereditary disease, and it is characterized by cardiac hypertrophy that cannot be explained solely by abnormal loading conditions (Ommen et al., 2020). The history of genetic research in HCM goes back to 3 decades, and up to date, over 450 causative mutations in at least 20 genes encoding for sarcomeric and myofilament-related proteins have been described (Geisterfer-Lowrance et al., 1990; Wolf, 2019).

Mutations in *MYBPC3* and *MYH7* are the most frequent genetic cause of HCM and attributed to more than 50% of all HCM cases. Other HCM causal mutations have been identified in *TNNT2*, *TNNI3*, and genes encoding for structural proteins (Sabater-Molina et al., 2018; Teekakirikul et al., 2019). However, in 30–40% of the cases, the origin of the disease still remains unclear despite extensive genetic testing using targeted gene panels (Wolf, 2019; Salazar-Mendiguchía et al., 2020). In the case of HCM associated with rare causative genes, the existing risk prediction models may not be accurate enough because they have not been validated for this particular population. Therefore, collecting clinical and genetic data of patient groups with the rare genetic background of HCM may facilitate the development of more accurate and personalized risk stratification algorithms.

TRIM63 (tripartite motif 63) is a gene only recently described in association with HCM (Chen et al., 2012; Salazar-Mendiguchía et al., 2020). *TRIM63* encodes muscle-specific RING-finger protein 1 (MuRF1), a member of ubiquitin ligases subfamily, such as MuRF-2 and MuRF-3.

In skeletal myocytes, upregulation of MuRF1 underlies a broad spectrum of muscle atrophy conditions (Peris-Moreno et al., 2020). In cardiac myocytes, overexpression of MuRF1 enhances susceptibility to heart failure in response to pressure overload, and its activation prevents cardiac hypertrophy (Arya et al., 2004; Willis et al., 2009). MuRF1 targets include sarcomere contractile, structural proteins, and signaling molecules (Witt et al., 2005; Polge et al., 2011; Chen et al., 2012; Maejima et al., 2014; Polge et al., 2018; Higashikuse et al., 2019; Bulatov et al., 2018). The involvement of *TRIM63* in various pathological processes has been documented in several experimental and functional studies (Chen et al., 2012; Su et al., 2014; Olivé et al., 2015; Salazar-Mendiguchía et al., 2020).

The original study of Chen et al. revealed three *TRIM63* variants in five unrelated probands among 302 probands with HCM. Additionally, they identified two loss of function variants (p.Ala48Val and p.Ile130Met) and one protein-truncation variant (p.Gln247*) detected in the heterozygous state. Experimental cellular and animal studies demonstrated the reduced colocalization of MuRF1 with α -actinin at the Z-disk level, impaired auto-ubiquitination, and depressed ubiquitination and proteasome degradation of substrates (Chen et al., 2012).

Later, the role of p.Gln247* as a single causative variant leading to HCM was challenged due to its relatively frequent detection in healthy European subjects and observation of its clinical phenotype only in the cases of compound heterozygosity or homozygous variants (Płoski et al., 2014). Su et al. found rare variants in MuRF1 and MuRF2 encoding genes in the healthy population but with a much lower frequency than in HCM. Moreover, carriers of these variants had greater maximum left ventricular wall thickness than non-carriers. Hence, rare variants in MuRF1 and MuRF2 encoding genes were associated with higher penetrance and more severe clinical manifestations of HCM, especially when coincided with other sarcomeric mutations, therefore being considered by the authors as modifiers in HCM. It is important to note that all detected rare variants were heterozygous (Su et al., 2014).

The final clarification of the *TRIM63* inheritance pattern became possible after studying 4,867 index cases with HCM (Salazar-Mendiguchía et al., 2020). *TRIM63* sequencing and subsequent familial evaluation revealed that only homozygous

and compound heterozygous carriers developed full clinical phenotype of the disease (15 patients with HCM and one with restrictive cardiomyopathy), while heterozygous individuals demonstrated mild or almost no phenotype. These data strongly support the hypothesis that *TRIM63* causes HCM with autosomal-recessive inheritance (Salazar-Mendiguchia et al., 2020).

Herein, we present two cases of *TRIM63*-associated HCM due to compound heterozygous mutations along with results of a 5-year follow-up.

CASE DESCRIPTION

Patient 1

A nineteen-year-old male patient was hospitalized due to ECG and echocardiography abnormalities detected during scheduled examination for military enlistment. The patient denied any chest pain, dyspnea, palpitations, headache, dizziness, or syncope. His medical history was notable for hypertension (maximum blood pressure of 140/90 mmHg), without antihypertensive therapy. His exercise tolerance was high, and he had been performing weightlifting for several years. The patient had normal childhood development and

demonstrated normal intelligence. He denied smoking and alcohol abuse and did not have a family history of sudden cardiac death (SCD) or early cardiovascular diseases. Physical examination revealed increased body mass index—25 kg/m² and prominent hypertrophy of upper limb muscles. ECG and Holter monitoring demonstrated sinus rhythm, signs of biventricular hypertrophy (Cornell voltage criteria is about 50 mm, R wave in ¹V 10 mm), and prolonged QT interval (QTc up to 563 ms on Holter) (**Figure 1A**). Echocardiography showed extreme asymmetric left ventricular (LV) concentric hypertrophy with a predominant increase of interventricular septum (up to 48 mm) without left ventricle outflow tract obstruction (LVOT), right ventricle (RV) hypertrophy, mild left atrium dilatation, and restrictive type of diastolic dysfunction without signs of pulmonary hypertension (**Table 1**; **Figures 1B,C**).

Stress-echocardiography excluded dynamic obstruction of LVOT (maximum pressure gradient 19 mmHg upon exertion). According to the European model “HCM Risk-SCD Calculator,” the 5-year risk of SCD was estimated as 3.6%. Therefore, an implantable cardioverter-defibrillator (ICD) implantation was not indicated, and the patient was discharged on metoprolol succinate (25 mg daily). Two years later, he noticed brief episodes of palpitations

FIGURE 2 | Instrumental findings of Patient 2. Electrocardiogram demonstrates voltage criteria of left ventricle hypertrophy and secondary repolarization changes (A). Echocardiogram correspondence to four-chamber (B) and long-axis view (C) and MRI images in the long (D) and short-axis view (E) confirm wall hypertrophy. Arrows indicate the late gadolinium enhancement phenomenon (F,G) in the basal anteroseptal segment.

resulting in clinical re-evaluation at the age of 23. Echocardiography documented an increase in LV and RV wall thickness (up to 50 and 11 mm, resp.), mitral valve systolic anterior motion, and LVOT and RV outflow tract obstruction at rest (Table 1; Figure 1 B,C). According to magnetic resonance imaging (MRI), circularly intramurally late gadolinium enhancement (LGE) was documented (Figures 1D–G; Supplementary Table S1). Re-evaluation of the 5-year risk of SCD resulted in a 4.94%

probability, a dual-chamber ICD was implanted, and metoprolol therapy was continued.

During the next 2 years, a progressive increase in myocardial mass, predominantly due to posterior wall thickness, was observed (Table 1). Holter monitoring demonstrated multiple single and paired polymorphic ventricular extrasystoles and episodes of non-sustained polymorphic ventricular tachycardia but no appropriate ICD discharges.

To uncover the molecular background of the disease, targeted genetic testing was performed using a SureSelect panel of 108 cardiomyopathy-associated genes for Patient 1 (Supplementary Table S2), and no disease-related variants were detected. A subsequent whole-exome sequencing for Patient 1 was performed as described previously using a SureSelect Human All Exon V6 r2 (60 Mbp) target enrichment kit (Agilent Technologies, Santa Clara, CA, United States) with an Illumina HiSeq instrument and SBSv4 chemistry (Vershina et al., 2020). Data curation, alignment strategy, variant calling, and filtering were performed according to GATK BestPractice recommendation using hg19 reference and annotated with ANNOVAR as previously published (Jorholt et al., 2020). Raw sequencing data are deposited at the SRA database under the reference number SRR16609854. Data interpretation was performed according to the guidelines of the American College of Medical Genetics (ACMG) (Richards et al., 2015). This resulted in the detection of two variants in the TRIM63 gene (NM_032588: c.T115G:p.C39G and NM_032588:c.481_482del: p.S161CfsTer8) in compound heterozygous form (Figure 3A; Table 2). The first variant, C39G, is newly described, absent in all available databases, and currently, according to ACMG, classified as a variant of unknown significance. A second variant, S161CfsTer8, has been described in a patient with HCM, reported in the GnomAD database (rs540072010), while being classified as a variant of unknown significance according to ACMG has been reported in ClinVar as pathogenic. No pathogenic or likely pathogenic variants or variants of unknown significance were detected in the genes causing storage diseases. Unfortunately, the parental DNA was not available for the analysis due to the parental refusal to participate in genetic analysis and *de novo*/inherited status of the variants remained unknown (Figure 3B).

Patient 2

A fifteen-year-old male, a professional soccer player, was examined due to the first syncope that occurred during a sports activity. Conventional ECG revealed ST-segment elevation and T wave inversions up to 6 mm in all precordial, I, and aVL limb leads; signs of severe LV hypertrophy (Sokolow–Lyon index was 66 mm); and borderline QTc interval (480 msec) (Figure 2A). Echocardiography demonstrated asymmetric LV hypertrophy with a maximal wall thickness of 16 mm in basal and middle anteroseptal segments without LVOT obstruction at rest and after the exercise stress test (Figures 2B,C). The cardiac MRI using gadolinium enhancement demonstrated fibrosis, but Holter monitoring did not reveal ventricular arrhythmia or conduction abnormalities (Figures 2D–G). His body mass index and physical and intellectual development were normal, and no signs of peripheral

ACMG, American College of Medical Genetics; MAF, minor allele frequency; VUS, variant of unknown significance.

myopathy were noted. The family history was free from SCD episodes, and parental ECG and echocardiography were normal. Over the next 9 years, the patient has been involved in active sport despite restrictive recommendations and remained asymptomatic. Echocardiography detected the progressive increase in septal and anterior wall thickness without LVOT obstruction and decreased LV cavity, and the appearance of LV diastolic dysfunction with mild enlargement of the left atrium was observed (Table 3). According to the ESC calculator, the estimated 5-year risk of SCD was high (7.8%) despite unremarkable Holter monitoring, but the patient refused the ICD implantation and remained only on metoprolol therapy.

A targeted sequencing using 176 cardiomyopathy-associated gene panel (Supplementary Table S3) resulted in the detection of two

variants in the *TRIM63* gene (NM_032588: c.739C>T: p.Q247X and NM_032588: c.224G>A: p.C75Y) in compound heterozygous form (Table 2; Figure 3C), and raw sequencing data are deposited at SRA database under the reference number SRR16946091. Both variants are present in GnomAD, have been previously reported in association with HCM in compound heterozygous form, and, according to ACMG, are classified as a variant of unknown significance. Similar to the previous case, no potentially causative variants were detected in the genes causing storage diseases. The parental DNA was not available for the analysis as the contact to the patient's parents was lost and he was brought up solely by his maternal grandmother. However, the Q247X variant was confirmed to be present in the maternal grandmother with no clinical and echocardiography signs of HCM (Figure 3D).

DISCUSSION AND CONCLUSION

The presented cases describe the clinical phenotype of *TRIM63*-associated HCM and extend our knowledge on rare genetic forms of one of the most common inherited human disorders. While HCM remains the most common genetically predicted cardiovascular disease, the vast majority of the cases are linked to the variants in eight sarcomeric genes (*MYBPC3*, *MYH7*, *ACTC*, *TTNI3*, *TTNT2*, *TPM1*, *MYL2*, and *MYL3*) with a clear predominance of *MYH7* and *MYBPC3* variants. Therefore, most clinical algorithms and guidelines are developed using these cohorts of patients (Ho et al., 2018; Lorenzini et al., 2020). Rare genetic forms of HCM account for only 1–2% of the cases (Lopes and Elliott, 2014). However, despite the small number of patients with rare variants, their total number makes up almost one-third of all patients with sarcomeric mutations (Ingles et al., 2019). Currently, it is not clear to what extent the common guidelines and recommendations are valid for these rare genetic groups of HCM. It is generally accepted that HCM associated with sarcomere gene mutations has a worse prognosis than non-sarcomeric forms of the disease (Ho et al., 2018; Marstrand et al., 2020). However, several exceptions exist, such as HCM, associated with *PRKAG2* gene mutations (Ahamed et al., 2020). Thus, such rare clinical variants are waiting for more cases reported along with broader clinical and prospective descriptions.

One of the rare HCM genetic variants is a form of the disease associated with the *TRIM63* gene. It has been described recently and represents one of the rare forms of autosomal-recessive or compound heterozygous form of HCM (Salazar-Mendiguchía et al., 2020). Despite the small number of cases reported by now, several characteristic features of the disease could distinguish this form from the “classical” sarcomeric phenotype. These specific characteristics include the relatively rapid increase in LV free wall thickness, the appearance of diastolic dysfunction from II to III grades with mild atria enlargements, and normal or borderline estimated pulmonary artery systolic pressure. For example, Patient 1 had extreme hypertrophy (septum up to 56 mm), progressing mainly due to posterior wall and RV wall thicknesses, shaping LVOT and RV outflow tract dynamic obstruction. To the best of our knowledge, it is the first report of *TRIM63*-associated HCM with such high magnitude hypertrophy (Chen et al., 2012; Su et al., 2014; Olivé et al., 2015; Salazar-Mendiguchía et al., 2020).

The diastolic dysfunction up to restrictive phenotype was already reported in *TRIM63*-mutation carriers by other authors (Olivé et al., 2015; Salazar-Mendiguchía et al., 2020). While not rare in some forms of HCM, restrictive phenotype had a malign prognosis in pediatric and adult patients with HCM (Maskatia et al., 2012; Li et al., 2020). In *TRIM63*-associated HCM, restrictive dysfunction could reflect the altered molecular interaction of MuRF1 with titin (Higashikuse et al., 2019). There is a MuRF1-binding site in titin adjacent to the titin kinase domain. Mutations of this region lead to hypertrophy and diastolic dysfunction in the medaka fish experimental model and Japanese patients with HCM associated with *TRIM63* (Higashikuse et al., 2019).

In addition, mutations of the titin MuRF1-binding site lead to the expression shift to the stiffer titin isoforms, increased titin binding to MuRF1, and enhanced titin degradation through ubiquitination. Thus, MuRF1–titin interaction contributed to sarcomeric protein turnover and titin isoforms switch, determining muscle compliance and diastolic function (Higashikuse et al., 2019).

The development of systolic dysfunction has been reported as a distinct feature of *TRIM63*-associated cardiomyopathies (Salazar-Mendiguchía et al., 2020). Thus, Salazar-Mendiguchía et al. demonstrated that *TRIM63*-homozygous HCM patients have significant degrees of the LGE phenomenon and progressed to LV systolic dysfunction more often than in the typical HCM, thereby representing a subgroup of increased risk of adverse events (Salazar-Mendiguchía et al., 2020). However, despite the marked degree of fibrosis reflected by LGE on MRI in both cases, no systolic dysfunction was noted in our patients. Possibly, this could be explained by the relatively young patient age, and a thorough follow-up within the next years will shed light on the frequency of systolic dysfunction in patients with *TRIM63*-associated cardiomyopathies and marked fibrosis.

MuRF1 tissue distribution raises the question of whether *TRIM63* mutations can cause skeletal myopathy. Olivé et al. reported a male patient with cardiac and skeletal myosin aggregate myopathy carrying the combination of homozygous *TRIM63* null-mutation and heterozygous *TRIM54* (encoding MuRF3) mutation (Olivé et al., 2015). Clinically, it presented as proximal muscle weakness and HCM with atrial flutter. Electron microscopy of muscle biopsy revealed, apart from I-bands and Z-discs disorganization, myosin-associated proteins aggregates and abnormal microtubules distribution in skeletal muscle cells. The latter demonstrated the possibility that MuRF1 and MuRF3 regulate not only sarcomere protein degradation but also spatial organization of the microtubules. However, whether the presence of both *TRIM63* and *TRIM54* variants or the homozygous *TRIM63* variant itself contributed to myopathic phenotype remains unclear (Olivé et al., 2015). Later, Jokela et al. described female patient with mild clinical symptoms of skeletal myopathy along with creatine kinase elevation and severe cardiac hypertrophy (in the absence of other diseases capable of producing the observed degree of hypertrophy) in association with *TRIM63*-homozygous variant alone (Jokela et al., 2019). Given that, the remarkable muscle hypertrophy of upper limbs observed in both patients potentially could reflect pseudohypertrophy due to the myopathic process. Of note, both patients performed sport and had, similar to the case presented by Olive et al., marked muscular hypertrophic phenotype (Olivé et al., 2015). Of note, Patient 1, who did sport with the prevalence of static load, displayed more severe hypertrophy. However, this notion needs further attention and deeper functional studies, including neuromyography and muscle MRI.

Our study has several important limitations. One of them is an inability to perform a genetic test on the parental DNA and identify whether three of four described variants are *de novo* or inherited.

TABLE 3 | Dynamics of echocardiography data in Patient 2

Parameter/age of examination	15 years old	19 years old	22 years old
LA, mm	39	45	47

Mitral regurgitation	mild	mild	mild
SAM of the MV	No	No	No

EDV, end-diastolic volume; EDVi, end-diastolic volume index; EF, left ventricle ejection fraction; ESVi, end-systolic volume index; ePASP, estimated pulmonary artery systolic pressure; GL strain, global longitudinal strain; LA, left atrium; LV EDD, left ventricle end-diastolic dimension; LV EDV, left ventricle end-diastolic volume; LV ESD, left ventricle end-systolic dimension; LV ESV, left ventricle end-systolic volume; LVOT PGmax, left ventricle outflow tract maximum pressure gradient; PW, posterior wall; RA, right atrium; RV, right ventricle; RVOT PGmax, right ventricle outflow tract maximum pressure gradient; RV WT, right ventricle wall thickness; RWT, relative wall thickness; SAM of the MV, systolic anterior motion of the mitral valve; SV, stroke volume; TAPSE, tricuspid annular plane systolic dysfunction.

Another important limitation is an inability to verify in both cases if two detected variants belong to the same or different alleles. In light of the recently published data on the polygenic impact of many genetic variants into HCM, the role of these and other concomitant variants in the genes not yet described in connection to the observed phenotype cannot be excluded and may need further elucidation.

In summary, we have described two new patients with HCM due to the compound heterozygous *TRIM63* variants. Both patients presented with marked progressed myocardial hypertrophy and diastolic dysfunction from II to III grades and demonstrated clear indications for ICD implantation according to the accepted risk prediction models. Further data collecting regarding rare cases of compound *TRIM63* variants associated with inherited cardiac pathology will allow developing a more personalized approach in this rare cardiac disorder.

(2022) Case Report: Next-Generation
Sequencing Identified a Novel Pair of
Compound-Heterozygous Mutations
of *LPL* Gene Causing Lipoprotein
Lipase Deficiency.
Front. Genet. 13:831133.
doi: 10.3389/fgene.2022.831133

Lipoprotein lipase deficiency (LPLD) is a rare disease characterized by the accumulation of chylomicronemia with early-onset. Common symptoms are abdominal pain, hepatosplenomegaly, eruptive xanthomas and lipemia retinalis. Serious complications include acute pancreatitis. Gene *LPL* is one of causative factors of LPLD. Here, we report our experience on an asymptomatic 3.5-month-old Chinese girl with only milky blood. Whole-exome sequencing was performed and identified a pair of compound-heterozygous mutations in *LPL* gene, c.862G>A (p.A288T) and c.461A>G (p.H154R). Both variants are predicted “deleterious” and classified as “likely pathogenic”. This study expanded the *LPL* mutation spectrum of disease LPLD, thereby offering exhaustive and valuable experience on early diagnosis and proper medication of LPLD.

Keywords: *LPL* gene, lipoprotein lipase deficiency (LPLD), familial hyperchylomicronemia syndrome (FCS), hyperlipoproteinemia, whole-exome sequencing (WES)

1 INTRODUCTION

Lipoprotein lipase deficiency (LPLD, OMIM #238600), also called familial hyperchylomicronemia syndrome (FCS) or type 1 hyperlipoproteinemia, is characterized by uncontrolled accumulation of chylomicronemia (Chait and Eckel, 2019). The frequency of LPLD is approximately 1 per million in the most populations (Brahm and Hegele, 2015), except that it is much more common in the province of Quebec, Canada due to founder effect (Gagne et al., 1989). This condition is a rare hereditary disorder with which patients usually developed signs or symptoms before the age of 10 (early-onset), with 25% presenting symptoms by the first year of life (Burnett et al., 1993). Clinical manifestations of LPLD include recurrent abdominal pain, acute pancreatitis, hepatosplenomegaly, eruptive xanthomas and lipemia retinalis. Acute pancreatitis is the most serious consequence of severe hypertriglyceridemia, with a mortality rate of 2–5% (Lowenfels et al., 2009; Omdal et al., 2011). Neurological features such as depression and intellectual decline have also been reported in patients with LPLD. Fortunately, these symptoms can be remedied after blood lipid levels normalize.

In LPLD patients, lipoprotein lipase (LPL) is usually malfunctioning or absent. The measurement of LPL enzyme activity in an assay system is an approach to establish the diagnosis but it is not routinely available. Since homozygous or a pair of compound-heterozygous variants in lipoprotein lipase protein gene (*LPL*, OMIM #609708) is the causative factor, the current mainstream approach

to diagnosing LPLD is to detect biallelic pathogenic variants in *LPL* gene. According to Human Gene Mutation Database (HGMD) professional version (Stenson et al., 2017), a total of 214 disease-causing mutations (DM) in *LPL* have been reported to be associated with LPLD or relevant phenotypes. Analysis of the distribution of mutations and expanding the mutation spectrum are necessary for further diagnosis and research on LPLD. Herein, we report the clinical, biochemical and genetic findings of a 3.5-month-old Chinese girl diagnosed with LPLD, who carries a pair of compound-heterozygous *LPL* variants including a novel one. We expanded the spectrum of *LPL* mutations associated with LPLD. We also summarized, illustrated and analyzed mutations reported worldwide.

2 METHODS

This research was approved by the Ethics Committee of Wuhan Children's Hospital (No.2017020). The patient's guardians were informed with a written consent for the investigation and publication of this study.

2.1 Clinical Data Collection

Clinical information of the patient was collected from official medical records and follow-up visits. Physical and biochemical examinations were performed in each visit, including lipid blood test, complete blood count (CBC), blood gas analysis, blood ammonia assay, blood lactic acid, blood sugar, coagulogram, antibody testing, urine organic acids (OAU) test. Abdominal and pelvic CT scanning, chest and abdominal X-ray imaging, brain MRI, brain magnetic resonance angiography (MRA), abdominal color doppler flow imaging (CDFI) and electroencephalogram (EEG) were performed. Blood amino acid and acylcarnitine profile was also analyzed by tandem mass spectrometry.

2.2 Whole-Exome Sequencing

Peripheral blood of the patient and her parents were collected and sent to Running Gene Inc. (Beijing, China) for whole-exome sequencing (WES). Genomic DNA samples were extracted using Blood DNA Kit V2 (#CW2553, Cowin Bio., Taizhou, China). Qubit dsDNA HS Assay Kit (#Q32851, Invitrogen, Carlsbad, CA) was used to determine concentrations. Gel electrophoresis were also performed for quality control. Qualified DNA samples were fragmented into 200–300 bp by sonication and then processed for DNA libraries preparation according to the manufacturer's protocol of KAPA LTP Library Preparation Kit (#KR0453, Kapa Biosystems, Wilmington, MA), which includes four standard steps: end-repair, A-tailing, adapter ligation and library amplification. Cleanups during each steps were carried out with Agencourt AMPure XP reagent (#A63882, Beckman Coulter, Brea, CA). Evaluation of prepared libraries were performed using Qubit dsDNA HS Assay Kit. Capture probes hybridized to pooled DNA libraries using the Agilent SureSelectXT2 Target Enrichment System (Agilent, Santa Clara, CA). Target fragments (exome) were fished out by hybridization with Dynabeads® MyOne™ Streptavidin T1

(#65601, Invitrogen). Purifications were performed using Agencourt AMPure XP reagent. Final libraries were evaluated by Qubit dsDNA HS Assay Kit. DNA libraries were sequenced on the Illumina NovaSeq 6000 platform as paired-end 150-bp reads.

Raw data of WES were stored as FASTQ format and processed by Fastp (Chen et al., 2018) for quality control. Qualified reads were aligned to human genome reference sequence (GRCh37/hg19) using Burrows-Wheeler Alignment (BWA) (Li and Durbin, 2009). Consensus single nucleotide polymorphisms (SNPs) and insertions and deletions (indels) were called by Genome Analysis Toolkit (GATK) (Van der Auwera et al., 2013). After quality control, called variants were annotated based on several public databases, such as 1kGenome (Genomes Project et al., 2015), ExAC (Lek et al., 2016), gnomAD (Karczewski et al., 2020), ESP6500 (Fu et al., 2013), ClinVar (Landrum et al., 2020), HGMD and in-house databases. Annotated variants were then filtered based on their relationship with disease and pathogenicity. The pathogenicity of candidate variants were predicted by multiple *in silico* algorithms, including MutationTaster2 (Schwarz et al., 2014), SIFT (Sim et al., 2012), Provean (Choi and Chan, 2015), Polyphen-2 (HDIV and HVAR) (Adzhubei et al., 2013), LRT (Chun and Fay, 2009), FATHMM (Shihab et al., 2013) and Mutpred2 (Pejaver et al., 2020). Variants were also classified based on American College of Medical Genetics and Genomics (ACMG) guidelines (Richards et al., 2015). Candidate variants, also including mutations in *PLIN1* gene (familial partial lipodystrophy type IV) and *SAR1B* gene (chylomicron retention disease), were then sent to Sanger for validation. Likely pathogenic variants were finally selected on the basis of their relationship to the disease, allele frequency in controls, pattern of segregation with disease, pattern of inheritance and predicted pathogenicity.

3 RESULTS

3.1 Clinical Presentation

A 3.5-month-old Chinese girl admitted to our hospital due to her pneumonia with fever and vomiting, but we found her blood with milky appearance during blood routine examination. She is the second child of her non-consanguineous parents (G2P2). She was born by caesarean section in the 40th gestational weeks, with a birth weight of 3.8 kg (90 percentile) and a birth height of 50 cm (50 percentile). She was under breast-fed and her mom's blood lipids were in the normal range (**Supplementary Table 1**). No abnormalities were found during pregnancy and delivery. No relevant medical history or family history was reported.

3.2 Physical Examinations

Her weight was 6 kg (25 percentile) and height was 63 cm (50 percentile) at the age of 3.5 months. A hemangioma-like red rash (1.0 × 1.0 cm) were identified on her right hypochondrium. The rash was excluded from eruptive xanthomas by dermatologists. Her liver is present 1.5 cm below the costal margin. No abnormalities found on her facial appearance, psychomotor development or muscular tension. No other relevant signs or symptoms were reported.

TABLE 1 | Biochemical examinations of blood lipid and lipoprotein levels.

ApoA1, apolipoprotein A-1; ApoB, apolipoprotein B; CHOL, cholesterol; HDL, high density lipoprotein; LDL, low density lipoprotein; LP (a), lipoprotein (a); TG, triglyceride; TG: 1 mol/L = 88.5 mg/dl.

3.3 Laboratorial Examinations

Lipid blood test revealed elevated blood triglycerides (TG) and cholesterols (CHOL) levels as well as decreased levels of low-density lipoproteins (LDL), high-density lipoproteins (HDL), apolipoprotein A1 (ApoA1) and apolipoprotein B (ApoB) (Table 1). Normal results were shown by other biochemical examinations mentioned above.

Abdominal and pelvic CT scanning with and without contrast presented peripancreatic effusion which indicates the occurrence of pancreatitis. Chest and abdominal X-ray imaging showed increased lung texture. Blood amino acid and acylcarnitine profile analysis revealed decreased levels of multiple amino acids (methionine, leucine, valine, glycine, glutamine and threonine), which may be caused by malnutrition. No clinically significant abnormalities were identified by brain MRI, MRA, abdominal CDFI and EEG.

3.4 Genetic Analysis

WES was applied to support the diagnosis. We identified a pair of compound-heterozygous variants, c.862G>A (p.A288T) and c.461A>G (p.H154R), in *LPL* gene (NM_000237, NP_000228) and validated them by Sanger sequencing (Figure 1C). Variant c.862G>A (chr8:19813438) is a missense, which leads to an alteration of protein sequence (p.A288T) (Figure 1D). The variant is located in a well-established functional domain (N-terminal lipase) (PM1). It is absent from controls or at extremely low frequencies (ESP6500, 0; ExAC, 4.12E-05; gnomAD, 5.97E-05; 1kGenome, 2.00E-04) (PM2_supporting). Variant c.862G>A has been detected *in trans* with pathogenic mutation c.836T>G (p.L279R) (PM3) (Ma et al., 1994). Multiple lines of computational evidence support the variant will cause a deleterious effect on its products (MutationTaster2, score = 1.000, disease causing; SIFT, score = 0.001 < cutoff = 0.05, damaging; Provean, score = -3.71 < -2.5, deleterious; Polyphen-2, HDIV score = 0.986 > 0.957, HVAR score = 0.933 > 0.909, probably damaging; LRT, deleterious; FATHMM, score = -3.17 < -1.5, damaging; Mutpred2, score = 0.923 > 0.7, pathogenic, gain of

phosphorylation) (PP3). Phenotypes of the patient are specific for LPLD (PP4). This variant has been recorded in dbSNP (rs1800011) and reported as likely disease-causing mutation (DM?) in multiple unrelated LPLD patients with the same phenotype according to HGMD database (PS4_moderate and PP5) (Ma et al., 1994; Rodrigues et al., 2016; Jin et al., 2018; Tada et al., 2019). Thus, c.862G>A (p.A288T) is classified as “likely pathogenic” (PS4_moderate+PM1+PM2_supporting+PM3+PP3+PP4+PP5) according to the ACMG guidelines.

Variant c.461A>G (chr8:19810852) is also a missense, resulting in an amino acid change from histidine to arginine (p.H154R) (Figure 1D). This variant is a novel one, which has not been reported in any cases before. It is located in a functional domain, N-terminal lipase domain (PM1) and is absent from controls (gnomAD, ExAC, dbSNP, 1kGenome) (PM2_supporting). It has been detected *in trans* with likely pathogenic mutation c.862G>A (PM3). Multiple lines of *in silico* algorithms predicted the variant deleterious (MutationTaster2, score = 1.000, disease causing; SIFT, score = 0.001 < 0.05, damaging; Provean, score = -7.65 < -2.5, deleterious; Polyphen-2, HDIV score = 0.983 > 0.957, HVAR score = 0.962 > 0.909, probably damaging; LRT, deleterious; FATHMM, score = -3.36 < -1.5, damaging; Mutpred2, score = 0.875 > 0.7, pathogenic, loss of catalytic residue) (PP3). Phenotypes of the patient are specific for LPLD (PP4). His154 is highly conserved across species (Figure 1E). Therefore, novel variant c.461A>G (p.H154R) is classified as “likely pathogenic” (PM1+PM2_supporting+PM3+PP3+PP4).

3.5 Treatment and Prognosis

The patient was admitted to hospital due to fever and vomiting with extremely high levels of TG and CHOL in the blood (Table 1). Anti-infective and symptomatic treatment was applied (Figure 2). Two days later, her symptoms of fever and vomiting disappeared, with a dramatic drop of TG and CHOL levels. Then, bezafibrate (10 mg/kg/d, bid) (60 mg/d) and levocarnitine (167 mg/kg/d, bid) (1 g/d) were administrated to

FIGURE 1 | Clinical and genetic information of the patient. **(A)** Pedigree analysis of this family. **(B)** Blood fractionations (set for 24 h) between control and the patient. **(C)** Sanger sequencing of variants c.862G>A and c.461A>G with corresponding wild-types. **(D)** Three-dimensional protein model of lipoprotein lipase. Polar contacts (yellow dash line) between His154 and Arg180 lost and new interactions between His154 and Tyr315 appeared after H154R alteration. With A288T variant, a new repulsion formed between Thr288 and Ile232 (red cylinder). **(E)** Multiple alignments of LPL protein sequence across 13 species. Mutation sites His154 and Ala288 are labelled by a red rectangular. "in" the last row indicates amino acid in this site is "highly conserved".

FIGURE 2 | Cholesterol (CHOL) and triglyceride (TG) levels with bezafibrate (BZF) and levocarnitine (LVC) administration. The patient was admitted to hospital with high levels of CHOL (12.58 mmol/L) and TG (67.84 mmol/L) at the age of 3 months and 16 days. Three days later, her CHOL and TG levels plummeted due to bezafibrate and levocarnitine administration. The levels kept decreasing until she was discharged. Her parents reduced the dose without professional medical advice, resulting in a severe relapse (a sharp increased TG level at the age of 6 months and 14 days). The dose of medications was then adjusted and CHOL and TG levels of the patient finally declined to normal and almost normal. (TG: 1 mol/L = 88.5 mg/dl).

enhance lipoprotein lipase activity and promote the β -oxidation of fatty acids, thereby reducing TG levels. As the patient gains weight, the dose of medications changed. During the treatment, TG and CHOL levels continued to decrease towards normal. Her apoprotein levels also recovered. Her LDL level increased and HDL level declined (still out of reference values). However, after discharge, her parents reduced the dose to a half (bezafibrate, 30 mg/d; levocarnitine, 0.5 g/d) without professional medical advice, resulting in a serious relapse (a sharp rise in TG levels at the age of 6 months and 14 days). The dose of bezafibrate was then adjusted to 60 mg/d (9 mg/kg/d, bid). Four and a half months later (the age of 11 months), the dose of bezafibrate and levocarnitine was adjusted to 100 mg/d (10 mg/kg/d, bid) and 1 g/d (100 mg/kg/d, bid), respectively. The patient's blood lipid levels finally fluctuated to nearly normal.

4 DISCUSSION

The *LPL* gene, located on chromosome 8p21.3, encodes the lipoprotein lipase which is the key enzyme of triglyceride metabolism. LPL has both triglyceride lipase and phospholipase activities in the physiological condition. It acts mainly as a triglyceride lipase with very low phospholipase activity (McCoy et al., 2002). LPL catalyzes the hydrolysis of TGs to remove lipids from circulating TG-rich lipoproteins, specifically chylomicrons and very-low-density lipoproteins

(VLDL), and thereby plays a critical role in lipid utilization and storage (Weinstock et al., 1995; Lutz et al., 2001; Pingitore et al., 2016). Lipoprotein lipase consists of two domains, lipase domain (17-338) and polycystin-1, lipoxygenase, alpha-toxin or lipoxygenase homology (PLAT/LH2) domain (343-463) (Figure 3). Same as the majority of mutations, both current variants are located on lipase domain, indicating the importance of its function and integrity. Mutations in *LPL* gene reduce or eliminate the activity of lipoprotein lipases. The absence of fully functional LPL disrupts the normal breakdown of TGs, preventing adequate clearance of circulating TG-rich lipoproteins. This impaired TG hydrolysis contributes to severely elevated TG levels (usually >16.95 mmol/L [1500 mg/dl]) in plasma (Chait and Eckel, 2019). Moreover, TGs accumulate in the blood vessels and tissues, resulting in pancreatitis, hepatosplenomegaly, eruptive xanthomas and other uncommon symptoms. Although variants in *LPL* gene usually caused lipase deficiency, the enzyme has been found overactivated in some cases, associating with lower TG levels (Smith et al., 2010). In this patient, two missense mutations resulted in reduced activity of LPL rather than complete deficiency, as bezafibrate effectively enhanced the activity of lipoprotein lipase.

There are totally 287 mutations and polymorphisms of *LPL* gene in HGMD (Figure 3), including 214 (74.6%) DM, 58 DM? 3 disease-associated polymorphisms (DP), 8 disease-associated polymorphisms with additional functional evidence (DFP) and 4 *in vitro* or *in vivo* functional polymorphisms (FP). Of these, all of 214 DMs were reported to cause LPLD or associated phenotypes clearly. In terms of the type of variants, HGMD collected 118 missense, 44 small insertion/deletion (41 frameshift and 3 inframe), 18 splice (16 canonical), 18 nonsense, 9 large insertion/deletion

(>21 bp), 2 regulatory, 3 noncoding and 2 initiation. Missense mutations account for more than half (118/214, 55.1%) of all DMs and are a common mechanism of LPLD, thereby enhancing the likelihood that the two variants reported here cause disease.

Common clinical features of LPLD include recurrent abdominal pain, acute pancreatitis, hepatosplenomegaly, eruptive xanthomas and lipemia retinalis. Some of these symptoms can be fatal for the patient, but none occurred in our patient. We attribute this to the early detection. The combination of results from biochemical examinations and genetic sequencing provides a clear direction for clinical diagnosis. More importantly, it has also led to early diagnosis and proper intervention. For LPLD patients, palliative treatment and medical nutrition therapy are commonly given depending on symptoms. Blood lipid-lowering medicines such as bezafibrate are usually administered to negatively regulate blood lipid concentrations (Bezafibrate Infarction Prevention, 2000). The maintenance of plasma TGs at less than 11.30 mmol/L (1000 mg/dl) could prevent severe complications such as severe pancreatitis, further preventing the high morbidity and mortality rate (Garg and Rustagi, 2018). In the current case, the concentrations of plasma TGs and CHOL in the patient sharply declined under the action of bezafibrate and levocarnitine. Since this early and proper administration of drugs, the patient's lipid levels are maintained at a normal level while severe complications did not occur. Meanwhile, medium-chain TGs are also recommended for daily diet, as they could be absorbed directly into the portal vein independent on chylomicrons (Burnett et al., 1993).

In summary, this study reported a novel pair of variants in *LPL* gene causing LPLD in a 3.5-month-old Chinese girl. The novel

variant, c.461A>G (p.H154R), further expended the disease-causing mutation spectrum of LPL deficiency. *LPL* mutations reported in HGMD were also reviewed and further analyzed. Missense mutations and mutations located in lipase domain account for the majority. Genetic screening can provide conclusive evidence for diagnosing LPLD. Our study and review are supportive for the early diagnosis and proper treatment of patients with LPLD in the future.

Background: Severe hyperlipidemia is characterized by markedly elevated blood triglyceride levels and severe early-onset cardiovascular diseases, pancreatitis, pancreatic necrosis or persistent multiple organ failure if left untreated. It is a rare autosomal recessive metabolic disorder originated from the variants of lipoprotein lipase gene, and previous studies have demonstrated that most cases with severe hyperlipidemia are closely related to the variants of some key genes for lipolysis, such as *LPL*, *APOC2*, *APOA5*, *LMF1*, and *GPIHBP1*. Meanwhile, other unidentified causes also exist and are equally worthy of attention.

Methods: The 29-day-old infant was diagnosed with severe hyperlipidemia, registering a plasma triglyceride level as high as 25.46 mmol/L. Whole exome sequencing was conducted to explore the possible pathogenic gene variants for this patient.

Results: The infant was put on a low-fat diet combined with pharmacological therapy, which was successful in restraining the level of serum triglyceride and total cholesterol to a low to medium range during the follow-ups. The patient was found to be a rare novel homozygous duplication variant-c.45_48dupGCGG (Pro17Alafs*22) in *GPIHBP1* gene-leading to a frameshift which failed to form the canonical termination codon TGA. The mutant messenger RNA should presumably produce a peptide consisting of 16 amino acids at the N-terminus, with 21 novel amino acids on the heels of the wild-type protein.

Conclusions: Our study expands on the spectrum of *GPIHBP1* variants and contributes to a more comprehensive understanding of the genetic diagnosis, genetic counseling, and multimodality therapy of families with severe hyperlipidemia. Our experience gained in this study is also contributory to a deeper insight into severe hyperlipidemia and highlights the importance of molecular genetic tests.

Keywords: severe hyperlipidemia, whole exome sequencing, *GPIHBP1* gene, novel variant, therapy

INTRODUCTION

Severe hyperlipidemia, with a typical feature of high concentration of lipidemia in fasting state, is primarily attributed to a genetic defect in intravascular lipolysis. Urgent clinical intervention is always required, especially for serious cases in that some severe complications, otherwise, may follow, such as pancreatitis, which contributes to 5–6% of the overall mortality, as well as pancreatic necrosis or persistent multiple organ failure that have been proved to be associated with the highest mortality rate (1). Amongst all the subtypes of severe hyperlipidemia, monogenic forms are the ones linked to the defects in metabolism of triglyceride (TG)-rich lipoproteins, namely lipolytic cascade. These defects may be caused by variants in no less than five different genes, predominantly (about 95%) inherited ones in both alleles of the lipoprotein lipase gene, which, alias as *LPL* (2), is responsible for encoding of the enzyme lipoprotein lipase (LPL; OMIM #238600). Previous studies have shown that the defects directly related to *LPL* gene variants are also relevant to the majority of severe hyperlipidemia cases (3–6). The rest 5% are the results of variants in other genes involving in LPL functioning, including *APOC2* (encoding apolipoprotein CII, activator of LPL; OMIM #207750) (7, 8), *APOA5* (encoding apolipoprotein AV, activator of LPL; OMIM #144650) (9, 10), *LMF1* (encoding lipase maturation factor 1, a tissue factor triggering the secretion of functional LPL and hepatic lipase; OMIM #611761) (11, 12), and *GPIHBP1* (encoding glycosylphosphatidylinositol-anchored high-density lipoprotein-binding protein 1, the molecular platform by which LPL is able to interact with TG-rich lipoproteins, apolipoprotein CII, and apolipoprotein AV on the endothelial surface of capillaries; OMIM #612757) (13, 14). Meanwhile, there are also other variants to be identified (3), and all these variants may result in LPL malfunction.

GPIHBP1, categorized as one of the lymphocyte antigen 6 (Ly6) family, is a capillary endothelial cell protein consisting of 184 aa. Being a critical protein for LPL transportation from the subendothelial spaces to capillary lumen, *GPIHBP1* can promote lipolysis by working as the main site to bind LPL on endothelial surface (15). So, variants of *GPIHBP1* may disturb lipolysis process and thus result in severe hyperlipidemia. However, although previous studies so far have offered some leads to the lipolytic mechanism of *GPIHBP1* and disclosed a handful of case reports concerning *GPIHBP1* variants, our understanding on *GPIHBP1*-deficient diseases is still to be deepened. In this study, we described the clinical features, genetic analysis and our hands-on experience of successful pharmacological management

of a 29-day-old baby with abnormally elevated plasma TG (25.46 mmol/L), who was subsequently identified as a rare novel homozygous duplication variant in *GPIHBP1* gene as the cause of her severe hyperlipidemia.

MATERIALS AND METHODS

Plasma Lipid Profile Analysis

Blood samples were collected after fasting for 6 h. The levels of serum glucose (Glu), TG, TC, HDL, LDL, APO-A1, and APO-B were measured enzymatically using an automatic analyzer (ADVIA 2400, SIEMENS, Germany).

Genetic Analysis

Enlightened by the abnormal clinical findings, hereditary hyperlipidemia was taken into the pediatricians' consideration for further confirmation using whole exome sequencing (WES, Illumina, San Diego, CA, USA). Details of the experiments, mutation frequency investigation, variant verification, and assessment of the conservation of amino acid residues were displayed in the **Supplementary Material** (shown in **Supplementary Material**-genetic analysis). The pathogenicity of the sequence variants was interpreted according to the American College of Medical Genetics and Genomics/Association for Molecular Pathology (ACMG/AMP) guidelines (16, 17).

The study was approved by the Ethics Committee of Guangdong Women and Children Hospital. Written informed consent was obtained from the patient's legal guardian for the publication of any potentially identifiable images or data included in this article. All the procedures carried out in our study were strictly in accordance with the Declaration of Helsinki.

RETROSPECTIVE ANALYSIS OF PATIENT'S MEDICAL RECORDS CONCERNING DEMOGRAPHICS, CLINICAL SIGNS AND SYMPTOMS, RESULTS OF BIOCHEMICAL, AND GENETIC ANALYSIS

Clinical Information

The patient was a 29-day-old Chinese female infant with a chief complaint of "irritability, fever, vomiting and convulsion for 2 days," who was enrolled in our study after consultation in the pediatric clinic of our hospital. The patient responded poorly to the treatment in previous visits to her local hospitals due to the limited health care resources there, making her condition worsening with the time. Therefore, she was referred to our hospital and finally placed in the pediatric intensive care unit. The infant is the first child of the non-consanguineous parents, with a full-term birth weight of 2,600 g. After admission to hospital, a physical examination was performed in the wake of history collection. The height of this exclusively breastfed infant was 52 cm (22.6th percentile), and the weight 3.7 kg (16.9th percentile). Appearance of low weight, malnutrition, poor response to external stimuli, and somnolence were noticed. Movement range of the joints and muscular tension of the four limbs were normal. Abdominal palpation indicated

Abbreviations: TG: triglyceride; TC: total cholesterol; HDL-C: high-density lipoprotein cholesterol; LDL-C: low-density lipoprotein cholesterol; LPL: lipoprotein lipase; APOC2: apolipoprotein CII; APOA5: apolipoprotein AV; LMF1: lipase maturation factor 1; GPIHBP1: glycosylphosphatidylinositol-anchored high-density lipoprotein-binding protein 1; Ly6: lymphocyte antigen 6; MCT: medium chain triglycerides; TPN: total parenteral nutrition; WES: whole exome sequencing; BWA: Burrows-Wheeler Aligner; GATK: Genome Analysis Toolkit; SNVs: single-nucleotide variants; OMIM: Online Mendelian Inheritance in Man; FATHMM: Functional Analysis through Hidden Markov Models; CVD: cardiovascular disease.

normal liver and spleen volume. After aggressive treatment, the infant was stabilized in vital signs, with physical examinations showing normal body temperature (axillary temperature, 37.1 degrees Celsius), normal muscle strength, muscle tension and physiological reflexes.

Unexpected discovery arose from milky blood sample (lactescent plasma) and the results of lipid testing (in fasting state), which revealed abnormally elevated TG (25.46 mmol/L; normal range, 0.46 to 2.28 mmol/L) as well as abnormal cholesterol metabolism-total cholesterol (TC, 14.53 mmol/L; normal range, 3.12 to 5.68 mmol/L), high-density lipoprotein cholesterol (HDL-C, 1.12 mmol/L; normal range, 0.91 to 2.18 mmol/L), and low-density lipoprotein cholesterol (LDL-C, 2.01 mmol/L; normal range, 1.28 to 3.41 mmol/L). The first therapeutic intervention for the infant was oral therapy free of long chain fatty acids, supplemented with high protein, high carbohydrate, and medium chain triglycerides (MCT), which lasted for 5 days but failed to control hyperlipidemia. Due to the potential risk of acute pancreatitis associated with high levels of plasma TG and the signs of hypoproteinemia as demonstrated by her low weight as well as a total serum protein and albumen of 51.2 and 28.8 g/L, respectively, enteral feeding was discontinued at the day when the baby was 1 month and 5 days old, and substituted by multimodality therapy including fasting, nasogastric drainage, total parenteral nutrition (TPN), and anti-infection treatment. After 7 days (1 month and 12 days old), plasma TG level decreased significantly to 1.50 mmol/L and TC to 9.66 mmol/L. Whereas, an evident rise in plasma TG up to 3.77 mmol/L was, again, detected after switching to breastfeeding

for 5 days (1 month and 17 days old). So the infant was put on a low-lipid formula diet, mainly STOLLE milk powder (Stolle Milk Biologics International Incorporated, New Zealand), a kind of formula low in fat and high in protein with proper amount of water-soluble vitamins added (the details of dietary interventions was shown in **Supplementary Table 1**). As a result, the plasma TG level declined promptly, ending up at 2.92 mmol/L when the infant was discharged from the hospital (2 month and 3 days old).

Considering the evidence of lipometabolic disturbance and presumed diagnosis of severe hyperlipidemia, the infant, after discharged, continued to be kept on a low-fat and high-carbohydrate protocol with proper amount of protein diet and supplementation of L-carnitine, coenzyme Q10 as well as water-soluble vitamins (B1, B2, B6, B12, C, and folic acid) during her treatment at home. Individualized dosage was given for her medication protocol and adjusted accordingly based on her clinical manifestation, the level of blood lipid, and other nutritional indicators (shown in **Supplementary Table 2**). Surveillance of her medical condition was also performed to avoid potential complications. Meanwhile, the infant continued to take examinations in our outpatient clinic, irregularly, on and off, because of poor compliance. In the follow-ups, the baby was monitored by serum TG, TC, HDL-C, LDL-C, apoprotein A1 (APO-A1), apoprotein B (APO-B), and glucose every 3 to 6 months (shown in **Supplementary Table 3**). Besides, evaluation of her physical development was conducted at a 3 month interval. The results revealed that the serum TG and TC kept fluctuating from low to medium levels (**Figure 1**), and in the last follow-up when the baby was 9 months old, she was 8.6 kg (42.2th

centile) in weight and 72 cm (56.1th centile) in height, with a head circumference of 44.5 cm (56.9th centile), indicating a good health and normal development. Likewise, laboratory tests also showed dramatic improvement as compared with her first visit, reflecting a sound developmental condition of the patient as well as the beneficial outcomes of this treatment protocol.

Based on the above findings and the latest research consensus (18), the baby was suspected of severe hereditary hyperlipidemia (triglyceride concentration >10 mmol/L), which is likely to have a monogenic cause, despite the fact that the patient's parents were healthy with normal levels of serum lipid and lipoprotein, and that the family history indicated neither hyperlipidemia nor pancreatitis. Therefore, aiming to identify the possible pathogenic gene variants for this infant, we performed this study using genetic analysis tools, with 100 Chinese healthy subjects recruited as the control group.

Genetic Findings

During hospitalization, the WES for this infant revealed the presence of a homozygous duplication variant-*c.45_48dupGCGG* (Pro17Alafs*22)-in exons 1 of *GPIHBP1* gene (Figures 2A,B). However, being heterozygote carriers of the variant, the parents did not show any symptoms of the disorder. This variant was computationally predicted to be deleterious and morbidogenic by CADD, PROVEAN, and Mutation Taster. Results of bioinformatic analysis also strongly suggested it a disease-causing variant. Moreover, this variant was not detected in any of the 100 Chinese healthy subjects in the control group, and also had not been disclosed by any public databases as mentioned above, thus ruling out the possibility of a polymorphism and suggesting its novel and rare occurrence. Ultimately, the variant was identified as a pathogenic factor according to the Sherloc/ACMG criteria: it was not recorded in

any of the existing population databases, and was assumed to be closely associated with a highly conserved amino acid, and also, to be disease-causing based on *in silico* algorithms used for pathogenicity prediction (17). In this case, the c.45_48dupGCGG duplication variant in exon 1 led to the substitution of the remaining 168 C-terminal amino acid residues with 21 mutant ones (Figure 2D), and the Ly-6 antigen/uPA receptor-like domain of this protein was also affected, thus likely to cause a direct impairment on the enzymatic activity of GPIHBP1. Meanwhile, the functional significance of the mutated amino acid is evident considering its high evolutionary conservation from mammals to invertebrates (Figure 2C). The outcomes from bioinformatic analysis strongly support that the novel homozygous variant c.45_48dupGCGG(Pro17Alafs*22) is with a disease-causing nature.

As far as we know, this is, in Chinese population, the first report of baby patient with hyperlipidemia due to *GPIHBP1* variant, and also the first case with the variant of c.45_48dupGCGG(Pro17Alafs*22) in *GPIHBP1* gene that was disclosed worldwide among patients with severe hyperlipidemia.

DISCUSSION

Clinical Management

In the present study, we delineated a 29-day-old female baby with incidentally found severe hereditary hyperlipidemia originated from a novel and homozygous *GPIHBP1* duplication variant. During the treatment, the elevated blood lipid associated with a possible risk of pancreatitis was promptly reduced to a safe level, which, we believe, was attributed to the early detection of the abnormalities in this patient, as well as the timely and effectively clinical intervention. The further administrated low-fat diet combined with pharmacological therapy, a success in constraining the blood lipid within a lower range, was considered a key contributor to the normal and healthy development of the baby over time. As things stand, hereditary hyperlipidemia, being a kind of ultra-rare monogenic disease, was commonly spotted by blood serum screening among the suspects-adults and children with obesity, pancreatitis, or xanthoma. However, even the reported cases of little baby or infant with hereditary hyperlipidemia, which were actually very few, were always with a chief complaint of fever (19, 20), vomiting (21), irritability (20), hemoptysis (22), or jaundice (23) instead of something directly linking to a confirmed diagnosis of hyperlipidemia. Therefore, it was not uncommon that the disease, in some cases, was not even on the suspect list of the pediatricians in the first place. All these facts remind us that we should be more alert and sensitive to the clues (such as the results of lipid tests) hidden behind the common presentations of infancy hyperlipidemia—a disease worthy of higher attention and deeper research. Only in this way can proper diagnostic tools (such as genetic analysis) possibly be recruited for further identification. In this study, our findings from genetic analysis have revealed the key role of genetic defects as a predisposing factor of severe hereditary hyperlipidemia, which also sheds a new light on the complexity underlying the etiology of these phenotypes.

It has been known that there are various ways to treat hyperlipidemia, including low-fat diet, pharmacological therapy, and even plasma exchange. Which one to choose usually depends on the initial diagnosis and the progression of the disease. So far, plasma exchange with direct removal of blood lipid, having been mentioned in the category III of the American Society for Apheresis 2010 guidelines, has been wildly used for hyperlipidemia treatment. However, whether plasma exchange has a beneficial effect on severe hyperlipidemia is still in dispute. In contrast, quite a few single-center clinical studies have shown that the efficacy of conservative treatment is similar to plasma exchange in lowering the serum triglyceride level, and there is no substantial difference between the two approaches in the overall benefit, specifically in terms of morbidity and mortality (24–26). In addition, the blood lipid concentration may return to the pre-apheresis levels after plasma exchange, while low-fat formula diet collocated with pharmacological therapy may be more gentle and sustainable. Moreover, the lack of availability of plasma exchange in most of medical centers as well as its rather high costs also limits its use in clinical settings. As a result, invasive therapeutic options such as plasma exchange were not considered as the first-line treatment in this case.

During hospitalization, since the patient's TG level once raised up to 25.46 mmol/L, putting her at a high risk of pancreatitis, oral medication (low-fat diet) had been suspended and replaced by total parenteral nutrition till her condition was stable, followed by a low-fat diet in combination with pharmacological therapy. This therapeutic option was proved to be sufficient in rapidly reducing the plasma TG to a safe level, and in maintaining the serum TG and TC within a low to medium range, which was also a key factor to ensure the normal growth of the patient in the following months.

Molecular Analysis

As is known that elevated plasma triglyceride may, as an independent risk factor, lead to cardiovascular diseases (CVDs). LPL plays a critical role in lipid metabolism and energy balancing by hydrolyzing the triglyceride in blood circulation. Although it is parenchymal cells that synthesize and secrete LPL, it somehow acts on the luminal capillary endothelium, so the mechanism of LPL migrating into the luminal capillary has long been among the list of relevant research (27). According to previous studies, hyperlipidemia was defined as two categories: severe (triglyceride concentration >10 mmol/L) and mild-to-moderate (triglyceride concentration 2–10 mmol/L). The former is more likely to have a monogenic cause triggered by gene variants which consequently cause LPL dysfunction (28–30). It has been understood that multiple factors can interact with LPL, positively or negatively, thus exerting an influence on TG lipolysis. Among them is a recently identified factor GPIHBP1, which is considered indispensable in transportation of LPL to the luminal capillary endothelium as well as in the establishment of the platform for TG hydrolysis (31). Currently, a large amount of evidence supports that GPIHBP1 functions in triglyceride-rich lipoprotein (TRL) metabolism of human in unique and diverse ways (32–34). Recent studies have shown that LPL mislocalization as a result of GPIHBP1 deficiency may cause severe hyperlipidemia (13, 35).

Therefore, the importance of GPIHBP1 in lipolysis is being recognized more widely with more relevant research published.

The human *GPIHBP1* gene consists of 4 exons which encode a 184 amino acid protein. An acidic domain being able to bind LPL and chylomicrons is located in the N-terminus of *GPIHBP1*. Its C-terminus is encoded by exons 3 and 4, including a cysteine-rich lymphocyte antigen 6 (Ly6) motif as well as a carboxylterminal hydrophobic sequence involved in the addition of a GPI anchor (36–39). A bunch of residues in the domain of C-terminus, such as Ser107, Thr124, and Leu135 also play a critical role in LPL binding and its transportation from subendothelial space to luminal capillary (40). Therefore, deleting exons 3 and 4 will produce a crippled protein characterized by the absence of a domain indispensable for LPL binding and translocation as well as for anchoring LPL to the cell surface. This makes sense of the phenotype in cases with severe hyperlipidemia and also explains the lack of circulating LPL and LPL activity in heparin-processed plasma. Since the initial description of hyperlipidemia resulting from the variant of *GPIHBP1* in 2007 (41), only about 50 cases have been reported worldwide (35, 42, 43). Meanwhile, the genotypic spectrum based on HGMD has recorded 47 various pathogenic variants in *GPIHBP1* that can result in severe hyperlipidemia, with most of them (33/47) identified as missense variants. Tendency of these variants toward any ethnicity or racial groups was not observed. Therefore, thorough analysis on these disease-causing variants probably linking to developmental malfunction and phenotypic changes is essential to pathogenesis clarifying and clinical treatment.

The patient in our study predominantly manifested fever, vomiting and convulsion, with unexpected discovery of severe hyperlipidemia and molecular genetic tests revealing the etiology. With the WES method, we found a novel homozygous variant, c.45_48dupGCGG(Pro17Alafs*22), in exons 1 of *GPIHBP1*, which, absent in all of the 100 healthy control samples, was inherited from both of her parents.

The c.45_48dupGCGG duplication variant in exon 1 may lead to the substitution of the remaining 168 C-terminal amino acid residues with 21 mutant ones, at a highly conserved position of this protein. Based on the clinical presentations, serum lipid level and bioinformatics study, an inference stood out from the potential pathogeneses that the disease of the proband was very likely to be attributed to the homozygous duplication variant, which, certainly, needs to be further verified by functional experiments in the future. Fortunately, these unexpected findings, together with timely and proper treatment, have resulted in a good prognosis observed in this patient. Furthermore, this orphan case gave us a lively lesson, and deepened our knowledge of this disease.

CONCLUSIONS

In this study, we presented a comprehensive delineation of the first-reported Chinese infant patient with severe

hyperlipidemia whose condition was rooted in a novel homozygous variant of the *GPIHBP1* gene. Our findings reveal that routine blood biochemical tests are crucial to the diagnosis, and by molecular genetic testing, an integral part of the tools for a confirmed diagnosis, the role of genetic defects as a vital predisposing factor can be identified in severe hereditary hyperlipidemia.

Case Report: Novel Mutations in the *PCCB* Gene Causing Late-Onset Propionic Acidemia

Guang Ji, Yaling Liu, Xueqin Song and Zhenfei Li*

Department of Neurology, Second Hospital of Hebei Medical University, Shijiazhuang, China

Introduction: Propionic acidemia is an autosomal recessive metabolic disorder and the patients with adult onset are very rare.

Methods: Two *PCCB* mutations were identified. Clinical data were collected from a patient, and metabolic screening and clinical exome sequencing analysis were performed.

Results: Two novel mutations were identified in the *PCCB* gene: M1:c.404_406del:p.G135del and M2:c.632C>T:p.T211I.

Conclusion: Late-onset propionic acidemia should be taken into account, and metabolic screening as well as gene analysis should be performed to make a definite diagnosis timely.

Keywords: *PCCB* gene, novel mutation, late onset, propionic acidemia, clinical exome sequencing

INTRODUCTION

Propionic acidemia (PA) is an autosomal recessive disorder of organic acid metabolism caused by the accumulation of toxic metabolites. It is due to the deficiency of the mitochondrial enzyme propionyl-CoA carboxylase (PCC), which catalyzes the carboxylation of propionyl-CoA to methylmalonyl-CoA (Wongkittichote et al., 2017). PCC is an $\alpha\beta 6$ multimer composed of α and β subunits, encoded by the genes of *PCCA* and *PCCB*, respectively (Campeau et al., 2001). The main function of PCC is to accelerate the conversion of propionyl-CoA to methylmalonyl-CoA.

According to the time of onset, PA can be divided into neonatal onset and late onset. The clinical manifestations are varied and lack of specificity. Neonatal-onset PA is within 1 year old. It is normal at birth and occurs a few days later. The initial symptoms are feeding difficulties, vomiting, dehydration, hypothermia, lethargy, hypotonia, convulsion, and dyspnea. If not treated in time, the condition will aggravate, with ketosis, metabolic acidosis, hyperammonemia, and coma.

Individuals with late-onset PA exhibit significant differences in clinical manifestations, which can occur from 1-year old to adulthood. The common early manifestations are anorexia, growth retardation, convulsion, hypotonia, and abnormal mental behavior. The acute metabolic crisis is often induced by fever, hunger, a high protein diet, and infection. The accumulation of organic acid metabolites, such as propionic acid, often causes bone marrow suppression, anemia, granulocytopenia, and thrombocytopenia, prone to infection and bleeding. Very few patients can also show optic nerve atrophy, hearing loss, chronic renal failure, and premature ovarian failure.

Here we report a patient with PA who was screened by tandem mass spectrometry (MS/MS) and urine gas chromatography MS. Using clinical exome sequencing (CES) analysis, two novel mutations in the *PCCB* gene were found in the patient.

FIGURE 1 | (A) Brain MRI showed symmetrical abnormal signals in bilateral basal ganglia. **(B)** The abnormal signal in the bilateral basal ganglia in the brain MRI disappeared.

FIGURE 2 | CES identified one heterozygous deletion mutation. M1: c.404_406del;p.G135del and one heterozygous missense mutation. M2: c.632C>T;p.T211I. Sanger sequencing results showed that the mutations M1 and M2 were inherited from the father and mother, respectively.

CASE REPORT

The patient was the only child in the family. The birth and development of the patient were normal. He felt tired in his

lower limbs with lumbago after a long-distance walk from the age of 22 years (Table 1). After a lot of exercises or a high-protein-diet intake, he developed nausea, vomiting, and, in severe cases, unconsciousness. On physical examination, the

TABLE 1 | The timeline with relevant data from the episode of care.

Time	Episode of care	Treatment and prognosis
2015.12	First onset	Protein-restricted diet and treatment of reducing ammonia; improvement of symptoms
2019.6	Second onset	Reducing-ammonia treatment; symptoms improved again
2019.10	Third onset	Cardiotonic and diuretic treatment; symptoms worsened
2019.11	Metabolic acidosis	Correct acidosis; dead

patient was alert and oriented, and no obvious abnormality was found in the nervous system examination.

The results of liver function showed an increased level of blood ammonia (98.9 $\mu\text{mol/L}$; normal range, 6–35 $\mu\text{mol/L}$) and a decreased level of ceruloplasmin (0.144 $\mu\text{mol/L}$; normal range, 6–35 $\mu\text{mol/L}$). Cerebrospinal fluid analysis showed normal cell count of 1/ mm^3 (normal <5/ mm^3), a decreased glucose of 3 mmol/L (normal range, 3.6–4.5 mmol/L), and a normal total protein of 35 mg/dL (normal value, <45 mg/dL). Brain magnetic resonance imaging (MRI) showed symmetrical abnormal signals in bilateral basal ganglia (**Figure 1A**). Electromyogram was normal.

After a protein-restricted diet and treatment of reducing ammonia, the symptoms of weakness in lower limbs and lumbago were once relieved. However, at the age of 26 years, he again developed nausea, vomiting, and diarrhea, followed by numbness and weakness of both lower limbs and transient unconsciousness in severe cases when walking (**Table 1**). The blood ammonia increased to 108 $\mu\text{mol/L}$, whereas the abnormal signal in bilateral basal ganglia of brain MRI disappeared (**Figure 1B**). The symptoms improved again after reducing-ammonia treatment. Four months later (**Table 1**), the patient developed chest tightness, dyspnea, and general fatigue. The blood gas analysis showed pH 7.438, Pco_2 26.2 mm Hg, and Po_2 105.2 mm Hg. Increased level of troponin (0.51 ng/mL) and brain natriuretic peptide (266 ng/mL) was also detected. Echocardiography showed noncompaction of the myocardium and normal left ventricular systolic function. After admission, the patient's symptoms gradually worsened with unconsciousness and irritability. The blood gas analysis upon admission showed pH 7.007, Pco_2 22.6 mm Hg, and lactate 20.05 mmol/L, which indicated metabolic acidosis. After correction of acidosis and ventilator-assisted respiration, the patient did not respond to the treatment and died at last (**Table 1**).

The level of propionyl carnitine was 8.71 μM (normal range, 0.30–5.00 μM). The ratio of propionyl carnitine to acetyl carnitine was 0.33 (normal range, 0.02–0.20). The increase in these indicators suggested methylmalonic acidemia or PA. By urine organic acid analysis, elevated indicators of hydroxypropionate 23.8 (normal range, 0–4.0 (μ)mol/mol creatinine), propionyl glycine 7.8 (normal range, 0–0.4 (μ)mol/mol creatinine), and methyl citrate 33.9 (normal range, 0.0–0.7 (μ)mol/mol creatinine) were detected, whereas methylmalonic acid (0.0 (μ)mol/mol creatinine) was not present in the urine sample. The above results indicated the diagnosis of PA.

Clinical Exome Sequencing

Peripheral blood was obtained from the patient and his parents. DNA was isolated from peripheral leukocytes using a commercial

kit (TIANGEN, China). The quantity/quality of DNA was assessed using Onedrop OD1000 spectrophotometer and by agarose gel electrophoresis. CES analysis was done in Shanghai We-Health Biomedical Technology Co., Ltd.

Two heterozygous mutations of *PCCB* were identified in the patient. According to the ACMG standards and guidelines for the interpretation of sequence variants, the clinical significance of these two mutations was still uncertain. The two *PCCB* mutations were confirmed by Sanger sequencing.

CES identified one heterozygous deletion mutation M1: c.404_406del:p.G135del, which resulted in the deletion of amino acid at position 153 in the *PCCB* gene but did not cause frameshift. Another missense mutation M2: c.632C>T: p.T211I, resulted in the change of codon 211 in the *PCCB* gene from threonine to isoleucine. Both mutations are novel. Sanger sequencing results confirmed that the mutations M1 and M2 were inherited from the father and mother, respectively (**Figure 2**). The results above indicated that the proband's healthy parents were heterozygous carriers. The abnormality of the *PCCB* gene can lead to autosomal recessive PA.

DISCUSSION

The dysfunctions of PCC cause propionyl-CoA accumulation in the body and produce a large number of abnormal metabolites (propionic acid, 3-hydroxypropionate, and methyl citrate) by activating the bypass metabolic pathway. Abnormal metabolites can produce a series of clinical symptoms, including feeding difficulties, vomiting, lethargy, coma, metabolic acidosis, and hyperammonemia.

According to the occurrence of the first symptoms, PA can be divided into early-onset (first symptoms occurred within 28 days of life) and late-onset (symptoms started after the neonatal period). Most PA patients develop symptoms within 1 year of age (Lehnert et al., 1994; Van der Meer et al., 1996). Very few patients have the first symptom after 1-year of age (Nyhan et al., 1999; Perezcerda, 2004). In this case, the first symptoms appeared at the age of 22 years.

The clinical and biochemical picture of late-onset PA is more heterogeneous. Clinical findings, neuroimaging, and neuropathology show a high frequency of basal ganglia lesions in late-onset PA patients (Hamilton et al., 1995; Bergman et al., 1996). While the pathogenesis of the basal ganglia abnormalities is not clear, a possible explanation is that the basal ganglia region is of high energy metabolism, which is more vulnerable to disease than other regions. Hyperammonemia may be one of the causes of basal ganglia damage. Studies have found that organic acids and hyperammonemia can cause brain damage in rats, including

vacuolization, ischemic neurons, and pericellular edema (Viegas et al., 2014). In this case, the abnormal signals in bilateral basal ganglia of brain MRI disappeared after he received reducing-ammonia treatment, which also suggests the close relations between hyperammonemia and the damage of basal ganglia.

Another typical clinical manifestation of the patient was fatigue intolerance. When the patient walked 100 m, he felt tired and needed a rest. This feature is similar to the manifestation of metabolic myopathy. Some studies have found that patients with PA had impaired lipolysis, blunted fatty acid oxidation (FAO), a compensatory increase in carbohydrate utilization, and low work capacity (Storgaard et al., 2020). In normal people, the level of palmitate and free fatty acid (FFA) increased after exercise, but in PA patients, the increase in palmitate and FFA was not obvious. Impaired lipolysis, lack of substrates for FAO, low plasma carnitine concentration, and impaired TCA cycle are most likely to cause the blunted increase in palmitate oxidation and total FAO. As a result, PA patients rely more on carbohydrates as an energy source than healthy people. Similarly, the low work capacity in PA patients may also be ascribed to a shortage of substrates in the TCA cycle. These findings are similar to those reported in a patient with neutral lipid storage disease, which suggests that PA should be added to the list of metabolic myopathies (Laforêt et al., 2012).

PA is a serious, life-threatening metabolic disorder, and several related complications have been described in cases published before. Cardiac complications have been observed in PA including cardiomyopathy and arrhythmias. Cardiomyopathy, dilated usually, has been described in several PA patients, and the age at onset ranged between 4 weeks of age and adulthood, although a portion of the patients were diagnosed during a metabolic crisis (Pena et al., 2012). Echocardiography did not find dilated cardiomyopathy in this patient but showed noncompaction myocardium. Unfortunately, before the results of the metabolic screening and CES analysis, the patient developed cardiac shock during hospitalization and died of circulatory failure within a few days, which may be caused by the myocardial damage involved in the metabolic crisis.

We found two novel compound heterozygous mutations in the PCCB gene causing late-onset PA, including a deletion mutation, which resulted in the deletion of amino acid at position 153 of the PCCB gene, but did not shift the frame, and a missense mutation in the PCCB gene, which resulted in the change of codon 211 of the PCCB gene from threonine to isoleucine. These two novel mutations may be related to mild impairment of PCC function so that clinical symptoms occurred

late. Most affected individuals of PA are compound heterozygotes (Pena et al., 2012). The majority of these mutations were missense mutations (40%), followed by small insertions/deletions and splicing mutations. There is a strong relationship between the genotype and phenotype observed in many cases of PA; some were found to affect the protein function and were associated with an early onset and severe clinical phenotype; on the other hand, some were found with mild phenotypes (Zayed, 2015). However, the fact that compound heterozygosity is present in the majority of patients makes it difficult to establish genotype–phenotype correlations; furthermore, population-specific mutations may exist, and it is hard to predict their effect on other ethnic groups with different genetic makeup (Zayed, 2015).

PA at adult onset is very rare. If the patient presents with fatigue intolerance, disturbance of consciousness, hypotonia, seizures, ataxia, vomiting, neutropenia, and thrombocytopenia, this disease should be taken into consideration. Screening of organic acid metabolism in blood and urine as well as gene analysis should be performed to make a definite diagnosis timely.

Statement: The appropriate intervention was not possible as the patient died before the diagnosis could be completed.

Alport syndrome (AS) is a genetic kidney disease of basement membrane collagen disorder accounting for approximately 2% of ESRD patients. Next-generation and whole-exome sequencing methods are increasingly frequently used as an efficient tool not only for the diagnosis of AS but also for the establishment of genotype–phenotype correlation. We herein report the identification of a novel heterozygous missense mutation in COL4A3 gene (c.G3566A: p.G1189E) causing variable phenotypes in an ADAS Family based on the combination of clinical, histologic, pedigree, and genetic sequencing information. The proband is a 48-year-old Chinese woman suffering from persistent subnephrotic proteinuria and intermittent hematuria without renal function impairment over a 10-year time-span. Renal biopsy showed diffuse thin basement membrane and focal interstitial foam cell infiltration. The proband's mother progressed to end-stage renal failure and the proband's sister presented with subnephrotic proteinuria and intermittent hematuria as well. AS was highly suspected and confirmed by exome sequencing which revealed a novel heterozygous missense mutation in COL4A3 gene (c.G3566A: p.G1189E) in all the affected family members, although their current medical conditions vary significantly. Our present finding emphasizes the significance of next-generation sequencing technology for genetic screening which gives us an accurate clinical diagnosis of ADAS patients. The identification of c.G3566A as a new ADAS-related mutation contributes to both genetic diagnosis of ADAS and further functional study of COL4A3. The variable phenotypes from the same genotype of our case also provide more information to genotype–phenotype correlation study.

Keywords: human genetics, next-generation sequencing, whole-exome sequencing, Alport syndrome, collagen type IV, COL4A3, novel variant

INTRODUCTION

Alport syndrome (AS) is a genetically and phenotypically heterogeneous disorder of glomerular, cochlear, and ocular basement membranes caused by mutations in the genes *COL4A3*, *COL4A4*, and *COL4A5*, which encode type collagen IV α 3, α 4, and α 5 chains, respectively (Kashtan, 2021). It is the second most common cause of genetic kidney disease after autosomal-dominant polycystic kidney disease (Savigne et al., 2021). The collagen α 3, 4, and 5 are the major components of the mature glomerular basement membrane (GBM) in the kidney, eye, and cochlea. Disruption or alteration of those collagen leads to breakdown of their structure and function. Various clinical manifestations ranging from isolated, asymptomatic hematuria, through hematuria and proteinuria, to progressive renal disease, sensorineural deafness, lenticonus, and retinal flecks may occur (Kashtan et al., 2018).

The disease is transmitted in an X-linked manner in the case of *COL4A5* mutation, in an autosomal manner when mutations are located in the *COL4A3* or *COL4A4* genes, or in a digenic inheritance manner when a combination of two mutations in different genes occurs (Quinlan and Rheault, 2021). X-linked is the major inheritance pattern which accounts for 70–80% of AS patients (Quinlan and Rheault, 2021). It has been increasingly recognized that autosomal-dominant AS (ADAS) accounts for a larger percentage of patients with AS than previously recognized, up to 19–31% of affected patients, which made it the second most common inheritance pattern of AS (Fallerini et al., 2014; Morinière et al., 2014; Quinlan and Rheault, 2021). Increased application of next-generation technology in the evaluation of familial renal disease has led to the confirmed diagnosis of AS patients, especially ADAS, in the molecular level and reveals its correlation with histology and clinical manifestation (Groopman et al., 2019).

In this study, three members of a Chinese AS family with various phenotypes were identified as having the same novel heterozygous missense mutation, c.G3566A: p.G1189E, in the *COL4A3* gene. The result allows us to conclude an accurate diagnosis of the family. More importantly, it expands the mutational spectrum of *COL4A3* gene associated with ADAS family, confirms that heterozygous mutations in *COL4A3* gene are associated with a spectrum of phenotypes ranging from asymptomatic abnormal urine analysis to progressive renal disease, which provides more information about genotype–phenotype correlation, and also highlights the efficiency of high-throughput next-generation sequencing technology for identifying candidate variants.

CASE PRESENTATION

Clinical History and Laboratory Data

A 48-year-old Chinese woman was referred to our nephrology department for consultation regarding persistent sub-nephrotic range proteinuria and intermittent hematuria over a 10-year

span. Her mother and her elder sister also had history of kidney disease and, possibly, her maternal grandmother as well. She is not from a consanguineous family and was delivered at full term with normal development (Figure 1). 10 years ago, she found herself with binocular edema and the following urine test showed sub-nephrotic-range proteinuria ranging from 1.0 to 2.9 g/g and mild intermittent hematuria with normal serum albumin and creatinine levels. Traditional medical drugs and ACEI (angiotensin-converting enzyme inhibitors)/ARB (angiotensin receptor blocker) were prescribed to her. But there was no significant improvement and she did not take the medications regularly. Renal biopsy was suggested and performed in the year 2018. Only mild mesangial expansion, diffuse thin GBM, and very focal interstitial foam cell infiltration was found. Gene analysis was suggested, but she refused because of financial reasons. Now she agreed to do gene analysis because her urine abnormalities persisted and had the tendency of getting worse, especially proteinuria, and most importantly, her mother reached ESRD and started renal replacement therapy.

Laboratory data when gene analysis was done included UPC of 3.26 g/g, hematuria of + with 70% dysmorphic RBCs, normal serum albumin level 41.1 g/L (34–54 g/L), serum creatinine 62 μ mol/L (0.7 mg/dl, 44–97 μ mol/L), and CHOL 7.06 mmol/L (3.38–5.17 mmol/L). Hepatitis C antibody, Hepatitis B surface antigen, HIV, antinuclear antibody (ANA), antineutrophil cytoplasmic antibodies (ANCA), and free light chain were all negative. No high-frequency hearing loss or ocular lesion was found.

The proband's elder sister (52 years old) also suffered from a similar medical history, but shorter and milder. She presented with persistent sub-nephrotic-range (0.5–2.4 g/g) proteinuria and mild intermittent hematuria for 4 years without kidney failure. She was also treated with ACEI/ARB and traditional Chinese medical drugs, but she was not quite compliant.

The proband's mother (80 years old) presented with chronic renal failure (CKD stage 4), sub-nephrotic-range proteinuria and intermittent hematuria for 5 years and reached ESRD this year and started with hemodialysis. Her mother had cataract surgery 8 years ago and intermittent tinnitus for a long time.

The proband's maternal grandmother also may have had proteinuria because of the symptomatic foamy urine, but she had already died and no medical test was done to confirm the suspicion.

The clinical characteristics of the family are summarized in Table 1.

Light Microscopy Examination

In multiple levels of section examined with H&E, PAS, trichrome, silver, and elastic tissue stains, up to 20 glomeruli were noted, 30% of which were globally sclerosed. The remaining glomeruli were slightly enlarged. Mesangial regions were segmentally minimally expanded

due to matrix deposition. No endocapillary hypercellularity or crescents were found. Chronic changes were noted in the interstitial compartment with focal mild fibrosis and tubular atrophy. Very focal foam cells were found in the interstitium (**Figures 2A,B**). Protein cast and RBC cast could be seen. Arterioles and arteries demonstrated mild hyalinosis.

Immunofluorescence Examination

Immunofluorescence study revealed that the $\alpha 3$ and $\alpha 5$ collagen IV chains were well distributed in the kidney (**Figures 2C,D**). No diagnostic glomerular or extra-glomerular staining was seen with antisera specific for IgG, IgA, IgM, C3, C1q, fibrin, and kappa and lambda light chains.

Electron Microscopy Examination

One glomerulus was examined by electron microscopy. The glomerulus showed diffuse thinning of the glomerular capillary membrane without lamination or splitting and with segmental effacement of overlapping foot processes (**Figures 2E, F**). Endothelial cells were activated. No discrete immune complex electron dense deposits were identified.

Gene-Panel Design Sequencing and Variant Identification

Peripheral blood (5 ml) from the proband (III:3) was collected in EDTA anticoagulant tubes, and DNA samples were obtained using an extraction kit. Gel electrophoresis was

used to identify, quantify, and purify nucleic acid fragments. The amount of DNA was quantified using a Qubit 3.0 fluorometer. DNA was randomly broken into 250–300 bp long fragments using a Covaris S2 Sonicator (Covaris). The DNA sequencing library was prepared including end-repair, A-tailing, and adapter ligation. After pooling with specific indexes, the DNA library samples were hybridized and captured by streptavidin-coated magnetic beads. Quality assessment was processed after PCR amplification. The target region of genetic kidney disease-related genes

(including AS) was enriched, and a total exon library was constructed. Targeted sequences and prepared samples were run on a Illumina NovaSeq PE150 high-throughput sequencing instrument. Average sequencing depth of the target area is 156.57 with 99.54% coverage.

Bioinformatics Analysis

The obtained sequences were compared to those of the human reference genome hg19 (UCSC) using Burrows–Wheeler Aligner software (version 0.7.15 <http://bio-bwa.sourceforge.net/>) to

acquire valid sequences, and variant calling was performed using GATK3.1.1 with HaplotypeCaller. The called variants were annotated using ANNOVAR.

Sanger Sequencing

To validate putative variants, Sanger sequencing was performed using an ABI 3730XL DNA analyzer. Primers flanking the candidate loci were designed based on the reference genomic sequences of the Human Genome from GenBank in NCBI and synthesized by Invitrogen, Shanghai, China. The heterozygous variants identified through targeted next-generation sequencing were verified through Sanger sequencing using the following primers: F:5-ACACTTTAGAGCTTACACCATGCTT-3, R:5-GGTAACATGAGGAGGAGTTGAAAA-3.

Identification of Novel Variants

A novel heterozygous missense mutation, c.G3566A, has been identified in the COL4A3 gene (chr2:228162390) in the proband (Figure 3). The heterozygous point mutation (c.3566G > A) in exon 42 of COL4A3 gene causes a codon that codes for a different amino acid which results in a substitution of glycine by glutamic acid at amino acid position 1189 (p.G1189E). It locates in position 1 glycine residues in the Gly-X-Y repeats in the intermediate collagenous domains. The variant was confirmed by Sanger sequencing, and her family members (II:2, III:1, III:3, and IV:1; Figure 3) were subsequently assessed. The c.3566G > A

(p.G1189E) COL4A3 variant was not detected in her son (who was also clinically normal), whereas her mother and her sister were both heterozygous (who were both affected by kidney diseases with different phenotypes) (Figure 3). This variant was not found in GnomAD, ExAC, or in 1000 Genome Databases. The REVEL computational prediction analysis tool produced a score of 0.974. According to the refining criteria of AS variant interpretation guidelines of the American College of Medical Genetics and Genomics (ACMG) (Richards et al., 2015; Savage et al., 2021), this variant is classified as a “Likely pathogenic” (PM1, PM2, PP3, and PP4). Combining through the clinical, pathology, and pedigree data, we came to the conclusion that this is the novel pathogenic variant for this ADAS family.

Follow Up

Once the diagnosis was made, the patient and her sister were prescribed with ACEI. She and her family were all satisfied because the diagnosis was made and the treatment and prognosis were clear. But unfortunately, she was lost to follow up after the diagnosis.

DISCUSSION

Six genes (COL4A1–COL4A6) are arranged in three pairs (COL4A1–COL4A2, COL4A3–COL4A4, and

FIGURE 4 | Location of p.G1189E in COL4A3 protein.

COL4A5–COL4A6) and locate on chromosomes 13, 2, and X, respectively. They encode six isoforms, $\alpha 1$ to $\alpha 6$ of type IV collagen, which is the major structural component of all basement membranes (Quinlan and Rheault, 2021). Type IV collagen is a heterotrimer composed of three α chains coiled around one another to form a helical protomer (Timpl, 1989; Jennette, 2015; Savige et al., 2021). Three distinct networks have been recognized: $\alpha 1.\alpha 1.\alpha 2$ – $\alpha 1.\alpha 1.\alpha 2$, $\alpha 3.\alpha 4.\alpha 5$ – $\alpha 3.\alpha 4.\alpha 5$, and $\alpha 1.\alpha 1.\alpha 2$ – $\alpha 5.\alpha 5.\alpha 6$ (Abrahamson et al., 2009; Quinlan and Rheault, 2021). In the mature kidney, the $\alpha 3\alpha 4\alpha 5$ network is the main component of the GBM, encoded by the *COL4A3*, *COL4A4*, and *COL4A5* genes, respectively (Kashtan et al., 2018; Kashtan, 2021; Quinlan and Rheault, 2021; Savige et al., 2021). Disease-causing mutations in these genes will lead to AS with various phenotypes transmitted in different ways. A milder disorder previously known as “benign familial hematuria” or “thin basement membrane nephropathy” has a common molecular basis and potentially may not be “benign.” The

entity “benign familial hematuria” or “thin basement membrane nephropathy” has been eliminated by the Classification Working Group in 2018 to avoid the possible harm of classifying a patient with a benign prognosis (Kashtan et al., 2018).

The family we reported here was clinically highly suspected of AS because the proband had hematuria occurring together with a family history of hematuria and renal impairment and an abnormal GBM appearance (Savige et al., 2013). But the intermittent but not persistent hematuria, the increasing proteinuria, no extra-renal symptoms, the foam cells in the kidney biopsy without GBM lamination, the podocyte effacement, and very different clinical phenotypes within the family called for definite gene variant identification to confirm AS diagnosis excluding other hereditary or non-hereditary disease such as podocytopathy, further understanding of phenotype–genotype relationship, and better prediction of prognosis to guide clinical management.

A novel heterozygous missense mutation, c.G3566A, was identified by next-generation sequencing, which locates in exon42 of the *COL4A3* gene on chromosome 2 in which G in the 3566rd position was changed to A (c.G3566A), leading to the amino acid change from glycine to glutamic acid (p.G1189E, **Figure 4**). This variant is absent from all population allele frequency databases (GnomAD, ExAC, and 1000 Genome Databases) and has to our knowledge not been reported in the literature. The normal $\alpha 3$ chain encoded by the *COL4A3* gene is composed of 1,670 amino acids. It has a 28-amino acid leucine-rich signal peptide, followed by a 1,410-amino acid collagenous domain, and a 232-amino acid C-terminal NC1 domain (Mariyama et al., 1994). The collagenous domain begins with a 14-amino acid noncollagenous sequence that includes 4 cysteines, and the collagenous repeat Gly-X-Y is interrupted 23 times by short noncollagenous sequences (Mariyama et al., 1994; Heidet et al., 2001). The collagenous domain is characterized by the repeated Gly-X-Y triplet sequence, in which every third amino acid is a glycine. The presence of glycine is crucial for proper triple-helix formation, because glycine is the only amino acid small enough to fit into the center of the triple helix (Heidet et al., 2001; Jennette, 2015). If glycine is substituted by any other residue, normal folding of the triple-helical collagen molecule would be disrupted and consequently lead to partial or complete absence of these collagens within mature GBM (Yeo et al., 2020). Also, the misfold collagen molecules would also be highly sensitive to proteases and thus prone to degradation (Yeo et al., 2020). The refining ACMG criteria for the molecular diagnostics of AS stated that most glycine residues in the collagenous domain of the collagen IV $\alpha 5$, $\alpha 3$, and $\alpha 4$ chains should be recognized as critical residues equivalent to a functional domain and, therefore, identified position 1 glycine residues in the Gly-X-Y repeats in the intermediate collagenous domains in the collagen IV $\alpha 5$, $\alpha 3$, and $\alpha 4$ chains as “mutational hotspots” (PM1) (Savigne et al., 2021). According to the refining criteria, the new variant, c.3566G > A (p.G1189E), locates in the collagenous domain, and PM1 can be applied. The REVEL computational prediction analysis tool produced a score of 0.974, which is above the threshold necessary to apply PP3. All three patients in the family identified with hematuria (PP4). This variant meets criteria to be classified as “likely pathogenic” for AS based on the refining ACMG criteria (Savigne et al., 2021). After associating with the clinical, pathology, and pedigree data, we eventually have the final diagnosis of ADAS with this novel heterozygous missense mutation c.G3566A in *COL4A3* gene as the pathogenic variant.

Autosomal-dominant inheritance was mistakenly considered to be very rare previously (Savigne et al., 2013; Zhang and Ding, 2018). But as the increasing application of gene sequencing technology, the old narrowed definition of AS was broadened, such as the reclassification of “thin basement membrane nephropathy” and focal segmental glomerulosclerosis with any variant of *COL4A3-5*, as both could be a manifestation of ADAS if the variant

located in *COL4A3* and *COL4A4* (Kamiyoshi et al., 2016; Kashtan et al., 2018; Kashtan, 2021; Quinlan and Rheault, 2021; Savigne et al., 2021). GBM thinning, which was previously considered to be a very important pathologic finding, can be found in various situations including young male patients with X-linked AS, female patients of any age with X-linked AS, young male and female patients with autosomal recessive AS, and male and female patients with heterozygous mutations in the *COL4A3* and *COL4A4* genes transmitted in an autosomal-dominant pattern who may or may not exhibit progressive renal disease (Kashtan et al., 2018), which is well demonstrated in our case. With a substantial portion of the unrevealed autosomal-dominant inheritance patients with various clinical presentations being identified by NGS (Kamiyoshi et al., 2016; Kashtan et al., 2018; Kashtan, 2021; Quinlan and Rheault, 2021; Savigne et al., 2021), ADAS is now considered to account for a larger percentage of patients with AS than previously recognized, which is up to 19–31% (Fallerini et al., 2014; Morinière et al., 2014; Kashtan et al., 2018; Kashtan, 2021; Quinlan and Rheault, 2021).

Accordingly, this makes phenotype-genotype correlation data lag behind for variants in *COL4A3* and *COL4A4* (Rehm et al., 2015). Men with X-linked AS invariably develop kidney failure, and their phenotype is strongly influenced by genotype in that large deletions and nonsense mutations conferred a 90% probability of kidney failure before age 30, compared with a 70% risk with splice site mutations and a 50% risk with missense mutations (Jais et al., 2000; Yamamura et al., 2020). The phenotype of ADAS can vary from isolated hematuria through progressive kidney disease to renal failure, hearing loss, and ocular lesions. What we know now is that renal failure is not common, but recognized increasingly, and hearing loss is unusual, affecting 4–13% of individuals, as are ocular lesions (Kamiyoshi et al., 2016; Kashtan, 2021). But the exact phenotype-genotype correlation has yet to be established. Our case demonstrated that heterozygous missense mutation c.G3566A in *COL4A3* gene can cause various phenotypes in one family. It suggested that the severity of clinical manifestations may not be entirely attributed to the *COL4A3* genetic variant itself in patients. The reasons for this variability of expression/incomplete penetrance are complicated, including modifier genes that ameliorate or exacerbate the effects of mutations on synthesis, assembly, deposition, or function (or a combination of these) of the collagen IV $\alpha 345$ and factors such as smoking, high blood pressure, and dietary levels of salt and animal protein (Kashtan et al., 2018). According to that, an estimated risk of ESRD is given to ADAS patients with 20% or more among those with risk factors, <1% among those without any risk factors including proteinuria, FSGS, GBM thickening and lamination, sensorineural hearing loss, or evidence of progression in patient or family, genetic modifiers (Kashtan et al., 2018). According to the prognosis estimation, the proband and her sister both have more than 20% risk for progression to ESRD because she has the risk factor of proteinuria and family history of ESRD. To delay renal failure,

ACEI should be continuously used. Because although there is no curative treatment for AS, early ACEI therapeutic interventions have been shown to be effective both in AS patients and AS animal models, especially if patients were treated before the occurrence of proteinuria and impaired renal function (Savigne et al., 2013; Torra and Furlano, 2019). So early detection of ADAS patients with risk to ESRD is extremely important which could be greatly diagnosed with the help of next-generation and whole-exome sequencing methods. Unfortunately, the cost of the technique is still quite expensive and health insurance cannot cover the cost in China.

In conclusion, the presented case demonstrates how NGS in the combination of bioinformatics analysis strategy, together with clinical, histologic, and pedigree information, provides a specific diagnosis in patients with a family history of kidney disease and illustrates different phenotypes of ADAS family members with the same genotype. More importantly, a novel heterogenous missense *COL4A3* mutation, c.3566G > A (p.G1189E), was identified. Our study showed the importance of application of NGS for early ADAS diagnosis which may potentially improve the prognosis of ADAS population. It also expands the spectrum of *COL4A3* mutations, helps illustrate genotype–phenotype correlation, and contributes to genetic diagnosis and counseling of Alport syndrome.

Type 3 hereditary hemochromatosis (HH) is a rare form of HH characterized by genetic mutation in the *TFR2* gene. Clinical features reported in patients with type 3 HH include abnormal liver function, liver fibrosis, cirrhosis, diabetes, hypogonadism, cardiomyopathy, and skin pigmentation. Since its original description in 2000, 33 pathogenic *TFR2* mutations associated with HH have been described until now. Here, we first reported a Chinese pedigree of *TFR2*-related hemochromatosis with a novel compound heterozygous mutation c.1288G > A (p.G430R)/c.960T > A (p.Y320X). Interestingly, different phenotypes were reported although the proband and his sister shared the same gene mutation. This inconsistency between genotypes and phenotypes indicates multifactorial etiology contributing to the development of HH. Our report broadens the mutation spectrum of the *TFR2* gene associated with HH.

Keywords: case report, *TFR2* gene, compound heterozygous mutation, hereditary hemochromatosis, Chinese

INTRODUCTION

Hereditary hemochromatosis (HH) is defined as an inherited iron overload disorder characterized by excessive absorption of iron (Kowdley et al., 2019). Over time, iron deposits in multiple organs including the liver, pancreas, heart, joints, and pituitary gland, further leading to liver cirrhosis, restrictive cardiomyopathy, heart failure, arthropathy, skin pigmentation, diabetes mellitus, and so on (Bacon et al., 2011). HH can be classified as types 1, 2, 3, and 4. Type 1 HH caused by the *HFE* gene mutation is the most prevalent form of HH in Caucasians (Brissot et al., 2018). Mutations in hemojuvelin BMP co-receptor (*HJV*) and hepcidin antimicrobial peptide (*HAMP*) genes (type 2a and 2b HH, respectively) result in juvenile hemochromatosis, the most severe form of HH (Papanikolaou et al., 2004). Type 4 HH, also known as ferroportin (FPN) disease, is the only autosomal dominant form of hemochromatosis due to the mutations in the solute carrier family 40-member 1 (*SLC40A1*) gene (Joshi et al., 2015). Type 3 HH is a rare form of HH characterized by the genetic alterations in the transferrin receptor 2 (*TFR2*) gene, with an estimated allele prevalence between 0.0001 and 0.0004 among European populations (Wallace and Subramaniam, 2016). The human *TFR2* gene is located on chromosome 7q22 and encodes transferrin receptor 2. *TFR2* is a type II transmembrane glycoprotein, a member of the TFR family. It provides iron to the cell by internalization of the transferrin iron complex through receptor-mediated endocytosis (Silvestri et al., 2014). Hepcidin is the central regulator of systemic iron homeostasis, which can not only prevent absorption of iron from the gut but also prevent the release of iron from macrophages (Worthen and Enns, 2014). Hepcidin expression at an abnormally low levels leads to iron overload.

Hemochromatosis, which is associated with mutations in *TFR2*, usually occurs at an earlier age than HFE-related hemochromatosis and usually has a more severe phenotype (Pietrangelo, 2010).

Here, we described a Chinese pedigree presented with typical features of HH. Also, we found a novel compound heterozygous mutation in the *TFR2* gene, namely, c.1288G > A (p.G430R)/c.960T > A (p.Y320X). To the best of our knowledge, this is the first report on a Chinese pedigree of *TFR2*-related hemochromatosis.

CASE PRESENTATION

The patient (**Figure 4**, II-1), a 48-year-old male, was admitted to Beijing YouAn Hospital due to liver cirrhosis. Abdominal ultrasound suggested cirrhosis and splenomegaly 4 months ago even when the patient had no discomfort. In another hospital, he was diagnosed with diabetes and treated with insulin. He hardly ever drank and denied a family history of liver diseases. Physical examination revealed that there are no other abnormalities except for skin pigmentation.

A thorough examination was carried out to find out the cause of cirrhosis. The liver function test showed that the levels of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were elevated (**Table 1**). Serum markers for viral hepatitis and autoimmune liver diseases were all negative. Notably, the patient had abnormal plasma iron indices: iron, 47 μmol/L; transferrin saturation, 97.9%; and ferritin >2000 ng/ml. HbA1c was significantly elevated. Testosterone was normal (18.26 nmol/L).

Pre-contrast computed tomography (CT) revealed hepatomegaly with an increased attenuation over the liver and spleen, splenomegaly, and collateral circulation formation (**Figure 1A**). Magnetic resonance imaging (MRI) showed a typical decrease in T2-weighted signal intensity over the liver (**Figure 1B**).

A liver biopsy was performed, and the liver histology was evaluated by an experienced pathologist. The findings confirmed established cirrhosis with a marked deposition of iron in the hepatocytes and biliary epithelia, which is consistent with hemochromatosis (**Figures 2A,B**).

We also investigated one of the patient's sisters (**Figure 4**, II-3), and the results showed that she had abnormal plasma iron indices as well: iron, 37 μmol/L; transferrin saturation, 94.9%; and ferritin >709 ng/ml (**Table 1**), while her HbA1c and sex hormones levels were normal (HbA1c 5.6%, estradiol <37 pmol/L, follicle stimulating hormone 58.02 IU/L, luteinizing hormone 25.86 IU/L, progesterone 0.5 nmol/L, prolactin 464.13 mIU/L, and testosterone 0.94 nmol/L). Also, a fine needle aspiration biopsy was performed, which showed iron deposition in the periportal hepatocytes (**Figures 2C,D**).

Genetic Testing Results

Genetic analysis was performed for the patient and his family to explore the genetic factor for hemochromatosis. Panel sequencing was performed for major genes involved in the liver metabolism and carbohydrate metabolism including the common HH-related genes, namely, *HFE*, *HJV*, *HAMP*, *TFR2*, and *SLC40A1*. The SureSelect Human All ExonV6 custom chip was used to capture exons, and the Illumina sequencing platform was used for high-throughput sequencing. BWA (0.7.12-r1039) (Li and Durbin, 2009) was used to compare next-generation sequencing data with the human genome; ANNOVAR (\$ Date: 2015-06-17) (Park and Park, 2021) was used to annotate mutation sites according to dbSNP, Clinvar, ExAC, 1,000 Genomes, and other databases. Possible pathogenicity of gene mutation was graded by the ACMG (American Society of Medical Genetics and Genomics) genetic mutation grading system. Then, the target sequence of the suspected pathogenic mutation was amplified by PCR and sequenced via an ABI3730xL sequencer (Applied Biosystems,

FIGURE 1 | Computed tomography and magnetic resonance imaging of the proband. **(A)** Precontrast CT showed hyper-attenuation of liver parenchyma; **(B)** MRI T2-weighted image showed diffuse low signal intensity of liver parenchyma obviously.

FIGURE 2 | The liver histopathology of the proband [Panel **(A, B)**, II-1] and the proband's sister [Panel **(C, D)**, II-3]. **(A)** Increased collagen fibers stained green by Masson Trichrome stain in the expanded fibrous portal tract with cirrhosis (Masson trichrome, 100 \times); **(B)** Marked iron deposition in the hepatocytes and biliary epithelium (Prussian blue, 200 \times); **(C)** Marked deposition of hemosiderin in the hepatocytes (H&E, 100 \times); **(D)** The proband's sister had iron deposited in the periportal hepatocytes (Prussian blue, 200 \times).

	Score	Prediction	Score	Prediction	Score	Prediction	Score	Prediction	Score	Prediction	Prediction
c.1288G > A p.G430R	1	Probably damaging	0	Deleterious	-6.81	Deleterious	1	Disease causing	0.51	Tolerated	Likely pathogenic
c.960T > A p.Y320X	—	—	—	—	—	—	1	Disease causing	—	—	Pathogenic

Foster City, CA, United States). Finally, the comparisons and analysis for Sanger sequencing data were performed by SeqMan (DNASTAR, Madison, Wisconsin, United States). Potential functional effects of detected missense mutations were predicted by PolyPhen-2 (<http://genetics.bwh.harvard.edu/pph2/index.shtml>), SIFT (<http://sift.jcvi.org/>), PROVEAN (<http://provean.jcvi.org/index.php>), MutationTaster (<http://mutationtaster.org/>), and FATHMM (<http://fathmm.biocompute.org.uk/>).

The results showed that the patient (II-1) had new heterozygous mutations c.1288G > A (p.G430R)/c.960T > A (p.Y320X) in the *TFR2* gene. These mutations were further confirmed by Sanger sequencing (**Supplementary Figure S1**). As a result, the novel c.960T > A mutation led to a premature stop codon at amino acid 320 (p.Y320X). According to the ACMG guideline, the mutation c.960T > A (p.Y320X) was identified as pathogenic (PVS1: null variant + PM2: absent from controls + PP4: the phenotype of the patient is highly consistent with HH type 3). The mutation c.1288G > A (p.G430R) is a pathogenic mutation that has been reported earlier (Majore et al., 2013). Here, we also predicted its

pathogenicity by utilizing six kinds of prediction software. All software programs except for FATHMM showed that the p.G430R mutation was damaging (**Table 2**). The mutation was identified as likely pathogenic according to the ACMG guideline (PM1: the variant is in the domain + PM3: there is a literature suggesting this variant + PM2: absent from controls + PP3: bioinformatics protein function comprehensive prediction software predicts outcomes as harmful + PP4: the phenotype of the patient is highly consistent with HH type 3). The PhastCons scores of these two mutations were both 1, and the corresponding PhyloP values were 4.594 and 4.844, respectively, suggesting the high conservation of these two amino acids. Moreover, amino acid sequence alignments for the corresponding parts in the TFR2 protein in multiple species were studied (**Supplementary Figure S3**). The results showed that the two amino acids at positions 430 and 320 were absolutely conserved.

The molecular structure of *TFR2* was constructed by SWISS-MODEL (<https://swissmodel.expasy.org/interactive>). Also, molecular graphics were analyzed by PyMOL software. As shown

FIGURE 4 | Family pedigree of patient. The parents of the proband should each had a heterozygous mutation (c.960T > A or c.G1288A). The proband's parents were not consanguineous.

in **Figure 3**, the secondary structure of the predicted mutation was not affected by the mutation c.1288G > A (p.G430R) but affected by the mutation c.960T > A (p.Y320X). There is no electricity in the blank space in the model evaluation graph (**Supplementary Figure S2**), indicating that the model quality is acceptable.

Moreover, we tested the mutations in the *TFR2* gene for his family members (**Figure 4**). The same heterozygous mutations were found in one of his sisters (II-3). In addition, one of the patient's sisters (II-4) was found to carry a heterozygous mutation c.1288G > A (p.G430R). However, *TFR2* gene mutation was not found in the other sister (II-2). The patient's parents had passed away, so we cannot perform their genetic sequencing. According to the genetic sequencing results of his sisters, we speculated the mutations in the proband were compound heterozygous. In addition, the nephew (III-1) of the proband was also confirmed to have a heterozygous mutation c.1288G > A (p.G430R).

ETHICAL STATEMENT

All procedures involving human participants were in accordance with the ethical standards of the Institute Ethical Committee of Beijing YouAn Hospital, Capital Medical University, Beijing, China, and with the Helsinki Declaration (as revised in 2013). Written informed consent was obtained from the patient and his family members.

DISCUSSION

In recent years, increasing mutations in the *TFR2* gene which are related to type 3 HH have been documented (Hernández et al., 2021; Joshi et al., 2015). As shown in **Supplementary Table S1**, a

total of 33 pathogenic *TFR2* mutations associated with HH have been described in the Human Gene Mutation Database (Stenson et al., 2020). Most patients were Caucasian (27/33, 81.8%), males (17/25, 68.0%). The average age of the patients was 31.4 years, and most of them had liver cirrhosis. The data on the mutations in the *TFR2* gene in Asian patients are relatively rare with only five articles reported.

In the present study, we described a Chinese Han pedigree suffering from type 3 HH with a novel compound heterozygous mutation c.1288G > A (p.G430R)/c.960T > A (p.Y320X) in the *TFR2* gene. The proband exhibits very high plasma transferrin saturation and deposition of iron in the hepatocytes and biliary epithelia, and this phenotype highly suggested hemochromatosis. The gene sequencing results confirm the diagnosis of type 3 hemochromatosis. One of his sisters shares the same *TFR2* gene mutation; however, her liver pathology is milder than that in the proband. Except for the hepatic manifestations, other clinical features including diabetes, hypogonadism, and skin pigmentation have been reported in patients with type 3 hemochromatosis. Given this, we evaluated these symptoms in the proband and his family members. As a result, the proband developed skin pigmentation and diabetes, while his sister showed no other extrahepatic manifestations. We considered that the difference in the phenotype between the proband and his sister can be ascribed to other factors including sex (menstruation), environment (iron intake), or possibly other unknown genetic factors. These factors apart from *TFR2* gene mutation probably contribute to the development of HH. At present, both the proband and his sister have received phlebotomy therapy and resulted in improvement in the laboratory test (**Table 1**).

This case report highlights three important clinical issues. First, our team discovered the *TFR2* gene c.960T > A (p.Y320X)

mutation, which led to a premature stop codon at amino acid 320 (p.Y320X). According to the ACMG genetic mutation grading system, this mutation is pathogenic. We also analyzed the predictive mutation structure and found that the Y320X mutation affects the secondary structure of the *TFR2* protein and may destroy its function. Our report expands the mutation spectrum of the *TFR2* gene associated with HH. Second, this is the first time to report a novel compound heterozygous mutation c. G1288A (p.G430R)/c.T960A (p.Y320X) in the *TFR2* gene in a Chinese pedigree. We analyzed the minor allele frequency (MAF) of the c. G1288A (p.G430R) mutation by utilizing different public databases in different populations (**Supplementary Table S2**). The MAF of c. G1288A (p.G430R) is between 0.000003978 and 0.000008 in different databases, which indicates that the mutation is extremely rare. Third, early diagnosis and treatment for patients with HH have been documented to improve the prognosis as well as decrease mortality. It is helpful to remind even physicians in Asia that where the incidence of HH is low, it is important to keep the diagnosis of HH in mind, when a patient is presented with symptoms such as iron overload, liver fibrosis, diabetes, and so on.

CONCLUSION

In conclusion, we first reported a Chinese pedigree of *TFR2*-related hemochromatosis with a novel compound heterozygous mutation c.1288G > A (p.G430R)/c.960T > A (p.Y320X). Our report broadens the mutation spectrum of the *TFR2* gene associated with HH. On the other hand, our results reveal inconsistency between genotypes and phenotypes, which indicates multifactorial etiology contributing to the development of HH.

Loss-of-Function *ABCC9* Genetic
Variant Associated With
Ventricular Fibrillation.
Front. Genet. 13:718853.
doi: 10.3389/fgene.2022.718853

Genetic variants in the *ABCC9* gene, encoding the SUR2 auxiliary subunit from K_{ATP} channels, were previously linked with various inherited diseases. This wide range of congenital disorders includes multisystem and cardiovascular pathologies. The gain-of-function mutations result in Cantu syndrome, acromegaly facial appearance, hypertrichosis, and acromegaly facial features. The loss-of-function mutations in the *ABCC9* gene were associated with the Brugada syndrome, early repolarization syndrome, and dilated cardiomyopathy. Here, we reported a patient with a loss-of-function variant in the *ABCC9* gene, identified by target high-throughput sequencing. The female proband presented with several episodes of ventricular fibrillation and hypokalemia upon emotional stress. This case sheds light on the consequences of K_{ATP} channel dysfunction in the cardiovascular system and underlines the complexity of the clinical presentation of *ABCC9*-related diseases.

Keywords: *ABCC9*, atrial hypertension, case report, K_{ATP} channels, ventricular fibrillation (VF)

INTRODUCTION

The *ABCC9* gene encodes a transmembrane protein SUR2 that forms the regulatory part of the ATP-sensitive potassium channel (K_{ATP}) in cardiac, skeletal, vascular, and nonvascular smooth muscle cells (Chutkow et al., 1996). K_{ATP} channels are heterooctamers, which consist of four pore-forming $K_{ir6.x}$ channels, associated with four regulatory SUR (sulfonylurea receptor) subunits. Their main function is to couple the cell metabolic state to its membrane potential, thus adapting the K^+ conductance to the ATP content via the ATP-specific channel blockade [for review see (Foster and Coetzee, 2016)]. The subunit composition of K_{ATP} channels depends on the tissue subtype. There are two main types of SUR splice variants (SUR2A and SUR2B), which contribute to the diversity of K_{ATP} channels (Chutkow et al., 1999). There are two main types of $K_{ir6.x}$ channels— $K_{ir6.1}$ and $K_{ir6.2}$ —encoded by *KCNJ8* and *KCNJ11* and two SUR proteins—SUR1 and SUR2—encoded by *ABCC8* and *ABCC9* genes, respectively (Aguilar-Bryan et al., 1995; Inagaki et al., 1995; Chutkow et al., 1996).

The gain-of-function (GOF) and loss-of-function (LOF) mutations of all genes encoding K_{ATP} subunits (*ABCC8*, *KCNJ11*, *ABCC9*, and *KCNJ8*) have been described in patients with completely different and surprisingly opposite phenotypes. The regulatory subunit SUR1 encoded by *ABCC8* and the pore-forming subunit $K_{ir6.2}$ encoded by *KCNJ11* are mainly co-expressed in insulin-secreting tissues. Their GOF mutations are associated with neonatal diabetes, while the LOF mutations cause hyperinsulinism (Galcheva et al., 2019; Pipatpolkai

et al., 2020). No cardiovascular phenotype has been reported for SUR1- and ABCC8-associated diseases. The regulatory subunit SUR2 encoded by ABCC9 and pore-forming subunit $K_{ir}6.1$ encoded by KCNJ8 are expressed in cardiomyocytes, vascular smooth muscles, endothelial cells, and in many other cells and tissues with different presentations of SUR2A and SUR2B isoforms. ABCC9 and rarely KCNJ8 GOF genetic variants are associated with the Cantu syndrome, which often presents with the cardiac phenotype (Grange et al., 2019). Although the most typical and recognized clinical signs of Cantu syndrome include hypertrichosis and a characteristic facial appearance with acromegaloïd features, the cardiovascular system's involvement often occurs in the form of cardiomegaly with normal cardiac function, patent ductus arteriosus (PDA), and dilated aortic root (Levin et al., 2016). Additionally, several GOF genetic variants in the KCNJ8 gene were reported in association with the isolated Brugada syndrome, atrial and ventricular fibrillation, and early repolarization syndrome (Haïssaguerre et al., 2009; Medeiros-Domingo et al., 2010; Barajas-Martínez et al., 2012; Delaney et al., 2012). In contrast, there have been several cases of LOF genetic variants in ABCC9 and KCNJ8. Tester and co-authors described and functionally characterized KCNJ8 LOF variants in a cohort of sudden infant death syndrome victims in 2011 (Tester et al., 2011). ABCC9 LOF variants have been reported only twice in a patient with dilated cardiomyopathy and in a case of isolated atrial fibrillation (Bienengraeber et al., 2004; Olson et al., 2007). There were no additional reports on ABCC9 LOF variants within the next 13 years. The clinical significance and accurate genotype–phenotype correlations of LOF variants in this gene remain unclear. Recently, a homozygous LOF genetic variant in the ABCC9 gene has been described as a cause of a novel phenotype called intellectual disability and myopathy syndrome (Smeland et al., 2019).

Here, we report another case of a LOF ABCC9 genetic variant associated with idiopathic ventricular tachycardia and arterial hypertension. The presented case further extends the phenotypic spectrum of ABCC9-related disorders and supports the role of K_{ATP} channels in cardiomyocyte and coronary smooth muscle electrophysiology and function.

CLINICAL REPORT

The study was conducted according to the guidelines of the Declaration of Helsinki and approved by the Institutional Ethics Committee of the Almazov National Medical Research Centre. Informed consent was obtained from all subjects involved in the study. Routine clinical examination was performed according to the standard protocols including electrocardiography, Holter monitoring, echocardiography, endomyocardial biopsy, and biochemical and hormonal tests. For genetic testing, a targeted panel of 172 cardiomyopathy-associated genes was analyzed using the SureSelect Target Enrichment System and Illumina MiSeq instrument (Agilent; Waldbronn, Germany). The list

of studied genes is presented in **Supplementary Table S1**. The data processing and filter strategy were performed as described earlier (Jorholt et al., 2020).

The proband – 32-year-old female patient with a previously uneventful life history presented with a sudden cardiac death that occurred outside the home after emotional stress. The patient was resuscitated by her husband until the emergency services arrived when ventricular fibrillation (VF) was registered (**Figure 1**). Effective defibrillation led to the recovery of sinus rhythms, but within the next 30 min, in the intensive care unit, several episodes of VF repeatedly occurred registered on the ECG monitoring system, which led to the deep sopor and clonic seizures. The patient's blood tests revealed hypokalemia (2.9 mmol/L) with additional remarkable changes. There were no alterations in the hormonal state, glucose metabolism, the concentration of electrolytes, and no evidence of endocrine genesis of arrhythmia. Acute cerebrovascular accident and myocardial injury were excluded. On the resting ECG on the first day after VF, changes in repolarization (–) T in I, aVL, and V1–V3 leads were recorded, not subsequently detected. During 15 days of ECG telemonitoring, the sinus rhythm was recorded with an average heart rate of 68 bpm. Single monomorphic ventricular ectopic complexes ($n = 3,185$) were found mainly in the daytime, and 11 unstable episodes of the monomorphic idioventricular rhythm with an average frequency of 92 bpm were registered for the entire period of telemonitoring (**Figures 2A,B**). There were no changes in the QT interval. Echocardiography demonstrated the slightly increased LV wall thickness (13 mm) and increased myocardium mass (92 g/m²) corresponding to concentric myocardial hypertrophy with a normal ejection fraction (65%). Cardiac MRI revealed no signs of myocarditis or arrhythmogenic dysplasia, normal chamber geometry, normal ejection fraction (62%), and an absence of a late gadolinium enhancement phenomenon.

The patient remained on ventilation support during the next 5 days, followed by successful restoration of spontaneous respiration and consciousness. ECG normalized on the seventh day after hospitalization; the number of single ectopic ventricular complexes reduced to 500 per day, and ventricular tachycardia and QT interval prolongation were not detected. The discharge with bisoprolol 5 mg/day was recommended. Stress echocardiography performed several months later demonstrated high exercise tolerance and no myocardial ischemia, but at the peak of physical activity, single ectopic ventricular complexes were registered (**Figure 3**). The implantation of the implantable cardioverter defibrillator was performed for secondary prevention, and the patient remained stable within the next 2 years on metoprolol therapy (100 mg daily).

According to the anamnesis, the patient developed normally and has an average intelligence. The patient did not have any difficulties in learning at school and demonstrated standard communication skills. The patient had no history of chronic diseases and no family history of sudden cardiac death. Holter monitoring performed during the pregnancy 6 years prior to the episode of abortive sudden death documented 2,683 single ventricular ectopic beats. The

patient had three natural self-deliveries with preeclampsia (moderate degree) and arterial hypertension (up to 160/100 mmHg) during the third pregnancy, and arterial hypertension retained after the delivery. No causes of the secondary hypertension were found; the patient remained normotensive on ACE inhibitor treatment with rare hypertensive crises upon intensive physical excises or emotional stress.

To exclude the inherited arrhythmic syndromes or early manifestation of cardiomyopathy, the genetic study was performed using a targeted gene panel of 172 cardiomyopathy-associated genes, as previously described (Jorholt et al., 2020). All disease-related genetic variants were confirmed using Sanger sequencing and classified according to the American College of Medical Genetics guidelines (Jorholt et al., 2020). Informed consent was signed prior to the investigation, and the study protocol was approved by the Ethical Committee of the Almazov National Medical Research Centre. All research studies have been performed in accordance with the Declaration of Helsinki.

The target panel sequencing identified a genetic variant in the *ABCC9* gene in the exon 37 *ABCC9* (NM_005,691.3): c.4570_4572delTTAinsAAAT (p.Leu1524LysfsTer5), rs869025349, classified as pathogenic and earlier reported in a family with dilated cardiomyopathy and ventricular arrhythmias. Previous characterization of recombinant K_{ATP} channels including this mutation suggests that the variant causes a decrease in current expression, suggestive of a LOF molecular phenotype (Bienengraeber et al., 2004). This variant was

confirmed in proband's father, sister, and young daughter but not in the mother and older daughter (<https://varsome.com/variant/hg19/chr12-21958186-TAA-ATTT>). The genotype-positive young daughter experienced several syncope episodes at age 12, but no ECG was registered at that time, and the precise link of these episodes to the arrhythmogenic events remains unclear. This variant was previously reported in ClinVar in connection to dilated and arrhythmogenic cardiomyopathy but is currently classified as a variant of unknown significance. However, the absence of this variant in the gnomAd exome or gnomAd genome database together with the loss of function nature and several reported clinical associations prompts to reclassify the variant as pathogenic according to ACMG guidelines. The only reported frequency available for this variant comes from the Kaviar database, where it was reported with relatively high frequency among 454 genomes from the Welllderly study (00,032%), but these data have not been confirmed in other datasets. Therefore taking into account gnomAd exome and genome data, the true frequency of rs869025349 seems to be very low. No other genetic variants, characterized as pathogenic or likely pathogenic, was identified in the proband.

In spite of the fact that the described genetic variant potentially has a LOF mechanism of action different from that in GOF variants linked to the Cantu syndrome, we prompted the deeper clinical phenotyping in order to search for Cantu-related clinical features and excluded the possibility of a mixed clinical phenotype linked to *ABCC9* variants. The patient revealed no signs of hypertrichosis, dysmorphic face, or enlarged acromegaloïd features. The patient did not present with

FIGURE 2 | (A) Representative ECG from telemonitoring, single monomorphic ventricular ectopic complexes. **(B)** Representative ECG from telemonitoring. Unstable episodes of the monomorphic idioventricular rhythm with frequency of 81 bpm are observed.

reduced motor skills or delayed development in childhood. Unlike the characteristic features observed in the autosomal recessive SUR2 LOF syndrome, AIMS, no hypotonia, skeletal abnormalities, or scoliosis were noted neither in the proband nor in other carriers of the L1524KfsTer5 variant. The patient did not complain of muscle pain or fatigue after physical exercise. All carriers of the aforementioned genetic variant had an average intelligence and no difficulties in school learning; the patient did not reveal any skin lesions or pathologies and did not complain of sleep apnea. However, no specialized somnological examination has been performed.

DISCUSSION

K_{ATP} channels are of key importance in metabolic stress sensing of the cell. The expression of these channels has been found in various organs and tissues, including the pancreas, nervous system, skeletal and smooth muscle cells, and cardiac myocytes (Miki and Seino, 2005). These channels are composed of pore-forming and regulatory subunits; the latter in the heart is represented by SUR2 protein encoded by the *ABCC9* gene. This gene is a member of the superfamily of the adenosine triphosphate (ATP)-binding cassette (ABC) transporter subfamily C, member 9, which is located on chromosome 12 at 12p12.1¹. The main isoform of SURs in the cardiac and vascular myocytes, SUR2A, consists of 17 transmembrane segments, organized in three domains: TMD0, TMD1, and TMD2. In addition, there is a highly conserved intracellular region called nucleotide-binding domain 1 (NBD1) with Walker A and Walker B motifs in the linker between TMD1 and TMD2. Another nucleotide-binding site of SUR2A is the NBD2 region localized in the C-terminal part. It is suggested that NBDs are responsible for channel activation (Foster and Coetzee, 2016).

K_{ATP} channel dysfunction leads to the abnormal cellular response to metabolic stress. The growing amount of evidence indicates that K_{ATP} plays an important role in the adaptive cardiac response to systemic metabolic stressors and vascular tone regulation. Numerous cardiac K_{ATP} GOF mutations have been described in the association with Cantu syndrome (Levin et al., 2015) giving a broad range of molecular pathophysiological events linked to K_{ATP} GOF (Huang et al., 2018; McClenaghan et al., 2018). In contrast, LOF mutations in the *ABCC9* gene were only a few times reported in association with quite distinct clinical phenotypes due to different allelic states (heterozygous mutations (Bienengraeber et al., 2004; Olson et al., 2007; Hu et al., 2014) and homozygous mutation reported by Smeland et al. (2019)). Therefore, the frequency and clinical consequences of *ABCC9* LOF genetic variants have not been thoroughly characterized until now. Here, we reported a patient with a LOF variant in the *ABCC9* gene (Leu1524LysfsTer5, rs869025349) associated with a complex clinical phenotype, including arterial hypertension and stress-induced ventricular arrhythmia. Despite pvc's at peak exercise, there were no genetic variants in genes responsible for CPVT, such as *RYR2* and *CASQ2*. Importantly, we did not observe any signs of cardiac remodeling in any of the carriers of the genetic variant, and the predominant cardiac phenotype linked to the variant was arrhythmic. However, it leaves the opportunity for the later development of dilated cardiomyopathy, as described previously in association with this genotype. The described case identifies the *ABCC9* gene as a potential causative candidate for inherited arrhythmic syndromes and underscores the significance of the use of broad target genetic panels in patients with cardiac rhythm abnormalities and no structural heart alterations.

The role of ATP-sensitive potassium currents in normal heart physiology has been illustrated by animal studies. Thus, $K_{ir}6.1^{-/-}$ and $SUR2^{-/-}$ mice demonstrated baseline arterial hypertension, coronary artery vasospasm, and predisposition to sudden cardiac

FIGURE 3 | Single monomorphic ventricular ectopic complexes during and at the peak of stress echocardiography.

death (Chutkow et al., 2002). In contrast, in experimental animal models, K_{ATP} GOF resulted in an increased concentration of intracellular calcium and massive cytosolic calcium overload, hypercontractility, and the development of heart failure upon stress (Levin et al., 2016). These data are well in line with the stress-induced nature of the arrhythmogenic episodes in our patient and require deeper molecular studies on *ABCC9* LOF variants to identify the proper anti-arrhythmogenic strategies. There is also a possibility that arterial hypertension, observed in a patient, contributed to the arrhythmic manifestation of the genotype. Importantly, hypertension was also reported in the patient's father carrying the same *ABCC9* variant. A similar observation can be noted for hypokalemia, observed in a patient during acute arrhythmogenic episodes. Due to abnormal K_{ATP} function, patients with *ABCC9* mutations are often reported to have a low potassium serum level which, by itself, can be a severe provocative factor for triggering ventricular fibrillation (Feest and Wrong, 1991).

Our study has several limitations. First, the number of genes tested was limited to 172 which potentially leave the possibility that other genetic causes are not well known or yet described in connection to arrhythmic disorders and cardiomyopathies can be linked to the observed phenotype. The increased number of genes studied, or the use of an exome sequencing approach potentially, will allow in excluding another genetic background linked to the patient's phenotype. Another important limitation is the lack of functional studies for the variant described and the inability to make a strong conclusion regarding the impact of the variant on the phenotype in the genotype-positive family members. Of note,

this variant was previously characterized as LOF due to the decrease in the channel expression (Bienengraeber et al., 2004). Finally, the complex effect of *ABCC9* genetic variants should be properly estimated in animal model studies, such as that conducted previously (Chutkow et al., 2002; Miki et al., 2002).

To conclude, we presented the second case of the heterozygous *ABCC9* LOF variant in a patient with arrhythmogenic cardiac phenotype, arterial hypertension, and no signs of structural heart diseases. This case expands the spectrum of *ABCC9*-related disorders and improves our understanding of the clinical consequences of K_{ATP} dysfunction.

doi: 10.3389/fgene.2022.810853

L1 cell adhesion molecule is a type I transmembrane glycoprotein belonging to the immunoglobulin superfamily. Pathogenic mutations of *L1CAM* can cause *L1* syndrome, referred to as a variety of disease spectrums characterized by hydrocephalus. In the present study, we reported two novel variants of *L1CAM* in two unrelated Chinese families with fetal hydrocephalus history. The woman of family 1, with three consecutive adverse birth histories of male fetuses with hydrocephalus, was identified by an exome sequence with a heterozygous mutation in the *L1CAM* gene, NM_000425.4: c.1696_1703 + 14del (p. S566Vfs*35), which was predicted to be pathogenic. It is predicted to disrupt RNA splicing and likely leads to an absent or disrupted protein product. In family 2, the mother, previously with once a voluntary termination of pregnancy owing to the fetus with hydrocephalus, was pregnant with a fetus with hydrocephalus in her second pregnancy. After fetal blood sampling, a pathogenic deletion of 1511bp in *L1CAM*, chromosome X: 153131395-153132905(hg19/GRCh37)/NM_000425.4: c.2043_2432-121del1511 leading to deletion of fibronectin type-III repeats I-II, was identified in the fetus with hydrocephalus inherited from the mother by an exome sequence. On her third pregnancy, a healthy female fetus was born without the *L1CAM* variant by preimplantation genetic testing for the monogenic disorder. This study emphasizes the importance of ultrasonic manifestation and family history of fetal hydrocephalus for *L1CAM* diagnosis. Our study expands the genotypes of *L1CAM* and aids the genetic counseling of fetal hydrocephalus and even preimplantation genetic testing for the monogenic disorder.

Keywords: *L1CAM*, hydrocephalus, exome sequence, prenatal diagnosis, case report

INTRODUCTION

Hydrocephalus is an important birth defect and not rarely seen in fetuses. The incidence of hydrocephalus is approximately 4.65 per 10,000 live births (Garne et al., 2010). X-linked hydrocephalus due to aqueductal stenosis is the most common genetic cause of fetal hydrocephalus (Schrander-Stumpel and Fryns, 1998). Mutations in *L1* cell adhesion molecule (*L1CAM*) were established as a pathogenic factor in X-linked recessive neural disorders (Rosenthal et al., 1992; Adle-Biasset et al., 2013).

FIGURE 1 | Pedigrees of two families with X-linked hydrocephalus; **(A)** Pedigree of family 1; **(B)** Pedigree of family 2; **(C)** Ultrasound view of the second fetus with severe hydrocephalus from family 2; **(D)** No hydrocephalus was found in II-3 individual with normal anomaly scan of ultrasound from family 2.

L1 cell adhesion molecule (*L1CAM*) belongs to the immunoglobulin supergene family and plays an essential role in neuronal migration, neuronal cell survival, development, and differentiation (Kenwrick et al., 2000). L1 syndrome is defined as a variety of phenotypes caused by mutations of *L1CAM*, including CRASH syndrome (corpus callosum hypoplasia, retardation, adducted thumbs, spastic paraplegia, and hydrocephalus; OMIM 303350), hydrocephalus due to stenosis of the aqueduct of Sylvius (HSAS; OMIM 307000), and hydrocephalus with Hirschsprung disease (OMIM 307000) (Vos et al., 2010).

To date, 292 pathogenic mutations of *L1CAM* were identified according to the Human Gene Mutation Database (HGMD). The characteristics of mutations revealed 36.8% missense mutations, 18.6% splice site changes, and 22.3% deletions. The classical phenotypes induced by mutations in *L1CAM* mainly included hydrocephalus, accompanied by other disorders. Here, we described two novel variants of *L1CAM*, which were both unreported previously, including NM_000425.4:c.1696_1703 + 14del (p.S566Vfs*35) and the intragenic base deletion of 1511bp, chromosome X: 153131395-153132905(hg19/GRCh37)/NM_000425.4: c.2043_2432-121del1511, in two unrelated families from the Chinese mainland.

CASE PRESENTATION

Case 1

A non-pregnant woman came to our center of prenatal diagnosis for consultation after three consecutive adverse birth histories of fetuses

with hydrocephalus but without image data. All fetuses were male. The pedigree is shown in **Figure 1A**. However, there were no chromosomal or genetic tests for the three fetuses. Karyotype results in this couple did not reveal any abnormality. The couple wanted to find out the etiology of the three consecutive adverse birth histories of hydrocephalus. We offered a whole-exome sequence (**Figure 2A**) for this couple and found a novel pathogenic heterozygous variation in the *L1CAM* gene in the woman, NM_000425.4: c.1696_1703 + 14delAGTGACAAGTGAGGACAGTGAC(p.S566Vfs*35). Sanger sequence results for the couple confirmed this variant (**Figure 3A**). But the variant has yet to be reported or present in population databases (1000 Genome Project, ExAC, EVS, and gnomAD). This variant is a deletion of part of exon 13 (c.1696_1703 + 14del), which may disrupt functions of the Ig-like C2-type 6 domain in the *L1CAM* gene. It is predicted to disrupt RNA splicing and likely leads to an absent or disrupted protein product. It is highly associated with the *L1CAM* gene and the phenotype of three consecutive males with hydrocephalus. Based on the standards and guidelines of the American College of Medical Genetics and Genomics, the variant was predicted to be pathogenic (PVS1+PM2_Supporting + PP4). However, her subsequent fertility condition cannot be acquired by a telephone follow-up.

Case 2

A 36-year-old woman was in her second pregnancy at 24 weeks of gestation (**Figure 1B**). She was referred to our prenatal diagnosis

FIGURE 2 | (A) Exome sequence for the couple from family 1 indicated that the woman was a carrier of the variant (NM_000425: c.1696_1703 + 14del) in the *L1CAM* gene (red arrows) **(B)** Exome sequence for family 2 displayed that the deletion of 1511bp in *L1CAM* chromosome X: 153131395 (hg19/GRCh37)/NM_000425.4:c.2043_2432-121del1511 in the II-2 fetus (green arrows).

department because of fetuses diagnosed with hydrocephalus and invisible cavum septum pellucidum by ultrasound. We confirmed hydrocephalus but did not find invisible cavum septum pellucidum by ultrasound (**Figure 1C**). In the first trimester, there was a normal ultrasound examination, and the nuchal translucency measurement was 1.5 mm. Nevertheless, she previously had one voluntary termination of pregnancy owing to the fetus with hydrocephalus in 24 gestational weeks, but genetic tests were not performed for this fetus. This couple was both healthy and not consanguineous. There were no abnormal karyotype results in the couple. After informed consent, we performed cordocentesis on this woman. The TORCH-IgM and karyotype results were normal. But trio medical exome sequencing identified a copy number variation

in *L1CAM* inherited from his mother in this male fetus, chromosome X: 153131395-153132905(hg19/GRCh37)/NM_000425.4: c.2043_2432-121del1511 (**Figure 2B**); this structural variant was confirmed by Sanger sequence (**Figure 3B**), whereas it has not been previously reported, and it was predicted to cause disruption in partial exon 16 and whole-exons 17 and 18, leading to deletion of fibronectin type-III repeats I-II. The parents requested to terminate the pregnancy but refused autopsy at 25 gestational weeks. After that, she chose preimplantation genetic testing for monogenic disorders (PGT-M) to gain an embryo with an absence of this mutation in her third pregnancy. Amniocentesis was performed in our department at 17 weeks of pregnancy, showing and confirming the absence of this mutation (**Figure 3C**; II-3). Chromosomal

FIGURE 3 | (A) Sanger sequence for the couple from family 1 confirmed that the woman was a carrier of the variant (c.1696_1703 + 14del) in the *L1CAM* gene. **(B)** Sanger sequence result for family 2 validated the deletion (c.2043_2432-121del) in *L1CAM* in II-2 fetus. **(C)** Agarose gel electrophoresis in the *L1CAM* result from family 2.

microarray analysis was normal. This healthy female fetus showed a normal anomaly scan of ultrasound in the second trimester (**Figure 1D**) and was born at 38 weeks of gestation by

cesarean section for social reasons. Her birth weight was 3.0 kg, and her head circumference was 33.1 cm. Apgar scores were 9 and 10 at 1 and 5 min after birth, respectively. There was no report of

hydrocephalus and mental disorders through the telephone follow-up.

MATERIAL AND METHODS

Karyotype and Chromosomal Microarray Analysis

To determine the karyotype of fetal cord blood, amniocytes, and peripheral blood, colchicines were used to arrest samples at the metaphase by conventional karyotyping. G-banding karyotype was performed at the 320–400 band level by analyzing 20 split phases. CMA analysis was performed using the Affymetrix CytoScan HD GeneChip Platform (Affymetrix, Santa Clara, CA, United States) with copy number variation (CNV) and single nucleotide polymorphism (SNP) probes, following the manufacturer's instructions. Genomic DNA was isolated from samples by using a QIAamp DNA Blood Midi/Mini kit (QIAGEN GmbH; Hilden, Germany). The CNVs were reported at a 100-kb threshold with a marker count of ≥ 50 .

Exome Sequence

Target enrichment in DNA samples was performed using Agilent SureSelect human exome capture probes (V6, Life Technologies, United States), according to the manufacturer's protocol. The DNA library was sequenced on HiSeq XTen (Illumina, Inc., San Diego, CA, United States) for pair-end 150-bp reads. Raw reads were filtered using Trimmomatic to remove adapter-contaminated reads and low-quality reads. Clean reads were aligned to the human reference genome (hg19/GRCh37) with BWA. BAM files were generated by SNP analysis, duplication marking, indel realignment, and recalibration by GATK and SAMtools. The minor allele frequencies (MAFs) of all known variants were annotated according to dbSNP, the 1000 Genome Project, ExAC, EVS, gnomAD, and our in-house database. Databases such as OMIM, ClinVar, and the Human Gene Mutation Database were used to determine mutation harmfulness and pathogenicity where appropriate. To predict biological effect analysis of candidate variant genes, multiple computational algorithms were used, including SIFT, MutationTaster, PolyPhen2, PROVEAN, CADD, Human Splicing Finder, MaxEntScan, and NNSplice.

DISCUSSION

L1 syndrome is referred to as an X-linked recessive disorder and includes broad phenotypic spectrums dominated by hydrocephalus. The diagnostic yield can become higher when identifying characteristics of the L1 syndrome and family history (Adle-Biassette et al., 2013). The detection rate of the L1 syndrome can reach up to 32% for patients with at least two additional cases (Ochando et al., 2016). Therefore, the clinician should not overlook this syndrome when hydrocephalus in fetuses is recognized by prenatal ultrasound, especially in women with an abnormal reproductive history of a male fetus.

From the mutation characteristics in *L1CAM*, variants of *L1CAM* seem unique in families, and there is no hotspot mutation. However, recent studies revealed the correlations between genotypes and phenotypes in the *L1CAM* gene. Phenotypic severity primarily depends on the location and type of mutation of *L1CAM* (Fransen et al., 1998). Extracellular mutations resulting in truncation or absence of *L1CAM* lead to a more severe phenotype. Milder to severe phenotype could be caused by missense mutations in the extracellular part. Cytoplasmic mutations tend to generate a milder phenotype which might affect signal transduction or interaction with the cytoskeleton (Sebens Mürcköster et al., 2007).

The woman from family 1 carried a novel heterozygous variant NM_000425.4: c.1696_1703 + 14del (p.S566Vfs*35). So we strongly believed that all the three consecutive male fetuses with hydrocephalus were with the hemizygous pathogenic mutation, although samples were unavailable. This variant results in a deletion of part of exon 13 and is predicted to disrupt RNA splicing and likely leads to an absent or disrupted protein product. It might lead to a more severe phenotype from the report of genotype–phenotype correlation in *L1CAM* (Fransen et al., 1998). Although this variant has not been reported in the literature with *L1CAM*-related diseases, it is known that the variant with loss-of-function in *L1CAM* was pathogenic (Vos et al., 2010). A similar variant NM_000425.5: c.1702_1703 + 14del reported from ClinVar (rs1603275315) was classified as likely pathogenic, showing spastic paraplegia. Furthermore, this variant from family 1 affected the integrity of the sixth Ig domain of *L1CAM*. The Ig-like domains of *L1CAM* play a major role in interactions with several extracellular ligands such as phosphacan and neurocan, integrins, axonin-1/TAG1, Sema 3A, and also itself (Ruppert et al., 1995; Castellani et al., 2000). Another report has also shown that an individual with a variant of splice site change (c. 1704-1G > A) was diagnosed with adducted thumbs, hydrocephalus, and spastic paraplegia, accompanying abnormal karyotype (47, XXY) (Kanemura et al., 2006). A mutation involving the sixth Ig domain of *L1CAM* (L1-6D) (c.1759 G > C; p. G587R) was previously associated with developmental delay, dysmorphic facies, adducted thumbs, truncated corpus callosum, and periventricular heterotopias associated with polymicrogyria in a 2.5-year-old boy (Shieh et al., 2015). Investigations of the L1-6D knocked-out mice revealed typical hydrocephalus. The L1-6D isoform lost its ability to bind to *L1CAM* in a homophilic manner and $\alpha 5 \beta 1$ integrin (Hortsch, 1996). In another report on L1-6D mice, the phenotype exhibited abnormal ensheathment of unmyelinated axons by Schwann cell processes, eventually leading to myelinated multiaxon bundles (Itoh et al., 2005). In conclusion, currently available evidence displays the pathogenicity of this variant, but further study is needed to confirm the observation.

In family 2, we identified a novel large deletion in *L1CAM* in the second fetus and the pregnant woman. First, there are various types of variants in *L1CAM*, which reminds us that besides employing sequencing to detect point mutation, we should consider using proper approaches to identify different variants in *L1CAM*, when one X-linked hydrocephalus is

suspected. Second, there were a few reports of a large deletion in *L1CAM*. To our knowledge, variants of more than 1 kb of deletion were found in our current study, and in addition, three cases of an *L1CAM* whole-gene deletion were previously described in other reports. Knops et al. have reported a 61 kb in size encompassing all of *L1CAM*, *AVPR2*, and part of *ARHGAP4*, leading to L1 syndrome and nephrogenic diabetes insipidus (Knops et al., 2008). This individual was diagnosed to require shunting due to significant hydrocephalus. The second case, identified with an *L1CAM* whole-gene deletion and *PDZD4* gene, was also found with hydrocephalus that needed shunting (Kutsche et al., 2002). Similar to the second case, the third report demonstrated a 4-month-old male with a *de novo* *L1CAM* whole-gene deletion and *PDZD4* gene (Chidsey et al., 2014). Simultaneous deletions in upstream or downstream were present in all three reports of *L1CAM* whole-gene deletion. Moreover, the variant from family 2 was predicted to cause deletion of fibronectin type-III repeats 1-2 (FN III 1-2). De Angelis et al. demonstrated that mutations located throughout Ig1-Ig6 and Fn2 disrupted both types of interactions by synthesizing *L1CAM*-Fc fusion proteins of disease-causing variants (De Angelis et al., 1999; De Angelis et al., 2002). One study found that FN III 1-5 in *L1CAM* could interact with the fibroblast growth factor receptor (FGFR), which was essential in neuronal differentiation and FGFR1 phosphorylation. Authors speculated that FN III 2 amino acids (AVNNQGKG) were crucial binding sites (Kulahin et al., 2008). Furthermore, FN III 2 plays an important part in interactions with *L1CAM* and enhances structural stability in the extracellular region (Kunz et al., 1998). Therefore, the variant of family 2 could disturb the interaction with FGFR to cause neural axon malformation, resulting in severe hydrocephalus. Further functional studies of the variant were being conducted in our laboratory.

Preimplantation genetic testing for monogenic disease (PGT-M) is a useful tool for the *in vitro* fertilization (IVF) process (Masset et al., 2019). A biopsy is performed for single or several cells from IVF embryos to exclude the curated disease-causing cells, selectively transferring the unaffected embryos. After the pathogenic variant in *L1CAM* was identified, the couple from family 2 benefited from the PGT technology and eventually delivered a healthy infant without this mutation.

In conclusion, this study described two novel pathogenic variants and phenotypes in two Chinese families, which effectively blocked the transmission of genetic birth defects. These patients presented here may provide insights to better

understand the L1 syndrome and probably help genetic counseling and PGT for prenatal X-linked hydrocephalus.

Mutant *B3GALT6* in a Multiplex Family:
A Dominant Variant Co-Segregated
With Moderate Malformations.
Front. Genet. 13:824445.
doi: 10.3389/fgene.2022.824445

B3GALT6 is a well-documented disease-related gene. Several *B3GALT6*-recessive variants have been reported to cause Ehlers–Danlos syndrome (EDS). To the best of our knowledge, no dominant *B3GALT6* variant that causes human disease has been reported. In 2012, we reported on a three-generation, autosomal-dominant family with multiple members who suffered from radioulnar joint rotation limitation, scoliosis, thick vermilion of both lips, and others, but the genetic cause was unknown. Here, exome sequencing of the family identified mutant *B3GALT6* as the cause of the multiplex affected family. We observed that, in the compound heterozygous pattern (i.e., c.883C>T:p.R295C and c.510_517del:p.L170fs*268), mutant *B3GALT6* led to severe consequences, and in the dominant pattern, an elongated *B3GALT6* variant co-segregated with moderate phenotypes. The functional experiments were performed *in vitro*. The R295C variant led to subcellular mislocalization, whereas the L170fs*268 showed normal subcellular localization, but it led to an elongated protein. Given that most of the catalytic galactosyltransferase domain was disrupted for the L170fs*268 (it is unlikely that such a protein has activity), we propose that the L170fs*268 occupies the normal *B3GALT6* protein position in the Golgi and exerts a dominant-negative effect.

Keywords: *B3GALT6*, autosomal dominant, heterozygous variant, dominant-negative effect, EDS

INTRODUCTION

Glycosaminoglycan (GAG), a key component of the extracellular matrix, is essential for the development and maintenance of bone, cartilage, skin, and other tissues. GAG synthesis is initiated by the formation of a tetrasaccharide linker region attached to a serine residue in the proteoglycan core protein (Prydz and Dalen, 2000). Synthesis of the linker region involves four successive steps catalyzed by distinctive enzymes: xylosyltransferases I/II (encoded by *XYLT1* and *XYLT2*) (Götting et al., 2000; Bui et al., 2014; Munns et al., 2015; Umair et al., 2018; LaCroix et al., 2019), galactosyltransferase I (β GalT7, encoded by *B4GALT7*) (Guo et al., 2013; Cartault et al., 2015; Ritelli et al., 2017; Sandler-Wilson et al., 2019), galactosyltransferase II (β GalT6, encoded by *B3GALT6*) (Malfait et al., 2013; Nakajima et al., 2013), and glucuronosyltransferase I (GlcAT-I, encoded by *B3GAT3*) (Yauy et al., 2018; Colman et al., 2019). Recessive pathogenic variants of any of these four genes lead to severe skeletal deformities and connective tissue disruptions.

B3GALT6 (NM_080605.3) is a single-exon gene on chromosome 1p36.33, which encodes beta-1,3-galactosyltransferase 6 (β GalT6). The enzyme localizes predominantly in the Golgi apparatus and catalyzes the addition of a third galactose to the second galactose of the GAG linker region. In 2013,

Missense variants identified so far were depicted above the WT- β 3GalT6, and indel variants were depicted below the WT- β 3GalT6. TM, transmembrane region. Note: variants depicted as red were found in this study.

Malfait et al. (2013) and Nakajima et al. (2013) reported *B3GALT6* pathogenic variants in human diseases. Since then, dozens of *B3GALT6* variants in the recessive status have been identified in approximately 40 unrelated families with Ehlers–Danlos syndrome (EDS) (Sellars et al., 2014; Vorster et al., 2015; Alazami et al., 2016; Trejo et al., 2017; Ben-Mahmoud et al., 2018; Van Damme et al., 2018; Caraffi et al., 2019).

In 2012, we reported on an autosomal-dominant (AD), three-generation family with multiple members presenting with radioulnar limitation, scoliosis, thick vermilion of both lips, and a shortened and thickened femur neck (Zhu et al., 2012). Exome sequencing (ES) of the family was performed. Variant analysis and validation tests identified the following: 1) *B3GALT6*-recessive (compound heterozygous) variants led to

severe phenotypes (EDS); 2) the frameshift-elongated variant (c.510_517del:p.L170fs*268) segregated with moderate deformities in three members of the family in a dominant manner. Functional experiments confirmed that the R295C variant was loss-of-function, but the elongated variant (p.L170fs*268) may exert a dominant-negative effect. This is the first report on *B3GALT6*-dominant variant leading to disease.

Exome Sequencing

ES was carried out on seven individuals (I:1, I:2, II:1, II:2, III:1, and III:2) (**Figure 1A**). The detailed ES pipelines have been reported previously (Yang et al., 2019). Briefly, genomic DNA was fragmented into 180–280 bp segments, libraries were prepared and captured using an Agilent SureSelect Human All Exon V6 kit for each individual, and the effective concentration of each sample was subsequently sequenced on an Illumina HiSeq X Ten Sequencing system (Illumina Inc., San Diego, CA, United States). The raw BCL file was then converted into a raw FASTQ file. Raw reads were filtered using FastQC to remove low-quality reads. Clean reads were then mapped to the reference genome GRCh37 using Bwa. After removing duplications, SNV and InDel were called and annotated using GATK. For each sample, 11.9 G bases were obtained. The average yield was 16.6 Gb with an error rate of <0.1%. Furthermore, >90% bases had a Phred quality score of ≥ 30 (Q30).

Cell Transfection and Western Blot

The empty vector pCMV-14-3 ×flag or *B3GALT6* expression constructs (WT, R295C, or L170fs*268) were separately transfected into HeLa cells using Lipofectamine 3000 (Invitrogen, L3000-015) for 48 h. Protein extracts were

collected and separated by 10% SDS-PAGE, electrotransferred to a polyvinylidene fluoride (PVDF) membrane (0.45 μ m, Merck Millipore Ltd.), blocked with buffer containing 5% non-fat milk, and incubated with mouse monoclonal anti-flag antibody (1:2500) (Sigma, F1804) overnight at 4°C and HRP-conjugated secondary antibodies for 1 h at room temperature and developed with an enhanced chemiluminescence HRP substrate kit (Millipore, WBKLS0500). The membrane was visualized using an iBright FL1500 imaging system (Invitrogen).

Cellular Immunofluorescence

HeLa cells were seeded on coverslips in 24-well culture plates. When the cells reached 80% confluence, the *B3GALT6* expression constructs were transfected for 48 h. Cells were blocked with 4% paraformaldehyde for 30 min, permeabilized with 0.2% Triton X-100 for 10 min, and blocked with 5% BSA for 1 h at room temperature. The solution was discarded, and the mouse monoclonal anti-flag antibody (1:500) (Sigma, F1804) and rabbit anti-GOLPH4 antibody (1:400) (Abcam, ab28049) were added onto the coverslips overnight at 4°C in a moist environmental box. The secondary antibody Cy3-conjugated goat anti-mouse IgG (Origene, TA130012) and FITC-conjugated goat anti-rabbit IgG (Origene, TA130021) were incubated for 1 h at room temperature in a dark place, and then DAPI was added onto coverslips for 5 min. Coverslips

were mounted on the slide. Cell images were captured with laser scanning confocal microscopy LSM 800.

RESULTS

B3GALT6 Variants in the Family

As previously reported, an autosomal-dominant family was investigated (Figure 1A; Table 1), and we suspected that the family was affected by Giuffre–Tsukahara syndrome at that time (Zhu et al., 2012). ES was successfully performed on seven family members (Figure 1A). After obtaining the variant list, we first focused on the loss-of-function variants (including canonical splicing variants, indels, or other truncating variants) as well as elongation frameshift variants. Because AD inheritance was observed in the index family (Figure 1A), and the disease is extremely rare, we focused on heterozygous, rare, coding variants with AF less than 0.0001 (Exac_eas; gnomAD_eas; 1000G_eas; gnomAD_genome all). Then, we only considered the variants (absent in our 700 in-house ES data) that co-segregated with the affected status in the index family; one variant remained, c.510_517del:p. L170fs*268, at *B3GALT6*. Because *B3GALT6* is a known gene for the connective tissue disorder (EDS), we reanalyzed all *B3GALT6* rare variants with AF less than 0.001 (including missense variants) and identified another *B3GALT6* missense variant, i.e., c.883C>T:p.R295C on three family

members (II:3, III:1, and III:2). Sanger sequencing validation confirmed that two family members with severe phenotypes (III:1 and III:2) had *B3GALT6* compound heterozygous variants (c.883C>T:p.R295C/c.510_517del:p. L170fs*268) (Figures 1A,B; Table 1). Unaffected family member II:3 was heterozygous for c.883C>T:p.R295C variant (Figures 1A,B; Table 1), and family members I:1, II:1, and II:2 with moderate phenotypes suffered by c.510_517del:p.L170fs*268 heterozygous variant (Figures 1A,B; Table 1).

Functional Characteristics of β 3Galt6 Variants

The c.883C>T:p.R295C is not located in the catalytic galactosyltransferase domain (Figure 1D). Protein sequence alignment indicated that residue 295 (arginine) was not highly conserved across different species (Figure 1C). Meanwhile, in the gnomAD database, there was a very low frequency (AF = 0.0005) in the East Asian population, and 13/23 silico software predicted it to be benign or tolerant (Supplementary Table S1). The c.510_517del:p.L170fs*268 variant was not found in the ExAC, 1000G, and gnomAD databases, and it was not observed in 700 exome databases of our in-house datasheet that are unrelated to skeletal diseases (data not shown).

According to the first in-frame ATG in the reference sequence (NM_080605.4), the c.510_517del variant led to a frameshift

FIGURE 2 | c.510_517del:p. L170fs*268 linked an elongated product. **(A)** Upper panel represents the wild-type (WT) β 3Galt6. Lower panel represents the c.510_517del:p. L170fs*268 elongation variant. Note: in wild-type β 3Galt6, the catalytic galactosyltransferase domain was depicted in blue; red: frameshift amino acid sequence caused by the deletion. **(B)** Western blot analysis of lysates from HeLa cells expressing WT and mutant *B3GALT6*. FIGURE 3 | Subcellular localization of $\beta 3$ Galt6. **(A)** HeLa cells were transfected with plasmid carrying the wild-type (WT), the c.883C>T, or the c.510_517del variant. Cells were stained with anti-FLAG (red), anti-GOLPH4 (green), and DAPI (blue). **(B)** Enlarged images of (a–c) point of (A).

mutation and introduced a termination codon delay. Consequently, it was predicted that the mutant-elongated protein contained 438 amino acids in contrast to the wild-type protein, which contained 329 amino acids (**Figure 1; Supplementary Material S1**).

$\beta 3$ Galt6 mainly functions in the Golgi (Bai et al., 2001). Previous studies have identified *B3GALT6* variants exerting pathogenic effects by subcellular mislocalization or unstable structure of the mutant protein or by the unstable/incomplete transcript at the RNA level (Nakajima et al., 2013; Ben-Mahmoud

et al., 2018). We then overexpressed $\beta 3$ Galt6 (WT, R295C, or L170fs*268) in the HeLa cells. Western blot analysis showed that: 1) the size of the R295C protein was the same as that of the wild-type protein, but the expression of R295C was increased significantly (**Figures 2B,C**); 2) in contrast to wild-type $\beta 3$ Galt6, a band with a larger molecular weight was observed for the frameshift mutant protein (L170fs*268), and a significantly reduced expression was observed (**Figures 2B,C**).

Second, we checked the subcellular localization of $\beta 3$ Galt6 (WT, R295C, or L170fs*268). In contrast to WT- $\beta 3$ Galt6

expressed in the Golgi (as it co-localized with GOLPH4, which is a marker of the Golgi) (**Figure 3**), the mutant R295C protein was found in the cytoplasm but not in the Golgi (**Figure 3**), indicating that the mutant R295C protein was functionally null. In contrast, $\beta 3\text{Galt6-L170fs*268}$ was located in the Golgi compartment, as it overlaps with GOLPH4. According to the ACMG/AMP criteria (Richards et al., 2015), both the variants were classified as pathogenic; the evaluation results of the L170fs*268 variant were PVS1, PM1, PM2, PP1, and PP4; and for the R295C variant, the evaluation results were PS3, PM2, PM3, PP1, and PP4.

Heterozygous *B3GALT6*- L170fs*268 Leading to a Moderate Phenotype

The family members III:1 and III:2 exhibited severe phenotypes (which were consistent with EDS). Other individuals in the family (I:1, II:1, and II:2) did not meet the criteria for EDS and clearly exhibited moderate phenotypes (**Table 1** and ref 22). The *in vitro* study identified that a plasmid with c.510_517del:p. L170fs*26 variant can express an elongated protein (**Figure 2**), and the mutant elongated protein can be correctly localized in the Golgi. Given that the L170fs*26 frameshift variant resulted in about half of the catalytic galactosyltransferase domain being disrupted (**Figure 2A**), we propose that the elongated protein (having no catalytic function) occupies the Golgi position disrupting normal GAG production, resulting in a dominant-negative effect.

In brief, the present study identified two novel *B3GALT6* pathogenic variants in a multiplex family: 1) in the recessive status, mutant *B3GALT6* causing EDS; and 2) in the dominant status, the elongation-mutant $\beta 3\text{Galt6}$ causing moderate phenotypes (although not reaching the level of a typical EDS).

DISCUSSION

As a key enzyme in GAG synthesis, $\beta 3\text{Galt6}$ is encoded by the *B3GALT6* gene (Bai et al., 2001). In an autosomal-recessive manner, pathogenic variants of *B3GALT6* lead to a multisystem disorder mainly comprising bone deformity and connective tissue disruption, that is, spondylodysplastic EDS (Malfait et al., 2013; Nakajima et al., 2013; Van Damme et al., 2018; Caraffi et al., 2019). Approximately, 60 patients from 40 families have been reported to have mutated *B3GALT6* (Malfait et al., 2013; Nakajima et al., 2013; Sellars et al., 2014; Ritelli et al., 2015; Vorster et al., 2015; Alazami et al., 2016; Trejo et al., 2017; Ben-Mahmoud et al., 2018; Van Damme et al., 2018; Caraffi et al., 2019; Zhang et al., 2020; Descartes et al., 2021; Leoni et al., 2021). Among these patients, 41 *B3GALT6* pathogenic variants have been reported (**Figure 1C**), including two start-codon loss (Nakajima et al., 2013; Van Damme et al., 2018), two in-frame deletion variants (Nakajima et al., 2013; Van Damme et al., 2018), two in-frame duplication variants (Alazami et al., 2016; Trejo et al., 2017), five frameshift variants that lead to truncation of the protein (Malfait et al., 2013; Nakajima et al., 2013; Ritelli et al., 2015; Van Damme et al., 2018; Caraffi et al., 2019), two frameshift variants that lead to

elongation of the protein (Van Damme et al., 2018; Caraffi et al., 2019), and 28 missense variants (Malfait et al., 2013; Nakajima et al., 2013; Sellars et al., 2014; Ritelli et al., 2015; Vorster et al., 2015; Alazami et al., 2016; Trejo et al., 2017; Ben-Mahmoud et al., 2018; Van Damme et al., 2018; Caraffi et al., 2019; Zhang et al., 2020; Descartes et al., 2021; Leoni et al., 2021). Frameshift variants that lead to protein elongation (combined with other missense variants) have been reported in several severe sporadic patients (Van Damme et al., 2018; Caraffi et al., 2019).

Given that 41 *B3GALT6* pathogenic variants (including elongation variants) have been reported on EDS as described previously, none of these variants caused a dominant phenotype. In the present study, we identified two novel *B3GALT6* pathogenic variants, i.e., the c.883C>T: p.R295C and the c.510_517del:p.L170fs*268. The *B3GALT6*-prolonged variant (c.510_517del:p.L170fs*268) was detected in five family members. In two members (who combined with another point R295C variant), severe phenotypes (typical components of EDS) were observed, which is consistent with previous studies, that is, in the recessive status, *B3GALT6* variants lead to EDS. The novelty of the present study is that in the other three family patients (I:1, II:1, and II:2), the heterozygous L170fs*268 variant co-segregated with less severe but obvious phenotypes, such as radioulnar joint limitation, “S”-shaped scoliosis, and thick vermilion of the lips.

To test the functional consequences of the elongation variant, we expressed *B3GALT6* L170fs*268 protein in HeLa cells. Western blot analysis identified an apparently elongated band (with a significantly reduced amount), which was consistent with the cell immunofluorescence assay in which the *B3GALT6* L170fs*268 protein could be detected in the cytoplasm. However, in the immunofluorescence assay, we did not observe a reduction in the L170fs*268 protein. Such a difference in protein amount between the Western blot assay and the immunofluorescence assay may contribute to the L170fs*268 proteins having less stability when they are separated from the *in vivo* cells.

Similar to WT- $\beta 3\text{Galt6}$, which is expressed in the Golgi, the $\beta 3\text{Galt6-L170fs*268}$ is also located in the Golgi. Therefore, the previous pathomechanism (subcellular mislocalization or haploinsufficiency) cannot explain the heterozygous $\beta 3\text{Galt6-L170fs*268}$ variant-causing phenotypes. Given that the heterozygous $\beta 3\text{Galt6-L170fs*268}$ variant co-segregated with moderate phenotypes in the family produced an elongated protein, and the mutant protein could localize to the Golgi apparatus, we propose that the disease-causing mechanism for this elongation variant is the L170fs*268 that occupies the Golgi apparatus and disrupts the normal CAG production. Nevertheless, to confirm the novel $\beta 3\text{Galt6}$ -pathogenic mechanism, further studies, such as galactosyltransferase activity assay, GAG synthesis assay, and CS and HS chain quantifications, are warranted to elucidate the detailed mechanism.

In conclusion, we identified heterozygous *B3GALT6*-causing phenotypes that implicate a new dominant inheritance pattern of the mutated *B3GALT6* or CAG syntheses.

doi: 10.3389/fgene.2022.808181

Developmental and epileptic encephalopathies (DEE) caused by heterozygous deleterious variants in Cut Like Homeobox2 (*CUX2*) is rare. To the best of our knowledge the only variant associated with a phenotype in this gene is the *de novo* missense variant c.1768G > A, p.Glu590Lys; however, further additional research is needed to characterize the relationship between disease and variants in this gene. In this study, we reported a patient from a non-consanguineous Chinese family presenting with epilepsy, developmental delay, and speech delay. Additionally, the patient responded well to levetiracetam, and at his last follow-up (5.5 years old), he had discontinued antiepileptic drug treatment and remained seizure-free for 6 months. To identify possible causative variants, trio-whole exome sequencing was performed. We identified a novel *de novo* missense *CUX2* c.2834C > T, p. Thr945Met variant in the patient. Based on clinical and genetics information associated with the bioinformatics analyses, we hypothesized that this variant was the cause of the reported phenotype. AlphaFold and SWISS-MODEL homology modeling servers were used to predict the three-dimensional (3D) structure of *CUX2* protein. Predictions based on the 3D-structure modeling indicated that the p.Thr945Met substitution was likely to alter the DNA-binding specificities and affect protein function. On the basis of clinical characteristics and genetic analysis, we presented one case diagnosed with DEE67. Our finding expanded the clinical and molecular spectrum of *CUX2* variants.

Keywords: trio-whole exome sequencing, developmental and epileptic encephalopathy 67, *CUX2*, levetiracetam treatment, *CUX2* clinical phenotype

INTRODUCTION

Developmental and epileptic encephalopathies (DEE) is characterized by onset in infancy/early childhood with refractory seizures, delayed psychomotor development or/and developmental regression. DEE is clinically and genetically heterogeneous, with over 50 genes known to be causative (Specchio and Curatolo, 2021). However, the genotype still has a limited effect on the phenotype. The Cut Like Homeobox 2 (*CUX2*) gene, which encodes a 1426 amino-acids transcription factor, plays an important role in the control of neuronal proliferation and differentiation in the brain (Quaggin et al., 1996). Recently, variants in *CUX2* were found to be

associated with developmental and epileptic encephalopathy 67 (DEE67, OMIM: 618141), an autosomal dominant disorder that typically manifests in infancy and is characterized by refractory seizures, global developmental delay with impaired motor and intellectual development, movement disorders, speech delay, and stereotypic or autistic behavior. To date, only 10 patients carrying recurrent *de novo* heterozygous Glu590-to-Lys (E590K) variant in the CUX2 gene have been reported (Barington et al., 2018; Chatron et al., 2018).

Here, we reported a 5.5 years old boy with epilepsy, developmental delay and speech delay. Trio (parents-proband) whole-exome sequence (WES) analysis revealed a novel *de novo* pathogenic missense variant c.2834C > T (p.Thr945Met) in the CUX2 gene. Our findings expand the genetic and phenotypic spectrum of DEE67 and contribute to our understanding of DEE on a genetic level.

MATERIAL AND METHODS

Patients

The proband was a 5.5-year-old boy, the third child of healthy non-consanguineous parents. He had two unaffected female siblings. The patient visited the hospital after experiencing seizures. A detailed clinical history, including a description of epilepsy, a detailed clinical, and a neurological examination was carried out. The study was approved by the Ethics Committee of Ganzhou Women and Children's Health Care Hospital.

Variant Analysis

After obtaining informed consent, samples were taken from the proband and his parents. The whole-exome capture was carried out (xGen Exome Research Panel v1.0, IDT, IA, United States) according to the manufacturer's protocol. High-throughput sequencing was performed using Illumina NovaSeq 6000 series sequencer (PE150), and at least 99% of the target sequence was sequenced. The sequencing process was performed by the Chigene Translational Medicine Research Center Co., Ltd., 100875, Beijing.

After eliminating adapters and low-quality reads, clean data were obtained and aligned to the Human genome (Hg19/GRC37) using the Burrows-Wheeler Alignment (BWA). The Genome Analysis Toolkit (GATK) was used to identify single nucleotide variants (SNVs) and insertion/deletion (InDel) variants. The Exome Aggregation Consortium ExAC was used to determine the allele frequencies of variants. Pathogenicity of nonsynonymous variants was predicted using the SIFT, Proven, REVEL, varianttaster, PolyPhen, and CADD tools. SNVs/indels were classified according to the standards and guidelines of the American College of Medical Genetics and Genomics (ACMG) and the Association for Molecular Pathology (AMP) (Richards et al., 2015).

Variants were confirmed by Polymerase Chain Reaction (PCR) analysis, followed by Sanger sequencing. CUX2 was amplified using the following primers: forward primer (5'-CAGCCTGGTACAAGTCCCAAC-3') and reverse primer (5'-CAGACTTATCCGCTGGTCCC-3'). DNA sequencing was

performed using the 3730xl DNA Analyzer (Applied Biosystems, United States). The rare variant identified has been submitted to the ClinVar database (Accession number: SCV001946791) (<https://www.ncbi.nlm.nih.gov/clinvar/variation/1296981>).

Multiple protein sequence alignments were performed using MEGA X, and the modeling of the 3D structure was analyzed and visualized using Swiss-PdbViewer v4.1.

RESULTS

Clinical Features

The proband (II:1) had the onset of febrile seizure at the age of 2 years with unconsciousness, up-rolling of the eyes, facial twitching, limb stretch, and no visible limb shaking; 6 months later, a second febrile seizure occurred, and 3 months later a third febrile seizure occurred. Each seizure lasted 3 min and was followed by spontaneous remission. At 2 years and 9 months the medical team started levetiracetam (40 mg/kg/day) and patient did not present any other febrile seizure. After 2 years without clinical or electrographic seizures, the boy has discontinued levetiracetam and remained seizure-free until the age of five. At 2 years and 9 months, the electroencephalograph (EEG) revealed a somewhat slower background activity and a small number of bilateral spikes and spike-wave discharges in the central, parietal, and posterior temporal regions during sleep, but subsequent magnetic resonance imaging (1.5T MRI) was normal. EEG performed at the age of 5 years without levetiracetam was normal. He was able to walk alone at 18 months. At the age of 2 years and 9 months, the patient was diagnosed with global developmental delay and he was not able to form three word sentences and just could pronounce few words with correct meaning. The results of the Gesell Development Diagnosis Scale (GDDS) revealed a total development quotient (DQ) of 56 (mild developmental delay). Then the patient has received home-based rehabilitation for 3 years. Now he is 5.5 years in kindergarten and the DQ score has been improved to 75 (borderline deficiency).

Variant Identification and Analysis

Trio-WES was performed and a heterozygous *de novo* missense variant (NM_015267.4: c.2834C > T, p.Thr945Met), in the CUX2 gene was identified in the proband. This c.2834C > T variant was not identified in the 1000 genome project or ExAC. Numerous computational tools, including PolyPhen (probably damaging, 1.0), Proven (deleterious, -4.16), SIFT (damaging, 0.0), mutationtaster (disease_causing, 1), and REVEL (deleterious, 0.582) suggested that the variant was deleterious and had a CADD score of 26.9. The *de novo* missense variant was confirmed by Sanger sequencing, the proband's parents and healthy sisters did not carry the variant (Figures 1A,B). Based on these findings, the variant was classified as "Likely pathogenic" by ACMG/AMP guidelines (PS2, PM2, PP2, and PP3) (Richards et al., 2015; Harrison et al., 2019).

Multiple sequence alignment of the protein shows that the Thr-945 residue is highly conserved across species (Figure 1C). This variant locates in the second CUT domain of the human homeobox protein CUX2 (Cut-like2) (Figure 1D) and results in a threonine to

FIGURE 1 | (A) Family pedigree. The black arrow indicates the proband. (B) Sanger sequencing of the patient and family members confirmed the *de novo* variant c.2834C > T. (C) Multiple-sequence alignment of CUX2 protein among species. Red arrow shows the Thr945 site. (D) Domain structure of CUX2 protein (CUT domain, green; Homeodomain, red). Localization of amino acid changes p.Glu590Lys and p.Thr945Met is indicated. (E–G) Structural model of the CUX2 protein. Ribbon representations show details of the second CUT domain for wild-type (p.Thr945) (F) and mutated (p.Thr945Met) (G) CUX2. Noted loss of the weaker hydrogen bond between Thr945 and Gly948. Green dashed lines: hydrogen bonds; grey dashed lines: weaker hydrogen bonds.

methionine amino acid substitution. By substituting a polar and uncharged residue with a non-polar and hydrophobic amino acid, this variant may further affect the formation of a weaker hydrogen bond between Thr 945 and Gly948 (Figures 1E–G).

DISCUSSION

In this study, we performed trio-whole exome sequencing and characterized a novel missense variant c.2834C > T (p.Thr945Met) in *CUX2* in a Chinese male patient with DEE. In previous studies, all known patients (ten unrelated probands with DEE) presented with a recurrent *de novo* missense variant, c.1768G > A (p.Glu590Lys) (Table 1) (Rauch et al., 2012; Allen et al., 2013; Geisheker et al., 2017; Barington et al., 2018; Chatron et al., 2018). The ten patients presented with a variety of epilepsy forms, including myoclonic seizures (3), absence seizures (2), focal, tonic, atonic, and generalized tonic-clonic. The age of onset ranged from 2 months to 9 years. EEG was performed in 9 of 10 patients. All participants had abnormal EEG findings, and 5 individuals presented with generalized spike-wave (GSW) or polyspike-wave (GPSW) patterns. Brain MRI was performed in 9 of 10 patients and was unremarkable in 6 of 9 patients. Cerebellar atrophy, hippocampal

asymmetry, thin posterior corpus callosum were observed in some patients. In our case, the EEG revealed bi-parieto-temporal discharges while the MRI was normal. All patients had developmental delays, in addition to a variety of other variable features such as nonverbal (7), movement disorders (6), and autistic features (3). Our patient presented with febrile seizure when 2 years old. Besides, he has developmental delay.

The majority of patients with the p.Glu590Lys variant failed to respond to multiple antiepileptic drugs, including valproate, carbamazepine, clobazam, levetiracetam, and lamotrigine. Only three patients achieved seizure-free status while using valproate or a combination of valproate and lamotrigine. In our case, seizures were controlled after treatment with levetiracetam (Barington et al., 2018; Chatron et al., 2018). At the last follow-up, he had discontinued antiepileptic drug treatment (at age of 5 years) and remained seizure-free for 6 months. Taken together, our patient had a less severe phenotype than previously reported in patients carrying the p.Glu590Lys variant, although the relationship between the reported variant and the described phenotype requires more case reports to be established.

The *CUX2* protein consists of three CUT domains and a homeodomain; which are important for DNA binding (Gingras et al., 2005). Additionally, the sequences of all four DNA-binding

TABLE 1 | Clinical features of individuals with the CUX2 variant.

Individual	<i>De novo</i> variant	Age	Sex	Type of seizure	Age at seizure onset	Seizure outcome	EEG features	MRI	ID	ASD	Non verbal	Movement disorder	Other features

domains are highly conserved (Quaggin et al., 1996). The CUT domain 1 is located between amino acids 549 and 627, while the CUT domain 2 is located between amino acids 892 and 967 in CUX2. The previously reported variant p.Glu590Lys, which is located at the CUT domain 1, destabilized the effect in-silico analyses and interfered with DNA binding (Chatron et al., 2018). In this study, we modeled the 3D structure of the wild-type CUX2 protein (1–1486) and examined the potential functional impact of the p.Thr945Met variant (**Figures 1E–G**). Firstly, the variant alters the charge at residue 945 (polar to non-polar) (CUPSAT: $\Delta\Delta G = -6.21$ kcal/mol, I-mutant3.0: $\Delta\Delta G = -0.37$ kcal/mol), potentially disrupting the structure and affecting inter and intramolecular interactions (Chatron et al., 2018). Additionally, the Thr945Met variant affects a highly-conserved threonine residue in the CUT domain 2, which could result in structural changes and alter DNA-binding specificities (Gingras et al., 2005). However, additional molecular functional studies will be required to confirm the potential mechanism of pathogenic variants.

In summary, patients with *de novo* CUX2 variants have developmental and epileptic encephalopathies characterized by developmental delay, speech delay, movement disorders, and autistic behavior. Our findings have further expanded the clinical and molecular spectrum of DEE67.

Paternal De Novo Variant of *TAOK1* in
a Fetus With Structural
Brain Abnormalities.
Front. Genet. 13:836853.
doi: 10.3389/fgene.2022.836853

A dilated lateral ventricle is a relatively common finding on prenatal ultrasound, and the causes are complex. We aimed to explore the etiology of a fetus with a dilated lateral ventricle. Trio whole-exome sequencing was performed to detect causative variants. A *de novo* variant of *TAOK1* (NM_020791.2: c.227A>G) was detected in the proband and evaluated for potential functional impacts using a variety of prediction tools. Droplet digital polymerase chain reaction was used to exclude the parental mosaicism and to verify the phasing of the *de novo* variant. Based on peripheral blood analysis, the parents did not exhibit mosaicism at this site, and the *de novo* variant was paternally derived. Here, we describe a fetus with a *de novo* likely pathogenic variant of *TAOK1* who had a dilated lateral ventricle and a series of particular phenotypes. This case expands the clinical spectrum of *TAOK1*-associated disorders. We propose a method for solving genetic disorders in which the responsible genes have not yet gone through ClinGen curation, particularly for prenatal cases.

Keywords: dilated lateral ventricle, *TAOK1*, trio-whole exome sequencing, rare disease, neurodevelopment disorder

INTRODUCTION

The TAO kinase family consists of three genes, *TAOK1*, *TAOK2*, and *TAOK3*, which encode *TAOK1*, *TAOK2*, and *TAOK3*, respectively (Dan et al., 2001; Miller et al., 2019). TAO kinases play multifunctional roles in many molecular and cellular events and can regulate neuronal survival and development in the nervous system (Fang et al., 2020; Hu et al., 2021). *TAOK1* is highly expressed in the human brain and plays a role in the establishment of neuronal polarity, neuronal differentiation, and early brain development (Biernat et al., 2002; Timm et al., 2006; Draviam et al., 2007; Breuss and Keays, 2014; Poon et al., 2016). Many studies have provided evidence that *TAOK1* dysfunction can result in neurodevelopmental disorders (NDDs) (Cooper et al., 2011; Xie et al., 2016; Deciphering Developmental Disorders Study, 2017; Dulovic-Mahlow et al., 2019; Satterstrom et al., 2020; van Woerden et al., 2021; Hunter et al., 2022). However, dysfunction of this kinase in prenatal cases has not been reported.

Here, we report structural brain abnormalities in a fetus with a *de novo* variant of *TAOK1*. To our knowledge, this is the first report of *TAOK1* dysfunction as a prenatal diagnosis.

Case Presentation

A healthy 32-year-old gravida 3, para 2 (G3P2) woman underwent a prenatal examination at Guangdong Women and Children Hospital. She delivered two normal male infants, in 2013 and 2018, through uncomplicated vaginal deliveries. At 25 weeks of gestation for the current

FIGURE 1 | (A,B) Enlarged left lateral ventricle (10.1 and 11 mm) at 25 and 31 gestational weeks. **(C)** Axial T2-weighted imaging at 32 weeks of gestation shows poor bilateral and frontal operculum formation and shallow bilateral lateral fissures (arrows). The left ventricle is slightly wider.

pregnancy, routine ultrasound scanning showed that the left lateral ventricle of the fetus was widened (10.1 mm compared to a reference of <10 mm) (**Figure 1A**). Common factors, such as infection and anemia, were ruled out, and COVID-19 nucleic acid tests were negative. Noninvasive prenatal testing (NIPT) indicated a low risk of fetal trisomy 13, 18, and 21. At 31 weeks of gestation, ultrasound scanning showed slight widening of the left lateral ventricle (11.0 mm compared to reference of <10 mm), with the umbilical cord surrounding the neck, of the fetus (**Figure 1B**). As shown in **Figure 1C**, magnetic resonance imaging (MRI) revealed poor bilateral and frontal operculum formation and shallow bilateral lateral fissures, which were more obvious on the right side. Bilateral polymicrogyria of the lateral fissure area could not be ruled out. The left ventricle was slightly wider. No abnormalities were observed in the corpus callosum, septum pellucidum, cerebellar vermis, or posterior fossa. Due to the abnormal

cortical structure detected by MRI, interventional prenatal diagnosis was performed, along with chromosomal microarray analysis (CMA) and trio whole-exome sequencing (trio WES), simultaneously. The CMA result was negative, but trio WES detected a *de novo* missense variant of *TAOK1* in the fetus. Whole-genome sequencing (WGS) and droplet digital polymerase chain reaction (ddPCR) was then performed to identify the source of the variation. Finally, the *de novo* variant of *TAOK1* was found to originate from the paternal allele.

METHODS AND RESULTS

Trio Whole-Exome Sequencing

Genomic DNA was extracted from amniotic fluid and peripheral blood from the fetus and parents, respectively,

using the QIAamp DNA Mini Kit (Qiagen), following the manufacturer's instructions. Trio WES was performed to detect genetic variants (see **Supplementary Methods**), and a *de novo* variant of *TAOK1* [GRCh37/hg19 chr17: 27802710, NM_020791.2: c.227A>G (p.Glu76Gly)] was found. No other variants were considered to contribute to the phenotype.

The *de novo* variant c.227A>G is absent in the general population according to public databases (gnomAD, 1000 Genomes Project, NHLBI Exome Sequencing Project 6500, and Exome Aggregation Consortium). This variation has not been previously reported in the ClinVar or PubMed databases (retrieved 15 January 2022). A variety of prediction tools (SIFT, DANN, and REVEL) were used to evaluate the possible functional impact of c.227A>G, and it is predicted to be a damaging variation by all three tools. Furthermore, various algorithms (GERP, phyloP, phastCons, and SiPhy) and multiple sequence alignments from the UCSC genome browser predicted that this position is conserved across multiple vertebrate species (from zebrafish to human). The variant p.Glu76Gly is located in the "Protein kinase" domain of *TAOK1* (UniProt ID #Q7L7X3) in which benign variants are not found in ClinVar database. Although the protein structure of *TAOK1* was not available in the PDB database, the structure of the kinase domain (amino acids 28–281) was predicted with the I-TASSER server, as illustrated in **Figure 2** (Roy et al., 2010). The model with the highest confidence (C-score) and topological similarity (Tm-score) is used. The identified variant p.Glu76Gly is predicted to be located in an alpha-helix of the protein (**Figure 2**).

Whole-Genome Sequencing

To identify the phase of the *de novo* variant, WGS was performed for the proband (see **Supplementary Methods**). A heterozygous variant, c.306+468G>T (GRCh37/hg19 chr17:

27803257G>T), in *TAOK1* was found, which is 547 bp downstream of c.227A>G and was used as the reference for ddPCR analysis.

To validate the *de novo* variant c.227A>G and the reference variant c.306+468G>T, Sanger sequencing was performed for the family (see **Supplementary Methods**). The results showed that the proband carried c.227A>G but that neither parent did (**Figure 3A**); c.306+468G>T was found in the proband and mother but not in the father (**Figure 3B**).

Droplet Digital PCR

ddPCR was used to assess parental mosaicism (see **Supplementary Methods**). As shown in **Figure 4**, the peripheral blood samples of the parents did not show mosaicism at the site of the *de novo* variant of *TAOK1*.

To determine whether the mutant alleles of the variants, c.227A>G and c.306+468G>T, in the proband were located on the same chromosome, ddPCR was used to verify the phase (see **Supplementary Methods**). First, the T allele of c.306+468G>T was used as a reference, and phasing was performed. The results showed that these alleles were not located on the same chromosome (**Figure 5A**). Subsequently, the wild-type allele (G) of c.306+468G>T was used as a reference. The results showed that the G allele of c.306+468G>T and the mutant allele (G) of c.227A>G were located on the same chromosome (**Figure 5B**). The phasing analysis confirmed that the *de novo* variant c.227A>G derived from the paternal chromosome.

DISCUSSION

To the best of our knowledge, only six studies have reported variants of *TAOK1* in 40 patients with NDDs (Xie et al., 2016; Dulovic-Mahlow et al., 2019; Satterstrom et al., 2020; Basel-Salmon et al., 2021; van Woerden et al., 2021; Hunter et al., 2022). The phenotypes of the affected individuals are summarized in **Table 1**. All had NDDs, mainly involving global developmental delay, intellectual disability, hypotonia, and behavior problems, as well as brain MRI abnormalities and eye/visual problems. In this study, the fetus with a variant of *TAOK1* had a dilated left lateral ventricle, and brain MRI imaging in six previously reported postnatal cases revealed dilated lateral ventricles. However, the published studies did not differentiate between unilateral and bilateral ventricular dilation. Therefore, it is uncertain whether variants of *TAOK1* are associated with asymmetric ventricles.

This is the first report of a variant of *TAOK1* in the prenatal stage. We sought to determine whether prenatal *de novo* variants of *TAOK1* can predict the risk of NDDs. To evaluate associations between the *de novo* variant of *TAOK1* we found and phenotypes in the prenatal stage, we compared the pregnancy statuses of the patients with variants of *TAOK1* (**Table 2**). As shown, few abnormal pregnancy statuses were found. MRI abnormalities in the fetus are relatively prevalent in patients with *TAOK1*-associated NDDs. We suggest that fetuses with brain MRI abnormalities accompanied by *de novo* variants of *TAOK1* have a higher risk for NDDs, and should be carefully managed. Our study not only fills the gap between the variant of *TAOK1* and the prenatal phenotypes

FIGURE 3 | Validation of the *de novo* variant c.227A>G of *TAOK1* (chr17: 27802710) identified by trio WES and the reference variant c.306+468G>T (chr17: 27803257) identified by WGS by Sanger sequencing. **(A)** c.227A>G was found in the proband, but not in either parent. **(B)** c.306+468G>T was detected in the proband and mother, but not in the father.

but also provides valuable information for disease management, prognosis judgment and prenatal consultation.

As shown in **Table 1**, *de novo* variants of *TAOK1* have been found in thirty-one of 40 previously reported patients (77.5%). An additional *de novo* variant of *TAOK1* was detected in the fetus in this study. Variants in five (12.5%) affected individuals, P8, P9, P23, P37, and P38, were considered to be inherited from an affected mother or father (**Table 1**), which are classified as pathogenic herein. The very mild cognitive phenotypes of some affected parents might be explained by incomplete penetrance and variable

expressivity (Hunter et al., 2022). Furthermore, no recurrent variants were reported in the region of 17q11.2 (chr17: 27064286-28761847), indicating that *TAOK1* is not prone to hotspot variant, which was also mentioned by van Woerden et al. (2021). The variant identified in this study is located at chr17: 27802710, within the range of previous findings. Based on the protein structure modeling result (**Figure 2**), p.Glu76Gly is predicted to be located in an alpha-helix structure, and glycine is generally considered to destabilize an alpha-helix. Accordingly, we predicted that this novel missense variant affects protein kinase function, though

F, female; M, male; NR, not report; NA, not available; p.?, the effect on protein is unknown; +, present; –, absence; P, pathogenic; LP, likely pathogenic; VUS, variant of uncertain significance; *, Patient 38 is the older sibling of patient 37.

TABLE 2 | Clinical features of patients with *TAOK1* variants.

	Previous Studies	Current Prenatal Case
Gender		
Male	21/36 (58.3%)	NR
Pregnancy status		
Normal	1/22 (4.5%)	Yes
Uncomplicated	13/22 (59.1%)	No
Complicated	1/22 (4.5%)	No
<i>In vitro</i> fertilisation	2/22 (9.1%)	No
Polyhydramnios	5/26 (19.2%)	No
Ventricular dilatation	1/22 (4.5%)	Yes
Preeclampsia	1/22 (4.5%)	No
Oligohydramnios	1/22 (4.5%)	No
Pregnancy-induced hypertension	1/22 (4.5%)	Unknown
No prenatal care	1/22 (4.5%)	No
Neurodevelopmental disorder		
Global developmental delay	29/34 (85.3%)	NA
Intellectual disability	24/34 (70.6%)	NA
Hypotonia	22/33 (66.7%)	NA
Behavior problems	21/33 (63.6%)	NA
Brain MRI abnormalities	9/20 (45.0%)	Yes
Eye/visual problems	9/27 (33.3%)	NA

NR, fetal gender in the current case is not reported; NA, the feature is too early to observe in the prenatal case.

FIGURE 4 | Droplet digital PCR (ddPCR) for mosaic variation detection. The four ddPCRs are divided by vertical dotted yellow lines for the proband, mother, father, and negative control. The pink line is the threshold, above which are positive droplets (blue and green), and below which are negative droplets (gray) without any target DNA. There is no target DNA for the mutant locus c.227A>G in the mother and father (top panel).

more functional experiments are needed to validate this assumption.

In this study, the *de novo* variant was confirmed to originate from the paternal chromosome by a ddPCR phasing strategy, consistent with the findings that *de novo* variants arise more frequently in paternal germ cells than in maternal germ cells (Kong et al., 2012; Goldmann et al., 2016). The primarily *de novo* variants on the paternal chromosome could be explained by fundamental differences in germ cell biology in the female and male lineages. Spermatogenesis requires regular mitotic cell divisions of spermatogonial stem cells throughout male reproductive life (Goriely and Wilkie, 2012). However, the influence of maternal chromosomes on *de novo* variants in offspring cannot be ignored (Gao et al., 2019; Goldmann et al., 2019). In recent years, *de novo* variants have been found to be a prominent cause of NDDs, including intellectual disability (ID), autism, and schizophrenia (SCZ) (Veltman and Brunner, 2012; Acuna-Hidalgo et al., 2016). The relationship between paternal-age-related *de novo* variants and the risk for psychiatric and developmental disorders has been assessed, including for autism spectrum disorder (ASD), congenital heart disease (CHD), NDDs with epilepsy (EPI), ID, and SCZ (Taylor et al., 2019). Recurrent risk of a *de novo* variant should be considered if a germline mosaic variant is detected in parental samples, and the sibling recurrent risk can be as low as 0.5% if absent from samples of both parents by highly sensitive screening technology (Wright et al., 2019).

Variants of a gene of uncertain significance should always be classified as having uncertain significance of pathogenicity (Richards

et al., 2015). When we obtained the trio WES results in November 2020, the *TAOK1* gene has not been associated with any Mendelian disorder in the OMIM (Online Mendelian Inheritance in Man) database. We further explored research articles and found that Dulovic-Mahlow et al. (2019) first reported eight patients, all with *de novo* variants considered pathogenic due to loss of function of the TAO kinase family. We then evaluated the gene-disease association following the ClinGen Gene-Disease Validity Standard Operating Procedures (Strande et al., 2017), and curated the *TAOK1* gene to “moderate” grade. Finally, the *de novo* variant c.227A>G of *TAOK1* in our case was classified as likely pathogenic (PS2+PM1+PM2+PP3) based on ACMG guidelines (Zhang et al., 2020). A clear understanding of the clinical validity of the gene-disease relationship is critical for accurate interpretation of variants and successful medical decision-making based on genetic testing results. Because of limitations of the prenatal phenotype, accurate genetic variant classification in prenatal diagnosis is especially important. It would benefit from cross-laboratory data sharing and evaluating the strength of a gene-disease relationship based on the ClinGen Gene-Disease Validity Standard Operating Procedures. During the revision of the manuscript, the definitive classification of the gene-disease relationship between *TAOK1* and syndromic intellectual disability was curated by the ClinGen Intellectual Disability and Autism Gene Curation Expert Panel on 4 August 2021. In addition, the *TAOK1* gene was associated with OMIM disease (developmental delay with or without intellectual impairment or behavioral abnormalities, MIM #619575) starting from 19 October 2021. All of these are essential for future work.

DATA AVAILABILITY STATEMENT

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession number(s) can be found below: Genome Sequence Archive (Genomics, Proteomics, and Bioinformatics 2021) in National Genomics Data Center (Nucleic Acids Res 2021), China National Center for Bioinformation/Beijing Institute of Genomics, Chinese Academy of Sciences (GSA-Human: HRA001877) that are publicly accessible at <https://ngdc.cncb.ac.cn/gsa-human>.

ETHICS STATEMENT

Written informed consent was obtained from the individual(s) for the publication of any potentially identifiable images or data included in this article.

AUTHOR CONTRIBUTIONS

All authors contributed to the study conception and design. Data collection was performed by LY, CY, NS, HD, and JZ.
