About Frontiers

Frontiers is more than just an open-access publisher of scholarly articles: it is a pioneering approach to the world of academia, radically improving the way scholarly research is managed. The grand vision of Frontiers is a world where all people have an equal opportunity to seek, share and generate knowledge. Frontiers provides immediate and permanent online open access to all its publications, but this alone is not enough to realize our grand goals.

Frontiers Journal Series

The Frontiers Journal Series is a multi-tier and interdisciplinary set of open-access, online journals, promising a paradigm shift from the current review, selection and dissemination processes in academic publishing. All Frontiers journals are driven by researchers for researchers; therefore, they constitute a service to the scholarly community. At the same time, the Frontiers Journal Series operates on a revolutionary invention, the tiered publishing system, initially addressing specific communities of scholars, and gradually climbing up to broader public understanding, thus serving the interests of the lay society, too.

Dedication to Quality

Each Frontiers article is a landmark of the highest quality, thanks to genuinely collaborative interactions between authors and review editors, who include some of the world's best academicians. Research must be certified by peers before entering a stream of knowledge that may eventually reach the public - and shape society; therefore, Frontiers only applies the most rigorous and unbiased reviews. Frontiers revolutionizes research publishing by freely delivering the most outstanding research, evaluated with no bias from both the academic and social point of view. By applying the most advanced information technologies, Frontiers is catapulting scholarly publishing into a new generation.

What are Frontiers Research Topics?

Frontiers Research Topics are very popular trademarks of the Frontiers Journals Series: they are collections of at least ten articles, all centered on a particular subject. With their unique mix of varied contributions from Original Research to Review Articles, Frontiers Research Topics unify the most influential researchers, the latest key findings and historical advances in a hot research area! Find out more on how to host your own Frontiers Research Topic or contribute to one as an author by contacting the Frontiers Editorial Office: frontiersin.org/about/contact

Nonketotic hyperglycinemia (NKH) is a lethal autosomal recessive disease resulting from alterations in glycine metabolism, commonly caused by mutations in glycine decarboxylase (*GLDC*). The symptoms of NKH usually manifest in the neonatal period, and can be categorized into severe NKH and attenuated NKH based on the clinical outcome. To date, only a few NKH cases have been reported in China. We here report a case of a neonate with severe NKH carrying a novel compound heterozygous variant in *GLDC*. The patient was a 68-h-old girl who had progressive lethargy, no crying, and poor sucking ability from birth, and was therefore transferred to our department. On admission, the patient was supported by intubation and ventilation and presented with profound coma. Metabolic investigation indicated a markedly increased glycine concentration both in the plasma and cerebrospinal fluid (CSF). Symptomatic treatments were administered, but the patient's condition did not improve substantially. Whole-exome sequencing identified compound heterozygous mutations (c.1261G>C, p.G421R and c.450 C>G, p.N150K) in *GLDC*, which were inherited from the mother and the father, respectively. The patient was hospitalized for 8 days in our department and died 2 days after discharge. We further summarize the clinical features, genetic characteristics, administered treatment, and prognosis of previously reported Chinese NKH patients for context. Our results highlight that due to the non-specific clinical phenotypes of NKH and difficulty in obtaining CSF samples, genetic testing is a crucial tool, not only for a diagnosis but also for predicting the clinical outcome and can potentially help to determine the optimal therapeutic strategy.

Keywords: nonketotic hyperglycinemia, *GLDC* variation, compound heterozygous variant, glycine cleavage enzyme system, inherited metabolic disease

INTRODUCTION

Nonketotic hyperglycinemia (NKH) is an autosomal recessive inherited metabolic disease characterized by deficient activity of the glycine cleavage enzyme system (GCS), leading to the accumulation of glycine in almost all body tissues. The GCS consists of four components: glycine decarboxylase (also known as P protein), aminomethyl transferase (T protein), hydrogen carrier

protein (H protein), and dihydrolipoamide dehydrogenase (L protein), encoded by *GLDC*, *AMT*, *GCSH*, and *DLD*, respectively. *GLDC* mutations account for ~80% of NKH cases, whereas *AMT* variants account for ~20% of cases (1). In the majority of NKH cases, symptoms first appear in the neonatal period or during early infancy. According to the clinical outcomes, NKH is classified into severe NKH and attenuated NKH. Approximately 85% of cases with neonate onset are classified as severe NKH (2), mainly presenting with progressive lethargy and marked hypotonia, as well as severe apnea that requires ventilation.

We here report the case of a neonate with NKH carrying a novel compound heterozygous variant in *GLDC*, and summarize the clinical and genetic features of children with NKH reported in China to date.

CASE DESCRIPTION

A 68-h-old girl presenting with lethargy and a poor nutritional state among other symptoms was transferred from a local hospital to our department. She was born at 37 + 3 weeks of gestation by cesarean section due to cephalopelvic disproportion from a gravida 1, parity 1 (G1P1) mother. She had a birth weight of 2,600 g, an Apgar score of 10, and did not present asphyxia. Her parents were healthy and non-consanguine. After birth, the child manifested with progressive lethargy, no crying, and poor sucking ability. She was admitted to a neonatal department in the local hospital at 40 h of life, where she showed low spirit, decreased spontaneous breathing, poor terminal circulation, and blood pressure of 39/22 mmHg. She was intubated and ventilated, and administered 0.9% sodium chloride and dopamine ($12 \mu\text{g}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$) intravenously, as well as cefoperazone. However, the patient's condition did not substantially improve, and she was therefore transferred to our department.

On admission, physical examination showed profound coma with intubation and ventilation, yellowish skin, no autonomic activity, no autonomic breathing, no response to orbital pressure stimulation, slow pupil response to light, soft limbs, and

poor peripheral blood circulation. Blood gas analysis showed respiratory acidosis ($\text{pH} = 7.197$, $\text{P}_{\text{CO}_2} = 65.7 \text{ mmHg}$, $\text{P}_{\text{O}_2} = 93.4 \text{ mmHg}$, $[\text{HCO}_3^-] = 24.9 \text{ mM}$, $[\text{Be}] = 4.1 \text{ mM}$, and O_2 saturation of 97.4%). Electrolytes and lactic acid levels were normal, and blood glucose was slightly high (7.8 mM).

DIAGNOSTIC ASSESSMENT

After admission, the patient continued to be supported by intubation and ventilation, indwelling catheterization, and administration of cefoperazone and sulbactam sodium to combat any potential infection. Because a diagnosis of congenital metabolic diseases could not be excluded, a regimen including

^bCopy number variation was not analyzed in the parents.

NA, Not available.

vitamin B12, vitamin B6, vitamin C, folic acid, coenzyme Q10, and levocarnitine was administered. Several subsequent blood ammonia checks were in the normal range, and there was no obvious metabolic/respiratory acidosis in the repeated blood gas analysis. Amplitude-integrated electroencephalogram both on 3 and 5 days of life all indicated a burst suppression pattern (the amplitude ranged from 1 μV to nearly 100 μV), absence of sleep-wake cycle and no convulsive activity. Cranial magnetic resonance imaging (MRI) demonstrated focal cerebral hemorrhage of the right frontal lobe and left paraventricular brain (**Figure 1A**), focal long T2 signal of the bilateral frontal parietal lobes, and high signals of diffusion-weighted imaging of several brain areas, including the bilateral radial crown, posterior limb of the internal capsule (**Figure 1B**), and pontine arm, and the thin corpus callosum (**Figure 1C**). On day five of admission, the blood amino acid and acylcarnitine spectrum analyses to check for inherited metabolic diseases showed that the glycine concentration was increased at 942 μM (normal range 100–500 μM). The metabolic spectrum of the cerebrospinal fluid (CSF) also showed a markedly elevated glycine level, reaching a value of 3,460 times the control. The ratio of CSF to plasma glycine was 0.12 (normal < 0.08). A comprehensive panel of urine organic acids was normal.

Whole-exome sequencing (Beijing Fulgent Technologies Inc., Beijing, China) indicated that the patient had compound heterozygous variants in *GLDC* (reference genome hg 19, NM_000170.2): c.1261G>C (p.G421R) in exon 9 and c.450 C>G (p.N150K) in exon 3, which have not been previously reported. Sanger sequencing also confirmed that the two mutations were inherited from her mother and father, respectively (**Figure 2**). According to American College of Medical Genetics and Genomics guidelines, these two missense mutations are classified as likely pathogenic. The two mutations were inherited from the mother and father, respectively. Mutations were absent from controls in the GnomAD, 1000 Genomes Project, Exome Aggregation Consortium, and dbSNP databases. Bioinformatic prediction analyses using Mutation_Taster, PolyPhen2, and SIFT indicated that they were deleterious. Two other two missense mutations, p.G421V and p.N150T, at the same amino acid position had been identified as pathogenic. A diagnosis of NKH was finally made based on the clinical symptoms, elevated glycine concentration in the plasma and CSF, and increased glycine CSF/plasma ratio.

After 8 days of comprehensive anti-infection treatment, mechanical ventilation, and other symptomatic care, the patient's conscious reaction, limb movement, and peripheral circulation improved, although she still had no obvious spontaneous breathing. Considering the poor prognosis, the parents ceased treatment, and the patient died 2 days after discharge.

DISCUSSION

Approximately 80% of the NKH-causing *GLDC* mutations are sequence variations, whereas the remainder are exonic copy number variations (CNVs) (3). Among the sequence variations, missense mutations are the most frequent, followed by nonsense mutations, splice-site mutations, and small insertions/deletions.

In addition, some recurrent mutations have been identified in the United Kingdom and Finland, because of a founder effect, almost all of them unique (3, 4).

To date, 13 *GLDC* variants, including seven missense mutations (53.8%), three CNVs (23.1%), two nonsense mutations (15.4%), and one splice-site mutation (7.7%), have been identified in 10 Chinese children with NKH from 7 different families (Table 1) (5–10). Among 11 alleles identified with single-nucleotide variants, three (27.3%) were in exon 21 and two (18.2%) were in exon 9. No mutations in *AMT* have been identified in Chinese children suffering from NKH to date. In this study, we detected two heterozygous missense mutations in a neonate with severe NKH, c.1261G>C (p.G421R) and c.450 C>G (p.N150K), which were inherited from the mother and the father, respectively.

Different types of genetic variants can lead to a complete absence or different degrees of residual GCS enzyme activity, thus leading to distinct clinical phenotypes. For example, loss-of-function mutations such as a copy number (11), frameshift, nonsense, or splice site variation (12) causing complete depletion of GCS activity can lead to a severe phenotype (3, 13–15). However, it is difficult to assess the residual GCS activity in the case of missense mutations (4, 16). In addition to the present report of a severe case of NKH, there have been seven severe cases of NKH and two cases of attenuated NKH reported in China. Among the 12 alleles associated with severe NKH (eight cases from six unique families), seven (58.3%) were missense mutations, whereas in the two alleles associated with the attenuated cases (two cases from one family), only one was a missense mutation. Although the effect of the novel mutations identified in this study, p.G421R and p.N150K, on GCS activity is not clear, this patient was diagnosed with severe NKH according to the age of onset and clinical characteristics, suggesting that both of them were null mutations. Furthermore, the same amino acid positions of *GLDC*, p.G421V and p.N150T have been previously reported in three different patients with NKH. A patient carrying the p.N150T and p.R790W mutations presented with hypotonia apnea, coma intraventricular hemorrhage since the 3 days of life; her electroencephalogram showed a suppression burst pattern and brain MRI was normal; the concentration of glycine in CSF and in serum, and the CSF/serum ratio were 270 $\mu\text{mol/L}$, 880 $\mu\text{mol/L}$ and 0.31, respectively. At 16 days of age, sodium benzoate and dextromethorphan were administered. Imipramine was initiated at 7 years of age. *In vitro* expression analyses showed that the mutant glycine decarboxylases with p.N150T had 1% normal enzyme activity. However, the patient had far better psychomotor development because the other mutation, p.R790W, retained 14% of the enzyme activity (16). Kure et al. reported another Asian patient with p.N150T and c.1926 + 1G>A mutations (14). Her glycine level in CSF and the CSF/serum ratio were 148 mM and 0.12, respectively. No other phenotype was described. For residue 421 of glycine decarboxylase, variations of p.G421V and p.A729Efs*3 have already been described as associated with NKH (3). No other clinical data are available.

Currently, there are no formal management guidelines for NKH. The current treatment strategy focuses on reducing the

plasma glycine concentration, blocking N-methyl-D-aspartate receptors, and symptomatic care (17, 18). Treatment information is available for six patients with severe NKH previously described in the literature (Table 1). Among three cases treated with dextromethorphan and/or sodium benzoate, one died at 4 months (case 2 in Table 1) and two were alive with severe intellectual disability when followed up at 1 year 7 months (case 1 in Table 1) and 7 months (case 9 in Table 1), respectively. The remaining three cases treated only with symptomatic care died from 4 to 13 days of life. Although information about the treatment provided was not available for the two siblings with attenuated NKH (case 5 and case 6 in Table 1), valproate administration leading to aggravation of the condition in the early stage of the disease was reported for case 5. Based on this, valproate is contraindicated for controlling epileptic seizures in NKH patients (19). In addition, based on previous case reports, vigabatrin should be avoided to treat West syndrome in NKH (20).

Since the genetic basis of NKH is well-defined and increased residual GCS activity has been associated with an improved clinical outcome, therapeutic strategies that can enhance the residual activity associated with a mutation should be pursued. For example, a translational read-through inducer has been used to promote translation through a premature stop codon (21), chemical chaperones have been used for unstable missense mutations to restore protein folding (22), and antisense oligonucleotides have been used to correct a splicing variation (23). Considering that CSF samples of neonatal children are not easily obtained, genetic testing is a powerful tool for diagnosing NKH, especially for patients with a normal plasma glycine level (case 2 in Table 1). Early use of genetic testing to diagnose NKH can avoid unnecessary drug-induced damage, as well as provide guidance to the family for future pregnancies.

CONCLUSION

We reported a patient with severe NKH who carried a novel compound heterozygous mutation and summarized the genetic and phenotypic characteristics, as well as the treatment strategy followed and prognosis of other NKH cases reported in China to date. This case report highlights the importance of genetic testing not only as a tool for NKH diagnosis but also for clinical outcome prediction, and the potential development of novel therapeutic strategies in the future.

Correlation Between Genotype and
Age of Onset in Leukoencephalopathy
With Vanishing White Matter.
Front. Genet. 12:729777.
doi: 10.3389/fgene.2021.729777

Purpose: Leukoencephalopathy with vanishing white matter (VWM) is an autosomal recessive leukoencephalopathy caused by mutations in any of the five genes encoding the subunits of eukaryotic translation initiation factor 2B (eIF2B). The severity of the disease varies considerably, and its genotypic-phenotypic correlation is still unclear. Age of onset is the only independent clinical predictor for VWM severity. In this study, the correlation between genotype and age at onset of patients was investigated.

Methods: Data were collected from patients with VWM in the available literature reports and from those diagnosed in Peking University First Hospital. The age of onset was divided into early-onset (≤ 4 years) and late-onset type (> 4 years) for the analysis of the correlation between genotype and age of onset in patients with VWM.

Results: A total of 341 patients were included, 281 were reported in 87 available articles and 60 were diagnosed in our center. A total of 180 different mutations were found, among which 86.1% were missense. The gene (*EIF2B1-5*) in which the mutation located, and the number of null alleles were not associated with age of onset in these patients. Certain mutations such as eIF2B ϵ [Arg195His] and eIF2B ϵ [Arg269Gln] that were predicted to have a serious influence on eIF2B structure were related to earlier age of onset. EIF2B γ [Ala87Val] which was predicted to have a minimal influence on eIF2B structure, was related to later age of onset. Whereas eIF2B β [Glu213Gly], eIF2B β [Gly200Val] and eIF2B ϵ [Thr91Ala], also predicted having a small effect on the structure of eIF2B, did not show correlation with the age of onset. The onset age of patients with one or biallelic missense mutations located in the catalytic domain or other homologous domains in catalytic subunits (eIF2B γ , ϵ) was earlier than that of patients with biallelic mutations located in the NT domain.

Conclusion: The onset age of patients with different genotypes varied greatly. The degree of influence in protein structure of some missense mutations was correlated with phenotypic severity, but the results were not completely consistent. The combined effect of biallelic mutations, the role of regulatory genes, environmental stress and other potential factors on phenotypes need to be further explored.

Keywords: leukoencephalopathy with vanishing white matter, EIF2B1-5, genotype, age of onset, correlation

FIGURE 1 | Brain MRI of four patients with WWM at different onset ages. **(A):** case 1 with onset in neonatal period, the age at MRI was 3 months; **(B):** case 2 with onset in infancy, the age at onset was 11 months, the age at MRI was 18 months; **(C):** case 3 with onset in childhood, the age of onset was 3 years old, the age at MRI was 3 years old; **(D):** case 4 with onset in adulthood, the age of onset was 43 years old, the age at MRI was 43 years old. The left column: T1 weighted sequences (T1WI); The middle column: T2 weighted sequences (T2WI); The right column: T2 FLAIR sequences. The white matter showed low signal on T1WI, high signal on T2WI and low signal liquefaction on T2 FLAIR. The earlier the age of onset, the wider the range of white matter liquefaction, while the liquefaction sign was not evident in adult patients. Furthermore, the subcortical white matter was involved in the early stage.

INTRODUCTION

Leukoencephalopathy with vanishing white matter (VWM) is an autosomal recessive leukoencephalopathy. In 1997, van der Van Der Knaap et al. (1997) reported the first clinically diagnosed case of VWM. From 2001 to 2002, it was revealed to be caused by mutations in any one of the five following subunits of the eukaryotic translation initiation factor 2B (eIF2B): *EIF2B1*(12q24), *EIF2B2*(14q24), *EIF2B3*(1p34), *EIF2B4*(2p23) and *EIF2B5*(3q27) (Leegwater et al., 2001; Van Der Knaap et al., 2002). The typical phenotype in children is progressive regression in motor function exacerbated by fever or head trauma. Brain MRI shows that the white matter liquefies progressively (Figure 1). Age of onset and disease severity vary substantially from neonatal period to adulthood. Early onset of this disease is usually correlated to fast progression and poor prognosis (Hamilton et al., 2018). Although the pathogenesis of VWM is increasingly recognized, the reasons for the wide phenotype are still unknown. A clear genotype-phenotype correlation has not been established. The relationship between genotype and phenotype is important in elucidating the pathogenesis of VWM, predicting the prognosis of VWM, and promoting genetic consultation. Previous studies have confirmed that age of onset is the only independent clinical predictor of disease severity (Fogli et al., 2004a; Hamilton et al., 2018). A thorough search on patients from published literatures and those diagnosed in our center (Pediatric Department, Peking University First Hospital) were conducted to analyze the correlation between the genotype and the age of onset.

PATIENTS AND METHODS

Inclusion of Patients

Literature Searching Strategy

Case series studies or case reports on VWM containing information on the clinical and genotypic spectra of patients were searched from the following databases: PubMed, Embase, Cochrane Library, Web of Science, China National Knowledge Infrastructure, and WAN FANG DATA (the latter two are Chinese public searching databases). The following search terms were used: leukoencephalopathy with vanishing white matter, vanishing white matter disease, childhood ataxia with central nervous system hypomyelination or Cree leukoencephalopathy (CLE). The publications were in either English or Chinese. The searching deadline was January 2021.

Inclusion Criteria of Patients From Our Center

The inclusion criteria were as follows: brain MRI showing symmetric abnormal signals on T1WI, T2WI and T2 FLAIR images in the white matter that was partially rarefied, and biallelic pathogenic or likely pathogenic variants in *EIF2B1-5* according to the American College of Medical Genetics Guidelines confirmed by sequencing (Richards et al., 2015). The study was approved by the Medical Ethics Committee of Peking University First

Hospital. Informed consents were obtained from the parents of the children.

Correlation Analysis of Genotype and Age of Onset

Age of onset was divided into early-onset type (≤ 4 years) and late-onset type (> 4 years). It was used as a typical phenotypic index to analyze the genotype-phenotype correlation. All data were analyzed using SPSS 20.0 software. $p < 0.05$ was considered statistically significant.

Correlation Between the Mutant Gene (*EIF2B1-5*) and Age of Onset

Enumeration data were expressed as frequency and percentage, and measurement data were expressed as median (range). Chi-square test was performed to compare the difference in mutant genes between the early- and late-onset patients. If the data were normally distributed, one-way ANOVA was used; otherwise, Kruskal-Wallis test was applied.

Correlation Between Numbers of Null Allele and Age of Onset

Null allele was defined as loss-of-function allele, which included nonsense, frameshift, +1 or +2 splicing mutations, -1 and -2 intronic mutations, and single or multiple exon deletion. They were divided into 1 and 0 null allele in accordance with the number of null alleles carried by the patients. If the data were normally distributed, T test was used to analyze the age of onset between the two groups; otherwise, non-parametric test was applied.

Correlation Between Missense Mutations With Reported Structural Effects and Age of Onset

Some missense mutations were reported to have multiple effects on eIF2B structure, but the variant was not completely related to the phenotype, thus suggesting the influence of another allele or other modifiers on the phenotype. In this study, patients with biallelic missense variants were included for the analysis. The differences in age of onset among patients with 0, 1 or 2 missense mutations reported to show structural effects were analyzed.

Correlation Between Missense Mutations Located Indifferent Structural Domain and Age of Onset

The eIF2B decamer consists of regulatory (α , β , δ) and catalytic (γ , ϵ) subunits. Catalytic subcomplexes eIF2B γ and eIF2B ϵ have four different domains (Figure 2): 1) NT domain; 2) I-patch domain: the NT domain and I-patch domain alone do not interact with other subunits, but certain mutations or disruptions within them affected the formation of eIF2B holo-complexes; 3) Catalytic domain: responsible for the interaction of eIF2B with eIF2 (the substrate); 4) other domains: except for the above three domains, the sequences are all highly homologous regions, but functional significance is still unclear. Given the wide range of effects of null allele on eIF2B and the unclear effects of intron mutations, the

correlation between the affected structural domain and age of onset was compared among patients with biallelic missense variants. If the data were normally distributed, ANOVA was used to analyze the age of onset between groups affected by different structural domains; otherwise, Kruskal-Wallis test was applied.

RESULTS

General Information of the Mutations

A total of 341 patients were included, among which, 281 were reported in 87 available articles and 60 were diagnosed in our center (Supplementary Table S1). In addition, 196 patients belonged to the early-onset type and 145 patients were categorized as late-onset type. The proportions of patients with mutations in *EIF2B1*, *EIF2B2*, *EIF2B3*, *EIF2B4*, and *EIF2B5* were 1.5% (5/341), 15.2% (52/341), 11.1% (38/341), 10.3% (35/341) and 61.9% (211/341), respectively. A total of 180 mutations were identified, including 154 missense (86.1%), 11 frameshift (6.1%), eight nonsense (4.4%), three in-frame small deletion (1.7%), 2 splice-site, and 2 intronic mutations (not splice-site).

Correlation Between the Mutant Gene and Age of Onset

Five patients carried mutations in *EIF2B1*, of which two were early-onset and three were late-onset, and the median age of onset was 10.0 (0.7–29.0) years. Fifty-two patients carried mutation in *EIF2B2*, of which 31 were early-onset and 21 were late-onset, and the median age of onset was 3.8 (0.2–43.0) years. Thirty-eight

patients carried mutation in *EIF2B3*, of which 24 were early-onset and 14 were late-onset, and the median age of onset was 3.6 (0–61.0) years. Thirty-five patients carried mutation in *EIF2B4*, of which 21 were early-onset and 14 were late-onset, and the median age of onset was 3.5 (0–41.0) years. A total of 211 cases carried mutation in *EIF2B5*, of which 119 were early-onset and 92 were late-onset, and the median age of onset was 3.5 (0–62.0) years. No statistical difference was observed between the proportions of patients with early-onset and late-onset types among different mutant genes ($\chi^2 = 1.51$, $p > 0.05$). No statistical difference also was observed in the age of onset among the five mutant genes ($H = 3.39$, $p > 0.05$) (Figure 3A).

Correlation Between Numbers of Null Allele and Age of Onset

Among the study population, 36 patients carried one null allele with the median age at onset of 2.5 (0–24.0) years, and 303 patients carried zero null allele with the median age at onset of 3.6 (0–62.0) years (two patients carried intronic variants in non-splicing sites were excluded). No statistical difference in the age of onset was observed between patients with one or zero null allele ($Z = 1.57$, $p > 0.05$) (Figure 3B).

Correlation Between Missense Mutations With Reported Structural Effects and Age of Onset

Some missense mutations were predicted to show variable structural effects on the protein, including *eIF2B* β [Thr91Ile], *eIF2B* β [Ser171Phe], *eIF2B* β [Gly200Val], *eIF2B* γ [Arg91His], *eIF2B* δ [Arg264Trp], *eIF2B* δ [Arg357Trp], *eIF2B* δ [Arg483Trp],

TABLE 1 | Correlation between age of onset among patients with 0, 1 or 2 above missense mutations and structural effect.

Predicted structural effects	Mutations	Numbers of mutations	N ^a	Age of onset(years)	Variable	P

		2	6	26.5(2.1–61.0)		
		1	4	38.5(2.3–57.0)		
		0	293	3.5(0–62.0)		

^aN: number of patients with 0, 1 or 2 missense mutations; H_a: people carried two eIF2B ϵ [Arg195His] compared with those without eIF2B ϵ [Arg195His] mutation; H_b: people carried two eIF2B ϵ [Arg195His] compared with those carried one eIF2B ϵ [Arg195His] mutation; H_c: people carried one eIF2B ϵ [Arg195His] compared with those without eIF2B ϵ [Arg195His] mutation. H_d: people carried one eIF2B ϵ [Arg269Gln] compared with those without eIF2B ϵ [Arg269Gln] mutation.

eIF2Be [Thr79Ile], eIF2Be[Glu81Leu], eIF2Be[Arg136His], eIF2Be[Arg195His], eIF2Be[His269Pro], eIF2Be[Arg316Gln], eIF2Be[Thr91Ala], eIF2Be[Glu213Gly], eIF2Be[Arg133His], eIF2Be[Gly386Val], [Ala403Val] and [Thr432Ile] (Slynko et al., 2021).

In this study, due to the small number of the above mutations in these patients, we only analyzed eIF2Be[Arg195His], eIF2Be[Arg269Gln], eIF2Bβ[Gly200Val], eIF2Bβ[Glu213Gly], eIF2Bγ[Ala87Val] and eIF2Be[Thr91Ala]. Among them, eIF2Be[Arg195His] and eIF2Be[Arg269Gln] were considered to have a serious effect on the structure of eIF2B and associated with a more serious phenotype, whereas eIF2Bβ[Gly200Val], eIF2Bβ[Glu213Gly], eIF2Bγ[Ala87Val] and eIF2B[Thr91Ala] were predicted to have a small effect on the structure of eIF2B and associated with a mild phenotype. Only patients with biallelic missense mutations were included for the analysis.

Differences in the age of onset among patients with 0, 1 or 2 above missense mutations were analyzed (Table 1). The age of onset in patients with eIF2Be[Arg195His] or eIF2Be[Arg269Gln] mutation was significantly earlier than that in patients without the mutations ($Z = 2.14$, $p < 0.05$; $Z = 2.77$, $p < 0.01$), thus supporting the previous results that patients with these two mutations have a more serious clinical phenotype. In addition, the patients with two eIF2Be[Arg195His] variants had an earlier age of onset than those with one or no eIF2Be[Arg195His], and patients with one eIF2Be[Arg195His] showed no statistically significant difference in the age of onset with those without the mutation. Similarly, the patients with one eIF2Be[Arg269Gln] had an earlier age of onset than those without the mutation. The age at onset in patients with eIF2Bγ[Ala87Val] or eIF2Bγ[Arg269Gln] mutation was significantly later than that in patients without the mutation ($Z = 2.68$, $p < 0.01$), indicating that the slight structural effect predicted mild disease severity. However, no significant difference in the age of onset was observed among patients with eIF2Bβ[Gly200Val], eIF2Bβ[Glu213Gly] or eIF2Be [Thr91Ala] compared with other patients ($Z = 1.34$, $p > 0.05$; $Z = 0.94$, $p > 0.05$; $Z = 0.11$, $p > 0.05$, respectively), suggesting that eIF2Bβ[Glu213Gly], eIF2Bβ[Gly200Val] and eIF2Be[Thr91Ala] have a slight correlation with age of onset in these patients.

Correlation Between Missense Mutations Located in Different Structural Domain and Age of Onset

Among the 154 missense mutations, four were *EIF2B1* mutations, 17 were *EIF2B2* mutations, 23 were *EIF2B3* mutations, 28 were *EIF2B4* mutations, and 82 were *EIF2B5* mutations (Supplementary Table S2).

Correlation Between Missense Mutations Located in Different Subunit and Age at Onset

Among the 303 patients carrying biallelic missense mutations, 81 patients carried mutations affecting the regulatory subunit, and the median age of onset was 4.0 (0–43.0) years, while 222 patients carried mutations affecting the catalytic subunit, and the median age of onset was 3.5 (0–62.0) years. No statistically significant

difference in the age of onset was observed among patients carrying mutations affecting the regulatory or catalytic subunit ($Z = 1.26$, $p > 0.05$) (Figure 3C).

Correlation Between Missense Mutations Located in Different Structural Domain and Age of Onset

A total of 222 patients carrying missense mutations in the catalytic subunit were classified into the following four groups: 1) 106 patients carried biallelic mutations in the NT domain, with the median age of onset 9.0 (0–61.0) years; 2) five patients carried biallelic mutations in the I-patch domain, with the median age of onset 4.0 (2.0–5.0) years; 3) eight patients carried one mutation affecting the catalytic domain, with the median age of onset 2.5 (0.7–13.2) years; and 4) 49 patients carried biallelic mutations affecting the other domains, with the median age of onset 2.5 (0.3–62.0) years. Significant difference in the age of onset was observed among these four groups ($H = 19.19$, $p < 0.001$). The age of onset in patients carrying one mutation in the catalytic domain was significantly earlier than that of patients with two mutations in the NT domain ($Z = 2.28$, $p < 0.05$). The age of onset in patients carrying biallelic mutations affecting other domains was earlier than that in patients with biallelic mutations in the NT domain ($Z = 3.99$, $p < 0.001$) (Figure 3D).

DISCUSSION

A genotype-phenotype correlation was reported in patients with VWM, but certain differences were found, in part because of differences in the phenotypic measures used in the studies (Fogli et al., 2004a; Van Der Lei et al., 2010; Matsukawa et al., 2011). Age of onset is the only independent clinical predictor of disease severity (Hamilton et al., 2018), which is easily accessible from the literature, and therefore served as a relatively reliable index of phenotype in our study. Data from 341 patients with VWM were collected, including 180 different mutations in *EIF2B1-5*, of which 86.1% were missense mutations. In this study, the proportions of patients with mutations in *EIF2B1*, *EIF2B2*, *EIF2B3*, *EIF2B4*, and *EIF2B5* were 1.5, 15.2, 11.1, 10.3 and 61.9%, respectively. Similar to the results of previous reports (Bugiani et al., 2010), the most common mutant gene was *EIF2B5*, followed by *EIF2B2*. The correlation between the age of onset and the different mutant genes was not identified.

EIF2B1-5 are house-keeping genes that play an important role in eukaryotic cells. They encode eIF2B, which is a critical factor in the initiation of protein translation. Null allele may result in the inability to synthesize eIF2B protein and loss of translation initiation function. Therefore, individuals carrying two null alleles could not survive to be born. No patients carrying two null alleles have been reported yet. In this study, we analyzed the correlation between numbers of null allele and age of onset. We did not find significant difference between the age of onset in patients with one or zero null allele. This finding may be due to the relatively small proportion of patients with null allele (10.5%).

Previous studies have reported a certain correlation between the degree of influence of missense mutations on protein structure and phenotypes, but the results are not consistent.

Results from protein prediction software or model analysis of the mutation site function prediction revealed that some mutations with multiple or substantial effects on the eIF2B structure were associated with severe phenotypes, such as eIF2Be[Thr79Ile], eIF2Be[Glu81Leu], eIF2Be[Arg136His], eIF2Be[Arg195His], eIF2Be[His269Pro], eIF2Be[Arg269Gln], eIF2Be[Arg316Gln], eIF2Bδ[Arg264Trp], eIF2Bδ[Arg357Trp], eIF2Bδ[Arg483Trp], and eIF2Bγ[Arg91His] (Slynko et al., 2021). Mutations such as eIF2Bβ[Thr91Ala], eIF2Be[Thr91Ala], eIF2Be[Ala87Val] and eIF2Be[Glu213Gly], with predicted minimal influence on the eIF2B structure, were associated with mild disease severity. However, the functional prediction of missense variants could not completely explain the phenotype. For example, mutations such as eIF2Be[Arg133His] and eIF2Bβ[Ser171Phe] were predicted to have a huge effect on protein structure, but they were related to mild phenotype. Mutations such as eIF2Bβ[Gly200Val], eIF2Be[Gly386Val] [Ala403Val] and [Thr432Ile], with small predict effects, were linked to serious phenotype (Fogli et al., 2004b; Campbell and Ashe, 2006; Slynko et al., 2021). In this study, 303 patients with biallelic missense mutations were analyzed. Those with eIF2Be[Arg195His] and eIF2Be[Arg269Gln] had a significantly earlier age of onset than those without the mutations. This finding is consistent with the genotype-phenotype correlation from previous reports. The phenotype of children carrying eIF2Be[Arg195His] mutation usually manifested as Cree leukoencephalopathy, a rapidly fatal phenotypic variant of infantile VWM with disease onset in prenatal or infancy; almost all of the affected patients died before 2 years of age (Van Der Knaap et al., 2003; Harder et al., 2010). In the present study, patients carrying eIF2Bγ[Ala87Val] had a significantly later age of onset than those without the mutation. Contrary to the results of previous studies, eIF2Bβ[Glu213Gly], [Gly200Val], and eIF2Be[Thr91Ala] showed a minimal correlation with the age of onset. Fogli et al. (2004a) reported that eIF2Bβ[Glu213Gly] mutation was associated with a mild phenotype, relatively late age of onset, and slow progression. van der Van Der Lei et al. (2010) found that the disease severity of patients with heterozygous eIF2Be[Arg113His] was milder than that of patients with heterozygous eIF2Be[Arg113His] and homozygous eIF2Be[Thr91Ala]. Meanwhile, the phenotype of patients with eIF2Be[Arg113His/Arg339any] was milder than that of patients with eIF2Be[Thr91Ala/Arg339any]. In our study, the age of onset among patients with two, one or without eIF2Be[Arg195His] variants were compared. The patients with biallelic eIF2Be[Arg195His] showed earlier onset than those with one or no variant, and the patients with one eIF2Be[Arg195His] showed no statistically significant difference in terms of age of onset compared with those without the variant. Similarly, the patients with one eIF2Be[Arg269Gln] mutation had an earlier age of onset than those without the mutation. These findings suggested that the correlation between genotype and phenotype required consideration of the combined effects of biallelic variants.

Whether the location of the missense mutations in different types of subunits or functional domains was associated with the age of onset was further analyzed. The results showed that the age of onset was not correlated with the location of the mutations in the regulatory (α , β , δ) or catalytic (γ , ϵ) subunits. Catalytic

subcomplexes eIF2Bγ and eIF2Be have four different domains: NT domain, I-patch domain, catalytic domain and other domains. eIF2Be has the most important catalytic domain (amino acids 518–712 at the C-terminus) with GEF activity (GDP/GTP conversion). Knockout of the catalytic domain fragment in the mouse model could substantially reduce GEF activity and eIF2Be binding to other subunits, suggesting that this region is important for the stability and activity of the eIF2B complex (Wortham et al., 2016; Moon and Parker, 2018a). Therefore, we further analyzed whether the location of missense mutations in different domains of the catalytic subunits influenced the age of onset. The results showed that patients carrying mutations located in the catalytic domain and other homologous domains had an earlier age of onset.

In VWM, stress is the triggering or aggravating factor, including head trauma, acute startle, and febrile infection (Labauge et al., 2009). Different cellular stresses lead to eIF2α phosphorylation, which then acts as a competitive inhibitor of eIF2B, inhibiting mRNA translation. A central mechanism in a cellular stress response is the inhibition of protein synthesis, known as unfolded protein response (Wong et al., 2019). This process aims to reduce the accumulation of denatured and misfolded proteins and escape translation inhibition through the transcription of mRNA with a special open reading frame (ORF), thus preserving cellular energy to enhance cell survival under stress. However, if the cellular stress state remains uncorrected for a long time and the unfolded protein response is overactivated and could not be recovered over a long period of time, it may lead to the logical deterioration and possible multi-organ dysfunction, which may be the possible cause of exacerbation of VWM (Moon and Parker, 2018b). Therefore, the observed considerable phenotypic variability indicated that genotype is not the only factor that determines phenotype; the environment may be an essential influential entity that affects disease severity. Exposure to factors causing episodic exacerbations could worsen the disease. Measures to prevent trauma and infection can improve the prognosis, and other factors, such as the regulation of upstream and downstream gene variation and epigenetics, have possible implications.

This study has some limitations. Most mutations have not been functionally studied, and their effects on protein functions need to be confirmed. The variants of only one allele were analyzed, and the other allele also contributed to the phenotype. The combined effect of the two alleles requires a larger sample data. Other regulatory genes and environmental factors also influence phenotypes, and they were not considered in this study. Age of onset is an independent risk factor for phenotypic severity. It was used as a phenotypic factor in this study to simplify and facilitate the extraction from the literature. However, it was likely to be inaccurate, and including indicators, such as the speed of motor function progression, is preferable.

CONCLUSION

A detailed genotypic-phenotypic association analysis was performed in 341 patients with VWM. The gene (*EIF2B1-5*) in which the mutation located, and the number of null alleles were not associated with age of onset in these patients. Certain mutations, such as eIF2Be[Arg195His] and eIF2Be

[Arg269Gln], which were predicted to have a serious influence on eIF2B structure, were related to earlier age of onset. And eIF2B γ [Ala87Val], which was predicted to have a minimal influence on eIF2B structure, was related to later onset. eIF2B β [Glu213Gly], eIF2B β [Gly200Val] and eIF2B ϵ [Thr91Ala] showed a slight correlation with age of onset. The age of onset in patients with one or biallelic missense mutations located in the catalytic domain or other homologous domains in the catalytic subunits was earlier than that of patients with biallelic variants located in the NT domain. The combined effect of biallelic mutations, the role of regulatory genes, environmental stress and other potential factors on phenotypes need to be further explored.

Carnitine palmitoyltransferase 1A (*CPT1A*) deficiency is an inherited disorder of mitochondrial fatty acid β -oxidation that impairs fasting ketogenesis and gluconeogenesis in the liver. Few studies implementing newborn screening (NBS) for *CPT1A* deficiency in the Chinese population have been reported. This study aimed to determine the biochemical, clinical, and genetic characteristics of patients with *CPT1A* deficiency in China. A total of 204,777 newborns were screened using tandem mass spectrometry at Quanzhou Maternity and Children's Hospital between January 2017 and December 2018. Newborns with elevated C0 levels were recruited, and suspected patients were subjected to further genetic analysis. Additionally, all Chinese patients genetically diagnosed with *CPT1A* deficiency were reviewed and included in the study. Among the 204,777 screened newborns, two patients were diagnosed with *CPT1A* deficiency; thus, the estimated incidence in the selected population was 1:102,388. In addition to the two patients newly diagnosed with *CPT1A* deficiency, we included in our cohort 10 Chinese patients who were previously diagnosed. Five of these 12 patients were diagnosed *via* NBS. All patients exhibited elevated C0 and/or C0/(C16+C18) ratios. No clinical symptoms were observed in the five patients diagnosed *via* NBS, while all seven patients presented with clinical symptoms, including fever, cough, vomiting, diarrhea, and seizures. Eighteen distinct *CPT1A* variants were identified, 15 of which have been previously reported. The three novel variants were c.272T>C (p.L91P), c.734G>A (p.R245Q), and c.1336G>A (p.G446S). *in silico* analysis suggested that all three novel variants were potentially pathogenic. The most common variant was c.2201T>C (p.F734S), with an allelic frequency of 16.67% (4/24). Our findings demonstrated that NBS for *CPT1A* deficiency is beneficial. The three novel variants expand the mutational spectrum of *CPT1A* in the Chinese population, and c.2201T>C (p.F734S) may be a potential hotspot *CPT1A* mutation.

Keywords: newborn screening, carnitine palmitoyltransferase 1A deficiency, *in silico* prediction, *CPT1A* gene, tandem mass spectrometry

INTRODUCTION

Carnitine palmitoyltransferase 1A (CPT1A) (OMIM 255120; EC 2.3.1.21) deficiency is an inherited autosomal recessive disorder of mitochondrial fatty acid β -oxidation that impairs fasting ketogenesis and gluconeogenesis in the liver. The causative gene, *CPT1A* (OMIM 600528), is located on chromosome 11q13.1-q13.2. Patients may present with a variety of symptoms, including seizures, lethargy, hypoglycemia, vomiting, diarrhea, fever, and hepatomegaly triggered by fasting. Sudden infant death and hypoketotic hypoglycemia have been reported in patients with severe deficiency (1).

Tandem mass spectrometry (MS/MS) has been widely used in newborn screening (NBS) for inherited metabolic diseases. CPT1A deficiency can be detected by MS/MS, with free carnitine (C0) and C0 to free long-chain acylcarnitine [C0/(C16+C18)] as the primary screening markers (2, 3). As early identification and timely treatment can prevent clinical symptoms, NBS is an important tool for diagnosing CPT1A deficiency.

Several patients have been reported worldwide since the first description of this disorder in 1981 (4). In particular, a high prevalence of CPT1A deficiency was observed in the Inuit, First Nations, and Alaska Native populations (5–8). However, few studies have used NBS to diagnose CPT1A deficiency in the Chinese population (9–13). In this study, we used NBS to diagnose CPT1A deficiency in a southern Chinese population. Furthermore, we systematically reviewed Chinese patients previously diagnosed with CPT1A deficiency to improve our understanding of this rare disorder.

MATERIALS AND METHODS

Study Population

A total of 204,777 newborns were screened by MS/MS at Quanzhou Maternity and Children's Hospital between January 2017 and December 2018, and newborns with elevated C0 levels (C0 > 60 $\mu\text{mol/L}$, cut-off value: 10–60 $\mu\text{mol/L}$) were recruited for the study. Additionally, all Chinese patients previously genetically diagnosed with CPT1A deficiency were reviewed and included in the study. Data from these patients were retrieved from PubMed (<http://www.ncbi.nlm.nih.gov/pubmed>) by searching the keywords “carnitine palmitoyltransferase 1A deficiency” or “CPT1A deficiency,” “Chinese” or “China,” and “*CPT1A*.” Written informed consent was obtained from the parents of all patients. This study was approved by the Ethical Committee of Quanzhou Maternity and Children's Hospital. Written informed consent was obtained from the parents of all patients for the collection of samples and the publication of medical data.

Abbreviations: CPT1A, carnitine palmitoyltransferase 1A; MS/MS, tandem mass spectrometry; NBS, newborn screening; C0, free carnitine; C0/(C16+C18), C0 to free long-chain acylcarnitine; NGS, next-generation sequencing; PCR, polymerase chain reaction; 3D, three-dimensional; ACMG/AMP, American College of Medical Genetics and Genomics and the Association for Molecular Pathology.

NBS for CPT1A Deficiency

Sample collection, delivery, and pre-processing were performed as described in our previous article (14). Amino acids and acylcarnitines were quantitated using an ACQUITY TQD mass spectrometer (Waters, Milford, MA, USA). Newborns with elevated C0 levels (cut-off value: 10–60 $\mu\text{mol/L}$) and/or C0/(C16+C18) ratios (cut-off value: 0–40) were recalled. Those who tested positive were subjected to genetic testing.

Genetic Analysis

Targeted next-generation sequencing (NGS) was performed as previously described (15). A multigene panel covering 94 genes associated with inherited metabolic disorders (including *CPT1A*) was applied. All candidate variants identified by NGS were validated using Sanger sequencing. *CPT1A* exons and flanking intron sequences were amplified by polymerase chain reaction (PCR) under standard conditions. Primer sequences are available upon request. PCR products were sequenced directly using an ABI Prism 3500 Genetic Analyzer (Applied Biosystems, Foster City, CA, USA). The sequencing results were analyzed using Chromas 2.6.5 (Technelysium Pty Ltd, Australia), and the sequences were aligned using the *CPT1A* transcript (NM_001876). DNAMAN 8 (Lynnon Biosoft, San Ramon, CA, USA) was used to identify nucleotide variants.

All candidate variants were searched in several frequently used databases, as previously described (15). The pathogenicity of the novel missense variants was predicted using several *in silico* tools, including SIFT, PolyPhen-2, PROVEAN, and MutationTaster. Evolutionary conservation was analyzed using ClustalX (<http://www.clustal.org/clustal2>), and homology modeling was performed using the Swiss Model Workspace to analyze changes in the three-dimensional (3D) structure. Finally, all novel variants were evaluated based on the standard recommendations and guidelines for sequence variant interpretation, as published by the American College of Medical Genetics and Genomics and the Association for Molecular Pathology (ACMG/AMP) (16).

RESULTS

NBS for CPT1A Deficiency

Of the 204,777 screened newborns, 199 exhibited elevated C0 levels during initial NBS, of which 3 had extremely high C0 levels and 18 were accompanied by elevated C0/(C16+C18) ratios. During the recall stage, 12 newborns had elevated C0 levels, and 6 had elevated C0/(C16+C18) ratios. Two patients were finally diagnosed with CPT1A deficiency; thus, the incidence in the selected population was estimated to be 1:102,388.

Biochemical and Clinical Characteristics

In addition to the two patients newly diagnosed with CPT1A deficiency, we included in our cohort 10 Chinese patients who were previously diagnosed. Five of these 12 patients were diagnosed *via* NBS. All 12 patients exhibited elevated C0 levels; 11 patients (91.7%) also exhibited elevated C0/(C16+C18) ratios. The median C0 concentration and C0/(C16+C18) ratio were $136.00 \pm 39.13 \mu\text{mol/L}$ (range: 79.65–193.61 $\mu\text{mol/L}$, cut-off

M, male; F, female; NBS, newborn screening; SMS, selective metabolic screening; y, years; m, months; cut-off value, C0: 10–60 $\mu\text{mol/L}$, C0/(C16+C18): 0–40; the novel CPT1A variants are in boldface type.

value: 10–60 $\mu\text{mol/L}$) and 840.55 ± 513.80 (range: 34.49–1,595.54 $\mu\text{mol/L}$, cut-off value: 0–40), respectively.

No clinical symptoms were observed in the five patients diagnosed *via* NBS. The follow-up period of patients (no. 1–3) were between 2 and 3 years, while follow-up data of patients (no. 9 and 10) were not available. In contrast, all seven patients presented with clinical symptoms, including fever, cough, vomiting, diarrhea, and seizures. The age of onset ranged from 6 months to 1 year and 10 months. Detailed information on the biochemical and clinical manifestations of these patients is presented in **Table 1**.

Genetic Findings

All patients harbored compound heterozygous CPT1A variants. Eighteen distinct variants were identified, among which 61.11% (11/18) were missense variants, 22.22% (4/18) affected splicing, 11.11% (2/18) were frameshift variants, and 5.56% (1/18) were large deletions. Fifteen of these CPT1A variants were previously reported, and the other three were novel. The novel variants were c.272T>C (p.L91P), c.734G>A (p.R245Q), and c.1336G>A (p.G446S). The most common variant was c.2201T>C (p.F734S), with an allelic frequency of 16.67% (4/24). Relatively common variants were c.281+1G>A, c.1131G>C (p.E377D), and c.1787T>C (p.L596P), which were each identified twice. Each of the remaining 14 variants was identified only once (**Figure 1**).

None of these novel variants were recorded in disease databases such as ClinVar and HGMD. The novel variants were absent or had extremely low allelic frequencies in the dbSNP, ExAC, 1000 Genome, and GnomeAD databases. *In*

silico analysis suggested that all three novel variants were potentially pathogenic (**Supplementary Table 1**). Alignment of the CPT1A sequences revealed that the amino acid residues at positions 91, 245, and 446 were strictly conserved (**Figure 2**). Protein modeling showed that Leu-91 was located in the extracellular segment between two transmembrane domains; the p.L91P variant may affect the quaternary structure of CPT1A by causing the loss of the side chain hydrogen bond with Thr-90, which may result in abnormal folding. p.R245Q was located in the C-terminal catalytic domain, which may affect the quaternary structure of CPT1A by eliminating the side chain hydrogen bonds with Gly-244, Gly-319, and Asp-323, possibly resulting in abnormal folding. Likewise, p.G446S was located in the C-terminal catalytic domain, and the beta turn in the secondary structure of CPT1A became a random coil, resulting in protein instability (**Figure 3**). All variants were classified as variants of unknown significance (PM2+PP3) according to the ACMG/AMP guidelines for interpretation of sequence variation.

Although the pathogenicity of these novel variants could not be confirmed, we provided the following evidence supporting an association between these variants and CPT1A deficiency: (i) the variants were inherited from the parents, who were carriers; (ii) the variants were not present or had extremely low allelic frequencies in population databases, altered the strictly conserved amino acid residues of CPT1A, and were predicted to be deleterious by different computational tools; and (iii) protein modeling analysis indicated that the variants could lead to structural damage or CPT1A dysfunction.

DISCUSSION

Except for in a few specific ethnic groups, CPT1A deficiency seems to be very rare in the general population. This study presented the biochemical, clinical, and genetic characteristics of Chinese patients with CPT1A deficiency, highlighting the value of NBS, and contributing to the body of knowledge needed for early diagnosis and timely intervention of this rare disorder.

The incidence of CPT1A deficiency varies significantly among different ethnic groups. NBS data from Germany, Australia, and the USA showed that the incidence of CPT1A deficiency was as low as 1:750,000 to 1:2,000,000 in 2010 (17). The actual

incidence of CPT1A deficiency in China remains unclear. The largest nationwide cross-sectional study using a standardized questionnaire showed that the overall incidence of CPT1A deficiency in mainland China is 1:546,128 (18). We identified two Chinese patients with CPT1A deficiency through our NBS program, which indicated an estimated prevalence of 1:102,388 in the southern Chinese newborn population. This incidence is higher than that reported in previous studies, and this variation may be due to differences in ethnic backgrounds, cut-off value settings, recall criteria, diagnostic methods, and awareness of the disease. It is noteworthy that the availability of NBS is relatively limited, and there

may be some patients that cannot be identified by MS/MS-based NBS.

All patients showed elevated C0 levels and/or C0/(C16+C18) ratios, and one patient had a normal C0/(C16+C18) ratio. Therefore, these two screening markers do not necessarily increase at the same time, and any significant increase in one marker should be interpreted as a positive NBS result. Although patients with *CPT1A* deficiency can be identified by NBS, previous studies have shown that milder forms of *CPT1A* deficiency can be difficult to diagnose because screening markers may be normalized or only slightly increased during follow-up (19, 20). These patients may be missed or not diagnosed until the patient presents with acute metabolic decompensations. To avoid delayed diagnosis, it has been proposed that all patients with abnormal NBS results suspected of *CPT1A* deficiency should undergo mandatory *CPT1A* sequencing and/or enzyme analysis (20).

None of the five patients diagnosed *via* NBS had any clinical symptoms, while all of the clinically diagnosed patients presented with a variety of clinical symptoms, indicating that NBS for *CPT1A* deficiency is beneficial. However, we should note that patients diagnosed using NBS may also develop clinical manifestations when energy demands increase, such as during fasting or febrile illness. Therefore, dietary management and avoidance of prolonged fasting are recommended, and careful follow-up is required to ensure that the patient has a good prognosis.

CPT1A is located on chromosome 11q13.3 and contains 19 exons spanning more than 60 kb of genomic DNA. To date, at least 30 *CPT1A* pathogenic variants have been reported. Most pathogenic variants appear to be unique or identified

only in a few pedigrees, except c.1436C>T (p.P479L) and c.2129G>A (p.G710E). c.1436C>T (p.P479L) was found to be highly prevalent in northern Canada, Greenland, Siberia, and the Alaska Native population (5, 7, 21). c.2129G>A (p.G710E) was recognized as a founder mutation in the Hutterite population (22, 23). Reports on Chinese patients with *CPT1A* deficiency are limited, and no hotspot *CPT1A* mutations have been reported to date. The cohort of Chinese patients in our study was characterized by wide allelic heterogeneity, with 18 different variants identified. c.2201T>C (p.F734S) was the most frequent variant, suggesting that c.2201T>C (p.F734S) may be a potential hotspot *CPT1A* mutation in the Chinese population. This variant has not yet been found in other populations; therefore, it could be unique to the Chinese population. The remaining variants were detected only once or twice. Three novel variants were identified, further expanding the mutational spectrum of *CPT1A*. Although computational prediction is helpful for assessing potential pathogenicity, further functional investigations are warranted to confirm the pathogenicity of these novel variants.

In conclusion, the incidence of *CPT1A* deficiency in Quanzhou, China, was estimated to be 1:102,388. Furthermore, the biochemical, clinical, and genetic characteristics of Chinese patients with *CPT1A* deficiency documented in this study may facilitate early diagnosis and intervention. Moreover, our findings demonstrated that NBS for *CPT1A* deficiency is beneficial. This cohort of Chinese patients was characterized by wide allelic heterogeneity. The three novel variants identified in this study expand the mutational spectrum of *CPT1A* in the Chinese population. c.2201T>C (p.F734S), the most frequent variant, may be a potential hotspot *CPT1A* mutation in this population.

Objective: GLUT1 deficiency syndrome (GLUT1-DS) is a rare, treatable neurometabolic disorder. However, its diagnosis may be challenging due to the various and evolving phenotypes. Here we report the first Chinese familial cases with genetically confirmed GLUT1-DS and analyze the characteristics of Chinese children with GLUT1-DS from clinical, laboratory, and genetic aspects.

Methods: We reported a Chinese family with three members affected with GLUT1-DS and searched for relevant articles up to September 2020 from PubMed, WOS, CNKI, and WanFang databases. A total of 30 Chinese patients diagnosed with GLUT1-DS (three newly identified patients in one family and 27 previously reported ones) were included and analyzed in this study.

Results: The median age of onset of the 30 patients (male: 18, female: 12) was 8.5 months (range, 33 days to 10 years). Epileptic seizures were found in 25 patients, most with generalized tonic-clonic and focal ones. Movement disorders were found in 20 patients—frequently with ataxia and dystonia, developmental delay in 25 patients, and microcephaly only in six patients. The cerebrospinal fluid (CSF) analysis showed decreased CSF glucose (median: 1.63 mmol/L, range: 1.1–2.6 mmol/L) and glucose ratio of CSF to blood (median: 0.340; range: 0.215–0.484). The genetic testing performed in 28 patients revealed 27 cases with pathogenic variations of the SLC2A1 gene, including 10 missense, nine frameshift, three nonsense, three large fragment deletions, and two splice-site mutations. Most patients had a good response to the treatment of ketogenic diet or regular diet with increased frequency. Although three patients in this Chinese family carried the same pathogenic mutation c.73C > T (p.Q25X) in the SLC2A1 gene, their symptoms and responses to treatment were not exactly the same.

Conclusion: The clinical manifestations of GLUT1-DS are heterogeneous, even among family members sharing the same mutation. For children with unexplained epileptic seizures, developmental delay, and complex movement disorders, detection of low CSF glucose or SLC2A1 gene mutations is helpful for the diagnosis of GLUT1-DS. Early initiation of ketogenic diet treatment significantly improves the symptoms and prognosis of GLUT1-DS.

INTRODUCTION

Glucose transporter type 1 deficiency syndrome (GLUT1-DS) is caused by impaired glucose transport through the blood–brain barrier and inherited in an autosomal dominant trait, which results from mutations of SLC2A1 gene encoding GLUT1 (Brockmann et al., 2001; Klepper et al., 2001). Autosomal recessive transmission has also been described in rare cases, whereas homozygosity showed embryonic lethality in a mouse model (Wang et al., 2006; Klepper et al., 2009; Rotstein et al., 2010). The classic phenotype is characterized by refractory infantile epilepsy, developmental delay, acquired microcephaly, and complex movement disorders, such as ataxia, dystonia, and spasticity, which was first described by De Vivo et al. in 1991 (De Vivo et al., 1991). Over the past few decades, its clinical spectrum has broadened to include non-classic phenotypes, such as paroxysmal exercise-induced dyskinesia and epilepsy, paroxysmal choreoathetosis with spasticity, atypical childhood absence epilepsy, and myoclonic astatic epilepsy (Wang et al., 2018). Additionally, paroxysmal non-epileptic events, including intermittent ataxia, paroxysmal eyeball movements, dysarthria, migraine, alternating hemiplegia, spastic paraparesis, and periodic confusion (De Giorgis and Veggioni, 2013; Pearson et al., 2013; Nicita et al., 2019), and some extraneurologic features, like hemolytic anemia and cataracts, have also been described (Weber et al., 2008; Flatt et al., 2011; Bawazir et al., 2012). Despite its complex and variable clinical manifestations, GLUT1-DS can be diagnosed based on the presence of hypoglycorrachia and pathogenic variants of SLC2A1 gene. Ketogenic diet (KD) is recognized as the most effective treatment, which can provide ketone bodies to serve as an alternative fuel for the brain, and the earlier it is used, the better the prognosis will be (Kass et al., 2016).

In 2008, Bao et al. diagnosed a Chinese GLUT1-DS patient for the first time in mainland China and then reported three Chinese GLUT1-DS ones in 2012 (Liu et al., 2012). However, most (90%) detected SLC2A1 gene mutations are sporadic and *de novo*, whereas familial cases are rare (Pearson et al., 2013). Here we reported a Chinese family with three members affected with genetically confirmed GLUT1-DS and evaluated the efficacy of KD. Meanwhile, we analyzed and summarized the clinical and genetic characteristics of GLUT1-DS in the newly identified and previously reported Chinese GLUT1-DS cases.

PATIENTS AND METHODS

Case Presentation

The clinical data and blood and cerebrospinal fluid (CSF) samples of three GLUT1-DS patients from one Chinese family were collected at the pediatric neurology clinics of Tongji Hospital. The study was approved by the Medical Ethics Committee of Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology. Informed consent was obtained from the patients and their parents.

Patient 1

The proband was a 6-year-old girl born to non-consanguineous parents. The pregnancy and the delivery were normal. She began to speak and walk independently at the age of 19 months and had a normal head circumference. The seizures occurred at the age of 8 months and 1 year, respectively, presenting with eyes rolling involuntarily and lips cyanosis, but there were no seizures in the next 2 years. Until the age of 4 years, her symptoms evolved into dystonia, majorly with the head backward, stiffness of the right lower limbs, and hallux dorsal flexion. Occasionally, her right arm was rotated inward and could not be flexed, accompanied by crying and shaking of the whole body. At the early stage, these symptoms were mild, with a frequency of three to eight times per month, each lasting about 1 to 2 min. The electroencephalogram (EEG) showed sharp waves and sharp slow waves in the right central temporal and left central region with a normal background during wake and sleep. Oral oxcarbazepine was then administered, but the attacks were not controlled completely. Since the age of 5 years, the frequency and duration of the attacks increased, ranging from once every 2 to 3 days to twice to thrice a day and lasting up to half an hour each time. Additionally, she experienced frequent paroxysmal hypokinesia with low muscle tone, which were relieved after resting. Nervous system physical examination was performed during the interictal period, and there was no abnormal muscle tension or strength and no positive ataxia signs, while the Assessment of the Child Development Scale indicated that her development was lagging behind mildly. The metabolic screening and other blood examinations were normal. KD was introduced along with oral oxcarbazepine when she was 5 years old, and it was tolerated well during the follow-up. Up to now, she has been free of these symptoms for nearly a year. The EEG returned to normal after initiating KD for 2 months.

Patient 2

The older brother of the proband was a 9-year-old boy without microcephaly. He started speaking after more than 12 months and still walked unsteadily at the age of 2 years and easily fell down. He also had paroxysmal hypokinesia which occurred about once to twice a month and lasted 1–5 min each time. At 3 years old, he had binocular gaze in a daze with clear consciousness, similar to an atypical absence seizure. His physical examination was unremarkable, and the developmental assessment showed that his development was lagging behind mildly as well. His brain magnetic resonance imaging (MRI), video EEGs, serum biochemistry values, and metabolic screening results were all normal. Considering the possible diagnosis of paroxysmal events related to epilepsy, sodium valproate (VPA) was added. He displayed some responses to VPA, with the symptoms alleviated only partly. Then, he received CSF analysis and gene panel sequencing, which indicated hypoglycorrachia (CSF glucose: 2.6 mmol/L; CSF/blood glucose ratio: 0.481) and a pathogenic mutation in the SLC2A1 gene c.73C > T (p.Q25X). All these results clarified the final diagnosis of “GLUT1-DS,” but his family did not pay attention to it further. His symptoms worsened at the age of 6 years when VPA was discontinued by his

FIGURE 1 | (A) The pedigree of the reported family with GLUT1-DS caused by a nonsense mutation c.73C > T (p.Q25X) in SLC2A1 gene. **(B)** Distribution of the reported mutations of SLC2A1 gene. The black boxes represent exons. The numbers to the left and the right of the intron–exon boundaries represent amino acid residues and nucleotides, respectively. The three large fragment deletion mutations and one missense mutation with limited information are not listed. **(C)** The conformational model of GLUT1 and the location of the reported mutations of the SLC2A1 gene. The three large fragment deletions and two splice-site mutations are not listed. The red dot represents a novel mutation c.73C > T (p.Gln25*) found in the familial cases. Some numbers between brackets represent the total number of patients identified with the mutation. Mutation hotspots are represented with an asterisk.

parents, accompanied with an inability to speak or speaking vaguely—also called dysarthria and attacks of hallux-dorsiflexion, which lasted for a few minutes each time and were relieved spontaneously. Therefore, KD was introduced, and his symptoms remitted within 1 month. Up to now, he could go to school normally.

Patient 3

The father of patients 1 and 2, now at 31 years old, began to experience paroxysmal hypokinesia and could not move or walk for up to 10 min every time since he was 10 years old, without typical epileptic seizures. Surprisingly, although without any therapy, his symptom disappeared about 2 years ago. All these data were obtained from his description but no adult nervous physical examinations have been conducted.

Family History

The pedigree is shown in **Figure 1A**. The uncle of patient 3 had similar attacks of movement disorder, but his information was incomplete and unavailable.

Genetic Analyses and *In Silico* Analyses

Whole-exome sequencing was performed in the proband (patient 1), and it revealed the pathogenic mutation c.73C > T (p.Q25X) in the SLC2A1 gene, which was identical to that of patient 2. The mutation was confirmed by Sanger sequencing in their parents and verified to be inherited from their father (patient 3). The nonsense variant was predicted by PVS1 as pathogenic based on the guidelines of the American College of Medical Genetics and Genomics.

The heterozygous substitution c.73C > T (p.Q25X) is a novel nonsense mutation in exon 2 that has not been previously reported, which is predicted to cause a premature termination at position 25 and the deletion of 467 amino acids (**Figures 1B,C**). The truncated protein contains only less than one of the wild type 12 transmembrane domains and easily degrades in the cell. A previous study has shown that, when the last 37 carboxyl-terminal amino acids of GLUT1 were lost, the truncated proteins would abolish transport activity completely (Oka et al., 1990).

Systematic Review

We searched literatures about Chinese case reports of GLUT1-DS in PubMed, WOS, CNKI, and WanFang databases (until September 2020). Patients who were described more than once in the literatures were included only one time. Based on the systematic review, 15 articles describing 27 Chinese patients with GLUT1-DS were found (Fung et al., 2011; Liu et al., 2012; Ye et al., 2012; Liu et al., 2013; Li et al., 2014; Yu and Long, 2015; Duan et al., 2016; Zhang et al., 2017; Ji et al., 2018; Liang et al., 2019; Wang et al., 2019; Wei et al., 2019; Zha et al., 2019; Pei et al., 2020; Wang et al., 2020). Thus, together with the three newly identified familial cases, a

total of 30 Chinese patients diagnosed with GLUT1-DS were included in this study.

RESULTS

Among the 30 patients, there were 18 males and 12 females. The median age of onset was 8.5 months (range, 33 days to 10 years). Epileptic seizures were reported in 25 patients (83.3%), presenting as the first symptom in 23 patients (76.7%) during infancy. The seizures were of mixed types, including 11 cases of generalized tonic-clonic (GTC) (36.7%), nine cases of focal (30%), four cases of tonic (13.3%), three cases of absence (10%), two cases of atonic (6.7%), one case of spasm (3.3%), one case of myoclonic-atonic (3.3%), and one case of febrile seizures (3.3%). Most seizures were resistant to antiseizure medications (ASMs), such as phenobarbital, valproic acid, lamotrigine, levetiracetam, and oxcarbazepine. Movement disorders were reported in 20 patients (66.7%), including ataxia in 15 cases (50.0%), dystonia in 14 cases (46.7%), gait disturbance in eight cases (26.7%), dysarthria in seven cases (23.3%), paroxysmal hypokinesia in three cases (10.0%), tremor in two cases (6.7%), paroxysmal limb paralysis in two cases (6.7%), and paroxysmal eye movement disorder in two cases (6.7%). Developmental delay was observed in 25 patients (83.3%), and microcephaly was found only in six patients (20%). The clinical characteristics of 30 Chinese patients with GLUT1-DS are summarized in **Table 1**.

A fasting lumbar puncture was performed in 24 patients, but only 17 patients reported definite values of CSF analysis, with low CSF glucose at 1.1–2.6 mmol/L (median, 1.63 mmol/L) and low CSF/blood glucose ratio of 0.215–0.484 (median, 0.340).

EEG was performed in 28 of 30 patients, showing generalized or focal epileptiform discharges or background slowing in 19 cases. No abnormalities were found in the remaining nine cases. Brain MRI was performed in 25 patients. Only nine cases exhibited abnormalities, such as mild brain atrophy, bilateral ventricle enlargement, hypomyelination, abnormal signals in the bilateral frontal cortex, widening of the bilateral frontotemporal sulci, and cerebral dysplasia.

Genetic testing was performed in 28 patients. Except for one patient who was negative for SLC2A1 gene mutation, 27 patients carried pathogenic mutations in the SLC2A1 gene, including 10 with missense, nine with frameshift, three with nonsense, three with large fragment deletion, and two with splice-site mutations (**Table 2**).

Twenty-three patients were treated with KD, 21 of whom became free from seizures and movement disorders. Two cases gave up KD treatment for intolerance, and their symptoms were not improved. Besides this, four patients were given a regular diet with increased frequency or advised to eat candy, three of whom had a significant improvement in their outcomes. The other three patients refused any treatment for their mild symptoms or were still counseled for KD treatment.

DISCUSSION

Glucose, the most essential energy source for brain metabolism, enters into the brain facilitated by GLUT1. The cerebral metabolic rate for glucose was low at birth and then increased rapidly to reach adult level by 2 years old. At about 3 to 4 years old, it reaches a peak that exceeds adult level by over two folds, keeps up until 9 years of age, and then gradually decreases to adult rate again by the age of 20 years (Chugani et al., 1987; Chugani, 1998). Consequently, the seizures generally occur at 1–6 months after birth as the most common initial symptom of GLUT1-DS and gradually reduce in adolescence, whereas these rarely appear during the neonatal period, but cyanotic or apnea episodes and paroxysmal eyeball movements—named aberrant gaze saccades—may occur before seizures in infancy (Pearson et al., 2017), which are easily ignored or misdiagnosed as focal seizures. Among the 30 patients in our study, the earliest onset age was 33 days, and the median age was 8.5 months. About 76.7% of the patients presented epileptic seizures as the first symptom.

Approximately 90% of GLUT1-DS patients have seizures of various types, including GTC, absence, focal, myoclonic, atonic, tonic, and spasm seizures, in which GTC and absence seizures are the most common (Pong et al., 2012). Although seizures are often resistant to ASMs, some of which even inhibit the GLUT1 function *in vitro*, such as phenobarbital, valproate, chloral hydrate, and diazepam (Klepper et al., 1999; Klepper et al., 2003; Wong et al., 2005), there are still about 8% of patients who respond positively to them (Pong et al., 2012). In this study, 83.3% of the 30 patients had epileptic seizures, and the seizure types in some patients evolved with age, with GTC (36.7%) and focal (30%) seizures mostly observed. Some patients achieved partial relief of seizures and motor disorders by taking ASMs, such as oxcarbazepine and levetiracetam. However, the epileptic seizures in such GLUT1-DS patients are not closely related to the epileptiform discharges on EEG. Our study showed that one patient without seizures was found to be with epileptiform discharges, while seven cases with seizures had normal EEG findings.

Two patients (Pt. 14 and Pt. 24) only showed limited information of mutations. One patient (Pt. 10) negative for SLC2A1 gene mutation and two (Pt. 3 and Pt. 25) without available mutation data were not presented here.

Compared with epileptic seizures, movement disorders are more common in older children and tend to replace seizures over the years (Leen et al., 2014). In this study, 66.7% of the 30 patients had movement disorders, with ataxia (50.0%), dystonia (46.7%), gait disturbance (26.7%), and dysarthria (23.3%) being more commonly observed.

Since infancy, the developing brain of GLUT1-DS patients is unable to obtain enough energy for its growth, leading to cerebral dysfunction and limited head growth. The majority of patients with GLUT1-DS have experienced some degree of cognitive impairment, ranging from mild learning disability to severe intellectual impairment. In this study, developmental delay was observed in 83.3% of the 30 patients, while microcephaly was not a key sign, only observed in 20% of patients. Furthermore, one patient with microcephaly had no developmental delay, indicating that microcephaly was not always accompanied by developmental delay.

The laboratory hallmark for GLUT1-DS is low glucose of the CSF (hypoglycorrachia) when normoglycemic. Generally, fasting CSF glucose values are less than 3.3 mmol/L (60 mg/dl). In the majority (>90%) of cases, the values are less than 2.2 mmol/L (40 mg/dl). Another less reliable biomarker is the glucose ratio of CSF to blood below 0.45 (De Vivo and Wang, 2008; Yang et al., 2011; Klepper, 2012; Leen et al., 2013), but normal CSF glucose has also been reported in some patients with milder phenotypes. In addition, the CSF lactate level from normal

to low (<1.4 mmol/L) can help differentiate GLUT1-DS from other causes of hypoglycorrachia, such as meningitis, encephalitis, subarachnoidal haemorrhage, and some metabolic disorders, in which the CSF lactate level is elevated (>2.0 mmol/L) (Chow, 2005). Leen et al. (2013) suggested that it was unlikely to diagnose GLUT1-DS if the CSF lactate was increased. The CSF glucose and CSF/blood glucose ratio were low in this study, ranging 1.1–2.6 mmol/L (median 1.63 mmol/L) and 0.215–0.484 (median 0.340), respectively, which was consistent with that described above.

To date, SLC2A1 is recognized as the only gene associated with GLUT1-DS mapped to the short arm of chromosome 1 (1p34.2), with a length of about 35 kb and containing 10 exons (Shows et al., 1987; Fukumoto et al., 1988). Its coded protein GLUT1 is a transmembrane glycoprotein and composed of 492 amino acids. It has 12 transmembrane domains that span the plasma membrane in an α -helical structure, forming a pore for the transport of glucose and other substrates, and is mainly distributed on brain endothelial cells, astrocytes, and erythrocytes (Mueckler et al., 1985). Since the first elucidation of its genetic–pathogenic roles (Seidner et al., 1998), more than 200 SLC2A1 gene mutations have been described, including missense, nonsense, frameshift, splice-site, and large fragment deletion mutations. Several mutation hotspots within the SLC2A1 gene have been identified, such as Asn34, Gly91, Ser113, Arg126, Arg153, Arg264, Thr295, and Arg333 (Leen et al., 2010).

However, about 5–10% of GLUT1-DS cases were reported with absence of mutations in the SLC2A1 gene (Yang et al., 2011; Klepper, 2013). In our study, there was one case with a negative SLC2A1 gene mutation as well. Therefore, some studies have suggested that GLUT1-DS may have undetectable variants in the non-coding regions or downstream of the DNA that could affect posttranscriptional modifications, such as mRNA splicing, protein assembly, folding, transportation, intracellular storage, and activation (Klepper and Leidencker, 2007).

Furthermore, the phenotypes and symptom severity of GLUT1 patients with the same mutations were heterogeneous even among affected family members sharing the same mutation, indicating that secondary genes (such as PURA gene) and other modifying proteins might be involved in glucose transport or that DNA variant regulatory elements of the wild-type allele may modulate the expression level of GLUT1 (Leen et al., 2010; Mayorga et al., 2018). Mayorga et al. (2018) reported a patient with a PURA gene mutation that had marked hypoglycorrachia, overlapping the clinical findings with GLUT1-DS, though no variants were found on the SLC2A1 gene. By western blot assays, they confirmed a significantly reduced expression of GLUT1 in the peripheral blood cells of the patient compared to controls. Based on the known functions of PURA as a transcriptional and translational regulator, they proposed GLUT1 as a new PURA target, and mutations in PURA can decrease GLUT1 expression.

Though familial cases were usually correlated with milder manifestations compared to sporadic *de novo* cases (De Giorgis et al., 2015), attention should be paid to prenatal genetic counseling in familial cases because of phenotypic heterogeneity—even if a patient has very few and mild symptoms, and it is possible that offspring with the same mutation will be severely affected. Herein the familial cases in this study, who carried a nonsense mutation c.73C > T (p.Gln25*) and inherited in an autosomal dominant manner, presented mild to moderate clinical phenotypes with overlapping but variable symptoms. The clinical manifestations of the father of the proband were mild, with only episodic hypokinesia but no intelligence or language disorder, which might be related to the late onset of the disease, while the phenotypes of the proband and her brother were moderate, including three main symptoms, and even evolved with age.

KD is the gold standard treatment for GLUT1-DS, which should be started as early as possible and maintained at least until adolescence to meet the increased energy demand of the developing brain (Klepper, 2012; Kass et al., 2016). In our study, most patients were free of seizures and movement disorders after initiation of KD, and intelligence development

and the head circumference of some patients recovered to normal levels. The other three patients treated with a regular diet of increased frequency also showed an improvement that might be classified as “carbohydrate-responsive” phenotype.

In conclusion, the diagnosis of GLUT1-DS is challenging due to its clinical heterogeneity. When children presented with unexplained epileptic seizures, developmental delay, and complicated movement disorder, GLUT1-DS should be suspected and a fasting lumbar puncture or genetic testing is recommended. Once the diagnosis of GLUT1-DS is confirmed, KD should be administered earlier and timely in order to gain a better prognosis.

DATA AVAILABILITY STATEMENT

The datasets for this article are not publicly available due to concerns regarding participant/patient anonymity. Requests to access the datasets should be directed to the corresponding author.

ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Medical Ethics Committee of Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology. Written informed consent to participate in this study was provided by the legal guardian/next-of-kin of the participant. Written informed consent was obtained from the individual(s) and minor(s) legal guardian/next-of-kin for the publication of any potentially identifiable images or data included in this article.

AUTHOR CONTRIBUTIONS

QH drafted the manuscript and analyzed the data. YS checked the data. TS and YL revised the manuscript. SX performed critical revision of the whole work and edited the final manuscript. All authors have read and approved the final manuscript.

Introduction: Combined malonic and methylmalonic aciduria (CMAMMA) is a rare metabolic disease caused by biallelic variants in ACSF3 gene. The clinical phenotype is highly heterogeneous in this disorder, ranging from asymptomatic to severe symptoms. No cases with CMAMMA were reported in China.

Materials and Methods: In this study, three Chinese pediatric patients were diagnosed with CMAMMA unexpectedly while being treated for other ailments. To better characterize CMAMMA in a Chinese population, we made a multidimensional analysis with detailed clinical phenotype, semi-quantitative detection of urine organic acid, and analysis of ACSF3 gene variants.

Results: The clinical presentation of these patients is quite different; their main complaints were anemia, jaundice, or abnormal urine test, respectively. They showed no symptoms of the classic methylmalonic academia, but urine organic acid analysis showed elevated malonic acid and methylmalonic acid in all the patients repeatedly. Variants were found at four sites in ACSF3 gene. Patient 1 carried the compound heterozygous variant c.689G>A (p.Trp230*)/c.1456G>A (p.Ala486Thr). A compound heterozygous variant c.473C>T (p.Pro158Leu)/c.1456G>A (p.Ala486Thr) was identified in patient 2. Patient 3 harbored a novel homozygous variant c.1447A>G (p.Lys483Glu).

Conclusions: Three Chinese patients were diagnosed with CMAMMA caused by ACSF3 variants. Their clinical course revealed that CMAMMA can be a benign condition that does not affect individual growth and development, but severe clinical phenotype may appear when other triggers exist. This study systematically elaborates CMAMMA in a Chinese population for the first time, broadens the spectrum of gene variant, and provides a strong basis for the etiological study of this disorder.

Keywords: combined malonic and methylmalonic aciduria, ACSF3 gene, benign condition, Chinese population, novel variant

INTRODUCTION

Methylmalonic academia (MMAemia) is a common inborn error of metabolism characterized by abnormal accumulation of methylmalonic acid in body fluids, resulting in many serious clinical manifestations. MMAemia is mainly caused by the defect of methylmalonyl-CoA mutase (MUT) or its coenzyme cobalamin (Cbl) (1). Combined malonic and methylmalonic aciduria (CMAMMA) is a rare atypical form of MMAemia featured with increased concentrations of malonic acid (MA) and methylmalonic acid (MMA) in urine (2). CMAMMA is caused by biallelic variants in the AcylCoA synthetase family member 3 (ACSF3, OMIM:614265) gene. ACSF3 encodes a mitochondrial acyl-CoA synthetase, which is essential for the synthesis of malonyl-CoA as well as methylmalonyl-CoA (3). Patients who carried ACSF3 gene variants excrete more MMA than MA in reported cases, which make them distinct from the patients with classical MMAemia (4).

The gene of ACSF3 is located on chromosome 16q24.3. It consists of 11 exons and encodes a 576-amino-acid protein with the first 83 residues representing the predicted mitochondrial transit peptide (4). To date, more than 50 patients worldwide have been reported to have CMAMMA caused by homozygous or compound heterozygous variants in ACSF3, including missense, nonsense, deletion, frameshift, and splice site variants. The clinical presentation of CMAMMA is quite controversial. Signs and symptoms reported so far are involved in neurological abnormalities in adults and infection induced encephalopathy in pediatric patients. Nevertheless, asymptomatic patients with normal outcomes strongly suggest that CMAMMA can be a benign state (2, 4–9). No case of the disease has been reported in China so far.

In this study, we summarized the clinical course, urine organic acid screening results, and analysis of ACSF3 gene variants in three Chinese patients with CMAMMA diagnosed in our hospital. We identified four variants inherited from the parents separately, among which c.1447A>G (p.K483E) is a novel variant. Based on the present study and literature review, we speculate that the CMAMMA is a benign state when other triggers are absent in Chinese population.

MATERIALS AND METHODS

Participants

Three patients at the age of 11 days to 8 months were diagnosed as CMAMMA in Tianjin Children's Hospital in China. There was no family history in these patients. The informed consents from guardians and the approval of the Medical Ethics Committee of Tianjin Children's Hospital were obtained.

Routine Tests and Metabolic Assay

Routine tests were conducted in three patients, such as physical examination, routine blood, urine and stool test, blood gas analysis, biochemical test, imaging examination, and etiological examination for infected patients. Semi-quantitative analysis of organic acid in urine was performed using gas chromatography–mass spectrometry (GC/MS).

FIGURE 1 | MA and MMA excretion in urine from all the patients. The x-axis represents different patients, and the value of the y-axis means metabolite peak area ratio to creatinine (Cr). Dotted lines represent reference range. **(A)** Peak area ratio of MA/Cr indicated the MA excretion in patients. **(B)** Peak area ratio of MMA/Cr indicated the MMA excretion in patients.

Whole Exome Sequencing and Analysis

The peripheral blood samples were collected to extract the genomic DNA. Peripheral blood from the patients and their parents were collected. A Blood Genomic DNA Mini kit was used to extract the genomic DNA according to the manufacturer's protocol. WES was performed to detect the pathogenic gene variants. Paired-end sequencing was performed on more than 95% of the target regions, with a read length of 150 bp and an average coverage depth of 100-fold, covering all coding regions and exon–intron boundaries. The Burrows-Wheeler Aligner (BWA) software was used to align the raw data with the human reference genome hg19. Insertions, deletions, and single-nucleotide polymorphism sites (SNPs) were analyzed by the Genome Analysis Tool Kit (GATK) software. Annovar software was utilized to add the annotated information of databases such as HGMD, dbSNP, OMIM, and 1000 Genomes. Protein function was predicted by SIFT and Polyphen2 software. The filtering of the variants was performed based on the phenotype, gene frequency, variant type, inherited pattern, and bioinformatics analysis. Suspected variants were validated by Sanger sequencing.

RESULTS

Clinical Data

Patient 1 was a 3-month-old girl. She was admitted to the hospital due to pale face for 2 weeks, fever, and cough for 2 days. Detailed physical examination and laboratory tests revealed that the patient had anemia, splenomegaly, hepatomegaly, thrombocytopenia, and bronchitis. Widened interval outside the cerebrum was noted in computed tomography. These clinical features were mainly attributed to suspected Evans syndrome and viral infection. The patient is 5 years old now and shows no sign of physical or psychomotor retardation.

Patient 2 was an 11-day-old boy. He was born at term by normal delivery. He was referred to the hospital due to

mo, month; d, day; y, year; ^avariant was inherited from mother; ^bvariant was inherited from father; –, no variant in coding exons or splice sites; n/a, not available.

jaundice for 7 days. Detailed physical examination showed neonatal omphalitis, myocardial damage, testicular hydrocele, and liver function damage. Laboratory tests showed that the direct bilirubin level was 17.1 $\mu\text{mol/L}$ (normal: 0–5 $\mu\text{mol/L}$), and indirect bilirubin level was 184.4 $\mu\text{mol/L}$ (normal: 3.4–10.3 $\mu\text{mol/L}$). These clinical manifestations were mainly caused by jaundice and infection. He is 3 years old now and attains a development milestone.

Patient 3 was an 8-month-old boy. He was born at term by cesarean section. He was admitted because of abnormal urine test for 3 months with red urine and urinary frequency. Urinary tract infection, pneumonia, and diarrhea were found in this patient. No obvious abnormality in his growth development was present. Infection factors were the main cause of his clinical presentations. He shows no sign of psychomotor retardation at the age of 5 in our recent follow-up.

Urine Analysis

GC/MS demonstrated elevated MA and MMA in all the patients repeatedly (Figure 1), which suggested the suspected diagnosis of MMAemia. However, the patients did not present with the clinical symptoms of classic MMAemia.

Gene Variation Analysis

All the patients were detected to carry variants in *ACSF3* gene (NM_174917.4) by WES. Patient 1 carried a compound heterozygous variant. The variant c.689G>A (p.Trp230*) was inherited from her mother and the other variant c.1456G>A (p.Ala486Thr) was inherited from her father. Besides, the compound heterozygous variant, c.473C>T (p.Pro158Leu)/c.1456G>A (p.Ala486Thr), was identified in the *ACSF3* gene in patient 2. The two heterozygous variants were inherited from the mother and father, respectively. Patient 3 harbored a homozygous variant of c.1447A>G (p.Lys483Glu) in *ACSF3* gene, which was inherited from his parents (Table 1). Sanger sequencing was used to confirm the variants (Figures 2–4). The homozygous variant c.1447A>G in *ACSF3* gene is a novel discovery.

DISCUSSION

CMAMMA is a rare inborn error of metabolism characterized by high excretion of MMA than MA in urine. The pathogenic

gene *ACSF3* catalyzes the initial reaction in intramitochondrial fatty acid synthesis by activating MA and MMA into their respective CoA thioesters. To date, about 52 patients with 31 homozygous or compound heterozygous variants of *ACSF3* have been reported worldwide, including missense, nonsense, deletion, frameshift, and splice site variants. The locations of these variants in *ACSF3* are graphically displayed in Figure 5. Most of the variants are missense, mainly located at the carboxyl terminal of the protein (Table 1) (2, 4–9). The most common *ACSF3* variants reported so far are c.1075G>A (p.E359K) and c.1672C>T (p.R558W), which are also the most common variants in asymptomatic patients. It indicates that the two variants are more likely to have a mild effect on gene function. Patients who carried the heterozygous variant c.1470G>C (p.E490D) have mild clinical symptoms, while the homozygous variant can result in significant developmental and speech delays. In the present work, we identified four variants of the *ACSF3* gene (one nonsense and three missense mutations) in three Chinese patients from three unrelated families, among which the variant c.1447A>G (p.K483E) is novel. The heterozygous variant c.473C>T (p.P158L) has also been reported in another patient with benign clinical presentation (8).

Patients who carried *ACSF3* variants exhibit controversial clinical phenotypes. Based on the literature review we did, severe clinical manifestations are mainly reported in adults, with the most common symptoms of neurological problems and psychiatric features (2). Because of the long-term damage accumulation, older people are at high risk for neurological illness even without *ACSF3* variants. The phenotype of pediatric patients is relatively mild or even asymptomatic. Three pediatric patients diagnosed with CMAMMA due to *ACSF3* mutation were reported to be clinically asymptomatic, and they had age-appropriate development (4). A retrospective study described the course of 25 CMAMMA individuals and suggested that CMAMMA is probably a benign condition (8). Another study showed that infection factors could provoke metabolic dysregulation in pediatric patients with CMAMMA, and normal levels of development could be obtained at follow-up (5). Therefore, CMAMMA may be considered as a risk factor instead of a disease, which could lead to clinical symptoms when other influencing factors exist.

ACSF3 variants that were only reported in patients with benign manifestations include c.689G>A, c.1456G>A,

c.473C>T, c.1447A>G, c.311A>T, c.1239+2T>G, c.1446_1447delCA, c.424C>T, c.820C>T, c.1553C>A, c.774_775del, and c.1081G>A. Patients carrying these variants were asymptomatic or had infection-induced symptoms that disappeared after treatment (2, 4–9). Besides, although the variant c.1456G>A has a high frequency in population, our

present study showed that patients carrying this variant had repeatedly elevated biochemical phenotype without obvious clinical phenotype, which could also be observed in other inherited metabolic disease. The β -ureidopropionase deficiency patients carrying the homozygous or compound heterozygous c.977G>A variant (high prevalence in normal Japanese

population) in *UPBI* gene could be asymptomatic as well (10). We speculate that the c.1456G>A variant in *ACSF3* may act in a similar way. High frequency of c.1456G>A in population indicates that CMAMMA may not be as rare as generally considered, and this kind of variant may contribute to the benign condition in patients. Accumulations of free MA and MMA were neurotoxic *in vitro*, while the concentrations might be insufficient to produce disease in CMAMMA patients (8). Actually, we cannot completely exclude the possibility that the accumulation of metabolites is associated with the occurrence of neurological symptoms as the patients grow up, or that the people with the *ACSF3* gene variants are more genetic susceptible to neurological problems later in life. Increased dependency on β -oxidation for energy production were observed in fibroblasts from CMAMMA patients. As a result, the subsequent increased risk for hypoxia and oxidative stress may be crucial for the onset of neurological symptoms in the long run (11).

CONCLUSIONS

In conclusion, our study included three Chinese pediatric patients under the age of 4 years. Their clinical features were mainly caused by infection or other reasons. They showed no sign of physical or psychomotor retardation in our follow-up. Combined with reported cases, our study strongly

suggested that the CMAMMA is a benign clinical course, especially for patients carrying certain variants. In addition, the present study had some limitations. Firstly, this study only involved the correlation analysis between genotype and phenotype. Functional verification of variants *in vitro* will help to elucidate the pathogenesis of CMAMMA, especially for the novel variant c.1447A>G (p.K483E), while functional studies were not available in this study due to the limitations of experimental condition. Secondly, a longer follow-up period is needed to better assess the growth and development of the patients.

Microhomology-Mediated Nonhomologous End Joining Caused Rearrangement of *EMD* and *FLNA* in Emery-Dreifuss Muscular Dystrophy

Danyu Song¹, Xiaomei Li², Wei Wei³, Xueqin Liu¹, Lin Wu⁴ and Hui Xiong^{1*}

¹Department of Pediatrics, Peking University First Hospital, Beijing, China, ²Department of Pediatric Cardiology, The First Hospital of Tsinghua University (Beijing Huaxin Hospital), Beijing, China, ³Beijing Kangso Medical Inspection Co., Ltd., Beijing, China, ⁴Department of Cardiology, Peking University First Hospital, Beijing, China

Background: Emery–Dreifuss muscular dystrophy (EDMD) is a rare disease characterized by early joint contractures, slowly progressive muscular dystrophy, and cardiac involvement, which includes arrhythmia, dilated cardiomyopathy, hypertrophic cardiomyopathy, heart failure, and sudden death.

Methods: Clinical data of the proband and family members were collected. The next-generation sequencing technology was used to analyze the pathogenic variants and copy number variations. Polymerase chain reaction was used to sequence the breakpoints of gene locus rearrangements.

Results: Here, we report two siblings with EDMD in a family. The proband, a 17-year-old boy, manifested a dilated right heart, bradycardia, mild muscle weakness, and joint contractures. His younger brother only showed a mild bowing limitation with elevated creatine kinase. Next-generation sequencing revealed the complete deletion of *EMD* and a rearrangement in *FLNA* (exon29_48dup) in these two patients. The *EMD* deletion and partial *FLNA* duplication were accompanied by a 5 bp overlap (GTCCC) on the background of the *FLNA-EMD* inversion. These findings support the pathogenic mechanism of microhomology-mediated nonhomologous end joining.

Conclusion: We report two siblings with complete *EMD* deletion and *FLNA* duplication in a family. A microhomology-mediated nonhomologous end joining event involving *EMD* and *FLNA* acts as the underlying mechanism.

Keywords: Emery–Dreifuss muscular dystrophy, microhomology-mediated nonhomologous end joining, *EMD*, *FLNA*, right heart abnormalities

INTRODUCTION

Emery–Dreifuss muscular dystrophy (EDMD) is a rare inherited disease that is characterized by early joint contractures, slow-progressive muscular dystrophy, and cardiac involvement (Madej-Pilarczyk, 2018; Heller et al., 2020), including arrhythmias, cardiomyopathy, heart failure, and sudden death. In the Online Mendelian Inheritance in the Man (OMIM) database, EDMD is divided into seven phenotypes, namely, EDMD 1 to 7, based on their causative genes and inherited manner. These genes include *EMD*, *LMNA*, *SYNE1*, *SYNE2*, *FHL1*, and *TMEM43* (Heller et al., 2020). In addition, *SUN1*,

SUN2, and *TTN* can also cause EDMD (Heller et al., 2020). Among these causative genes, *EMD* and *LMNA* are the most common (Bonne and Quijano-Roy, 2013). *EMD*, located in Xq28, is assigned to the X-linked EDMD (also named EDMD 1). In patients with X-linked EDMD, joint contractures (elbows, Achilles tendons, and cervical spine) frequently emerge in the first decade of life, and muscle weakness (in a “humero-peroneal” pattern) usually occurs in the second decade of life. Cardiac involvement typically starts after joint contractures and muscle weakness. Here, we report two EDMD patients with an *EMD* deletion and partial *FLNA* (a neighboring gene of *EMD*) duplication in an unsanguineous family, supporting the pathogenic mechanism of microhomology-mediated nonhomologous end joining.

MATERIALS AND METHODS

Clinical Data Collection

The research protocol (2015[916]) was reviewed and approved by the Ethics Committee of Peking University First Hospital. Written informed consent, which also included consent for the publication of medical data, was obtained from the patients and their parents.

Medical records of the patients were reviewed. Clinical and laboratory data, including age of onset, onset of recognizable symptoms, motor development, contractures, creatine kinase (CK) levels, electrocardiography (ECG), Holter, ultrasound cardiography (UCG), cardiac magnetic resonance imaging (MRI), limb muscle MRI, and muscle biopsy findings, were collected.

Variant Screening and Pathogenicity Verification

Genomic DNA of the proband, the younger brother, and their parents was extracted from leukocytes isolated from peripheral blood. A muscular disease gene panel and whole exome sequencing (WES) were successively used to detect genetic variations in the proband. Candidate variants in the probands were validated by Sanger sequencing in the family. Disease association databases and population databases, including the HGMD (HGMD: <http://www.hgmd.cf.ac.uk/ac/index.php>), LOVD (LOVD: <http://www.dmd.nl/>), ClinVar database (<https://www.ncbi.nlm.nih.gov/clinvar/>), 1000 Genomes (<http://www.1000genomes.org/>), ExAC (ExAC: <http://exac.broadinstitute.org/>), and gnomAD (gnomAD: <http://gnomad.broadinstitute.org/>) databases, were used to identify previously reported mutations and discover potential novel mutations. Predictions for the pathogenicity of missense mutations were obtained using PolyPhen-2, SIFT, and Mutation Taster. The predicted splicing mutations were tested through the Human Splicing Finder. The pathogenicity of candidate variants was classified according to the American College of Medical Genetics and Genomics and the Association for Molecular Pathology (ACMG-AMP) guidelines (Richards et al., 2015).

Next-Generation Sequencing Data Analysis for Copy Number Variation

Next-generation sequencing (NGS) data were also analyzed to detect copy number variations (CNVs) by comparing the number of sequence reads between the patient and control samples. First, the number of reads in each amplicon was counted for the patient and control samples. For the purposes of this comparison, sequencing data from at least three control samples (genomic sequencing had been performed for patients diagnosed with other diseases) were used as the reference. Subsequently, the patient/control ratios were calculated by dividing the number of patient reads in each amplicon with the average of the total reads regarding this amplicon from control samples. For the genes, including *EMD* and its neighboring gene *FLNA*, located on the X chromosome, patient/control ratios near 0.5 indicated the presence of heterozygous deletions in female patients (control samples were female). Ratios near 0 indicated deletions in male patients (control samples were male). In contrast, ratios near 1.5 indicated the presence of heterozygous duplications in female patients (control samples were female), and ratios higher than 1.75 indicated duplications in male patients (control samples were male). Polymerase chain reaction (PCR) was used to confirm the deletion of *EMD* in male patients. Statistical results were illustrated using GraphPad Prism 8 software (GraphPad Software, La Jolla, CA).

PCR for Deletion Validation and the Sequencing of Breakpoints of the CNVs

PCR and Sanger sequencing were performed to verify *EMD* deletion and to sequence the breakpoints of the CNVs. Primers were designed separately for exons 1–6 of *EMD* using Primer 5.0 (Premier Biosoft, Palo Alto, CA, United States). The two primers designed for exon 1 were Primer F 5'-ACCGCGAGA CCTTTGCTC-3' and Primer R 3'-GCGAGGCTCTCACCA GAGAA-5'. The two primers designed for exon 2 were Primer F 5'-CGCACGGGCTGTAGTAGGT-3' and Primer R 3'-GAC GAAGTCGGGTGAAGGTG-5'. The two primers designed for exon 3 were Primer F 5'-CGGCCAGGATCAACTCGTAG-3' and Primer R 3'-TCCTAAGGCTGCTGGAGTGG-5'. The two primers designed for exon 4 were Primer F 5'-ACCTTCACC CGACTTCGTCA-3' and Primer R 3'-TCCTGAATGGCTCTG GGTGT-5'. The two primers designed for exon 5 were Primer F 5'-GAGCCATTGAGGAGGTGTG-3' and Primer R 3'-GCT GAAACAGGGCGGTAGTG-5'. The two primers designed for exon 6 were Primer F 5'-TGTGGGTTCTGGCCTCTAA-3' and Primer R 3'-AAAAATGCGGACCCAACAAA-5'. For the breakpoints, two primers were designed for a location in exon 2 of *FLNA* (Primer F GRCh37/hg19, chrX:153599438-1535994, 5'-CACTTCAGGTGCTCGTT-3') and exon 29 of *FLNA* (Primer R GRCh37/hg19, chrX:153585865-153585883, 3'-GGATCTCGT CACCACCGTA-5'). PCR amplifications were performed using GoldStar Taq DNA Polymerase in an Applied Biosystems Veriti Thermal Cycler (4375305, Thermo Fisher Scientific, Waltham, MA, United States). Each PCR amplification was repeated for 35 cycles (30 s at 95°C, 30 s at 60°C, and 45 s at 72°C). Before

FIGURE 1 | Clinical Results. (A) Muscle biopsy. (a) Hematoxylin and eosin (H&E) staining of serial sections of the skeletal muscle from a normal control. (b) H&E staining of the skeletal muscle of the proband shows dystrophic changes: variability in the size of muscle fibers, fibrosis, and fat replacement. (B) Limb muscle MRI showed infiltration of fatty tissues in the soleus. (C) Echocardiography showed enlargement of the right heart. (D) Cardiac magnetic resonance imaging revealed an obviously enlarged right heart and evident thinning of the lateral wall of the right ventricle. The red arrows show fatty tissues in the local cardiac muscle. (E) Holter monitoring showed bradycardia and a junctional ectopic rhythm.

sequencing, the PCR products were analyzed by electrophoresis on a 2% agarose gel.

RESULTS

Clinical Findings of the Proband

The proband was referred to our hospital at the age of 17 due to suspected “skeletal muscle cardiomyopathy”. He started to feel physical activity-related tiredness and chest distress at the age of 13. He was suspected of having “myocarditis” and was given nutritional therapy without regular follow up. At the age of 15, he visited the local hospital again due to poor exercise tolerance and chest discomfort. Subsequently, bradycardia and enlargement of the right heart were found by Holter monitoring and UCG. Due to the symptomatic right heart problem, he was suspected of having “right ventricular cardiomyopathy” and received indolapril as a treatment. At the age of 16, he presented with bilateral brachial muscle pain and aggravated chest distress. His motor and cognitive development was normal. None of his family members exhibited any clinical abnormalities. Physical examination at the age of 17 revealed a heart rate of 56 bpm, normal oxygen saturation, and no dyspnea at rest. Neurological examination showed obvious bilateral brachial and peroneal muscle atrophy, elbow contracture, a mild rigid spine, and a tight Achilles tendon with normal gait. The muscle strength grade of the upper proximal arms was IV⁺, while that of the distal arms was V. The muscle strength grade of the proximal lower limbs was V⁻ with a distal dorsal flexion power of IV and a plantar flexion power of V⁻. Bilateral knee tendon reflex could not be induced. To confirm the diagnosis, laboratory tests were performed. The level of CK was 500–2,500 U/L (normal 0–200 IU/L). Skeletal muscle biopsy indicated muscular dystrophic changes (Figure 1A). Limb muscle MRI showed infiltration of fatty tissues, predominantly in the soleus (Figure 1B). UCG showed

enlargement of the right heart with a left ventricular ejection fraction (LVEF) of 68% (Figure 1C), and the Holter monitoring showed a junctional ectopic rhythm of 36 bpm (Figure 1E). A cardiac MRI subsequently revealed a markedly enlarged right heart, evident thinning of the lateral wall of the right ventricle, and fatty tissues in the local cardiac muscle with LVEF of 57% (Figure 1D). Combining the predominant cardiac involvement, muscle weakness, and joint contractures, he was clinically diagnosed with EDMD. This was confirmed by genetic tests (listed below). Considering bradycardia and the risk of sudden cardiac death, he was referred to implant a cardiac pacemaker. In addition, he was suggested to undergo rehabilitation training with regular follow up.

Genetic Results

A muscular disease gene panel that was performed in a local hospital detected no pathogenic variation in the proband. We reanalyzed the NGS data. We did not find any pathogenic variation but found that the depth of coverage was low in the whole region of *EMD*. This suggests *EMD* deletion. The PCR results confirmed the entire deletion of *EMD* (exons 1–6) (Figure 2A) in the proband. Then, we needed to further detect the deleted region and breakpoints. Due to the lack of designed probes and the small size of *EMD*, we failed to analyze the deleted region by using multiplex ligation-dependent probe amplification (MLPA) and array CGH. Finally, we used the NGS data of WES combined with PCR to help verify the region of deletion. The depth of coverage was used to detect the CNV by comparing its copy number ratio between the patient and the control. The ratio was 0 in the region of *EMD*, suggesting the deletion of the entire *EMD* gene (Figure 2B). On the other hand, the ratios were almost all greater than 1.75 in one segment (exon 29_48) and approximately 1 in another segment (exon 2_28) of *FLNA*, a gene adjacent to *EMD*. These findings suggest partial duplication of *FLNA* corresponding to exons 29–48 (Hg19, NM_001110556, Figure 2B). However, due

FIGURE 2 | Family pedigree and genetic results. **(A)** In the gel, numbers 1 to 4 represent the proband, his brother, his mother, and the control, respectively. The target bands of *EMD* exons 1–6 were deleted in the proband and his brother. **(B)** Column chart shows ratios between the patient and the control patients in terms of the number of reads, suggesting the deletion of exons 1–6 of *EMD* and the duplication of exons 29–48 of *FLNA* in the proband. **(C)** Family pedigree is shown.

FIGURE 3 | Model of *FLNA* rearrangement and *EMD* deletion. The first allele shows the normal *FLNA-EMD* region. The second allele is a polymorphic inversion containing the entire *FLNA-EMD* region. The unshaded rectangle represents *FLNA*, whereas the shaded rectangle represents *EMD*. Two arrows point to the two large reverted repeats flanking the *FLNA-EMD* region. Between homologous X or sister chromatids, 5 bp (GTCCC) overlap between *FLNA* intron 28 and intron 1 on the background of *FLNA-EMD* inversion was confirmed.

to the lack of reads designed to cover exon 1 of *FLNA*, the WES data were lost in *FLNA* exon 1, which is a non-coding region (Patrosso et al., 1994). The whole *EMD* deletion involving partial *FLNA* duplication was similar to the genomic arrangement of the first reported EDMD case with *EMD* deletion (Small et al., 1997). Therefore, according to the case reported before (Small et al.,

1997), we proposed that the genomic rearrangement in the proband may be caused by nonhomologous end joining on the background of *FLNA-EMD* inversion. Considering that the duplicated region of *FLNA* (exon 29_48) starts from exon 29, we proposed that one breakpoint in *FLNA* was located in intron 28 of *FLNA*. Besides, *FLNA* exon 2 was unaffected. Therefore, another

breakpoint in *FLNA* may occur in intron 1 of *FLNA* to the linkage region of *FLNA-EMD*. A model including the inversion of *FLNA-EMD* is shown (Figure 3) to explain the rearrangement of *FLNA*. To verify the breakpoints, PCR and Sanger sequencing were performed. Two primer sets were designed to be located in exon 2 of *FLNA* and exon 29 of *FLNA*. After sequencing, deletion boundaries and sequences were found. Between homologous X or sister chromatins, a microhomology-mediated nonhomologous end joining event was confirmed, accompanied by a 5 bp overlap (GTCCC) between *FLNA* intron 28 and *FLNA* intron 1 on the background of *FLNA-EMD* inversion.

Analysis of Other Family Members

The family pedigree is shown in Figure 2C. The family members were then evaluated. The 14-year-old younger brother complained of a mild bowing limitation. His CK level was 549 U/L. His echocardiograph and electrocardiograph revealed no problems. Their parents showed no symptoms, with normal CK and cardiac test results. After the same genetic test, the younger brother was identified as a patient with *EMD* deletion and partial *FLNA* duplication. He was followed up and given rehabilitation training regularly. The mother was confirmed as a carrier.

DISCUSSION

The proband had symptomatic right heart disease accompanied by mild muscle weakness. Due to his normal primary motor milestones, his mild elbow joint contracture and rigid spine may not have received enough attention. After a detailed physical examination, he was found to have mild muscle weakness, humeroperoneal muscle atrophy, mild elbow joint contracture, and a rigid spine. Based on his muscle weakness, high CK level, and pathological muscular dystrophic changes, the diagnosis of muscular dystrophy could be confirmed. Combining both cardiac and muscle involvement, skeletal muscle cardiomyopathy was confirmed. Given the severe cardiac involvement, humeroperoneal distributed muscle weakness, and special locations of the contractures, he was suspected to have EDMD. Finally, this diagnosis was confirmed by genetic analysis.

EMD, located in Xq28, encodes the nuclear protein emerin. The complete deletion of *EMD* in the proband caused an X-linked EDMD phenotype. The cardiac phenotype often emerges within the end of the second decade along the third decade of life in classical X-linked EDMD (Heller et al., 2020). The fact that the obvious right heart involvement started at 14 years of age is unusual. The involvement of the right side of the heart is also not a classical feature of the cardiological spectrum of X-linked EDMD. Significant right heart abnormalities and an early age of onset were features in the proband, with mild weakness and joint contractures. Regarding the mutation type, most mutations reported in *EMD* are nonsense mutations, missense mutations, frameshift mutations, or splicing mutations that cause a truncated protein. There have been five cases in which the complete deletion of *EMD* was reported (Small et al., 1997; Small and Warren, 1998; S et al., 1999), which was found in the proband.

Filamin-A is encoded by *FLNA*. It promotes orthogonal branching of actin filaments and links actin filaments to membrane glycoproteins with wide tissue expression. *FLNA* mutations can cause several severe syndromes, including periventricular nodular heterotopias, otopalatodigital syndromes, skeletal dysplasia, lung involvement, and cardiovascular abnormalities (Sankararaman et al., 2013; van der Werf et al., 2013; Deng et al., 2020; Meliota et al., 2021). In heterozygous females, the *FLNA*-related phenotype ranges from the absence of overall symptoms to severe manifestations. Male patients typically have a very severe phenotype and almost die prenatally or in the first years of life due to multisystem involvement (Sankararaman et al., 2013; van der Werf et al., 2013; Walsh et al., 2017; Cannaerts et al., 2018). This 17-year-old proband only manifested joint contractures and cardiac and muscle involvement without other systems involved. He had relatively minor symptoms compared with typical *FLNA*-related male patients. In addition, the duplication of exons 29–48 of *FLNA* did not influence the primary *FLNA* exons 2–48 (containing the entire open reading frame). Given this consideration, we predicted that *FLNA* is not a causative gene in this patient, despite the *FLNA* rearrangement.

For the molecular pathogenic mechanism, a microhomology-mediated nonhomologous end joining event involving *EMD* and *FLNA*, with a 5 bp overlap (GTCCC), acts as the underlying mechanism. Microhomology-mediated end joining is an error-prone repair mechanism for DNA double-strand breaks. It needs longer microhomology (more than 2 bp) and is independent of Ku70/Ku80, which is distinct from classic nonhomologous end joining (Kent et al., 2015; Sinha et al., 2016; Wang and Xu, 2017; Seol et al., 2018). The *FLNA-EMD* inversion in Xq28 is a common inversion mediated by inverted repeats (Small et al., 1997). The presence of an inversion of the *FLNA-EMD* region among X chromosomes was frequent (33% in females and 11% in males) (Small et al., 1997). The first reported case of EDMD with *EMD* deletion and a partial duplication of *FLNA* revealed an emerin-associated Alu with 2 bp of overlap between one pair of misaligned and inverted repeats (Small et al., 1997). Two other reported cases revealed 2 bp of overlap in *FLNA* (Small and Warren, 1998). They are all different from the proband reported here.

In conclusion, we reported two cases of EDMD with a complete *EMD* deletion and partial *FLNA* duplication. A microhomology-mediated nonhomologous end joining event involving *EMD* and *FLNA* acts as the underlying mechanism.

Idiopathic infantile arterial calcification (IIAC), also known as generalized arterial calcification of infancy (GACI), is a heritable ectopic mineralization disorder that results in diffuse arterial calcifications and or stenosis, which are attributed to mutations in the ENPP1 gene. In this case study, we report the development of IIAC in a 2-month-old male preterm infant. The patient presented with severe hypertension and seizures, which revealed diffused calcifications and c.130C > T and c.1112A > T mutations in the ENPP1 gene. With bisphosphonate, antihypertensive, and control epilepsy therapy, his blood pressure was maintained at 110–120/50–60 mmHg. Intellectual motor development retardation was anticipated in this patient. To the best of our knowledge, this is the first case in which a novel c.130C > T mutation in the ENPP1 gene has been identified, and the administration of bisphosphonates to patients with IIAC has been assessed.

Keywords: genetic mutation, case, preterm, infant, hypertensive, artery, calcification, report

INTRODUCTION

Idiopathic infantile arterial calcification (IIAC), also known as generalized arterial calcification of infancy (GACI), is a rare autosomal recessive genetic disorder characterized by abnormalities in calcium and phosphorus metabolism. Approximately 69–80% of cases are caused by mutations in the ENPP1 gene on chromosome 6q23. A small fraction of cases results from mutations in the ABCC6 gene on chromosome 16p13.11. The first description of the clinical manifestation of GACI in the medical literature was published in 1901 (Bryant and White, 1901). IIAC is primarily diagnosed after observing hydroxyapatite deposits in the internal elastic layer of the large and medium arteries that causes vascular lesions, soft tissue calcification around joints, and various other life-threatening conditions due to the development of vascular lesions. Hypertension and heart failure are common clinical manifestations. Most infants develop arterial stenosis and heart failure within the first month of life. IIAC progresses rapidly; 80% of children with IIAC die within 6 months, and older children may die suddenly (Guimarães et al., 2010). This case report of neonatal GACI enriches the literature with data on a new familial mutation of the ENPP1 gene and provides details of the specific clinical course.

CASE DESCRIPTION

The boy was delivered at the 36th gestational period by cesarean section due to “suspected intrauterine distress” with a birth weight of 2,240 g. His Apgar scores were 7 at 1 min, 9 at

5 min, and 10 at 10 min. The amniotic fluid and umbilical cord were normal, and the placenta was calcified. The mother had two previous pregnancies and had complicated diabetes mellitus and hypothyroidism during pregnancy. At birth, he presented with respiratory distress, and blood gas analysis suggested severe respiratory failure. Echocardiography confirmed that the right ventricle was enlarged with moderate tricuspid regurgitation, and the pulmonary artery pressure was high, up to 70 mmHg. He developed severe hypertension 3 days after birth (systolic and diastolic blood pressure range, 100–120 and 40–70 mmHg, respectively). After Captopril treatment, the systolic blood pressure stabilized at 70–80/40–50 mmHg, and echocardiogram confirmed a thickened left ventricular wall, an enlarged left atrium, and a LVEF of 55%. Abdominal computed tomography (CT) detected diffuse calcifications of the abdominal aorta and its major branches and slight luminal stenosis (**Figure 1**).

Two months after birth, he presented with a hypertensive crisis with severe heart failure and persistent convulsions. The liver and renal functions of the patient were abnormal. The systolic blood pressure was high, at 170 mmHg; the diastolic blood pressure was high, at 120 mmHg; the blood calcium level was low, at 1.6 mmol/L (normal value 2.11–2.52 mmol/L); and the blood phosphorus level was high, at 2.27 mmol/L (normal value 0.85–1.51 mmol/L). Chest radiography showed a few exudative lesions in both lungs and an enlarged cardiac shadow. Echocardiography revealed significant thickening of the left ventricular wall, enlarged left atrium and left ventricle, patent ductus arteriosus (small left-to-right shunt), and LVEF of 50%. The EEG had persistent multichannel sharp waves. Arterial Doppler ultrasound was performed and showed extensive calcification of the walls of the bilateral common carotid, bilateral femoral, carotid, vertebral, and internal carotid arteries, extensive calcification of the walls of the abdominal aorta and the right renal artery, and local luminal stenosis (**Figures 2A–D**). Flow velocity in the calcified

abdominal aorta increased, and blood flow velocity in both renal arteries increased. Cranial MRI revealed bilateral frontal, parietal, and temporal lobe atrophy with dilated ventricles (**Figure 3A**). The cranial MRA showed bilateral internal carotid artery patchy luminal stenosis, left vertebral artery fibrillation, and left anterior cerebral artery, left middle cerebral artery luminal stenosis, and bilateral posterior cerebral artery luminal stenosis (**Figure 3B**). Cranial ultrasound showed bilateral calcification of the lenticular artery on both sides. No joint or skeletal calcification was observed on radiography, and prenatal ultrasound images were also retrospectively reviewed, but no arterial calcifications were detected.

These singularities were consistent with those of the IIAC. The genotype of the patient was analyzed. Genetic testing of the child and parents suggested two heterozygous mutations in the ENPP1 gene 1) c.130C > T (mutation of nucleotide 130 in the coding region from cytosine to thymine), resulting in an amino acid change p.Q44X (nonsense mutation). The father had a suspected heterozygous variant at this locus. 2) c.1112A > T (mutation of nucleotide 1112 in the coding region from adenine to thymine), resulting in an amino acid change p.Y371F (mutation of amino acid 371 from tyrosine to phenylalanine) which is a missense mutation. The father showed no mutation at this locus, and the mother had a heterozygous variant at this locus. The genetic results were consistent with those for idiopathic infantile arterial calcification. The c.130C > T mutation has not been described in the literature or mutation databases (**Figure 4**).

The main treatment consisted of three courses: 1) Circulatory system: Severe heart failure treatment with cardiac and vasodilator therapy with Foxglove preparation and sodium nitroprusside (0.1 µg/kg min to 4 µg/kg min) and oral administration of Norvasc and Losartan. The blood pressure of the patient gradually reduced to approximately 120/60 mmHg (95–99th percentile). 2) Nervous system: The child developed a persistent state of convulsions and was considered to have hypertensive encephalopathy. Luminal and midazolam were administered successively, and continuous multichannel sharp wave discharges were observed in the EEG. After propofol was administered for 2 days, the abnormal EEG discharge was reduced, and propofol and midazolam dosages were gradually reduced. 3) Zoledronic acid was administered intravenously (0.02 mg/kg once every other week for three times). Blood pressure was maintained at 110–130/60–70 mmHg (approximately 95th percentile of normal blood pressure in children of the same age). Blood calcium level was 1.92 mmol/L and blood phosphorus level was 2.68 mmol/L. His blood pressure stabilized, heart failure was corrected, no further convulsions occurred, and he was discharged in good condition.

During the long-time follow-up, with Norvasc and Losartan antihypertensive treatment, his blood pressure leveled at around 110–120/50–60 mmHg. Currently, he orally takes Etidronic acid as well as Clonazepam and Topamax to control epilepsy. His Gesell testing at 2 years old suggested he has moderate intellectual-motor retardation. At 3 years old, ultrasound showed that extensive vascular calcification was still present

FIGURE 1 | Enhanced contrast CT scan of the abdomen shows calcification of the abdominal aorta and its branches.

FIGURE 2 | Vascular ultrasound images. **(A)** Strong echo in the aortic arch and its branches is indicated by the arrows. **(B)** Strong echo in the left coronary artery wall is indicated by the arrows. **(C)** Strong echo in the abdominal aortic wall is indicated by the arrows. **(D)** Strong echo in the femoral artery wall is indicated by the arrows.

but was not progressing. The five-year-old child also suffers from cerebral palsy and receives rehabilitation training now.

His mother had another pregnancy 3 years ago, and prenatal genetic testing showed that the fetus carried the same mutations. A boy was born by full-term delivery, is now 3 years old, and is developing normally.

DISCUSSION

The first report of an association between IIAC and mutations in ENPP1 was reported by Rutsch et al. (2003). Animal experiments further confirmed that mutations in the ENPP1 gene can cause IIAC (Li et al., 2013, 2014). The gene is located on chromosomes 6q22 to q23, has a length of 83 kb, and contains 25 exons. ENPP1 is an external nucleotide pyrophosphatase/phosphodiesterase 1, an enzyme that causes vascular smooth muscle cells, chondrocytes, and osteoblasts to produce inorganic pyrophosphate (PPi). Mutations in the ENPP1 gene can lead to decreased levels of PPi and the production of hydroxyapatite crystals that are deposited in various layers of arteries, including the aorta, coronary arteries, heart valves, and renal arteries,

causing vascular lesions, soft tissue calcification around joints, and various life-threatening conditions due to vascular lesions such as myocardial infarction, renal failure, cerebral infarction, and hypertensive encephalopathy (Numakura et al., 2006).

Less frequently, IIAC is linked to a mutation in the ATP-binding cassette subfamily C, member 6 (ABCC6) gene (GAC12, OMIM 614473) (Nitschke et al., 2012) which encodes ABCC6 (Nitschke and Rutsch, 2017). The ABCC6 gene on chromosome 16p13.11 is affected by the classic form of Pseudoxanthoma Elasticum (PXE). There is a genotypic overlap between IIAC and PXE, with some patients harboring mutations in ABCC6, and some patients with clinical manifestations consistent with PXE have mutations in ENPP1 (Nitschke et al., 2012). The main manifestations are calcification of the skin elastic fibers, systemic arterial vascular calcification, and cervical vertebral fusion (Ferreira et al., 2021a).

Genetic testing of our patient revealed two compound heterozygous mutations in the ENPP1 gene originating from his parents. Firstly, c.130C > T (mutation of nucleotide 130 in the coding region from cytosine to thymine) results in an amino acid change, p.Q44X, that causes a partial deletion of the protein from 44 amino acids onwards, a class I pathogenic form of mutation.

FIGURE 3 | (A) Cranial MRI showing bilateral frontal and temporal lobe atrophy and abnormally high signal in the white matter around the anterior horn of the ventricle. The lesions are indicated by arrows. **(B)** Cerebrovascular artery MRI showing multiple luminal stenoses of the bilateral anterior, middle, and posterior cerebral arteries and vertebral arteries. The lesions are indicated by arrows.

This novel familial mutation in the ENPP1 gene has not yet been described in the literature or mutation databases. The other mutation is a missense mutation c.1112A > T (mutation of nucleotide 1112 in the coding region from adenine to thymine) that leads to an amino acid change, p.Y371F (mutation of amino acid 371 from tyrosine to phenylalanine), and is a pathogenic mutation that has been reported (Cheng et al., 2005) and is associated with IIAC.

The clinical manifestations of IIAC vary widely and can be broadly divided into two categories: early and late-onset (Sluis et al., 2006; Chong and Hutchins, 2008; Shaireen et al., 2013). Early onset (approximately 48%) refers to cases that occur in the fetal period or within 1 month of birth. The main manifestations are respiratory distress, fetal edema, severe

heart failure, pulmonary hypertension, and hypertension. Late-onset (approximately 52%) refers to cases where the onset is 1 month after birth, and the main manifestations are respiratory failure, heart failure, cyanosis, hypertension, and nonspecific ischemic and hypoxic damage to other organs, such as abdominal pain and microvascular thrombosis (Rani et al., 2010; Zhang et al., 2011). Convulsive episodes and brain damage revealed old strokes and marked gliotic changes, but bilateral occipital necrosis is less commonly reported (Staretz-Chacham et al., 2019). If calcified plaques are deposited in the renal artery this can lead to renal artery stenosis and renal failure can occur. In our case, the child was born with heart failure, persistent hypertension, and progressive multisystem damage to liver function and kidney, consistent with the clinical features of the disease. The presence of the hypertensive crisis is suggestive of the aggressiveness of the disease. In contrast, the significant cerebrovascular calcification and neurological ischemic-hypoxic brain parenchymal damage presented in our case has not been reported previously.

Imaging examinations are of great value in the clinical diagnosis of IIAC. The main imaging manifestations are widespread calcification of the aorta and its branches, including the aortic arch, unnamed artery, abdominal aorta, femoral artery, and other large vessels. The inner wall of each vessel is not smooth; there are calcified plaques of different sizes attached, combined with stenosis of the diameter of the vessel, and the local blood flow velocity is significantly increased (Whitehall et al., 2003; Tran and Boechat, 2006; Bolster et al., 2015).

Based on the clinical features of large artery calcification combined with genetic testing, IIAC can be diagnosed (Borromini et al., 2016). Arterial biopsy indicates that hydroxyapatite deposits in the internal elastic membrane of large- and medium-sized arteries are the current gold standard bases for the diagnosis of IIAC (Dayapala et al., 2016).

FIGURE 4 | Sanger sequencing of ENPP1 in the parents and the patient. The c.130C > T, c.1112A > T locus mutations were detected in the gene. The ENPP1 gene was inherited from both parents with heterozygous c.130 C > T and c.1112A > T compound heterozygous mutations. The mutation sites are indicated by the arrows.

The disease can be diagnosed during the fetal period. Fetal edema is the most common sign, and intrauterine distress and heart failure have been observed (Cansu et al., 2010; Esmer et al., 2015; Yi et al., 2017). Vascular ultrasound revealed intimal calcification and luminal stenosis of the aorta and abdominal aorta vessels, mostly in the second trimester. If an older sibling has a disease, the detection rate can be greatly improved by using multiple ultrasound examinations and genetic testing of amniotic fluid in the fetus of a subsequent pregnancy in early gestation (Mastrolia et al., 2015; Votava-Smith et al., 2017). In our case, no arterial calcifications were detected on prenatal ultrasound images.

As IIAC is a rare metabolic disorder, there are no guidelines for its treatment. Bisphosphonates are commonly used to treat IIAC, In 2008, (Rutsch et al., 2008). Rutsch used phosphonate analogs and performed a multicenter genetic study and retrospective observational analysis, suggesting that the survival of children was not significantly related to genetic mutations. Moreover, the survival rate was higher in children with well-controlled blood phosphate values and no hyperphosphaturia when treated with phosphonates. Therefore, phosphonate analogs are the first-line agents used in IIAC treatment (Ramjan et al., 2009). In recent years, different approaches for treating GACI have been intensively investigated, including early generation bisphosphonates, orally administered PPI, and soluble recombinant ENPP1-Fc protein (Albright et al., 2015; Dedinszki et al., 2017; Nitschke et al., 2018), and some cases have reported that sodium thiosulfate can improve ectopic calcification of IIAC (Omarjee et al., 2020), and animal experiments suggest that enzyme replacement therapy can have therapeutic effects on IIAC (Luo et al., 2020). The mechanism may be that this treatment reduces bone renewal, thus inhibiting further calcium deposition at sites of existing calcified injury, interferes with the formation of hydroxyapatite crystals, and/or provides analogs of inorganic pyrophosphates that can affect calcium deposition. Intravenous zoledronic acid therapy at doses of 0.25, 0.5, and 0.5 mg/kg for weeks 1, 2, and 3, respectively, and subsequent monthly doses of 0.5 mg/kg can be applied. It has recently been reported that switching administration to oral phosphonates at 20 mg/kg d after 3 weeks of intravenous therapy, with a gradual reduction to 50 mg/d for long-term oral maintenance, depending on vascular ultrasound treatment, can also provide relief (Edouard et al., 2011). In our case, treatment with symptomatic support and zoledronic acid every other week was switched to oral zoledronic acid after three courses, and blood pressure was largely maintained at the 95th–99th percentile of normal values in children of the same age, and the condition resolved. This also provides valuable insight for the treatment of other children with IIAC. The most common side effect of long-term administration of phosphonate preparations is severe skeletal lesions, similar to rickets manifestations (Otero et al., 2013; Ferreira et al., 2016) that must be monitored and treated.

The prognosis of patients with IIAC is poor. Combined coronary artery calcification is a major risk factor for a poor prognosis. Most deaths occur in infancy, and rapidly progressive malignant heart failure is often the main cause of death (Nael et al., 2014; Ferreira et al., 2021a). Individuals may die suddenly due to myocardial infarction. A small number of survivors may have intractable hypertension, recurrent cardiopulmonary failure

(Nael et al., 2014) renal impairment, cervical spine fusion, and hearing loss (Ferreira et al., 2021b). Survivors require long-term oral antihypertensive drugs and medications to improve cardiac function. Patients with combined severe renal impairment require peritoneal dialysis (Stojanovic et al., 2013). Intractable heart failure eventually requires heart transplantation (Glatz et al., 2006; Giovannoni et al., 2014). Only two patients with IIAC who survived for 22 and 25 years have been reported. The patient in the present case successfully survived for 5 years, with hypertension and heart failure under effective control, but with severe brain damage and intellectual motor development retardation, and the long-term prognosis of the patient is not optimistic.

CONCLUSION

IIAC is a rare autosomal recessive disorder characterized by abnormal calcium metabolism due to genetic mutations. A novel c.130C > T mutation in ENPP1 was identified. Hypertension, heart failure, and central nervous system involvement due to vascular calcification are typical clinical manifestations. Treatment with oral phosphonates is expected to improve the long-term prognosis. Early recognition of the disease by obstetricians enables intrauterine diagnosis and prenatal genetic screening, which can effectively improve informed healthcare decision-making for parents. The limitation of this case was that vascular calcification was not treated. In the follow-up, his vascular calcification did not deteriorate further.

DATA AVAILABILITY STATEMENT

The original contributions presented in the study are included in the article/Supplementary Material, further inquiries can be directed to the corresponding authors.

ETHICS STATEMENT

Ethical approval was not provided for this study on human participants because this research was performed as part of a routine molecular diagnosis of patients. Written informed consent to participate in this study was provided by the participant's legal guardian/next of kin. Written informed consent was obtained from the individual(s) and minor(s) legal guardian/next of kin for the publication of any potentially identifiable images or data included in this article.

AUTHOR CONTRIBUTIONS

LY, HT, and WJ clinically followed the patient and were responsible for the initial manuscript writing as well as reviewing the literature. TX was responsible for the development of the final version of the manuscript. All authors contributed to the study and approved the manuscript for publication.

Primary coenzyme Q10 deficiency-6 (COQ10D6), as a rare autosomal recessive disease caused by COQ6 mutations, is characterized by progressive infantile-onset nephrotic syndrome resulting in end-stage renal failure and sensorineural hearing loss. Here, we report two Chinese siblings with COQ10D6 who primarily presented with severe metabolic acidosis, proteinuria, hypoalbuminemia, growth retardation, and muscle hypotonia and died in early infancy. Using whole-exome sequencing and Sanger sequencing, we identified two rare recessive nonsense mutations in the COQ6 gene segregating with disease in affected family members: c.249C > G (p.Tyr83Ter) and c.1381C > T (p.Gln461Ter), resulting in two truncated protein products. Both mutations are located in a highly conserved area and are predicted to be pathogenic. Indeed, the death of our patients in early infancy indicates the pathogenicity of the p.Tyr83Ter and p.Gln461Ter variants and highlights the significance of the two variants for COQ6 enzyme function, which is necessary for the biosynthesis of coenzyme Q10. In conclusion, we discovered a novel compound heterozygous pathogenic variant of the COQ6 gene as a cause of severe COQ10D6 in the two siblings. Based on the clinical history and genetic characteristics of the patients, our cases expand the genotypic spectrum of COQ10D6 and highlight the heterogeneity and severity of clinical features associated with COQ6 mutations. For patients with clinical manifestations suggestive of COQ10D6, early testing for COQ6 mutations is beneficial for disease diagnosis and therapeutic interventions as well as disease prevention in future generations.

INTRODUCTION

Nephrotic syndrome (NS) is a chronic kidney disease that involves massive proteinuria, hypoalbuminemia, hyperlipidemia, and edema. When occurring in the first year of life, NS is considered a life-threatening clinical condition with poor prognosis and high mortality if not treated in time (Noone et al., 2018). NS is generally classified as steroid-dependent nephrotic syndrome

(SDNS), steroid-resistant nephrotic syndrome (SRNS), or steroid-sensitive nephrotic syndrome (SSNS) based on its response to steroid therapy (Greenbaum et al., 2012; Trautmann et al., 2017). SRNS is a common cause of end-stage renal disease (ESRD) in children, affecting approximately 10–20% of all pediatric NS cases (Warejko et al., 2018; Park et al., 2020), and the renal biopsies of affected patients usually show focal segmental glomerulosclerosis (FSGS) (Lovric et al., 2016).

Recently, large cohort studies have shown that approximately 30% of childhood-onset SRNS cases are associated with genetic defects (Sadowski et al., 2015; Wang et al., 2017; Nagano et al., 2020). Different variants of the genes involved in coenzyme Q10 (CoQ10) biosynthesis may lead to a renal phenotype, either syndromic SRNS (*PDSS2*, *COQ2*, and *COQ6*) or isolated SRNS (*COQ8B*) (Cheong 2020). Primary CoQ10 deficiency-6 (*COQ10D6*, OMIM # 614650) is an autosomal recessive disorder that manifests as severe progressive infantile-onset NS resulting in end-stage renal failure and sensorineural hearing loss (SNHL) due to homozygous or compound heterozygous mutations in the *COQ6* gene located on chromosome 14q24.3, which encodes an evolutionarily conserved flavin-dependent monooxygenase required for CoQ10 biosynthesis. Heeringa et al. (Heeringa et al., 2011) first reported that 11 children from five families with *COQ10D6* manifest as NS and SNHL, and some of these patients responded favorably to oral CoQ10 supplementation at early stages of the disease can ameliorate the neurological and renal symptoms (Heeringa et al., 2011; Quinzii et al., 2014; Stanczyk et al., 2018). Nevertheless, patients may not benefit from CoQ10 therapy when severe renal and neurological damage is established. Hence, an early and accurate diagnosis of *COQ10D6* and simultaneous CoQ10 intervention are critical in improving prognosis.

In this study, we identified a novel compound heterozygous variant of the *COQ6* gene in a nonconsanguineous Chinese family with two siblings presenting severe metabolic acidosis, proteinuria, hypoalbuminemia, growth retardation, and muscle hypotonia; the female proband also developed seizures. Genetic findings showed that both mutations, located in the Ubi-OHase domain of *COQ6*, are present in a region that is highly evolutionarily conserved across species. The mutations are predicted to be pathogenic, as confirmed by the death of our patients in early infancy. Collectively, our findings widen the spectrum of known *COQ6* mutations and provide an expanded understanding of the clinical spectrum of the rare genetic disease *COQ10D6*.

RESULTS

Clinical Presentations of the Family

The two affected siblings were conceived by a healthy, nonconsanguineous couple who denied having hepatitis, tuberculosis, diabetes, allergic diseases, or a history of hereditary disease. The mother of the patients has a history of miscarriages. A summary of the molecular findings and clinical and biochemical characteristics of the two cases harboring *COQ6*

mutations is shown in **Table 1**. The pedigree of the family and the confirmation of the *COQ6* mutations are presented in **Figure 1A**.

Patient 1

The proband (III-3) was a Chinese girl born at full term *via* spontaneous vaginal delivery who weighed 3.1 kg. According to her parents, the infant had not achieved the expected increases in height and body weight by the age of 3 months. At the age of 4 months and 28 days, she was sent to our hospital due to repeated convulsion for 5 days. Metabolic and hearing exams were normal. The blood gas analysis indicated compensatory metabolic acidosis with an elevated lactate level (5.4 mmol/L), a pH of 7.39, and a bicarbonate level of 13.4 mmol/L. Biochemical assays revealed significantly decreased albumin (23.7 g/L) and increased blood lipids (triglyceride (TG), 15.80 mmol/L; total cholesterol (TC), 9.54 mmol/L). A decline in immunity was also observed with IgG <0.75 g/L, IgA <0.01 g/L, and IgM <0.20 g/L. The urine organic acid (UOA) analysis showed increased levels of lactate, 3-hydroxybutyric acid-2, pyruvic acid-OX-2, 4-hydroxy-phenyllactate-2, palmitic acid-1, and malic acid-3. A widening of the bilateral frontotemporal subarachnoid space was detected by enhanced computed tomography (CT) (**Figure 2C**), though her electroencephalogram (EEG) was normal. During hospitalization, the patient developed a seizure during which her hands were clenched; the seizure abated after half a minute. The girl was then transferred to a higher-level hospital at the request of her parents. Magnetic resonance imaging (MRI) demonstrated a widening of the bilateral frontotemporal subarachnoid space (**Figures 2D,E**) and delayed myelination of white matter (**Figure 2F**), but long-term EEG showed no abnormality. Laboratory testing indicated a markedly elevated TC level of 9.79 mmol/L, an IgG level of 0.1 g/L, a CD19⁺ B cell percentage of 14.7%, a CD3⁺ T-cell percentage of 72.8%, and a CD4⁺ T-cell percentage of 50.3%. The girl's parents declined further genetic testing, and she was discharged home the next day.

At the age of 5 months and 22 days, she was admitted again to the Department of Pediatrics of our hospital because of pneumonia and dyspnea. Physical examination indicated that she had growth retardation, with a height of 54 cm and body weight of 5.5 kg, which were both below −3 SD, and she was unable to raise her head steadily. Laboratory tests revealed hypoalbuminemia (16 g/L), massive proteinuria (3+, total urine protein of 2,570 mg/24 h), edema, and elevated blood lipids (TG, 27.51 mmol/L; TC, 13.77 mmol/L), accompanied by metabolic acidosis and electrolyte disturbances including decreased Na⁺ (119 mmol/L) and elevated K⁺ (6.48 mmol/L). After admission, the patient received anti-infection and symptomatic treatment including repeated albumin for protein supplementation and repeated acid correction. Given the proband's clinical symptoms and age of onset, NS was considered and a blood sample was then collected for genetic testing. Unfortunately, she had persistent metabolic acidosis, hyponatremia, and hypoalbuminemia. She continued to deteriorate and died of respiratory failure and heart failure at the age of 5 months and 26 days.

TABLE 1 | Clinical characteristics and molecular findings in subjects with COQ6 mutations.

Proband (III-3)		Sibling of proband (III-2)
COQ6 mutation	c.249C > G/c.1381C > T	c.249C > G/c.1381C > T
Sex	Female	Male
Pregnancy duration	Full term	Full term
Type of delivery	Spontaneous vaginal delivery	Spontaneous vaginal delivery
Age at presentation	4 months + 23 days	3 months + 22 days
Birth Weight (kg)	3.1	2.95
Birth length (cm)	50	50
Feeding difficulties	–	–
Respiratory distress	+	+
Muscle hypotonia	+	+
Seizure	+	–
SNHL	–	–

Note: SNHL, sensorineural hearing loss; UOA, urine organic acid; MRI, magnetic resonance imaging; CT, computed tomography; n/a, not done or not available.

Patient 2

Patient III-2 was the brother of the proband. He was also born at full term *via* spontaneous vaginal delivery with a birth weight of 2.95 kg. At the age of 3 months and 22 days, he was admitted to our hospital because of repeated abdominal distension for 3 months, along with dyspnea and cyanosis for half an hour. Upon hospitalization, physical examination was unremarkable except for dyspnea and poor growth and development, with a body weight of 4.5 kg and a height of 57 cm, which were both below –2 SD. Laboratory examination showed cytomegalovirus infection, proteinuria (2+), and occult blood (2+). Blood gas analysis indicated compensatory respiratory alkalosis combined with metabolic acidosis with lactate at 7.8 mmol/L. Moreover, he exhibited significant decreases in albumin (24.8 g/L) and total protein (40.7 g/L), along with an IgA level of 0.02 g/L and increased lactic acid dehydrogenase (1123 U/L) and TG (6.02 mmol/L). Cardiac ultrasound revealed an atrial septal defect and pulmonary hypertension, and an electrocardiogram showed altered sinus rhythm T waves. The patient did not undergo a metabolic study, but his neonatal screening was normal. Regrettably, the boy remained in a critical condition after the application of symptomatic treatment.

The patient was then transferred to a higher-level hospital at the request of the parents. Chest and abdominal CT detected pulmonary inflammation and slightly enlarged liver, and abdominal ultrasound showed enlarged kidneys and poor liver texture. A widening of the bifrontal frontotemporal region of the subarachnoid space was indicated by the cranial CT exhibited (Figures 2A,B). Meanwhile, laboratory tests showed hypoalbuminemia, proteinuria (2+), and edema as well as a decreased level of IgG (2.2 g/L). However, hypoalbuminemia was not ameliorated by symptomatic treatment, and he

subsequently developed exacerbated lung infection and degressive transcutaneous oxygen saturation. Unfortunately, despite all treatments, he died due to pulmonary hemorrhage and respiratory failure at the age of 4 months and 13 days.

Genetic Findings

The proband (III-3) underwent genetic testing by WES. DNA samples from her parents and brother were tested to verify the variants using Sanger sequencing. As illustrated in Figure 1B, novel compound heterozygous mutations in the COQ6 gene (NM_182476.3:exon2:c.249C > G (p.Tyr83Ter) and exon12: c.1381C > T (p.Gln461Ter)) were found in the proband (III-3) and her brother (III-2), and Sanger sequencing validation identified their parents as heterozygous carriers for one of the mutations.

Figure 3A shows a schematic of the COQ6 gene containing the two identified variants, and the COQ6 protein with its functional domains was created. The first variant c.249C > G (p.Tyr83Ter) in exon 2 of 12 causes a change of amino acid 83 from tyrosine to a stop codon that results in a truncated protein or degradation and thus probably greatly affects the structure and function of the COQ6 enzyme. COQ6 variant c.1381C > T (p.Gln461Ter) occurs at the last exon and leads to a deletion of seven amino acids from the Ubi-OHases domain of COQ6. Evolutionarily, a tyrosine at position 83 and a glutamine at position 461 of the COQ6 enzyme are highly conserved among various species (Figure 3B). According to the gnomAD database, these variants are detected with no homozygosity at allele frequencies of 0.00003185 and 0.00003188, demonstrating that they are not common benign variants in the populations included in the database. Furthermore, both variants are absent from ClinVar, and no previous patient with either variant has been described in

FIGURE 1 | Family pedigree and confirmation of the compound heterozygous variants of *COQ6*. **(A)** Pedigree shows the cosegregation of *COQ6* mutations in the family. the literature to date. Using MutationTaster, p.Tyr83Ter and p.Gln461Ter are predicted to be disease-causing variants and p.Tyr83Ter may lead to nonsense-mediated decay (NMD).

DISCUSSION

In the present study, we report two novel pathogenic *COQ6* mutations: c.249C > G (p.Tyr83Ter) and c.1381C > T (p.Gln461Ter), which, in a compound heterozygous state, resulted in two siblings with clinical presentations of COQ10D6 characterized by renal involvements including hypoalbuminemia, proteinuria and edema, and extra-renal manifestations including growth retardation, muscle hypotonia, and/or seizures. Both mutations cosegregated with the disease, and the pathogenicity of the two *COQ6* variants was confirmed by the clinical symptoms of our patients, the analysis of human genome variation databases, and *in silico* predictions.

CoQ10, also known as ubiquinone, is an important component of the mitochondrial electron transport chain; this compound exerts many effects, such as countering oxidation,

regulating calcium homeostasis, improving mitochondrial function, and preventing cellular apoptosis (Hargreaves et al., 2020). To date, pathogenic mutations in 10 genes (*PDSS1*, *PDSS2*, *COQ2*, *COQ4*, *COQ6*, *COQ7*, *COQ8A/ADCK3*, *COQ8B/ADCK4*, and *COQ9*) involved in the biosynthesis of CoQ10 have been reported to cause primary CoQ10 deficiency, which has variable clinical symptoms ranging from fatal neonatal multisystem disorder to adult-onset encephalopathy or nephropathy (Desbats et al., 2015; Acosta et al., 2016). Several pathogenic mutations in the *COQ6* gene are known to cause kidney dysfunction such as SRNS and extrarenal manifestations such as SHNL, seizures, growth retardation, and mild muscle weakness in the lower extremities (Heeringa et al., 2011; Cao et al., 2014; Park et al., 2017). The clinical manifestations in our cases and other reported patients are summarized in **Table 2**.

A mutation of the *COQ6* gene was first reported as a cause of primary CoQ10 deficiency in the study of Heeringa et al. (2011). The authors reported that all affected patients ($n = 11$) presenting with SRNS and SNHL showed proteinuria with a median onset age of 1.2 years (range, 0.2–6.4 years) and ESRD with a median onset age of 1.7 years (range, 0.4–9.3 years); five cases also

presented with extrarenal involvement such as white matter abnormalities, seizures, ataxia, and facial dysmorphism. Gigante et al. (2017) reported an 8-month-old Italian boy with SRNS that progressed to ESRD when he was 20 months old but with no extra-renal involvements; the pathogenicity of the *COQ6* p.Pro261Leu allele was then confirmed by rescue experiments in yeast. Park et al. (2017) reported six unrelated Korean children with SRNS and hearing loss, and mild muscle weakness of the lower extremities and ocular manifestations including bilateral optic nerve atrophy and exotropia were observed in four patients. The patients developed SRNS with onset at a median onset of 29 (range, 15–47) months and ERSD with onset at a median onset of 45 (range, 17–73) months; five of the patients underwent kidney transplantation without FSGS recurrence. Of note, these above patients with *COQ6* defects manifested SRNS during childhood, and all cases progressed to ERSD within 1–2 years of onset. Furthermore, some affected individuals received timely high-dosage oral CoQ10 administration after *COQ6* mutations were detected, and their renal function and psychomotor development have been improved (Cao et al., 2017; Stanczyk et al., 2018; Justine et al., 2020). Remarkably, patients may not benefit from CoQ10 therapy after severe renal and neurological damages occur. These observations suggest that once *COQ10D6* is suspected clinically, immediate CoQ10 treatment and detection of *COQ6* mutations would be helpful for the improvement of patient prognosis.

Notably, clinical heterogeneity has been observed in patients carrying the same *COQ6* mutations (see **Table 2**). For example, a 7-year-old girl from Turkey showed only SRNS without other systemic symptoms due to a homozygous *COQ6* mutation c.1058C > A (p.Ala353Asp), while her elder brother harboring

the same *COQ6* mutation exhibited normal renal functions without any neurological presentations and developed SNHL at 10 years old (Yuruk et al., 2020). Additionally, Heeringa et al. (Heeringa et al., 2011) reported six patients with the *COQ6* variant c.763G > A (p.Gln255Arg) who all had SRNS with or without other extrarenal presentations such as SNHL, seizures, white matter abnormalities, and facial dysmorphism. Similarly, our patients with the same *COQ6* mutations displayed variable clinical presentations, whereby the proband satisfying the diagnostic criteria of NS also showed growth retardation and muscle hypotonia in addition to seizures, which were not present in her older brother. Unlike most cases reported previously, our cases died in early infancy. Our findings highlight the clinical heterogeneity and the severity of the disorder caused by *COQ6* defects.

Moreover, we uncovered two novel and rare pathogenic mutations in *COQ6*, which are essential for CoQ10 biosynthesis, and these findings contribute to the known genotypic spectrum of *COQ10D6*. To date, seven mutations in *COQ6*, including missense mutations, indels, and frameshifts, have been reported in the Human Gene Mutation Database (HGMD). To confirm the deleterious effect of p.Gln461Ter on *COQ6* function, we evaluated the secondary structure of *COQ6* with p.Gln461Ter mutation using PredictProtein and found that it affected the secondary structure and solvent to some extent (**Figure 4A**). The Gln461Ter led to a deletion of seven amino acids of the *COQ6* C-terminus located on the surface of the active site (Doimo et al., 2014), which was confirmed to be functionally important by a recent study demonstrating that the deletion of 25 amino acids at the *COQ6* C-terminus leads to impaired CoQ10

FIGURE 3 | Schematic of the gene structure and domain structure of COQ6 protein and conservation analysis of the two nonsense mutations detected in the family. **(A)** The COQ6 gene containing 12 exons (yellow boxes) was exhibited using the UDSD online database, and the location of the two variants is tagged in the COQ6 exon region and its corresponding Ubi-OHases domain. **(B)** Comparative analysis of genome sequences or CDSs across species indicates that the two mutant sites are evolutionarily highly conserved.

synthesis (Acosta et al., 2019). These results suggest that the two novel COQ6 mutants identified in our study are likely both loss-of-function variants; the p.Tyr81Ter causes NMD and p.Gln461Ter perturbs the active site and secondary structure of the COQ6 protein. In addition, COQ6 was found to correlate closely with COQ3, COQ4, COQ5, COQ7, and COQ9 in a PPI network (Figure 4B). Human PDSS2, COQ4, COQ6, and COQ7 could form a protein complex in human mitochondria, and the knockdown of COQ6 markedly resulted in reduced levels of COQ3; this, in turn, causes an obvious decrease of COQ7, which is crucial for maintaining the mitochondrial function (Yen et al., 2020). Furthermore, the decreased expression of the COQ6 protein was revealed to cause kidney damage by inducing mitochondrial dysfunction and apoptosis in

podocytes (Song et al., 2018). Thus, we suspect that the candidate pathogenic variants (p.Tyr83Ter and p.Gln461Ter) may impede the interaction between COQ6 and other mitochondrial proteins in the CoQ complex, thus disrupting the pathway of CoQ10 biosynthesis and ultimately impairing renal function. This may be the reason for the more severe phenotype in the current cases.

However, the present study had some limitations. Due to premature mortality in infancy, we could not confirm our molecular finding through the detection of CoQ10 levels in skeletal muscle and the level of COQ6 protein in skin fibroblasts from patients. Although the pathogenicity of the two novel COQ6 variants identified in our study is explained by several findings, including the clinical phenotype of the two

probands overlapping with patients harboring *COQ6* mutations as previously reported, the segregation with the disease, and bioinformatics predictions, in-depth studies are still needed to further determine the impact of the two candidate mutations on *COQ6* gene expression and function.

In conclusion, our study provides the first report of a novel compound heterozygous pathogenic variant of the *COQ6* gene in a Chinese family with severe COQ10D6. Our cases widen the genotypic spectrum of COQ10D6 and highlight the heterogeneity and severity of clinical features associated with *COQ6* mutations. An early diagnosis of *COQ6* pathogenic mutations in such cases with clinical presentations suggestive of COQ10D6 will facilitate disease diagnosis and therapeutic interventions as well as disease prevention in future generations.

MATERIALS AND METHODS

Ethics Statement

The study was performed in accordance with the Declaration of Helsinki and approved by the Ethics Committee of Taizhou Hospital of Zhejiang Province Affiliated to Wenzhou Medical University. Informed consent was obtained from the family before gene testing.

Subjects

We collected blood samples and pedigrees after obtaining informed consent from the family. The two affected siblings were diagnosed with infantile NS by pediatric nephrologists based on the age of presentation (4–12 months) and the diagnostic criteria of NS, including serum albumin ≤ 25 g/L, proteinuria (24 h urine greater than 50 mg/kg/day), and hyperlipidemia (elevated cholesterol and/or triglycerides) (Lombel et al., 2013); (Wang and Greenbaum 2019). The clinical and molecular biological characteristics of the affected individuals were analyzed retrospectively.

Genetic Testing

Genomic deoxyribonucleic acid was isolated from the patient's whole blood, and exome sequencing was conducted using an Illumina NovaSeq 6000 sequencing system with 150 bp paired-end reads at an average 100 \times sequencing depth to cover the maximum genomic variations. The DNA sequence was aligned to the UCSC hg19/GRCh37 reference sequence. Variant calls and annotation were performed with a pipeline based on the Burrows–Wheeler aligner, in-house software, the Genome Aggregation Database (gnomAD), ClinVar, and custom annotation scripts. Thereafter, Sanger sequencing analysis was performed for variant confirmation and segregation using target sequence-specific primers on an ABI 3730xl sequencer and analyzed using Sequencing Analysis Software v5.2 (Applied Biosystems) and SeqMan (DNASTAR) according to the manufacturer's instructions.

In Silico Analysis

For the evolutionary conservation analysis of *COQ6* candidate variants, the alignment of gene sequences and complete coding

sequences from different species were conducted using DNAMAN, including human (NP_872282.1), rhesus monkey (XP_014999576.2), house mouse (NP_766170.2), Norway rat (NP_001011 983.1), and zebrafish (NP_001038869.1). Next, the pathogenicity of the variants was predicted by using MutationTaster, and the possible influence of the detected variants on the structure and function of the *COQ6* protein was evaluated by PredictProtein. The diagram of the functional protein association network was depicted based on the STRING (<https://string-db.org/>) database, which was used to predict protein–protein interactions.

The datasets for this article are not publicly available due to concerns regarding participant/patient anonymity. Requests to access the datasets should be directed to the corresponding authors.

ETHICS STATEMENT

The studies involving human participants were reviewed and approved by The Ethics Committee of Taizhou Hospital of Zhejiang Province affiliated with Wenzhou Medical University. Written informed consent to participate in this study was provided by the participants' legal guardian/next of kin. Written informed consent was obtained from the individual(s), and minor(s)' legal guardian/next of kin, for the publication of any potentially identifiable images or data included in this article.

AUTHOR CONTRIBUTIONS

NW conceived of the study, analyzed the data and wrote the manuscript. YZ provided the clinical samples. YZ and LZ participated in the clinical data collection and clinical evaluations. XT conducted the bioinformatics analysis. FC interpreted the brain MRI and head CT of the patients. MQ, JD, and SC performed the genetics analysis. SC and JL conducted the biochemical analysis. BS and LW critically commented and revised the manuscript. All authors have read and approved the final version of the manuscript.

ACKNOWLEDGMENTS

We would like to thank the patients and their family members for participating in our study. We also thank Dian Diagnostics for their excellent technical assistance. Finally, we sincerely thank Children's Hospital of Fudan University and The Children's Hospital, Zhejiang University School of Medicine for providing patient imaging data.

Arylsulfatase B is an enzyme present in the lysosomes that involves in the breakdown of large sugar molecules known as glycosaminoglycans (GAGs). Arylsulfatase B chemically modifies two GAGs, namely, dermatan sulfate and chondroitin sulfate, by removing the sulfate group. Mutations in the gene encoding the arylsulfataseB enzyme causes lysosomal storage disorder, mucopolysaccharidosis type VI (MPS VI), or Maroteaux–Lamy syndrome. In this study, we report a case of congenital hearing loss with mild pigmentary changes in the retina, indicative of Usher syndrome, and a missense variant reported as likely pathogenic for MPS VI. Sequencing results identified a pathogenic missense variant p.Arg1746Gln in the *CDH23* gene. However, another missense variant *ARSB*:p.Arg159Cys was reported as likely pathogenic to the treating physician. Mutations in *ARSB* gene have been associated with MPS VI. Subsequently, *ARSB* enzyme activity was found low twice in dried blood spot (DBS), suggestive of MPS VI. The patient did not have the clinical features of MPS VI, but considering the wide clinical spectrum, progressive nature of MPS VI, and the fact that a treatment for MPS VI is available to prevent disease progression, further biochemical, enzymatic, and *in silico* studies were performed to confirm the pathogenicity of this variant. *In silico* tools predicted this variant to be pathogenic. However, the results of urine and serum GAGs and *ARSB* enzyme levels measured from patient's fibroblast were found normal. Based on clinical and biochemical findings, *ARSB*:p.Arg159Cys is likely benign and did not support the diagnosis of MPS VI. However, *CDH23*:p.Arg1746Gln, a pathogenic variant, supports the underlying cause of hearing loss. This study highlights the importance of a robust correlation between genetic results and clinical presentation, and biochemical and enzymatic studies, to achieve a differential diagnosis.

Keywords: arylsulfatase B, glycosaminoglycans, non-syndromic hearing loss, *Cdh23*, whole exome sequencing

INTRODUCTION

Mucopolysaccharidoses (MPSs) are lysosomal storage disorders (LSDs) caused by inherited deficiencies of lysosomal hydrolases responsible for the catabolism of mucopolysaccharide molecules known as glycosaminoglycans (GAGs) (1). To date, 13 enzyme deficiencies have been identified that lead to an accumulation of different species of GAGs including dermatan sulfate (DS), heparan sulfate (HS), keratan sulfate (KS), chondroitin sulfate (CS), and hyaluronic acid in blood, tissues, and urine (2). MPSs are autosomal recessive disorders, except for MPS type II also known as Hunter syndrome, which is an X-linked disorder (3). MPS VI have a variable clinical phenotype in terms of severity and progression of disease, with multisystemic involvement that can include skeletal deformities, coarse facial features, and organomegaly. Hearing loss is one of the most common clinical presentation in MPSs (4). Studies have reported confirmed cases of conductive hearing loss, sensorineural hearing, and mixed hearing loss in MPS VI (5). However, patients with MPSs usually do not present with congenital hearing loss. Therefore, an intensive clinical evaluation is crucial to establish a differential diagnosis. MPS VI, or Maroteaux–Lamy syndrome, is caused by a deficiency of N-acetylgalactosamine-4-sulfatase deficiency (arylsulfatase B), leading to an accumulation of DS (OMIM: 253200). In newborns, the incidence of MPS VI is 1 in 250,000–600,000. However, the prevalence was observed to be higher in consanguineous populations (6, 7). Primary treatment options for MPSs include hematopoietic stem cell transplantation (HSCT) and enzyme replacement therapy (ERT) (8). ERT in MPS VI has been shown to reduce GAG accumulation in clinical trials (9). However, the effects of ERT on the hearing loss is inconclusive (10). Differential diagnosis based solely on clinical observations are rarely conclusive, and therefore, additional biochemical and genetic confirmatory tests are often required. Liquid chromatography tandem mass spectrometry (LC-MS/MS) is an effective method for the measurement of metabolites such as disaccharides derived from glycosaminoglycans (11). The CDH23 is a long protein made up of 27 extracellular cadherin (EC) repeats and a non-canonical domain. Each EC repeat is composed of approximately 110 residues. Linker regions that connect different EC repeats are highly conserved and are important for the binding of Ca^{2+} ions (12).

In this study, we report a pathogenic variant *CDH23*:p.Arg1746Gln in a case of congenital hearing loss with mild pigmentary changes in the retina, indicative of Usher syndrome, and a missense variant reported as likely pathogenic for MPS VI identified through whole exome sequencing (WES). However, biochemical confirmatory results for MPS VI were found negative. This report highlights the importance to identify, classify, and characterize variants using computational, biochemical, and clinical approaches.

MATERIALS AND METHODS

Ethical Approval

The Ethical Approval was obtained from Abu Dhabi Health Research and Technology Committee, reference number

(DOH/CVDC/2020/1185). The affected case was diagnosed with hearing loss at birth and referred to Tawam Hospital, Abu Dhabi, for further clinical evaluation. Different biological samples such as blood, urine, and fibroblasts were collected to conduct several assays as part of the clinical investigation. Patient was consented for WES, and after that, his blood was spotted on CentoCard (Centogene AG, Germany).

Biochemical Analysis

Arylsulfatase B Fluorimetry Assay

The enzymatic assay is a screening method for MPS VI based on the quantitative determination of ARSB (aryl-sulfatase B) activity in dried blood spots (DBS). The patient's blood was spotted on CentoCard, left to dry for 24 h, and was shipped to Centogene AG (Rostock, Germany). The protocol involves extraction of the ARSB from the DBS, incubation with a specific synthetic substrate for 20 h, and detection of the enzymatic product using fluorimetry. Quantification was performed on a fluorimeter using an external calibration line of the enzymatic product. Affected MPS VI patients show low activity of ARSB, while the healthy controls show high activity of the same enzyme (13).

Dimethylene Blue Assay

Total urine GAGs were measured using the dimethylene blue (DMB) assay, which involves binding of GAGs to the dye DMB followed by a spectrophotometric analysis of the GAG-DMB complex (14).

Mucopolysaccharidosis Quant S

The patient's serum sample was shipped to Mayo Clinic (FL, USA) for quantification of glycosaminoglycans (GAGs). The selected reaction monitoring (SRM) mode in liquid chromatography–electrospray ionization–tandem mass spectrometry (LC–ESI–MS/MS) was used for quantitative measurement of GAGs. The simultaneous quantification of 23 differently sulfated disaccharides from four GAG classes (8 chondroitin/dermatan sulfates, 1 hyaluronic acid, 12 heparan sulfates, and 2 keratan sulfates) was achieved using MS/MS technique. Apart from the internal disaccharides as mentioned previously, some saccharides derived from the non-reducing terminal were also observed. The chain length of GAGs was estimated based on the simultaneous quantification of both internal and non-reducing terminal saccharides (15).

Arylsulfatase B Enzymatic Assay

Enzymatic assay was performed on the fibroblast cell culture obtained from the index skin biopsy. Enzyme assay is the gold standard for diagnosis of patients with MPS VI. It can also determine the pathogenicity effect of the detected novel variants. Skin biopsy was shipped to South Australia Pathology Laboratory (Adelaide, Australia). In normal physiological conditions, the ARSB enzyme chemically modifies chondroitin-4-sulfate and dermatan sulfate by removing the sulfate group. The kinetic parameters, Michaelis–Menten constant (K_m), and maximum velocity of human ARSB activity in cultured skin fibroblasts were measured with a different synthetic substrate similar to chondroitin 4-sulfate and dermatan sulfate. The natural

FIGURE 1 | The affected patient's family pedigree and the results of a confirmatory hearing loss test. **(A)** Family pedigree of the index patient, showing a highly inbred family. Family has a history of Ehler Danlos syndrome and history of cardiac arrhythmia. The index patient is indicated with filled square. Male and female are shown in squares and circles, respectively. **(B)** Threshold test indicating the level of hearing loss recorded from the auditory brainstem response (ABR), classifying it to be severe. Background colors represent the severity of hearing loss. Normal hearing (gray and white), mild hearing loss (green), moderate hearing loss (yellow), moderately severe hearing loss (orange), severe hearing loss (purple), and profound hearing loss (red). Measurements were recorded in both ears at three frequencies. Red circle indicates the value recorded in left ear, blue cross in a red circle indicates the value recorded in right ear.

substrate's aglycon structures were desulfated up to 4,400 times faster than the substrates specific for arylsulfatase-B (N-acetylgalactosamine 4-sulfate). The enzyme activity of arylsulfatase B in skin fibroblast was measured using O-(beta-N-acetylgalactosamine 4-sulfate)-(1→4)-O-D-(beta-glucuronic acid)-(1→3)-O-D-N-acetyl[1-3H] galactosaminitol 4-sulfate. These substrates are used to identify Maroteaux-Lamy syndrome patients from normal controls or/and MPSs patients (16).

DNA Extraction and Whole Exome Sequencing

The patient's blood was spotted on CentoCard and left to dry for 24 h. DNA extraction was performed on QIAcube instrument with QIAamp DNA Blood Mini QIAcube Kit (Qiagen, Valencia,

CA, USA) following the manufacturer's instructions. NanoQuant plate was used for the quality and quantity analysis of DNA samples. The diagnostic WES was carried out by Centogene AG (Rostock, Germany). Briefly, twist Human Core Exome Plus kit was used for the exome capture, and the captured libraries were target enriched and indexed. A Novaseq 6000 sequencer was used to sequence the target enriched libraries. For the WES data analysis, sequencing reads were initially converted into normal FastQ format and were processed via locally maintained bioinformatics pipeline. The short reads were aligned to the GRCh37 (hg19) build of the human reference genome. Aligned sequences were further converted to a binary BAM file format, followed by variant calling, which was performed on the secondary alignment files using GATK Haplotype Caller, free

TABLE 1 | Description of variants detected during whole exome analysis.

Gene	Variant coordinates	Amino acid change	Zygosity	Type	Clinvar ACMG Classification
CDH23	NM_022124.5:c.5237G>A	p.(Arg1746Gln)	Homozygous	Missense	Pathogenic
ARSB	NM_000046.3:c.475C<T	p.(Arg159Cys)	Homozygous	Missense	Variant of unknown significance

bayes, and sam tools. Locally maintained bioinformatics tools and Annovar were used for variants annotation. Alignments were conducted and visually confirmed by using Alamut v.2.4.5. The identified variants were further analyzed for genotype phenotype correlation according to the guidelines of the American College of Medical Genetics (ACMG).

In silico Analysis

To further examine the deleterious effect of the identified missense variants on CDH23, and ARSB, several *in silico* tools, namely, Sorting Intolerant from Tolerant (SIFT) (17), Polymorphism Phenotyping v2 (PolyPhen-2.0) (18), Fathmm (19), and Mutation Taster (20), were used. Multiple sequence alignment (MSA) was performed to determine the conservation of amino acids at the missense position (p. Arg159Cys) in ARSB and (p.Arg1746Gln) in CDH23, and Jensen–Shannon Divergence (JSD) scores were also calculated (21). Amino acid sequences of CDH23, and ARSB protein from *Homo sapiens* (human), *Mus musculus* (house mouse), *Rattus norvegicus* (Norway rat), *Callorhinchus milii* (elephant shark), *Bos taurus* (cattle), *Danio rerio* (zebrafish), *Felis catus* (domestic cat), *Pan troglodytes* (chimpanzee), and *Vulpes Vulpes* (red fox) were retrieved from National Center for Biotechnology Information (NCBI) RefSeq and aligned using Clustal Omega (22). JSD scores were calculated using aligned sequences in FASTA format. The protein sequence of the human CDH23 (accession number: Q9H251) and ARSB (accession number: P15484) were obtained from UniProt for homology modeling. Protein databank (PDB) IDs 1FSU and 5VVM were used as templates to produce the homology models of wild-type and mutant CDH23 and ARSB, respectively, using SWISS-MODEL. PyMOL was used for the evaluation and visualization of generated models (23).

RESULTS

Case Report Summary

A male proband was born after full-term pregnancy *via* spontaneous vaginal delivery (SVD) to consanguineous Emirati parents. During newborn screening, hearing loss measurements were performed using distortion product oto-acoustic emission with the interacoustic instrument at 30–40 db prior to the infant's discharge. The proband failed the test at 40 db and was suggestive of congenital hearing loss. A diagnostic auditory brainstem response (ABR) was performed to measure the degree of hearing loss, and threshold estimation was computed during normal sleep. ABR results revealed no reproducible wave V traced out at 90 dB nHL for click stimulus and tone burst (0.5, 1.0, and 2.0 kHz) in both ears, indicative of bilateral hearing loss. Cochlear microphonics was absent. Moreover, two

additional audiology tests performed every 2 months showed no repeatable and reliable response even at 90dB nHL for clicks at 0.5, 1.0, 2.0, and 4kHz tone burst in both ears, confirming a profound sensorineural hearing loss (**Figure 1B**). Patient underwent an ear tube surgery at 8 months of age followed by a cochlear implant at the age of 10 months. Mild pigmentary changes in the retina were observed during an eye examination, suggestive of Usher syndrome. To investigate the genetic causes of congenital hearing loss, gene panel for hearing loss at Prevention Genetics (Marshfield, WI, USA) was ordered, and results came negative. Additionally, the results of microarray were also found to be negative when compared to a normal male array. The patient is from a highly consanguineous family, and his parents are first cousins. The proband also had a family history of Ehlers–Danlos syndrome (EDS) and sudden cardiac death for several family members (**Figure 1A**). Whole exome sequencing was ordered to determine the genetic reasoning of hearing loss. Sequencing results identified a missense variant CDH23:p.Arg1746Gln in a homozygous state associated with hearing loss. *In silico* tools predicted this as pathogenic. ClinVar ACMG classifies it as pathogenic. Furthermore, an incidental finding of likely pathogenic mutation ARSB:p.Arg159Cys based on Centogene ACMG criteria, suggestive of MPS VI diagnosis, was also reported to the treating physician. As per Centogene local database, this variant has been previously identified in one second affected patient in a homozygous state with partial phenotype overlap with no enzymatic analysis. ARSB enzyme activity (EA) measured twice in DBS revealed low levels of EA. Based on this, ARSB:p.Arg159Cys variant was reported as likely pathogenic. At that time, this variant was not reported in any public database. However, this variant has recently been classified as variant of unknown significance (VUS) in ClinVar. MPS VI is a disease that progresses slowly or quickly, but early intervention is critical for the patient's outcome. The proband had a history of inguinal hernia repair, recurrent ear infection, recurrent fever, and reactive airway disease. Patient's developmental milestones were normal, rolling over 40 days, sitting at 6/12 months, standing at 1.5 years. Gross motor and fine motor skills were also observed normal. Moreover, he received a speech therapy three times per week. Physical examination performed at 30 months of age showed head circumference of 47 cm (5th percentile), height of 92 cm (25th percentile), weight of 13 kg (25th percentile), no corneal clouding, no coarse fascial feature, no organomegaly, and no joint restriction. Furthermore, skeletal survey did not show any evidence of dysostosis multiplex; ultrasound of abdomen was observed normal with no hepatosplenomegaly. Echo of the heart was also normal. The patient did not have the clinical features of MPS VI, but considering the wide clinical spectrum, progressive nature of MPS VI, and the fact that a treatment

TABLE 2 | Results of mucopolysaccharides quant assay performed on patient's serum.

Mucopolysaccharides quant, S	Concentration (ng/ml)	Reference value
Dermatan sulfate	61.16	<300
Heparan sulfate	16.52	<55
Total keratan sulfate	1,078.87	<1,800

for MPS VI is available to prevent disease progression, further *in silico*, biochemical, and enzymatic studies were performed to confirm the pathogenicity of ARSB:p.Arg159Cys variant. *In silico* tools predicted this variant to be pathogenic. However, the results of urine and serum GAGs came normal. ARSB enzyme levels measured from patient's fibroblast were also found normal. These studies conclusively ruled out the diagnosis of MPS VI.

Molecular and Biochemical Studies

WES was performed to determine the genetic basis of hearing loss. Variants were prioritized on the basis of clinical phenotypes of the patient, family history, suspected disease pathways, and minor allele frequency (≤ 0.05). Sequencing results identified a homozygous missense variant *CDH23*:p.Arg1746Gln. It has already been reported in ClinVar as pathogenic. This confirmed the diagnosis of hearing loss (Table 1). Additionally, a missense variant ARSB:p.Arg159Cys was found during WES analysis in a homozygous state. At the time of identification, this variant was not reported in any public database. Moreover, variant around this region in ARSB has been found associated with MPS VI (24). ARSB enzyme was estimated in DBS, and results showed low levels of ARSB enzyme 6.3 $\mu\text{mol/L/h}$ (reference, $> 8.8 \mu\text{mol/L/h}$), supporting the diagnosis of MPS VI. Since it is a screening assay and has high false-positive rate, further biochemical and enzymatic studies were performed. Urine GAGs assay was performed as part of the biochemical clinical investigation, and the result was normal at 18.8 mg/mmol creatinine (reference value, $< 24.0 \text{ mg/mmol creatinine}$). MPS serum assay was carried out, and results indicated the GAGs levels including dermatan sulfate, heparin sulfate, and total Keratan sulfate to be normal (Table 2). Furthermore, an enzymatic assay was performed on the patient's skin fibroblast to determine the deficiency in ARSB enzyme. However, ARSB enzyme levels were found to be normal at 12.0 pmol/min/mg protein (reference range, 11.8–39.4 pmol/min/mg/protein). This variant has recently been deposited in ClinVar database and classified as VUS based on ClinVar ACMG classification. However, our results conclusively indicated the likely benign nature of ARSB:p.Arg159Cys variant.

In silico Analysis

Several *in silico* variant predictions tools and molecular modeling were utilized to assess the variant pathogenicity effect on the overall protein structure, stability, and function. CDH23 and ARSB protein sequences of different mammals were retrieved from NCBI's reference sequence (RefSeq), and MSA was carried out using Clustal Omega (22). Arg1746 and Arg159 residues of CDH23 and ARSB are highly conserved as indicated by their JSD

scores (Figures 2G,H). *In silico* tools consistently predicted these variants to be pathogenic. I-Mutant tool was used to compute the impact of *CDH23*:p.Arg1746Gln and ARSB:p.Arg159Cys variants on the overall stability of the protein. Both variants decreased the protein stability as indicated by their Gibbs free energy change value ($\Delta\Delta G$) (Figures 2G,H). Importantly, the results of *in silico* tools for the ARSB:p.Arg159Cys variant were found to be contradictory to its functional studies. Moreover, three-dimensional models of wild-type and variants of ARSB and CDH23 were generated using SWISS-MODEL to observe the effect of missense variants on the protein structure and function. Initially, the full amino acid sequence of human CDH23 was used for the identification of appropriate templates. However, no good quality template was found. In order to obtain a reasonable template, only EC17 and EC18 residues of human CDH23 were selected for template search. Human CDH23 (EC17 and EC18) produced 90% sequence identity with three-dimensional structure of mouse CDH23 (EC17 and EC18), indicating a good template for modeling. Arg1746Gln variant is located in EC17 of CDH23 (Figure 2A). The substitution of a charged residue arginine to glutamine is physiochemically significant (Figures 2B,C). Arg1746 forms a hydrogen bond with Glu1749. The substituted Gln1746 is likely to disrupt this interaction. It is also perceivable that this loss of charge mutation could likely affect salt bridges and hydrogen bonds that are essential in the CDH23 cis homodimer interface.

The 3D structure of human ARSB is available in PDB (PDB ID: 1FSU) and was used as a template for generating the 3D model of ARSB:p.Arg159Cys variant (Figure 2D). Arg159 is located in a loop region of ARSB (Figures 2E,F). This region is considered the probable recognition site for targeting to the lysosomes (25). The substitution of arginine to cystine is physiochemical significant. However, Arg159 is not the part of residues that line the active site pocket of ARSB, which is essential for enzyme activity. Aside from the loss of a charged residue at the surface of enzyme, no notable impact is expected.

DISCUSSION

This study presents a pathogenic variant p.Arg1746Gln in *CDH23* gene associated with congenital hearing loss with mild pigmentary changes in the retina, indicative of Usher syndrome, and an incidental finding of a missense variant (ARSB:p.Arg159Cys) reported as likely pathogenic for MPS VI in an Emirati patient.

A series of biochemical and enzymatic assays were performed to establish the pathogenicity of ARSB:p.Arg159Cys associated with MPS VI. The normal results of enzyme activity on fibroblast and normal level of GAGs indicate that this variant is likely benign. This study also highlights the limitations of *in silico* tools that consistently predicted this variant to be pathogenic. Therefore, a careful evaluation of clinical phenotypes and functional studies is imperative to confirm variant pathogenicity.

It is critical to establish a clear genotype–phenotype correlation early in the diagnostic process. Generally, a

FIGURE 2 | The generated homology models for CDH23 and ARSB. The proteins are shown in cartoon representation, and the amino acid is demonstrated with a stick representation. The boxed region in A and D is enlarged in subsequent images. (A) Modeled structure of CDH23. (B) Wild-type R1746. (C) Mutant Q1746. (D) Modeled structure of ARSB. (E) Wild-type R159. (F) Mutant C159. Conservation of each amino acid is shown across species for both CDH23 (G) and ARSB (H). combination of clinical and laboratory findings is needed to establish the diagnosis of MPSs. The patients of MPS VI often present with skeletal deformities, coarse facial features, conductive hearing loss, and corneal clouding. It is worth mentioning that the physical examination of index patient was inconsistent with the clinical signs and symptoms of MPS VI. Despite a clear physical examination, the patient's history of inguinal hernia repair, the detection of ARSB:p.Arg159Cys variant, and positive results of ARSB enzyme activity in DBS, this patient was suspected with MPS VI. It is also worth mentioning that the variant present close to this region in ARSB is reported to be associated with MPS VI (1, 26).

Interestingly, the gene panel performed in the first place failed to identify any variant associated with hearing loss. There are several limitations associated with the use of gene panel assays, such as variants are limited to pre-selected gene. Additionally, it requires regular updates, as new variants are being discovered (27). It is also important to mention that CDH23, a disease-causing gene linked with hearing

loss was not included in the design of gene panel. This is why the gene panel failed to identify any mutation in genes linked to hearing loss. However, WES results identified a pathogenic variant CDH23:p.Arg1746Gln associated with hearing loss.

Finding likely pathogenic variants necessitates immediate action in patients' management plan, especially if a treatment is available. According to ACMG/AMP guidelines, pathogenic and likely pathogenic variants are reported with 99.1 and 90% confidence (28). However, physicians generally interpret both pathogenic and likely pathogenic variants to be disease associated. According to a recent study that evaluated 36,808 variants classified as likely pathogenic in ClinVar, only 2.16% were reclassified to other categories (29). Interestingly, only four variants were reclassified from likely pathogenic to likely benign (29). This suggests that likely pathogenic variants are rarely found to be benign. Therefore, exhaustive interpretation of genetic data should be performed, before reporting genetic results to the treating physicians.

Here, sequencing results initially reported a likely pathogenic variant ARSB:p.Arg159Cys. ARSB gene variants have often been associated to the lysosomal storage disorder MPS VI (30). Conductive hearing loss has been linked to MPS VI and other MPS subtypes (31). ARSB enzyme levels in the patient's DBS were measured twice, and the results supported the MPS VI diagnosis. It is worth highlighting that this assay is a screening assay and has high false-positive rate. Therefore, additional biochemical assays should be performed to confirm the diagnosis of MPS VI due to its experimental limitations. Measuring ARSB in DBS is performed using a fluorescence-based method that is being used for detecting LSD in newborn screening (NBS), where different β -methylumbelliferone sulfate (β -MU)-derived substrates similar to natural substrates are applied to quantify lysosomal enzyme deficiency in DBS samples (32). β -MU molecule is known to be highly fluorescent; its detection is often hindered when it is found in a DBS (13). Normally, known standards of β -MU are prepared in an aqueous matrix lacking blood components. Therefore, the enzyme activity (EA) calculated by interpolating sample fluorescence values in a blood-free calibration curve provides data that underestimate the real EA. This could potentially explain the reason why enzyme ARSB on DBS was found lower twice (32). Therefore, enzymatic screenings performed in DBS are not always conclusive, and it required further confirmatory biochemical assays. Additional biochemical and enzymatic studies were performed to establish the pathogenicity of ARSB:p.Arg159Cys; however, results were found normal (Table 2). These findings concluded that the enzyme is functional, and thus, the patient cannot be diagnosed with MPS VI.

As the number of genetics and genomics tests are increasing, interpreting sequence variants becomes more difficult. Recently, several sequence variants of VUS have been identified (31). Although ACMG guidelines provides a robust framework for laboratories to determine the pathogenicity of sequence variants in a systematic manner, the degree of uncertainty provided by these guidelines can produce contrary classification among different clinical laboratories (32). A study performed on variants reported in ClinVar observed a conflicting interpretation rate of 11.7% among four clinical laboratories (33). Moreover, variability in the *in silico* tools and classification of functionally relevant variants also pose a challenge on the interpretation of variants. In clinical settings, predictions from *in silico* algorithms are considered as one of the eight evidence criteria recommended for variant interpretation by ACMG guidelines (34). *In silico* tools often produce high rate of false-negative and false-positive results. In our study, multiple *in silico* tools consistently predicted ARSB:p.Arg159Cys variant as pathogenic,

contradicting functional studies that found the variant to be likely benign. Therefore, the patient does not require immediate enzyme replacement therapy.

CONCLUSION

In this study, we report the utility of WES in identifying the genetic variants associated with clinical phenotypes. A robust genotype–phenotype correlation and functional studies are needed to establish the pathogenicity of detected variants during differential diagnosis. Our biochemical and enzymatic studies indicate that ARSB:p.Arg159Cys variant is likely benign and should be reclassified from VUS to likely benign.

Molecular and Phenotypic Expansion
of Alström Syndrome in
Chinese Patients.
Front. Genet. 13:808919.
doi: 10.3389/fgene.2022.808919

Alström syndrome (ALMS) is a rare inherited metabolic disease and ciliopathy. Large cohorts of ALMS are lacking around the world. Detailed genetic and phenotypic data were obtained from all affected individuals. Olfactory function was evaluated by the Chinese Smell Identification Test and facial pattern was analyzed with Face2gene. Fifty ALMS patients were included in this study, aged from 0.3 to 21.7 years old. Sixty-one *ALMS1* variants in 50 patients from 47 different families were confirmed, including 59 truncating and two exon deletions. Twenty-four of those variants were novel. We also summarized all previously reported cases of Chinese ALMS patients (69 patients) and identified specific and common variants within the Chinese population. Besides, the Chinese Smell Identification Test scores in patients was lower than that in controls (11.97 Vs. 10.44, $p < .05$), indicating olfactory identification impairments in ALMS patients. The facial pattern in ALMS patients was also distinctive from that of the controls ($p < .05$). In conclusion, this is the largest cohort of Chinese ALMS patients. We have successfully identified both specific and common variants in our cohort. We found a new phenotype of olfactory impairments in ALMS patients through a case-control study.

Keywords: alström syndrome, *ALMS1*, next-generation sequencing, rare disease, variants

INTRODUCTION

Alström syndrome (ALMS; MIM #203800), a ciliopathy caused by mutations of the *ALMS1* gene, is inherited in an autosomal recessive pattern. The incidence of this disease is approximately 1/1,000,000 (Tahani et al., 2020). ALMS is a complex multisystem disease whose main symptoms include retinal dystrophy, hearing loss, early-onset obesity, cardiomyopathy, type 2 diabetes mellitus, and multiple organ fibrosis. Retinal dystrophy occurs in all ALMS patients and is a critical manifestation that can be detected from a few weeks to 6 months of age. Hearing loss usually presents with progressive bilateral sensorineural hearing loss, and obesity is usually observed within 6 months to 2 years of age alongside an increased appetite. There are two forms of cardiomyopathy: infantile- and later-onset cardiomyopathy, both of which vary in severity and prognosis. Infantile-onset cardiomyopathy is severe and usually transient; however, later-onset cardiomyopathy is progressive and has a poor prognosis (Tahani et al., 2020).

The *ALMS1* gene is located in chromosome two at locus 2p13 and spans 23 exons. Most disease-causing variants of *ALMS1* are truncating mutations that result in loss-of-function proteins (Marshall et al., 2015). To date, 278 variants of *ALMS1* have been identified according to The Human Gene Mutation Database with the mutational hotspots being in exons 8, 10, and 16. There have been no disease-causing variants identified in exons 1, 2, 6, 7, 13, 22, and 23 thus far (Marshall et al., 2015). Such variants were mainly reported by studies of ALMS patient cohorts from Turkey, American, and Poland (Ozantürk et al., 2015; Zmyslowska et al., 2016; Brofferio et al., 2017). However, although there are a few case reports of ALMS patients in China (Rethanavelu et al., 2020), large-scale cohort studies of Chinese patients are still lacking, making it difficult to summarize the common features of ALMS in China.

The ALMS1 protein is located in the basal body of the primary cilia and plays an important role in ciliary function. Therefore, ALMS is a ciliopathy (Hearn et al., 2005). The defective ALMS1 protein is believed to affect primary cilia function in ALMS patients (Hearn et al., 2005; Heydet et al., 2013). Primary cilia are present in most mature mammalian cells. They are essential in

many organs such as the eyes, inner ears, and hypothalamus, which may explain the phenotypes of retinal dystrophy, hearing loss, and obesity in ALMS patients. Additionally, primary cilia contribute to olfactory sensory neuron function. Olfactory dysfunction has been identified in other ciliopathies such as Bardet-Biedl syndrome (BBS) (Kulaga et al., 2004). However, it has not been reported in ALMS patients.

Here, we report the clinical and genetic spectrum of 50 ALMS patients in China, which is, to our knowledge, the largest ALMS cohort in East Asia. In total, we identified 61 variants in the *ALMS1* gene, including 50 truncating variants and two exon deletions, of which 24 are novel. Notably, we also identified the first variant c.1415_1416insTCCT in exon 7. Furthermore, genotype-phenotype correlations were analyzed, and the phenotypes of ALMS patients in China were compared to those found in three cohorts from Turkey, American, and Poland. We also summarized all of the variants identified in the Chinese ALMS patients ($n = 69$) from our study and previous reports. We identified distinct and common variants within the Chinese patients. To expand on new phenotypes and explore new diagnostic tools, we further designed a cases-control study to

^eRenal symptom includes proteinuria, fat liver, and elevated liver enzymes.

^fHepatic symptom includes hepatic steatosis, fat liver, and elevated liver enzymes.

^g33/44 patients from Turkish cohort were included for the including criteria of carrying at least one pathogenic/likely pathogenic variant of ALMS1.

^hObesity and overweight was defined as BMI ≥ 28 kg/m² or BMI ≥ 24 kg/m² for adults according to the WGOC, criteria. For children between 6 and 18 years old, overweight/obesity was defined according to Chinese reference values released by the National Health and Family Planning Commission of the People's Republic of China. For patients aged 5,6 years, obesity was defined as a BMI-for-age greater than two SD, above the WHO, growth reference median; and overweight is greater than one SD, above the WHO, Growth Reference median. Obesity in children less than 5 years was defined as a weight-for-height ≥ 2 SD, and overweight ≥ 3 SD, above the WHO, growth reference median.

assess the facial patterns and the olfactory function of ALMS patients, which may be used as auxiliary diagnostic methods for ALMS.

MATERIALS AND METHODS

Patients

A total of 50 patients, aged from 0.3 to 21.7 years old, were recruited through the Alström Syndrome Greater China Association, a patient-centered group for ALMS (<https://www.alstrom.cn/>) for genetic consulting in Shanghai Children's Medical Center. They were diagnosed with ALMS at different districts throughout China. Phenotypic and genetic data were obtained from all affected individuals, including general information, medical history, personal history, inspection reports, and laboratory reports. Diagnosis was then confirmed by professional physicians at Shanghai Children's Medical Center. Obesity was defined as BMI ≥ 28 kg/m² and overweight was defined as BMI ≥ 24 kg/m² for adults according to the criteria from Working Group on Obesity in China (WGOC) (Pan et al., 2021). For children between 6 and 18 years old, overweight/obesity was defined according to Chinese reference values released by the National Health and Family Planning Commission of the People's Republic of China (China, N.H.C. o.t.P.s.R.o., 2018; Liu, 2021). Obesity in children less than 5 years was defined as a weight-for-height ≥ 2 standard deviation (SD) and overweight ≥ 3 SD above the WHO Growth Reference median (<https://www.who.int/news-room/fact-sheets/detail/obesity-and-overweight>). And in children aged 5,6 years, obesity was defined as a BMI-for-age greater than two SD

above the WHO Growth Reference median; and overweight is greater than one SD above the WHO Growth Reference median (<https://www.who.int/news-room/fact-sheets/detail/obesity-and-overweight>). Written informed consent was obtained from all the participants or their guardians before information was collected.

Genetic Sequencing

For patients 36 and 42–46, exome sequencing was performed at Shanghai Children's Medical Center as previously described (Hu et al., 2018; Li et al., 2019). Candidate variants were screened by a minor allele frequency $< 1\%$ against the 1,000 Genomes Project, the NHLBI exome variant server or in 50 HapMap control exomes. Then retinal degeneration, obesity, and cardiomyopathy were selected as the filtering clinical symptoms to further analyze those variants. Next-generation sequencing (NGS) in other patients were performed through other commercial companies or hospitals. Variants detected were confirmed by Sanger sequencing in each proband and their parents except for patients 35, 42, 44, and 45. The potential pathogenicity of the variant was evaluated with PolyPhen-2 (<http://genetics.bwh.harvard.edu/pph2/>), SIFT (<http://sift.jcvi.org/>), and MutationTaster (<http://www.mutationtaster.org/ChrPos.html>). The allele frequencies of all identified variants were much lower than 0.1%. All variants were re-identified by the geneticists at Shanghai Children's Medical Center according to the guidelines recommended by the American College of Medical Genetics and Genomics (ACMG) (NM_015120.4).

Automated Image Analysis

Face2Gene (<https://face2gene.com>) was used as a tool to analyze phenotypic traits based on pattern recognition of frontal

FIGURE 2 | Summary of *ALMS1* variants. **(A)** *ALMS1* variants identified in this study. Novel variants are shown in red. **(B)** Pie chart for the number of variants identified in our study and other cohorts.

photographs of the patients. Because Face2Gene's CLINIC application was not yet designed to differentiate ALMS patients, we used the Face2Gene RESEARCH application to analyze facial features (Knaus et al., 2018).

Olfactory Identification Assessment

ALMS patients and healthy children (controls) were included if the following criteria were met: 1) aged 6–18 years; 2) willing to participate in this study; 3) no difficulty in language

communication. Cases and controls were excluded if they had a history of respiratory allergies, upper respiratory infections, rhinitis within the past 14 days, smoking or drinking. Controls with any chronic diseases were also excluded.

The smell identification test includes 16 different odorized items selected from the Chinese Smell Identification Test (CSIT), which has been used as a validated tool to assess olfactory function in the Chinese people (Feng et al., 2019; Wu et al., 2019). The test was conducted in a quiet room free of odors and

with proper ventilation. During the CSIT, felt-tip pens containing different odorants were placed 2 cm below the individuals' noses for 2 s after removing the cap. Participants were requested to distinguish the correct smell from four different odor options. Each correct choice was scored one point; otherwise, 0 point was recorded. Each individual only had one chance to complete the test to avoid smell fatigue. After the CSIT, a self-reported olfactory scale was obtained based on a 5-point scale.

Statistics Analysis

Qualitative data are expressed as frequency (%) and compared using Chi-squared test of Fisher test, quantitative data showed as mean \pm SD and comparisons were performed by unpaired *t*-test or nonparametric tests where appropriate. SPSS 25.0 (Statistical Package for the Social Sciences Inc., Chicago, IL, United States) was used for statistical analyses. $p < .05$ was considered statistical significance with two-sides.

RESULTS

Clinical Manifestations

A total of 50 patients from 47 different families were included in this study (19 women and 31 men, **Supplementary Table S1**). Families 17, 21, and 47 each had two siblings. All probands from a non-consanguineous family are of Han nationality, except for patients 49 and 50, who are of Tibetan nationality. Among them, sixteen patients (patients 1–8, 10–13, 15, 19, 21–22) were previously reported by Rethanavelu et al. (Rethanavelu et al., 2020) and one patient (patient 9) was reported by Xu et al., (2016). Most patients are from East China, Central China, and South China (**Figure 1A**) and younger than 10 years of age

(**Figure 1B**). Patient heights are almost close to normal ranges according to the Chinese Growth Reference (**Figures 1C,D**) (Li et al., 2009). Furthermore, the distribution of height among girls is higher than that among boys.

Detailed clinical manifestations of the patients are summarized in **Supplementary Table S1**. The average age at onset (vision impairment or cardiomyopathy) is 0.7 years, and the average age at diagnosis is 4.7 years. Visual impairment, including nystagmus, photophobia, and impaired vision, is the first symptom in 72% of the patients, and the remaining 28% of patients are referred to the hospital for infantile-onset cardiomyopathy. Overall, one-third of the patients (18/49, 37%) have a history of cardiomyopathy. Obesity and hepatic symptoms are observed in more than 50% of the patients. The prevalence of diabetes mellitus (DM), late-onset cardiomyopathy, and renal symptoms is lower than that of other symptoms (9%, 8%, and 20% respectively).

Phenotypic Comparison Between Our Chinese Cohort and Cohorts From Other Countries

To understand whether the major clinical manifestations of ALMS are consistent across patients worldwide, we compared phenotypes between our Chinese cohort and three cohorts from other countries: Turkey, America, and Poland (Ozantürk et al., 2015; Zmyslowska et al., 2016; Brofferio et al., 2017) (**Table 1**). The overall clinical features were similar between these cohorts. Vision loss, the typical symptom of ALMS, occurred in all patients from all four cohorts. There were also no significant differences in the incidence of overweight status, cardiomyopathy, and hepatic symptoms between these cohorts. However, we observed significant differences in the incidence of sensorineural hearing loss (SNHL), DM, and renal symptoms between the Chinese cohort and the other cohorts. This could be because of differences in patient ages with an average of 7.0 years in the Chinese cohort and an average of 15.1 years in the other cohorts (**Table 1**). Thus, the different clinical symptoms could occur or become more severe as age increases. In addition, many patients in the Chinese cohort lacked the necessary renal function and liver function evaluations, which could have resulted in the incidence of associated symptoms being underestimated. In general, we believe that the major clinical symptoms are common for ALMS patients in the world.

Spectrum of *ALMS1* Variants in Chinese Patients

Next, we sought to define the variant spectrum of *ALMS1* in the Chinese ALMS patients, aiming to identify the prevalent variants in patients globally, and the distinct variants in the Chinese patients. We totally identified 61 different variants of *ALMS1* (59 truncating variants and two exon-deletions) in total in the 50 patients using exome sequencing (**Figure 2A**). The allele frequencies of these variants were $<0.1\%$ against the 1,000 Genomes Project and the Exome Aggregation Consortium databases. Additionally, a variety of in silico studies were conducted to evaluate the pathogenicity of these variants.

19	242	3	1.2

^aAllele rate = Number of alleles/Exon size.

According to the guidelines recommended by ACMG, all of the 59 truncating variants were classified as pathogenic. Among them, twenty-four were novel and are located in exons 5, 7, 8, 10, and 19 (Table 2 and Figure 2A). Notably, we identified the first *ALMS1* variant in exon 7, i.e., c.1415_1416insTCCT. The remaining 37 variants have been reported previously in other cohorts (Minton et al., 2006; Flintoff and Josifova, 2007; Liang et al., 2013; Consugar et al., 2015; Marshall et al., 2015; Ozantürk et al., 2015; Wang et al., 2015; Rethanavelu et al., 2020). To better understand the commonality of those 37 variants, we summarized the variants reported by other Chinese cohorts and cohorts from other countries. We retrieved 24 Chinese

ALMS patients from 22 families from the literature (Liu et al., 2009; Liang et al., 2013; Wang et al., 2015; Xu et al., 2016; Yang et al., 2017; Rethanavelu et al., 2020; Zhou et al., 2020). All variants of the *ALMS1* gene from 69 Chinese families are summarized in Table 3 and the distribution of these variants in Chinese and other countries' cohorts are shown in Figure 2B. Twenty-four variants were only identified in our cohort and 23 variants were identified in both our cohort and the other Chinese cohorts. Of them, ranking variants included c.2090C > A (11/138, 7.97%), c.10825C > T (9/138, 6.52%), c.10831_10832del (5/138, 3.62%), c.4917_4920del (5/138, 3.62%), c.3902C > A (5/138, 3.62%), and c.6169_6170dup (4/138, 2.9%). Variant c.9154_9155del (7/138, 5.07%) was recurrent in our cohort but was not found in the other cohorts. Interestingly, c.2090C > A was a distinct variant in the Chinese patients and only identified in them. Based on our analysis, exons 8, 10, and 16 were mutational hotspots, harboring 51.45%, 20.29%, and 18.84% of variants, respectively. Exon 16 had a particularly high mutation rate considering its size (Table 4). Generally, we found that the spectrum of *ALMS1* variants in Chinese ALMS patients showed clusters in some exons (8, 10, and 16) and specific variants.

Genotype-Phenotype Correlations

Interestingly, the siblings from family 17 suffered from severe infantile-onset cardiomyopathy, which indicated the possibility

TABLE 5 | Genotype-Phenotype correlation for Infantile-onset cardiomyopathy ALMS patient.

Subjects	Patients with a history of infantile-onset cardiomyopathy N = 16	Patients without a history of infantile-onset cardiomyopathy N = 34	p Value
Age (mean \pm SD, y)	5.84 \pm 4.01	7.46 \pm 4.39	.201 ^a
Gender (male/female)	8/8	23/11	.230 ^b
Carrying variants before exon 8, n (%)	15 (93.75)	23 (67.65)	.097 ^c

of a genotype-phenotype correlation. Therefore, we tried to find genotype-phenotype correlations in the ALMS patients. We analyzed patients with a history of infantile-onset

cardiomyopathy and compared them to patients without a history of cardiomyopathy. In total, 32% (16/50) of the patients suffered from infantile-onset cardiomyopathy in our

FIGURE 4 | Olfactory assessment in ALMS patients and controls. **(A)** The CSIT self-scores of ALMS patients and controls. **(B)** The tested CSIT scores of ALMS patients and controls. **(C)** The identification rate of each odor in ALMS patients and controls. * $p < .05$.

cohort. Of these patients, 93.75% (15/16) carried at least one truncated variant before exon 8 (including exon 8); only 67.65% (23/34) of the patients without cardiomyopathy had similar truncated variants (Table 5). However, no significant statistical difference was identified ($p = .097$), likely because of the limited number of patients. These results suggest that earlier translation termination may be correlated with infantile-onset cardiomyopathy and that the fragment encoded by exon 8 may be important for cardiac function.

Computer Facial Recognition Analysis

Next, we wondered if we could develop novel methods which might aid in the diagnosis of ALMS. Firstly, we tested whether ALMS patients had distinct facial features. We used the

Face2Gene RESEARCH tools to assess patient facial patterns. Thirty-three facial photographs of ALMS patients were collected, along with those from 33 age- and sex-matched controls. The receiver operating characteristic (ROC) curves showed that the facial patterns in ALMS patients were indeed different from those in the controls, with an Area Under Curve (AUC) of 0.96 ($p < .001$) (Figures 3A,B). This suggests that the facial recognition analysis could be an auxiliary diagnostic method for ALMS.

Olfactory Assessment

Next, we tended to find other potential diagnosis method. *ALMS1* variants have been reported to result in defective cilia structures and trafficking of key signaling molecules in

TABLE 6 | Detailed information of Chinese Smell Identification Test in ALMS patients and controls.

Smell	Patients N = 16 (%)	Control N = 32 (%)	p Value

^dp value by the Pearson Chi-square with continuity correction. * $p < .05$.

the cilia (Hearn et al., 2005; Heydet et al., 2013). Therefore, ALMS patients have visual and auditory dysfunctions. Interestingly, olfactory sensory neurons detect volatile odorants using olfactory receptors and other signaling molecules located in the cilia. However, it is unknown if olfactory function is normal in ALMS patients. We used CSIT, a toolkit specifically designed to assess olfactory function in the Chinese population, to evaluate olfactory function in ALMS patients (Feng et al., 2019; Wu et al., 2019). Sixteen patients were recruited and were matched with 32 individual controls by age and sex. The average age of patients was 9.50 ± 2.28 years and of controls, 9.63 ± 2.12 years. Although the CSIT self-score was higher in patients than that in controls, the tested CSIT score in patients was 10.44 in patients and 11.97 in controls. The slightly lower but significant CSIT score in ALMS patients

indicated that olfactory identification (OI) impairments occurred in ALMS patients (Figures 4A,B). Further analysis showed that, for most odors, the identification rate was slightly lower in patients than that in controls. Only the identification rate of rose odor in the patients was significantly lower in patients than that in the controls (Table 6 and Figure 4C). We further compared the differences in age, sex, early-onset cardiomyopathy, and genotypes between ALMS patients who could identify the rose odor and those who could not (Table 7). Unfortunately, no differences between the two groups were found. It should be noted that the patients and controls included in this study were very young and may not have been able to describe the odors correctly, which could have resulted in the olfactory impairment in ALMS patients being underestimated. In conclusion, the olfactory assessment could be used as another auxiliary diagnosis method for ALMS.

DISCUSSION

In this study, we recruited 50 Chinese ALMS patients for genetic and phenotypic analyses. To the best of our knowledge, this is the largest cohort study of Chinese ALMS patients. The average age of this Chinese cohort is also the youngest in the world of all ALMS cohorts. Most of the patients in this study were diagnosed before 7 years old, possibly owing to the rapid development of NGS in China. Furthermore, the time from age at onset to age at diagnosis was approximately 4 years in our cohort compared to approximately 13 years in the Polish cohort (Zmyslowska et al., 2016).

Our study has revealed that exons 8, 10, and 16 are mutational hotspots, which is consistent with previous reports (Marshall et al., 2015). However, previous studies directly sequenced exons 8, 10, and 16, whereas we performed NGS without exon bias. The preference of *ALMS1* variants in those exons is partly due to the relatively larger sizes of these exons. Among these three exons, exon 16 has the highest mutation rate (Table 4). Further, ethnicity greatly contributed to the distribution of the *ALMS1* variants. According to our study, c.2090C > A (11/138, 7.97%) in exon eight is the most common variants in

TABLE 7 | Comparison analysis between ALMS patients who could identify the rose odor and those could not.

Subject	Group 1 ^a N = 10	Group 2 ^d N = 6	p Value
Gender (M/F)	7/3	3/3	.089 ^a

China. The high carrier rate of this variant in East Asians (0.006%) may account for this pattern (Marshall et al., 2015). Other recurrent variants included: c.2041C > T (3/138, 2.17%), c.3902C > A (5/138, 3.62%), c.4917_4920del (5/138, 3.62%), and c.6169_6170dup (4/138, 2.90%) in exon 8; c. 9154_9155del (7/138, 5.07%) in exon 10, and c. 10549C > T (3/138, 2.17%), c. 10825C > T (9/138, 6.52%), and c. 10831_10832del (5/138, 3.62%) in exon 16. Of those 8 recurrent variants, c. 2041C > T, c. 2090C > A, c. 3902C > A, c. 6169_6170dup, c. 9154_9155del, and c. 10831_10832del are specific to Chinese patients, whereas c.10825C > T is common worldwide. Regarding recurrent variants in other countries, c.8177_8187del, c.8164C > T, and c.10945G > T are specific to patients of West Asian/Middle Eastern kindreds, whereas c.10775del (24/557) and c.11449C > T (15/557) are specific to Northern European and American populations (Marshall et al., 2015).

ALMS symptoms either develop or become more severe with age; thus, diagnosis is difficult during the early ages of patients. Consequently, exploring new diagnostic tools is necessary. In this study, we explored the possibility of two auxiliary diagnostic methods. The first is computer facial recognition, which has been successfully applied in diagnosis of some diseases, such as Noonan syndrome with characteristic facial features (Li et al., 2019). Facial patterns in ALMS patients are rarely mentioned, likely because of the low incidence of this disease. Since we had 50 patients, we performed facial analysis. We showed that there are significant differences in facial patterns between ALMS patients and age- and sex-matched controls. However, further studies are still required to identify the distinctive facial features of ALMS patients, which will greatly benefit the clinical diagnosis of ALMS, especially in juveniles. The second is olfactory assessment. We used the CSIT that was specifically developed for Chinese populations to evaluate the olfactory function in patients. We observed olfactory identification impairments in ALMS patients. However, we could not exclude the possibility that the patients were simply unfamiliar with the odors due to their limited exposures to them. In addition, we found that the ALMS patients particularly struggled to recognize the rose odor instead of other odors. This may suggest that *ALMS1* is expressed in subsets of olfactory sensory neurons that detect distinct volatile odors. We will continue to follow-up with these patients and perform computer facial recognition and olfactory assessment annually, which may further validate our findings as the patients grow up.

In summary, we reported 50 Chinese ALMS patients with 61 pathogenic variants, including 24 novel variants. We identified recurrent variants of 138 variants in 69 Chinese ALMS families totally. Olfactory identification impairments can occur in ALMS patients, and these patients have some distinctive facial features. Early-onset cardiomyopathy is likely related to earlier transcription termination of the *ALMS1* gene. Our study expands on the *ALMS1* gene genetic and phenotypic spectrum and provides new insights into the understanding of ALMS.

Methylmalonic acidemia (MMA) and ornithine transcarbamylase deficiency (OTCD) are both intoxication-type inborn errors of metabolism (IEM). Presently, genetic testing is the primary method for prenatally diagnosing these diseases. However, some reports have demonstrated that mass spectrometry approaches can prenatally diagnose some forms of inborn errors of metabolism using amniotic fluid. Therefore, in this study, genetic and mass spectrometry approaches were used for prenatally diagnosing MMA and OTCD. We collected amniotic fluid samples from 19 fetuses referred, 15 cases were referred for MMA and 4 for OTCD. Of the 15 MMA cases, seven were affected, as determined by genetic testing and the metabolite levels; the characteristic metabolites propionylcarnitine (C3), C3/acetylcarnitine (C2) ratio, methylmalonic acid and methylcitrate levels were significantly higher than the reference range. Eight fetuses were unaffected, and the C3, C3/C2 ratio, methylmalonic acid and methylcitrate levels were within the reference range. The C3, C3/C2, methylmalonic acid, and methylcitrate levels in the amniotic fluid significantly differed between the affected and unaffected fetuses ($P = 0.0014$, $P = 0.0014$, $P = 0.0003$, $P = 0.0014$, respectively). Moreover, the homocysteine level increased in the amniotic fluid of affected fetuses with *MMACHC* gene mutations. Of the four OTCD cases, genetic testing confirmed that two fetuses were affected and two were unaffected. However, the characteristic metabolite levels were within the reference range for all fetuses, including citrulline, orotic acid, and uracil. The genetic testing results were confirmed to be correct through the abortion tissue of the fetus and the postnatal follow-up. Our results suggest that mass spectrometry approaches are convenient method for improving the prenatal diagnosis of MMA. The characteristic metabolites C3, C3/C2, methylmalonic acid, and methylcitrate levels in amniotic fluid were reliable biochemical markers for the prenatal diagnosis of MMA.

Keywords: methylmalonic acidemia, ornithine transcarbamylase deficiency, gas chromatography mass spectrometry, tandem mass spectrometry, prenatal diagnosis

INTRODUCTION

Methylmalonic acidaemia (MMA) and ornithine transcarbamylase deficiency (OTCD) are both common intoxication-type inborn errors of metabolism (IEM) in China (1, 2). The estimated incidence of MMA is 1.5–3 cases per 100 000 people, and the OTCD incidence is between 1 case per 77 000 people and 1 per 14,000 people (3, 4). MMA is an autosomal recessive organic acidaemia associated with methylmalonyl-CoA mutase and cobalamin metabolic defects. There are five common clinical MMA subtypes, namely mut, cblA, cblB, cblC, and cblD. OTCD is an X-linked inherited metabolic disease caused by pathogenic variants of the OTC gene, and is the most common type of congenital urea cycle disorder (5). MMA and OTCD patients either die shortly after birth or present with acute deterioration, metabolic acidosis, or hyperammonaemia, and later in life, the presentations include intellectual disabilities or abnormal growth and development (1, 6, 7). Early diagnosis and treatment can prevent complications, and prenatal diagnosis is an important way for families with an IEM proband to prevent IEM recurrence.

Presently, tandem mass spectrometry (MS/MS) and gas chromatography-mass spectrometry (GC/MS) are important methods for screening and clinically diagnosing IEM (8, 9). Some reports have demonstrated that MS/MS and GC/MS can prenatally diagnose some forms of IEM using amniotic fluid, such as MMA, propionic acidaemia, isovaleric acidaemia, and β -ketothiolase deficiency (10–14). Therefore, together with gene sequencing, mass spectrometry provides a new method for prenatally diagnosing IEM.

Since the MS/MS and GC/MS methodologies are mature for diagnosing IEMs, this study describes our experiences with prenatally diagnosing IEM by measuring metabolites in the supernatant of amniotic fluid together with direct mutation analysis in MMA and OTC high-risk pregnancies.

MATERIALS AND METHODS

Probands

From January 2019 to June 2021, we recruited 15 unrelated families with MMA probands, 4 unrelated families with OTCD probands, and 73 pregnant women undergoing routine prenatal diagnoses with no history of IEM referrals. Five amniotic fluid samples from the referred MMA cases were collected by the Centre for Prenatal Diagnosis of Xinhua Hospital, Shanghai, China, all other samples were collected by our hospital (The Sixth Affiliated Hospital of Sun Yat-sen University, Guangzhou, China). The probands were diagnosed based on clinical symptoms, GC/MS and MS/MS biochemical results, and genetic testing. Written informed consent was obtained from all participants. The study protocols were approved by the Ethics Committee of the Sixth Affiliated Hospital of Sun Yat-Sen University (ethics committee batch number 2019ZSLYEC-105).

Amniocyte Samples

The pregnant women with MMA or OTCD probands underwent amniocentesis by an experienced obstetrician; 10 mL of amniotic

fluid was obtained from each pregnant woman. The amniotic fluid was centrifuged at 3000 r/min. Then, the amniotic fluid cells were collected for DNA extraction, and the supernatant was collected for mass spectrometry detection in separate sterile test tubes and stored at -80°C until use. All samples were collected before beginning the analyses, and the tests for all samples were performed at the same time.

Metabolite Detection and Analysis

The characteristic metabolites detected by MS/MS in the peripheral blood of MMA patients were propionylcarnitine (C3), the C3/acetylcarnitine (C2) ratio (C3/C2), methylmalonic acid, and methylcitrate (15). We also assessed the level of homocysteine (Hcy), which is a specific metabolite of the MMA cblC subtype (16); cblC is caused by mutations of the metabolism of cobalamin associated C (*MMACHC*) gene. The characteristic metabolite detected by MS/MS in the peripheral blood of OTCD patients was citrulline, and the metabolites detected by GC/MS were orotic acid and uracil (3, 5).

The diagnostic criteria for characteristic metabolites of MMA and OTCD are consistent between amniotic fluid and peripheral blood. We used the 95th and 5th percentile mass spectrometry results from the 73 cases of normal (i.e. control) amniotic fluid to establish the upper and lower limits of the normal reference interval, the reference range of the different metabolites were displayed in the results section. All samples were sent to the Inborn Errors of Metabolism laboratory of the Sixth Affiliated Hospital of Sun Yat-sen University for MS/MS and GC/MS testing.

MS/MS Analysis

Several amino acid and carnitine, methylmalonic acid, methylcitrate, and total Hcy determination kits (Zhipu Biotechnology Corporation, Shandong, China) were used for the analysis. MS/MS (Xevo TQ-DIVD, Waters Corporation, Milford, MA, USA) was used to detect the metabolites in 3 μL of amniotic fluid.

GC/MS Analysis

GC/MS (Q1000, Japan Electronics Co., Ltd.) was used to evaluate orotic acid and uracil in 100 mL of amniotic fluid. The amniotic fluid samples were processed by adding internal standard, deproteinizing, vacuum drying, and trimethylsilyl derivatization (BSTFA/TMCS) before testing.

Mutation Analysis

The QIAamp DNA Blood Mini Kit (Qiagen Inc., Valencia, CA, USA) was used to extract DNA from the amniotic fluid exfoliated cells, and then, polymerase chain reaction amplification and Sanger sequencing were used to test the candidate variants. The reference gene sequences were obtained from National Centre for Biotechnology Information GenBank database. Short tandem repeat analyses were performed to exclude maternal blood contamination and perform linkage analysis.

Diagnostic Criteria

Foetuses were considered affected by MMA if the characteristic metabolites in the amniotic fluid were higher than the upper

MMA, Methylmalonic Acidemia; OTCD, Ornithine transcarbamylase deficiency. *The Mutation is Hemizygous.

limit of the reference range and the genetic test results of the amniotic fluid cells were consistent with the genetic test results of the proband.

Foetuses were considered affected by OTCD if the concentration of citrulline in the amniotic fluid was lower than the lower limit of the reference range and the concentrations of orotic acid and uracil were higher than the upper limit of the reference range. Further, the genetic test results of the amniotic fluid cells must be consistent with the genetic test results of the proband.

Statistical Analyses

SPSS version 21.0 (IBM Corp., Armonk, NY, USA) was used for the analyses. The reference range for each analyte was determined by a nonparametric approach, identified the 95th and 5th percentiles from the cumulative levels of the 73 normal foetuses as the upper and lower reference limits, respectively. Wilcoxon rank-sum tests with exact P-values were performed to compare the levels of the characteristic metabolites between affected and unaffected groups. $P < 0.05$ was considered statistically significant.

RESULTS

Patient Demographics

We included 19 pregnant women with MMA or OTCD probands aged between 27 and 36 years with gestational ages from 16–21 weeks. We also included 72 pregnant women undergoing routine prenatal diagnosis (i.e. healthy controls) aged between 25 and 38 years with gestational ages from 16–23 weeks.

Table 1 presents the gene mutation spectrum for cases in this study. There were 9 MMA probands with methylmalonyl-CoA mutase (i.e. *MMUT*) mutations, 5 with *MMACHC* mutations, and 1 with metabolism of cobalamin associated B (i.e. *MMAB*) mutations. The OTCD probands all had the ornithine transcarbamylase (*OTC*) gene mutations.

Reference Range

We established a reference range for each analyte using the 95th and 5th percentiles. The following values were considered normal: C3 = 0.16–1.53 $\mu\text{mol/L}$, C3/C2 = 0.08–0.57 $\mu\text{mol/L}$, methylmalonic acid 0.97–1.81 $\mu\text{mol/L}$, and methylcitrate 0.01–0.79 $\mu\text{mol/L}$. Further, the specific product of cblC also has Hcy 2.40–6.95 $\mu\text{mol/L}$, citrulline (Cit) > 3.30 $\mu\text{mol/L}$, orotic acid (Orotate) 0.00 mmol/mol creatinine, and uracil (Uracil) 0.00 mmol/mol creatinine.

MMA and OTCD Diagnoses

We found no maternal contamination in the amniotic fluid samples by short tandem repeat analysis. **Table 2** presents the amniotic fluid metabolite and DNA sequencing results of the 15 pregnancies from MMA families referred. The genetic and metabolite analyses had high consistency. Seven foetuses were affected by MMA, and eight were unaffected. The seven affected foetuses had the same compound heterogeneous mutations as their probands. The C3 (median: 8.47 $\mu\text{mol/L}$, range: 3.56–15.55), C3/C2 (median: 1.46, range: 0.76–2.20), methylmalonic acid (median: 35.85 $\mu\text{mol/L}$, range: 9.81–66.78), and methylcitrate (median: 6.48 $\mu\text{mol/L}$, range: 3.69–17.62) levels in amniotic fluid were higher than the reference ranges. The Hcy concentration in the amniotic fluid of two foetuses

OTCD, Ornithine transcarbamylase deficiency; Cit, Citrulline; orotic acid, Orotate; Reference range: citrulline > 3.30 $\mu\text{mol/L}$, orotic acid (Orotate) = 0.00 mmol/mol creatinine, and Uracil = 0.00 mmol/mol creatinine. *The Mutation is Hemizygous.

with compound heterogeneous *MMACHC* gene mutations was significantly higher than the concentration of the normal range and other affected amniotic fluid samples.

The eight unaffected fetuses carried one heterogeneous mutation ($n = 5$) or no mutation ($n = 3$), and the median levels of C3, C3/C2, methylmalonic acid, and methylcitrate in the amniotic fluid were 0.87 $\mu\text{mol/L}$ (range: 0.48–1.79), 0.16 (range: 0.07–0.25), 4.17 $\mu\text{mol/L}$ (range: 1.30–10.60), 1.29 $\mu\text{mol/L}$ (range: 0.80–1.63), and 0.22 $\mu\text{mol/L}$ (range: 0.02–0.70), respectively. The

C3, C3/C2, methylmalonic acid, and methylcitrate levels in the 7 samples amniotic fluid were within normal ranges. The C3 and Hcy levels in F1 was slightly higher than the normal range, while the levels of the other three metabolites were in the normal range. The C3, C3/C2, methylmalonic acid, and methylcitrate levels did not overlap between the affected and unaffected fetuses (Figure 1).

Table 3 presents the amniotic fluid metabolite and DNA sequencing results of the 4 pregnancies from OTCD families

referred. Two fetuses were affected, and two were unaffected based on the *OTC* gene mutations analysis, but the citrulline (8.86–15.27 $\mu\text{mol/L}$, Reference range: Cit > 3.30 $\mu\text{mol/L}$), orotic acid, and uracil (0.00 mmol/mol creatinine, Reference range: 0.00 mmol/mol creatinine) levels were in the normal ranges for all samples. The amniotic fluid metabolite and genetic testing results were inconsistent. Thus, the prenatal diagnosis was based on the genetic test results. The abortion tissue of the fetus and the postnatal follow-up confirmed the genetic testing.

DISCUSSION

Currently, the standard method for prenatally diagnosing IEM is the detection of genetic mutations in amniotic fluid cells or chorionic tissues, but the disease-causing genes and mutation sites of the proband must be confirmed to complete the prenatal diagnosis. The genetic testing process is also complicated and slow, usually taking 10–25 days. Further, studies have shown that for autosomal recessive diseases, the fetus has only one causative variant as same as the proband, and the genetic testing results of the fetus cannot give a clear conclusion, but mass spectrometry can detect specific metabolite levels in the amniotic fluid, helping the prenatal diagnostic of fetus (13, 17). Importantly, the speed of mass spectrometry is advantageous; the samples in this study were tested by MS/MS and GC/MS within one day. Also, only a small amount of amniotic fluid is required for testing and provides results for multiple metabolites. Therefore, mass spectrometry is a powerful supplement to genetic testing. Current domestic and foreign research indicate that the prenatal diagnosis of genetic metabolic diseases, such as MMA, propionic acidemia, isovaleric acidemia, and β -ketothiolase deficiency, can be performed using mass spectrometry (10–14). This study highlights our experience in prenatally diagnosing MMA and OTCD with genetic testing and mass spectrometry.

Some studies have shown that MS/MS detection of C3, methylmalonic acid, and methylcitrate concentrations in amniotic fluid can be used for prenatally diagnosing MMA (10, 12). In this study, the C3, C3/C2, methylmalonic acid, and methylcitrate levels in amniotic fluid were tested by MS/MS in 15 samples from women referred with MMA. These results showed that four biochemical markers significantly differed between the unaffected and affected groups without overlap. Furthermore, all of the three biochemical markers (C3/C2, methylmalonic acid, and methylcitrate) were identical and consistent with the genetic analysis results. However, the C3 levels in F1 was slightly higher than the normal range; the likely reason might be associated with the selection of the reference range. One study suggested that clinical reference ranges may need to be adjusted in response to the degree of overlap between the normal population and the disorder range (18). However, due to the small number of affected samples, it is difficult to establish more reasonable ranges in this manner. Moreover, the normal samples selected in this study are only 73 cases, so the 95th and 5th percentiles were identified as the upper and lower reference limits, respectively. If the number of samples is large enough, the 99.5th and 0.5th percentiles as the upper and lower reference

limits may be more reasonable. Nevertheless, our results are also consistent with other related studies, confirming that C3, C3/C2 ratio, methylmalonic acid, and methylcitrate detection in amniotic fluid by MS/MS is feasible for the prenatal diagnosis of MMA.

In this study, we evaluated three MMA subtypes (mut, cblB, and cblC). The cblC subtype, the most common subtype, is caused by biallelic pathogenic variants in the *MMACHC* gene, which encodes a protein involved in the processing and trafficking of intracellular cobalamin. This subtype is also associated with increased Hcy and methylmalonic acid plasma concentrations (17, 19). In our study, five women were referred with MMA type cblC. Three fetuses were unaffected, and two were affected. Except C3, C3/C2, methylmalonic acid, and methylcitrate, the Hcy level in the amniotic fluid of these affected fetuses was significantly higher than the normal reference range and the Hcy level in the other affected MMA subtypes, consistent with the genetic analysis results. This result suggests that the Hcy level in amniotic fluid is an indicator for the prenatal diagnosis of cblC subtype. However, the Hcy levels in F1 was higher than the normal range, the likely reason may be the same as the C3, further data are warranted to prove the reliability of Hcy in the prenatal diagnosis.

OTCD, also known as hyperammonaemia type II, is an X-linked recessive genetic disorder; therefore, almost all hemizygous males develop this disease. Approximately, 20% of female carriers present some neurocognitive disorders due to random X-inactivation. However, the symptoms are substantially milder than those experienced by male patients. Presently, genetic testing is the primary method for prenatal diagnosis of OTCD; although male fetuses can be diagnosed, due to the unpredictability of random X chromosome inactivation, it is impossible to determine whether foetal female carriers have the disease. Prenatal diagnosis of OTCD in female fetuses using mass spectrometry will therefore be difficult. In this study, four women were referred with OTCD, and all fetuses were confirmed to be male through genetic testing. The MS/MS and GC/MS results showed that the citrulline, orotic acid, and uracil levels in all amniotic fluid samples were within the reference range, suggesting that none of the fetuses had OTCD. However, the genetic testing indicated a c.512A > G hemizygous mutation and c.867 + 1G > C hemizygous mutation in the *OTC* gene in two samples, consistent with the proband, there was no mutation in the other two samples. The metabolite and genetic testing results were inconsistent, suggesting that metabolite analyses using amniotic fluid at 16–22 weeks of pregnancy is not suitable for prenatally diagnosing OTCD. This result has not been suggested in other studies, and more data are warranted to prove the conclusion.

In summary, mass spectrometric approaches are a convenient prenatal diagnostic method for pregnancies at risk for MMA. Characteristic metabolite (C3, C3/C2, methylmalonic acid, and methylcitrate) levels in the amniotic fluid were reliable biochemical markers for prenatally diagnosing MMA. A combined genetic

and biochemical approach would provide increased diagnostic accuracy.

ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Ethics Committee of the Sixth Affiliated Hospital of Sun Yat-sen University (Ethics Committee Batch no. 2019ZSLYEC-105). The patients/participants provided their written informed consent to participate in this study.

AUTHOR CONTRIBUTIONS

XX conceived and designed the study. CS wrote the manuscript draft. SL, ZD, HH, and XX enrolled the patients. YG performed amniocentesis. CS and SL performed the metabolite test,

mutation test, and data analysis. All authors read and approved this manuscript.

FUNDING

This work was supported by Guangzhou Science and Technology Plan Project (No. 201604020154) and Guangdong Science and Technology Plan Project (No. 2020A1414010111).

ACKNOWLEDGMENTS

We acknowledge all patients and their family for participating in this study. Moreover, thanks to the team of Prof. Lianshu Han (Centre for Prenatal Diagnosis, Xinhua Hospital, School of Medicine, Shanghai Jiao Tong University, Shanghai, China) for their support for our research and helpful discussion.

(2022) The Follow-Up of Chinese
Patients in *cbIC* Type Methylmalonic
Acidemia Identified Through Expanded
Newborn Screening.
Front. Genet. 13:805599.
doi: 10.3389/fgene.2022.805599

Objective: The *cbIC* type of combined methylmalonic acidemia and homocystinuria, an inherited disorder with variable phenotypes, is included in newborn screening (NBS) programs at multiple newborn screening centers in China. The present study aimed to investigate the long-term clinical benefits of screening individual.

Methods: A national, retrospective multi-center study of infants with confirmed *cbIC* defect identified by NBS between 2004 and 2020 was conducted. We collected a large cohort of 538 patients and investigated their clinical data in detail, including disease onset, biochemical metabolites, and gene variation, and explored different factors on the prognosis.

Results: The long-term outcomes of all patients were evaluated, representing 44.6% for poor outcomes. In our comparison of patients with already occurring clinical signs before treatment to asymptomatic ones, the incidence of intellectual impairment, movement disorders, ocular complications, hydrocephalus, and death were significantly different ($p < 0.01$). The presence of disease onset [Odd ratio (OR) 12.39, 95% CI 5.15–29.81; $p = 0.000$], variants of c.609G>A (OR 2.55, 95% CI 1.49–4.35; $p = 0.001$), and c.567dupT (OR 2.28, 95% CI 1.03–5.05; $p = 0.042$) were independently associated with poor outcomes, especially for neurodevelopmental deterioration.

Conclusion: NBS, avoiding major disease-related events and allowing an earlier treatment initiation, appeared to have protective effects on the prognosis of infants with *cbIC* defect.

Keywords: methylmalonic acidemia combined with homocystinemia, long-term outcome, newborn screening, MMACHC gene, tandem mass spectrometry

1 INTRODUCTION

Methylmalonic acidemia combined with homocysteinemia (OMIM 277400) is a series of inherited autosomal recessive defects in cobalamin [vitamin B12 (VitB12)] metabolism resulting in impaired synthesis of adenosylcobalamin (AdoCbl) and methylcobalamin (MeCbl), which both are essential coenzymes for the conversion of methylmalonyl-CoA to succinyl-CoA (catalyzed by methylmalonyl-CoA mutase) and remethylation of homocysteine to methionine (catalyzed by methionine synthase) (Dionisi-Vici et al., 2006; Lerner-Ellis et al., 2009; Watkins and Rosenblatt, 2011). The cblC type of combined methylmalonic acidemia and homocystinuria is the most common defect in the intracellular cobalamin metabolism pathway (Nogueira et al., 2008), characterized by variable and non-specific symptoms, especially in childhood. The phenotype has a wide expression, with early-onset (before 1 year from birth) often associated with multisystem involvement, neurological deterioration, maculopathy, failure to thrive, cytopenias, renal and hepatic dysfunction (Rosenblatt et al., 1997; Carrillo-Carrasco et al., 2012; Fischer et al., 2014; He et al., 2020). Neurological damage is often with hydrocephalus, cerebral atrophy, white matter abnormalities, and basal ganglia lesions (Weisfeld-Adams et al., 2013; Fischer et al., 2014; Zhang et al., 2019). Developmental delay and intellectual deficits are also frequently impaired (Weisfeld-Adams et al., 2013).

The incidence of cblC defect ranges from 1:46,000 to 1:200,000 in European and American countries (Morel et al., 2006; Weisfeld-Adams et al., 2010) and varies hugely from 1:3,220 to 1:21,488 in China (Zhou et al., 2018; Wang et al., 2019). Previously, individuals with cblC defects were diagnosed symptomatically. However, since tandem mass spectrometry (MS/MS) has been increasingly used in newborn screening (NBS) programs in China, technically enabling identification of more than 30 inherited metabolic diseases (IMDs) by using a single method, it is recommended to identify those infants who are at risk for IMDs, including cblC defect. Most NBS pilot studies have demonstrated a positive effect on early identification of cblC defect by NBS and the neonatal start of treatment on the neurological outcome to a variable extent (Martínez-Morillo et al., 2016; Mütze et al., 2020). However, the impact on the long-term outcome of individuals with cblC defects in the era of newborn screening is yet to be comprehensively explored. This national multicenter retrospective study, therefore, aims at elucidating the long-term outcome of screened individuals and at investigating the impact of different factors on the disease outcome.

2 PATIENTS AND METHODS

2.1 Patients

From January 2004 to December 2020, a total of 560 patients with cblC defects identified by NBS were diagnosed and treated at multiple hospitals in China. Among them, 9 cases died and 22 cases were lost to follow-up. All patients were ascertained on DNA-based and MS/MS NBS and most receive personalized treatment as

well as regular follow-up. To evaluate clinical outcomes, patients were divided into two groups, with the normal outcome group being healthy and the poor outcome group suffering from varying degrees of physical and mental damage. Among poor outcomes, five different types of clinical parameters were included—intellectual impairment, movement disorders, ocular complications, hydrocephalus, and death. “Intellectual impairment” was categorized based on the presence of developmental delay according to age, or neuropsychological test results, or in the absence of neuropsychological test results on educational level or professional employment. “Movement disorders” mainly manifested as involuntary tremor, gait instability, and disability to walk that developed throughout the disease course, objectified during follow-up examinations by pediatricians and physiotherapists shortly after the symptomatic phase. “Ocular complications” included the presence of strabismus, nystagmus, and a range of ocular findings from unremarkable and mild phenotypes to significant retinopathy. “Hydrocephalus” was detected at cranial MRI, which usually depicted ventriculomegaly, extensive cerebral parenchyma atrophy, and subdural effusion. And the most severe clinical outcome is failure to thrive. Parents or legal guardians of the participants signed an informed consent form, approving analysis of their clinical records, and publication of the anonymous data, in agreement with institutional and national legislation. This study was approved by the Ethics Committee of Xinhua Hospital (approval number XHEC-D-2021-140).

2.2 Newborn Screening and Confirmatory Testing

NBS samples of dried blood spots are taken between the ages of 72–120 h according to the recommended time frame (Mak et al., 2013). Blood levels of acylcarnitines, including propionylcarnitine (C3) and acetylcarnitine (C2) were detected by MS/MS (API 4000, American Bio-System Inc., Foster City, CA, United States,) using blood filter papers. The ratio of C3/C2 was calculated at the same time. Second blood spots were requested upon abnormal first-screening results (Niu et al., 2010). To further confirm the diagnosis, urinary organic acids, including methylmalonic acid (MMA) and methylcitric acid (MCA) were measured by gas chromatography-mass spectrometry (GC-MS) (Shimadzu Limited., Shimadzu, Kyoto, Japan, QP 2010) (Al Dhahouri et al., 2018; Al-Dirbashi et al., 2019). Moreover, plasma total homocysteine (tHcy) were assessed using fluorescence polarization immunoassay.

2.3 Molecular Genetic Analysis

Genomic DNA was extracted from peripheral blood using the DNA extraction kit (TIANGEN Biotech, Beijing, China) according to the manufacturer’s instructions. All coding exons and flanking regions of *MMACHC* were amplified using polymerase chain reaction (PCR) with primers designed by Primer3 Input (v. 0.4.0, <http://bioinfo.ut.ee/primer3-0.4.0/>). After PCR, Nucleotide variations were identified using a reference sequence from Genbank (*MMACHC*: NM_015506). We used the ClinVar database, the HGMD database, and previous literature to identify whether the mutations had been

reported. The pathogenicity of novel variants was evaluated based on the American College of Medical Genetics and Genomics (ACMG) standards and guidelines.

2.4 Treatment

The treatment of cblC defect varies with different vitamin B12 responsiveness and is adjusted depending on the condition of individual patients (Baumgartner et al., 2014). According to the guideline, the long-term therapy involved parenteral cobalamin, L-carnitine, and oral betaine (Forny et al., 2021). Then, the treatment is adjusted based on levels of biochemical metabolites. Generally, for most patients, intramuscular injections of hydroxocobalamin were the first choice at a dose of 1–20 mg each time, once every 1–20 days, L-carnitine at 50–100 mg/kg/day and oral betaine at 50–100 mg/kg/day.

All patients followed a normal diet. In patients with methionine deficiency, methionine was supplemented orally (Manoli et al., 2016; Huemer et al., 2017).

2.5 Statistical Analysis

All statistical analyses were performed using SPSS 24.0 (IBM, Chicago, IL). Continuous data are expressed either as medians

and interquartile range or mean \pm standard deviation (SD). Categorical variables are presented as percentages (%). The demographic, clinical, and biochemical characteristics were compared between patients with or without symptoms and patients with different prognoses using 2-sample *t* test, χ^2 /Fisher exact test, or Wilcoxon rank-sum test as appropriate. Overall univariate odds ratios and by different categories of poor outcome were calculated using the logistic regression. Multivariate logistic regression analysis was performed using variables that were significantly associated with a poor outcome in univariate analysis to determine the independent risk factors. A value of $p < 0.05$ was considered to indicate statistical significance.

3 RESULTS

3.1 Study Population

Among all 538 (280 males, 253 females) patients, who were enrolled in our study, 298 (55.4%) were with normal physical and neurocognitive development, 240 (44.6%) had poor outcomes, in which 9 children died of frequent and severe

relapses of metabolic decompensations or hydrocephalus. For nearly all patients, data were available from NBS to the last moment of follow-up. **Table 1** is a comparison of demographic variables between those with and without poor outcomes. The median age during the follow-up period in two groups was 3.34 years (range 0.63–4.52 years) and 3.8 years (range 0.48–5.25 years), respectively. The age at diagnosis was 1 month (range 0.8–1.5 months) in the normal outcome group, while 1.5 months (range 1–2.2 months) in the poor outcome group. Although all patients were identified by NBS, a total of 201 (37.4%) patients already developed symptoms before treatment, which included poor feeding, vomiting, drowsiness, seizures, developmental delay, and so on. The incidence of variable clinical features was compared between individuals with or without normal physical and neurocognitive development. As shown in **Table 1**, the incidence of different kinds of initial symptoms was significantly higher in the poor outcome group ($p < 0.05$), which indicates the onset of symptoms might have an adverse impact on the long-term outcome.

3.2 Biochemical Features

In the study, all the patients were screened by MS/MS presented with elevated C3 levels ($>4 \mu\text{mol/L}$), an increased C3/C2 ratio ($>0.2 \mu\text{mol/L}$) in dried blood spots. Subsequently, the increased MMA and MCA levels in urine as well as elevated total plasma

homocysteine were exhibited in confirmatory testing. Importantly, the ratio of blood C3/C2, the level of urinary MMA, and MCA in the NBS sample were higher in the poor outcome group than in the normal group (all $p < 0.05$), except for the blood C3 ($p = 0.119$). Data about tHcy levels showed similar differences between the two groups ($p < 0.05$). As can be seen from **Table 1**, the biochemical markers after treatment showed the difference between individuals with different outcomes, which the blood C3, blood C3/C2 ratio, urinary MMA, urinary MCA, and tHcy were lower in the normal outcome group than those in poor outcome group (all $p < 0.05$). Additionally, all of the biochemical parameters reached the normal range after treatment, laboratory values of blood C3, blood C3/C2 ratio, urinary MMA, urinary MCA, and tHcy showed remarkably decrease tendency than those before treatment, with a significant statistical difference (all $p < 0.01$). As is evident from **Table 2**, the greatest differences in biochemical data including the blood C3/C2 ratio, urinary MMA, and MGA, tHcy, were observed between asymptomatic or symptomatic subjects as well. However, there were no statistically significant differences in blood C3 at NBS ($p = 0.087$). The urinary MCA at the last available visit between affected infants with or without symptomatic presentation also did not reveal statistically significant results ($p = 0.086$), which may be the reason for there being limited and insufficient data, partly caused by the patient referral process.

3.3 Gene Analysis

MMACHC mutations were found on both alleles in 510 of 534 patients (95.5%), whereas a single mutation on one allele was noted in 24 patients (4.5%). Among them, 74 different mutations were identified, including 16 nonsense mutations that account for 52.5% (552/1,052) of alleles; the remainder consisted of 18 missense mutations, 3 duplications, 27 deletions, 5 insertions, 5 splice-site mutations. Sequencing analysis identified *MMACHC* mutation in 97.8% (1,052 of 1,076) of all disease alleles. Among them, the common mutation was c.609G>A (p.W203X), c.658_660delAAG (p.K220del), c.482G>A (p.R161Q), c.80A>G (p.Q27R), c.567dupT (p.I190Yfs*13), which accounted for 41.3% (434 of 1,052), 9.2% (97 of 1,052), 9.0% (95 of 1,052), 8.3% (87 of 1,052) and 4.9% (51 of 1,052), respectively. Between groups with good and poor outcomes or groups whether showed symptoms when therapy was initiated, the types of mutation sites strongly differed. In poor outcome group, the variant of c.609G>A (p.W203X) was more common (74.2% vs. 58.1%), as was c.567dupT (p.I190Yfs*13) (12.5% vs. 6.7%), while these patients appeared to have less incidence of c.482G>A (p.R161Q) (4.2% vs. 25.8%) and c.80A>G (p.Q27R) (10.8% vs. 18.5%) in *MMACHC*. In analogy, c.609G>A (p.W203X) and c.567dupT (p.I190Yfs*13) in *MMACHC* were increasingly observed in symptomatic patients, while c.482G>A (p.R161Q) and c.80A>G (p.Q27R) were more often in asymptomatic patients. Therefore receiving a disease-specific therapy, individuals with these variants in our cohort were more likely to have a better prognosis.

3.4 Follow-Up and Outcomes

We evaluated the current health condition of the patients up to December 2020. The prognosis is shown in detail in **Table 1**. However, of the 240 patients who showed poor prognosis, 234 (97.5%) developed progressive intellectual impairment, 104 (43.3%) manifested movement disorders, 31 (12.9%) exhibited ocular problems, 9 (3.8%) had hydrocephalus and 9 (3.8%) died from disease onset. By dividing them into two groups which depend on whether they suffered from early symptoms of disease before therapy, there is a significant difference between good or poor outcomes ($p < 0.01$). Unfortunately, patients detected by newborn screening but treated after disease onset were more likely to show poor outcomes. In comparison with individuals who remained asymptomatic before treatment, the proportion of intellectual impairment (72.6% vs. 26.1%), movement disorders (32.3% vs. 11.6%), ocular complications (12.4% vs. 1.8%), hydrocephalus (3.5% vs. 0.6%), and death (3.5% vs. 0.6%) were higher in symptomatic group. It is worth noting that among patients deceased, all developed severe symptoms, except two cases without specific symptoms at first who then progressively developed clinical manifestations later even if they received therapy. This might be due to poor treatment compliance.

3.5 Factors Affecting Variable Outcomes

Two hundred and forty patients with different types of poor outcomes were analyzed by both univariate and multivariate logistic regression. Factors including the onset of symptoms,

nucleotide variants, biochemical markers at NBS, time from onset to treatment initiation were analyzed.

Univariate analysis showed onset of symptom [Odd ratio (OR) 13.16, 95% CI 8.71–19.89; $p = 0.000$], presence of c.609G>A (OR 2.07, 95% CI 1.43–3.00; $p = 0.000$), and c.567dupT in the *MMACHC* gene (OR 1.99, 95% CI 1.1–3.6; $p = 0.023$), baseline C3 (OR 1.06, 95% CI 1.01–1.12; $p = 0.031$) and C3/C2 (OR 1.5, 95% CI 1.04–2.17; $p = 0.031$) were associated with poor outcomes in the whole sample (**Table 3**). In multivariate logistic regression analysis, onset of symptom (OR 12.39, 95% CI 5.15–29.81; $p = 0.000$), the presence of c.609G>A (OR 2.55, 95% CI 1.49–4.35; $p = 0.001$), and c.567dupT in the *MMACHC* gene (OR 2.28, 95% CI 1.03–5.05; $p = 0.042$) remained independently associated with poor outcomes.

The results of the logistic regression analysis for the poor outcomes are listed in **Table 3**. In subjects with intellectual impairment, the multivariate logistic regression analysis showed that onset of symptoms (OR 12.31, 95% CI 5.11–29.66; $p = 0.000$), the mutation of c.609G>A (p.W203X) (OR 2.53, 95% CI 1.48–4.31; $p = 0.001$) and c.567dupT in the *MMACHC* gene (OR 2.57, 95% CI 1.17–5.66; $p = 0.019$) independently predicted the outcome of intellectual impairment (**Table 4**). While in patients who had ocular abnormalities, the mutation of c.567dupT in the *MMACHC* gene (OR 3.72, 95% CI 1.55–8.94; $p = 0.003$) was an independent predictor as well as the onset of symptoms (OR 5.84, 95% CI 1.13–30.12; $p = 0.035$) (**Table 5**). In the group with movement disorders, the independent predictor was the onset of disease (OR 13.47, 95% CI 5.6–32.33; $p = 0.000$) as well as the concentration of MMA (OR 1.00, 95% CI 1.00–1.00; $p = 0.027$), whereas the type of nucleotide variant was not significantly correlated with it (**Table 6**). Additionally, none of the factors were independently associated with the outcome of hydrocephalus (**Table 7**).

4 DISCUSSION

Previous NBS programs enormously improved the health outcomes of affected individuals, since early diagnosis is known to have a great benefit for effectively treating some inborn errors of metabolism (Mütze et al., 2020; Lüders et al., 2021). However, many European countries do not generally advocate widespread screening for the disease of propionate metabolism on the basis that long-term outcomes may not be significantly influenced by early detection (Leonard et al., 2003). In the United States, screening is advocated: it has been argued that even in the absence of clear clinical benefit, early diagnosis enables families to receive genetic counseling more promptly and avoids expensive and time-consuming radiologic and biochemical investigations in affected children. Although there are no national detailed expanded NBS standards in China due to regional differences in the application of MS/MS and lack of valid studies, some work has been done on epidemiology, technical aspects, and clinic validity of MS/MS screening in several provinces and cities in China (Zhang et al., 2021), indicated that NBS programs can prevent irreversible neurological damage

and death by allowing treatment to be started, ideally, before the onset of symptoms. We conducted a national multicenter study including 538 patients identified by NBS with confirmed cblC defect to investigate their long-term outcome and to identify the major predictors of the disease outcome.

In the present study, we investigated the clinical and biochemical characteristics of patients with different outcomes to discuss the potential risk factor of poor outcomes. As expected, there were significant differences in clinical phenotypes, pathogenic variants, and biochemical features both at NBS and during follow-up. Meanwhile, infants with poor outcomes appeared to take therapeutic measures after disease onset, conversely, the normal group was more likely to take timely treatment once positive NBS results had been reported at birth, underlining the importance of optimal diagnostic process quality and early NBS results. Importantly, cblC defect is with a high frequency of severe and potentially fatal neonatal decompensations often already during the first days of life

(Heringer et al., 2016), a delay in treatment might lead to irreversible damage, pointing out emphatically the importance of pre-symptomatic treatment (He et al., 2020). The mortality rate of patients identified by NBS tended to be lower (Dionisi-Vici et al., 2006). The nine deceased patients in our study, though detected by newborn screening, were all treated after disease onset. Among them, eight died because of recurrent metabolic decompensation and only one died of hydrocephalus, suggesting that onset of the disease is negatively correlated with prognosis.

To identify the effect of onset disease on the long-term outcomes of neonatally screened individuals with cblC defect, we analyzed the detailed information between asymptomatic individuals and symptomatic ones before treatment. In the majority of asymptomatic individuals, the long-term outcomes tended to be more favorable. Unfortunately, two of them appeared no clinical symptoms firstly before therapy but died of acute metabolic crisis due to poor treatment compliance. NBS, though not preventing clinical disease course in all screened

individuals, is associated with favorable long-term outcomes. With pre-symptomatic treatment, developmental milestones of the majority of patients detected by newborn screening were normal. These cases benefited from early diagnosis, the timely start of treatment, and the prevention of severe complications.

Regarding biochemical data at NBS, patients with poor prognosis had slightly elevated blood C3/C2 ratio, urinary MCA, but obviously increased plasma tHcy and urinary MMA, which are considered to be correlated with severe brain damage (Kruman et al., 2000; Huemer et al., 2017). However, the relevant metabolic indicators still need to be further explored. Besides, there is no significant difference in the value of blood C3 between groups, which is the opposite of the blood C3/C2 ratio, representing a significant difference. This serves to illustrate that the absolute value of C3 is not sensitive enough since it can be affected by body weight, breastfeeding, and so on. Moreover, compared to severely affected individuals who appeared symptoms before treatment, mildly affected patients who remained asymptomatic showed lower blood C3 and blood C3/C2 ratio concentrations. Interestingly, blood C3 of some patients with the milder disease might not reach the cutoff because of low plasma carnitine obscured elevations in C3 (Ahrens-Nicklas et al., 2015), which results in the possibility of missing mild disease with newborn screening and questioning the sensitivity of newborn screening in identifying these infants. As a consequence, some reports suggested that the C3/C2 ratio can be used as a marker for cblC defect due to the fact that this ratio was elevated on the first and second newborn screens whereas C3 was not above the cutoff (Ahrens-Nicklas et al., 2015). Besides C3/C2 ratio, low methionine could be an additional secondary analyte and was demonstrated to be associated with improved specificity and positive predictive value in one study (Weisfeld-Adams et al., 2010). Moreover, there exists a mild difference in the cut-off value nationwide and a high false-positive or false-negative rates of NBS results based on MS/MS, some experts suggested using next-generation sequencing (NGS) as a second-tier diagnostic test for abnormal NBS results (Luo et al., 2018).

It is noteworthy that genotype-phenotype correlations seem to have a huge impact on the onset of this disorder as well as the prognosis (Lerner-Ellis et al., 2009). For example, in comparison with individuals who remained asymptomatic, those who had already shown clinical manifestations before initiation of treatment were more likely to carry c.609G>A as well as c.567dupT in the *MMACHC* gene. Consistent with previous reports (Liu et al., 2010), both pathogenic variants showed early onset of disease, usually during the neonatal period. This could be related to the fact that c.609G>A variant is nonsense and results in a premature termination codon, which is predicted to cause a truncated or absent *MMACHC* protein. Similarly, c.567dupT in the *MMACHC* gene, a duplication and frameshift mutation, can also have an adverse effect on the function of this protein. Furthermore, patients carrying these homozygous or heterozygous variants are more likely to develop bad outcomes. On the contrary, individuals who remained asymptomatic before initiation of treatment appeared to carry c.482G>A or c.80A>G in the *MMACHC* gene, both missense

pathogenic variants, which predicted excellent clinical outcomes. This result was nearly in line with previous reports (Lerner-Ellis et al., 2009; Huemer et al., 2014; Liu et al., 2020), which described that c.482G>A (p.R161Q) and c.80A>G (p.Q27R) variants were known to predict an attenuated or even benign phenotype with late onset. In a more recent study, Almannai et al. showed that patients with c.482G>A pathogenic variant have a milder disease as indicated by later-onset of symptoms (Almannai et al., 2017), thus when detected by NBS, they were still asymptomatic and once treatment was to be started, the irreversible damage caused by the onset of symptoms could be prevented.

Our findings suggested that symptomatic onset, independently from other predictors like pathogenic variant, metabolic analytes, and treatment, is a strong predictor of poor outcomes, such as intellectual impairment, movement disorders, ocular complications except for hydrocephalus. But the underlying mechanism remains obscure. Results from this current study also suggested that c.609G>A and c.567dupT variants were independent factors of poor prognosis, especially for intellectual impairment. In addition, the odds ratio of c.609G>A variant is a little higher than that of c.567dupT variant in poor outcome, but when intellectual impairment was analyzed, the odds ratio of c.567dupT variant was higher than that of c.609G>A variant. Considering a much higher carrier prevalence of c.609G>A in the *MMACHC* gene among the Chinese population, we proposed that c.609G>A mutant allele, the mutational hotspots, could be potential candidates for gene screening and should be listed in the pre-pregnancy carrier screening panel in China (Qiao et al., 2020). Furthermore, eye diseases are common in patients with the *MMACHC* gene c.271dupA homozygous mutation and are characterized by early maculopathy (Gizicki et al., 2014; Brooks et al., 2016). Ruxuan He et al. showed that the incidence of ocular problems in patients with the c.609G>A variant is much lower (He et al., 2020). And in our study, there is a strong link between c.567dupT variant and ocular abnormalities which is not reported before. This may be because we included the presence of strabismus and nystagmus, which are obvious phenotypes, as criteria of ocular complications. Due to the lack of formal assessment of ocular complications, this result remains to be investigated in the future. In addition, our study found that MMA seems to be a strong biochemical marker of movement disorder because MMA is associated with a high risk of basal ganglia stroke (Dionisi-Vici et al., 2006). This result substantiates the fact that movement disorder could be recovered after treatment once MMA decreases (Matos et al., 2013). However, in our study, we did not observe any risk factors that independently predict the outcome of hydrocephalus.

Although the incidence of cblC defect is low, the outcomes of affected patients are not favorable. The rate of death in our cohort (3.8%) is lower than that of a historical cohort diagnosed before initiation of NBS (26%) (Rosenblatt et al., 1997). In addition, compared to previous studies (Liu et al., 2018; He et al., 2020), the proportion of poor outcomes as well as mortality in our study is lower, demonstrating that NBS reduces mortality and allows a favorable outcome. For late-onset patients, there is no doubt that early detection by NBS and timely treatment improved long-term outcomes (Weisfeld-Adams et al., 2010). Several studies have demonstrated that early-onset patients, though identified by NBS, still have suboptimal outcomes with a high residual burden of

neurologic and ophthalmologic disease (Weisfeld-Adams et al., 2013; Ahrens-Nicklas et al., 2017). In our study, NBS data were typically reported at 2–3 days of life, which enable early diagnostic treatment, thus reducing the frequency of hospitalization and severity of symptoms. Overall, based on our large sample, NBS for cblC defect should be considered since survival and prevention of severe complications in early-onset patients can be improved by early treatment (Dionisi-Vici et al., 2006; Weisfeld-Adams et al., 2010; Huemer et al., 2015; Huemer et al., 2017).

In all screened individuals, there is still a minority at risk of mild to severe psychomotor impairment or complications. This might be the reason that some patients had already developed neonatal disease manifestations, therefore initiation of treatment with intramuscular hydroxocobalamin should even precede recalling screening.

5 CONCLUSION

The present study has discussed a large cohort of individuals with cblC defects. Our study emphasizes the factors affecting outcomes in individuals with cblC defects. Those with a better prognosis have milder diseases as indicated by less symptomatic manifestations, less prominent biochemical abnormalities on NBS, and easier control as made evident by the biochemical profile on the last follow-up. The onset of symptoms is an independent risk factor for poorer outcomes and independently carries a greater risk than pathogenic variants. Newborn screening facilitates early diagnosis, improves the quality of therapy, allows longer survival, and prevents the damage of symptoms, which is the most important prognostic factor. There is no doubt that NBS is a highly successful preventive care program, resulting in favorable clinical outcomes for screened individuals.

Background: Mitochondrial 3-hydroxy-3-methylglutaryl-CoA synthase deficiency (HMGCS2D) is a rare autosomal recessive metabolic disorder caused by mutations of the *HMGCS2* gene. To date, no more than 60 patients have been reported throughout the world.

Purpose: To analyze the clinical, biochemical, molecular, and outcome features of HMGCS2D in a case series of 10 new Chinese patients.

Methods: This retrospective study includes 10 Chinese patients diagnosed with HMGCS2D. We collected and analyzed clinical data for all patients. We also reviewed clinical data for 39 cases that had been reported previously.

Results: All of our patients had experienced their first metabolic crisis before 12 months old. The most common clinical manifestations were anorexia, dyspnea, and disturbance of consciousness (10/10), followed by vomiting (8/10), fever (7/10), cough (4/10), diarrhea, and seizures (3/10). Each patient (10/10) had a different degree of hepatomegaly and increased aminotransferase, severe metabolic acidosis, and hypofibrinogenemia. 9 patients presented with severe hypoglycemia and weak positives on qualitative tests of urinary ketone body. Patient 3 was the only one without hypoglycemia. Five patients had hypocalcemia, five patients had hyperammonemia, four patients had hyperuricemia, and three had hypertriglyceridemia. During the metabolic acidosis episode, we observed high dicarboxylic acid values in urine, and the elevated ratio of blood acetylcarnitine to free carnitine may have been an additional biochemical signature. However, all returned to normal during the interictal interval. Molecular analysis identified 15 variants in the *HMGCS2* gene, of which 10 were novel (c.220G>A/p.E74K, c.407A>G/p.D136G, c.422T>A/p.V141D, c.719A>C/p.D240A, c.821G>A/p.R274H, c.39dupA/p.L14Tfs*59, c.1394delA/p.N465Tfs*10, c.788delT/p.L263Cfs*36, c.717T>G/p.Y239*, and c.1017-2A>G). Combining these with previous cases, the known mutation c.1201G>T/p.E401* has

been found in 6/40 (15.0%) of mutated alleles in 21 Chinese patients from 20 families, while none have been found in other populations. We found that patients with biallelic truncation mutation appeared to show a more severe clinical condition through a literature review.

Conclusion: This study analyzed the phenotypic and genetic features of HMGCS2D in a Chinese case series. We also expanded the *HMGCS2* mutational spectrum with 10 novel variants. The c.1201G>T/p.E401* mutation was the most frequent, representing 15.0% of the mutated alleles in reported unrelated Chinese patients, and thus, it may be a hot spot mutation.

Keywords: 3-hydroxy-3-methylglutaryl-CoA synthase deficiency, hypoglycemia, ketogenesis, HMGCS2 gene, HMGCS2D

INTRODUCTION

Mitochondrial 3-hydroxy-3-methylglutaryl-CoA synthase deficiency (mitochondrial HMG-CoA synthase deficiency; HMGCS2D; OMIM#605911) is a rare autosomal recessive metabolic disorder caused by mutations in the *HMGCS2* gene (OMIM#600234). The *HMGCS2* gene encodes mitochondrial HMG-CoA synthase, which catalyzes the reactions of acetyl-CoA and acetoacetyl-CoA into HMG-CoA during ketone body synthesis. Ketone bodies are an important energy supply for the brain, heart and kidneys during long-term fasting and carbohydrate deprivation. Pathogenic mutations on the *HMGCS2* gene cause mitochondrial HMG-CoA synthase deficiency which disrupts the ketogenesis and blocks the energy supply to the brain during the fasting state. Patients present with intermittent vomiting, lethargy, respiratory distress, encephalopathy, and hepatomegaly, usually precipitated by an intercurrent infection or prolonged fasting (Aledo et al., 2006). Hypoketotic hypoglycemia, metabolic acidosis, increased transaminitis and dicarboxylic aciduria are common laboratory findings during the acute attack stage. Nevertheless, the clinical manifestations and biochemical abnormalities usually return to normal during the interictal period. In 1997, Thompson described the first case of mitochondrial HMGCS2D (Thompson et al., 1997). To date, no more than 60 patients carrying over 40 variants have been reported throughout the world among different ethnic groups. Among them, only 11 patients, from 10 families, are of Chinese descent.

In the present study, we report 10 new Chinese patients with HMGCS2D, and summarize their clinical, biochemical, molecular and outcome characteristics. We reviewed 39 patients with relatively complete clinical data reported for overall understanding of the molecular genetics features of Chinese patients, and to explore the correlation between genotype and clinical features and disease severity. This has not been reported in previous studies.

MATERIALS AND METHODS

Subjects and Clinical Evaluation

Ten unrelated patients (two boys and eight girls) from different Chinese families identified between 2015 and 2021

were included in this retrospective analysis. They had each been diagnosed with HMGCS2D based on clinical features (encephalopathy, and hepatomegaly, usually precipitated by an intercurrent infection or prolonged fasting), biochemical detection results (hypoketotic hypoglycemia, transaminitis, metabolic acidosis and dicarboxylic aciduria), as well as molecular analysis. We collected clinical data through the review of patients' medical records, including the age at onset, primary clinical symptoms, medical management, and biochemical and clinical outcomes following therapy.

Biochemical Analysis

We performed routine blood and urine examination to assess blood gas analysis, ammonia, glucose, liver function, renal function, blood lipids and plasma electrolytes. Then, we applied tandem mass spectrometry to test serum amino acids and acylcarnitines, and analyzed the results using ChemoView software. To analyze urine organic acids, we used gas chromatography-mass spectrometry and the Inborn Errors of Metabolism Screening System. We also performed abdominal ultrasonography and cranial MRI on most patients.

Molecular Analysis

We extracted genomic DNA from peripheral blood leucocytes using a QIAamp DNA Blood Midi kit (Qiagen, Hilden, Germany), and generated sequences using the Agilent Bioanalyzer. Then, we applied whole-exome sequencing for mutation screening. Additionally, we performed Sanger sequencing validation on all patients who we found to be harbouring gene mutations, as well as their parents. The pathogenicity of novel variants was evaluated according to the American College of Medical Genetics and Genomics (ACMG) standards and guidelines (Richards et al., 2015). For the novel mis-sense variants, multiple sequence alignment studies were performed to verify the amino acid conservation using the UCSC Genome Bioinformatics Database, and potential pathogenicity was analyzed using Mutation taster, PolyPhen-2, and Sorting Intolerant From Tolerant (SIFT). Swiss model (<https://swissmodel.expasy.org/>) was also used to predict the protein 3D structure and evaluate the impact of these novel missense variants on protein structure.

Treatment, Follow Up and Outcome Evaluation

When initial metabolic decompensation occurred, all patients were admitted to the hospital and received regular supportive treatment including intravenous glucose and sodium bicarbonate. We also administered liver-protecting and carnitine therapy. We gave mechanical ventilation and continuous renal replacement therapy to any patients who were critically ill because of persistent metabolic acidosis and multiple organ dysfunction. Once the HMGCS2D diagnosis was confirmed, all patients were instructed to avoid long periods of fasting, and put on a low-fat diet.

All patients were enrolled into a simple follow-up study. During the follow-up period, each patient had several telephone survey or outpatient visits. We performed physical growth and psychomotor evaluation, as well as routine laboratory tests such as urine organic acids, plasma amino acids and acylcarnitines and other biochemical investigations, every 6–12 months. Psychomotor evaluation was based on the intellectual test results according to Gesell Developmental Schedules at the last follow-up.

Case Review and Grouping

For overall understanding of Chinese patients' molecular genetics features, and to explore the correlation between genotype and clinical features and disease severity, we reviewed 39 previously reported patients with relatively complete clinical data, including the genetic analysis results. In our study, we divided the patients into 3 phenotypic groups according to their clinical severity: A deceased group, a severe group, and a mild group. The deceased group included patients who had died because of disease onset. The severe group included patients who met one of the following conditions: Recurrent attacks on multiple occasions; blood pH value lower than 7.0 in metabolic decompensation; had required mechanical ventilation or CRRT treatment in metabolic decompensation; had become cognitively disabled after disease onset. The mild group included patients with milder symptoms. According to their disease-causing variation type, we divided them into 3 genotypic groups: The A group included patients carrying 2 truncating mutations on the *HMGCS2* gene; the B group included patients carrying only 1 truncating mutation on the *HMGCS2* gene; and the C group included patients carrying no truncating mutations.

Statistical Analysis

We performed statistical analysis in SPSS 22.0. We analyzed the correlations between different phenotypic groups and genotypic groups with a Cochran-Mantel-Haenszel test. We considered any results with $p < 0.05$ as having a statistically significant difference.

RESULTS

Patients' Clinical Characteristics, Biochemical Detection

As summarized in **Table 1**, there were 8 females and 2 males in our study. All of their parents were non-consanguineous. Among

the 10 cases, patient 1 had a deceased sister who had died of a sudden coma after respiratory infections at the age of 8 months, while patient 4 had an older brother who had died of Reye Syndrome at 1 year and 10 months. For patient 10, his mother had experienced spontaneous abortion in her first two pregnancies with no specific cause. None of the other patients had positive family history. Patients had experienced their first metabolic crises at ages ranging from 5 to 12 months. The most common clinical manifestations were anorexia, fever and cough, which then developed into vomiting, dyspnea and disturbance of consciousness. The time from onset to progression to dyspnea and disturbance of consciousness ranged from 2 to 7 days. During the course of disease, all patients had anorexia, dyspnea and disturbance of consciousness (10/10). The second most common symptom was vomiting (8/10), followed by fever (7/10), cough (4/10), diarrhea and seizures (3/10).

Routine biochemical laboratory results at onset are shown in **Table 1**. Each patient had a different degree of hepatomegaly, about 2–7 cm below the right costal margin. Laboratory examinations showed severe metabolic acidosis (10/10), increased aminotransferase from mild to severe (10/10), hypofibrinogenemia (10/10), slightly increased creatine kinase isoenzyme (8/10), increased creatine kinase (3/10), and normal lactate (10/10). Among all patients, 9 presented with severe hypoglycemia and weak positives in qualitative urinary ketone body tests, while we observed no hypoglycemia in Patient 3. Five patients (Patient 1, 2, 4, 5 and 9) had hyperammonemia. Five (Patient 1, 2, 4, 9 and 10) had hypocalcemia. Three (Patient 2, 4, and 8) had hypertriglyceridemia. Eight received cranial MRI examinations, and 3 cases (Patient 1, 2 and 3) showed widening of the sulcus and bilateral frontal and temporal subarachnoid space, two (Patient 3 and 10) showed abnormal signal in the basal ganglia, one (Patient 2) showed delayed myelination in white matter, while four (Patient 6, 7, 8 and 9) were normal. During acute metabolic decompensation, eight patients (all except for Patient 5 and 6) received mechanical ventilation for respiratory failure resulting from serious metabolic acidosis. Four (Patient 3, 4, 8, and 10) had to undergo continuous renal replacement therapy (CRRT) because of serious and/or obstinate metabolic acidosis.

We performed urine organic acid analysis during the acute episode of metabolic acidosis. While we detected a massive amount of dicarboxylic acid in all patients, ketone body excretion was only mildly elevated. Plasma amino acids and acylcarnitine analysis revealed that free carnitine levels were low with a mildly increased acetylcarnitine in Patients 1–3, 5 and 7. Patients 4 and 6 had decreased free carnitine but normal acetylcarnitine, while Patients 8–10 had normal free carnitine but elevated acetylcarnitine.

Molecular Genetic Analysis

We performed molecular analysis on all patients, and detected biallelic mutations in the *HMGCS2* gene in all of them. In our study, we identified fifteen molecular variants in the *HMGCS2* gene, ten of which were novel. Five were known mutations, including 2 missense mutations (c.160G > A/p.V54M, c.1502G > A/p.R501Q), 2 splicing mutations (c.559+1G > T, c.1187+1G >

Reference range: ALT: 0–40U/L; AST: 0–40U/L; CK: 20–200U/L; CKMB: 0–24U/L; Triglyceride: 0.38–2.25 mmol/L; Lactic acid: 0–2.2 mmol/L; Blood ammonia: 9–33umol/L.

C) and one nonsense mutation (c.1201G > T/p.E401*). The ten novel potentially pathogenic variants have not been previously reported in the literature or registered in the HGMD, ClinVarMiner, ExAC or gnomAD databases. This includes the 5 missense mutations (c.220G > A/p.E74K, c.407A > G/p.D136G, c.422T > A/p.V141D, c.719A > C/p.D240A, c.821G > A/p.R274H), 3 frame-shift mutations (c.39dupA/p.L14Tfs*59, c.1394delA/p.N465Tfs*10, c.788delT/p.L263Cfs*36), one nonsense mutation (c.717T > G/p.Y239*) and one splicing mutation (c.1017-2A > G). Multiple sequence alignment studies suggested all the amino acids were conserved. Multiple lines of computational evidence supported a deleterious effect on the gene about the novel mutations. Detailed results of the 15 variants and prediction of effects of some novel mutations are shown in **Table 2**. In addition, we have performed a computational evaluation of the impact of the novel missense variants on protein structural using Swiss-model software. The results show that the 3D structure of HMGCS2 protein may be affected by these 5 novel mis-sense variants. Detailed results were shown in **Supplementary Figure S1**.

Outcome Evaluation

Except for Patient 4 who died of multiple organ failure due to severe metabolic disorder at onset, all patients had complete recovery with symptomatic and supportive treatment. Each maintained well-being by avoiding long-term fasting and taking glucose supplements during illness. Hitherto, all 9 cases had followed up, made good progress, and reported no further episodes. The follow-up time varied from 7 months to 5 years and 3 months. As of October 2021, their ages ranged from 2 to 6 years and 9 months. During follow-up, we surveyed the routine laboratory tests including plasma amino acids and acylcarnitines, urine organic acids and other biochemical investigations. All results were within the normal range. We also summarized patients' physical growth and developmental quotients (DQ) at the latest follow up, and found normal outcomes in all patients. Both height and weight were between mean \pm 1SD. For the four individuals older than 4 years (Patients 1, 2, 6, and 7), all performed well in school. Additionally, DQ tests revealed that all patients examined had age-appropriate intelligence. Detailed results are shown in **Table 1**.

Case Review and Exploration of the Correlation Between Genotype and Clinical Features and Disease Severity

A review of previous literature has revealed that from October 1997 to January 2021, 59 patients, carrying 54 variants of the *HMGCS2* gene, have been reported. Among them, only 11 individuals, from 10 families, were of Chinese descent. Including the 10 cases in our research, 27 mutations have been identified in the 21 Chinese patients from 20 families, including 15 (15/27, 55.6%) missense mutations, 5 (5/27, 18.5%) frame-shift mutations, 4 (4/27, 14.8%) nonsense mutations and 3 (3/27, 11.1%) splicing mutations. The frequency of the *HMGCS2* variants in the 20 unrelated Chinese patients is shown in **Table 3**. The recurrent *HMGCS2*

mutations in the Chinese population were c.1201G > T/p.E401* (detected in 7 individuals from 6 unrelated families, mutated allele frequency 6/40, 15.0%), c.559+1G > T, c.1187+1G > C and c.1502G > A/p.R501Q (respectively detected in 3 mutated alleles, 3/40, 7.5%), c.220G > A/p.E74K (detected in 2 unrelated individuals, mutated allele frequency 2/40, 5.0%).

Including our 10 patients and the previously reported 39 patients with relatively complete clinical data, we analysed the clinical and molecular characteristics of 49 patients to explore the correlation between genotype and clinical features and disease severity. Detailed clinical data is presented in **Supplementary Table S1**, and the statistical analysis results are shown in **Table 4**. 16 patients carried biallelic truncating mutations (either nonsense, frame-shift or splicing mutation) (Group A). During acute metabolic decompensation, 4 of them (25%) died, and 7 (43.7%) had severe phenotypes. 13 patients carried monoallelic truncating mutations (Group B). Among them, one patient (7.7%) died, and 10 (76.9%) had severe phenotypes. For the 20 patients carrying biallelic non-truncating mutations (Group C), only one (5%) died, and 7 (35%) showed severe phenotypes, while 12 (60%) had mild symptoms. From another perspective, within the deceased group 66.7% (4/6) had 2 truncating mutations; within the severe group 70.9% (17/24) had at least 1 truncating mutation; and within the mild group 63.2% (12/19) had non truncating mutations. We analysed the correlation between phenotypic groups and genotypic groups with a Cochran-Mantel-Haenszel test. The results indicated that disease severity was correlated with how many truncating variations the patients carried ($p < 0.05$).

DISCUSSION

Mitochondrial *HMGCS2D* is a life-threatening, but treatable, inherited metabolic disorder caused by a defect in the critical enzyme that regulates ketone body formation (Aledo et al., 2006). Therefore, patients with *HMGCS2D* are prone to episodic metabolic decompensation triggered by fasting or stressful conditions that require fatty acid decomposition for the provision of energy. In the present study, we reported 10 new unrelated Chinese patients with *HMGCS2D*. All patients had suffered their first metabolic crisis before their first birthday. Prior to metabolic crisis, there had been prodromic infection of either the digestive tract or the respiratory tract in all cases. The most common clinical manifestations before admission were poor intake, fever, cough and vomiting, which progressed rapidly to life-threatening dyspnea and coma. One third of patients had seizures, although each had only one throughout the disease course. Nonetheless, this still suggests there may have been an insufficient energy supply to the brain which may have harmed the nervous system, or even caused sequelae. All of our patients presented with severe metabolic acidosis with significantly increased anion gap, hepatomegaly, increased aminotransferase, and abnormal coagulation function, but normal lactate. Although their primary clinical characteristics were similar to those previously reported, there were several points of concern.

All of our patients, with the exception of Patient 3, had hypoglycemia. According to previously reported data, 3 patients had no hypoglycemia during metabolic decompensation (Lee et al., 2019; Conlon et al., 2020; Wang et al., 2020a). The specific mechanism for this is unknown, and it may be related to compensatory glycogen decomposition and gluconeogenesis. However, the evidence suggested that hypoketotic hypoglycemia was important, but not indispensable, to HMGCS2D diagnosis. Similar to the patients observed by other researchers (Fukao et al., 2014; Conboy et al., 2018), urinary ketones in all of our patients were weakly positive (i.e., not negative). This may have interfered with the initial HMGCS2D diagnosis. Moreover, the observed ketones may have been due to the moderate amounts of ketone bodies produced by leucine catabolism pathway. In addition, in our study, four patients developed hypocalcemia during acute decompensation. Previously, this had only been reported in two patients (Wolf et al., 2003; Kilic et al., 2020). The specific pathogenesis of hypocalcemia remains unclear. We speculate the activation of coagulation and the fibrinolytic system, cell membrane damage caused by severe acidosis and tissue energy deficiency, Vitamin D deficiency and insufficient calcium intake in the acute stage could each be factors. Three patients had transient hyperuricemia, similar to the recent Turkish cases (Kilic et al., 2020). Many organic acids can stimulate the transporter, increasing the reabsorption of uric acid, which may account for the hyperuricemia (George and Minter, 2021). Moreover, Patient 3 had a concomitant disease, congenital laryngeal web, which had

been diagnosed when she was 10-months-old based on clinical symptoms including recurrent cough, asthma, laryngeal stridor and hoarseness, and the results of electronic bronchoscopy. Then she accepted interventional therapy, with exceptional results. To our knowledge, this is the first time this has been reported in patients with HMGCS2D.

Detection of metabolic markers are crucial to diagnosing most inherited metabolic diseases. However, as far as we know, there are no specific biochemical markers in HMGCS2D. All patients in this study showed elevated dicarboxylic acid in their urine during decompensation. It has been reported that this can provide an indication, but cannot differentiate HMGCS2D from other fatty acid metabolic disorders (Kilic et al., 2020; Wang et al., 2020b). It has been reported that increased urine 4-hydroxy-6-methyl-2-pyrone (4-HMP) can be a specific biochemical hallmark indicator which can distinguish HMGCS2D from fatty acid oxidation defects (Pitt et al., 2015; Wang et al., 2020a). Unfortunately, in our study, only 3 patients received urine 4-HMP tests. Among them, 2 had elevated urinary 4-HMP and the other patient's urinary 4-HMP was normal. These results indicated that using 4-HMP as a positive prediction needs further study through more patients. We also detected the blood acylcarnitine profile in all individuals. As previously reported in the literature, blood acetylcarnitine (C2) can be either normal or increased during decompensation (Aledo et al., 2006; Ramos et al., 2013; Liu et al., 2019). In our study, the blood C2 level in 8 of the patients increased, while the free carnitine (C0) level in 7 of the patients

TABLE 3 | The frequency of *HMGCS2* variations in 20 unrelated Chinese patients (total number of mutated alleles = 40).

decreased. This led to elevated C2/C0 ratios in all cases. These data suggest that for clinically suspected patients, the high ratio of C2 to C0 may have been more specific and informative than the solitary high C2 or low C0 levels. Consequently, we considered that simultaneous detection of blood acylcarnitine profile and urinary organic acids was essential for HMGCS2D diagnosis. An elevated C2/C0 ratio combined with plenty of dicarboxylic acids in urine during an episode of acute hypoglycemia and metabolic acidosis may be an additional biochemical signature of HMGCS2D. This observation needs further research to identify whether there is sufficient specificity for clinical utilization.

As mentioned above, the lack of specificity in clinical and biochemical characteristics, as well as any abnormalities, may turn normal during intermissions. This complicates HMGCS2D diagnosis. On the other hand, detecting enzyme activity is invasive and complex, and the results are unstable. Therefore, at present, molecular genetic analysis of the *HMGCS2* gene still consists of the recommended diagnostic method (Zschocke et al., 2002; Ramos et al., 2013). In recent years, more and more patients have been confirmed as carrying biallelic pathogenic variants on *HMGCS2* gene by genetic testing. The *HMGCS2* gene is located on chromosome 1p13-p12, with a length of 20.9 kb. It consists of 10 exons, encoding 508 amino acids. Since the first description of

the disease in 1997 (Thompson et al., 1997), over 40 variants have been identified. Prior reports have shown that these mutations have an irregular distribution and involve all exons (Wang Q. et al., 2020). Most of them are sporadic, specific to families, and have ethnic and regional differences. The c.634A > G/p.G212R has been identified in 3 families, respectively from Poland (Conlon et al., 2020), Britain (Pitt et al., 2015) and Germany (Zschocke et al., 2002). This implies that it was a common HMGCS2D mutation in Europe. The large deletion on exon 1, denoted as c.1-?_104+?del, has only been identified in patients of Mediterranean descent (Pitt et al., 2015), while c.725-2A > C has only been reported in two families from Turkey (Kilic et al., 2020). No relevant research on phenotype-genotype correlations has been reported to date.

Our finding is unlike similar studies conducted on other populations. In our cohort, the recurrent variants were c.1201G > T/p.E401*, c.559+1G > T and c.220G > A/p.E74K. If combined with the 11 patients reported previously (Thompson et al., 1997; Ma and Yu, 2018; Liu et al., 2019; Wang et al., 2019; Wang et al., 2020a; Wang et al., 2020b; Yang et al., 2020), the most frequent mutation was c.1201G > T/p.E401*. This may result in a premature termination codon at amino acid residue 401 located in exon 7 of *HMGCS2*. This leads to a truncated protein, and causes the loss of gene function. We detected this mutation as compound heterozygous in 7 Chinese patients from 6 families, while no patient in any other population has been a carrier of c.1201G > T/p.E401* in prior studies. All of these observations suggested that c.1201G > T/p.E401* may be a hot-spot mutation in Chinese HMGCS2D patients. The second most common mutations were c.559+1G > T, c.1187+1G > C and c.1502G > A/p.R501Q, all accounting for 3/42 mutated alleles, respectively. All had been reported in previous Chinese HMGCS2D patients, but not in other populations. c.559+1G > T was reported to be the second described splicing mutation of the *HMGCS2* gene, and

minigene assay results revealed that it may influence protein structure and function (Wang et al., 2020b). c.1187+1G > C is the classical site splicing mutation, which may cause abnormal splicing resulting in loss of protein function. We detected the missense mutation c.1502G > A/p.R501Q in Patient 6 in the compound heterozygous state, and a previous study has reported a Chinese case in the homozygous state (Ma and Yu, 2018). Previous reports have also suggested that arginine at position 501 is critical to enzymatic function (Bagheri-Fam et al., 2020). Moreover, variation in amino acids in the same position, c.1502G > C/p.R501P, has also been found in two Thai patients (Rojnueangnit et al., 2020). All of these factors imply that it was a causative variant.

Furthermore, our study also identified 10 novel mutations of *HMGCS2*. The c.1017-2A > G was the fifth splicing mutation of *HMGCS2*. It occurred at a classical splicing site and may lead to abnormal formation of *HMGCS2* protein, demonstrating its pathogenicity. c.717T > G/p.Y239*, c.39dupA/p.L14Tfs*59, c.788delT/p.L263Cfs*36 and c.1394delA/p.N465Tfs*10 all led to a premature termination codon respectively in exons 4, 1, 4, and 8. This led to encoded truncated peptides, thereby resulting in an enzyme defect. The 5 missense mutations each occurred in highly conserved regions. They were predicted to be damaged by Mutation taster, SIFT, and Polyphen 2. The computational evaluation using Swiss-model software showed that they may affect the 3D structure of *HMGCS2* protein. Among them, c.220G > A/p.E74K was detected in two unrelated patients. We speculated that it is a common mutation in Chinese patients.

In order to explore the correlation between genotype and clinical features and disease severity, which had remained unknown according to previous studies, we analysed the clinical and molecular characteristics of 49 patients. This included our 10 patients, as well as the previously reported 39 patients with relatively complete clinical data (as shown in **Supplementary Table S1**). In **Table 4**, Group A (patients carrying biallelic truncating mutations) had the highest mortality (25%), while Group C (patients carrying biallelic non-truncating mutations) had the highest percentage of mild cases (60%). Group B (carrying monoallelic truncating mutations) had the highest percentage of severe cases (76.9%). Statistical analysis showed a correlation between disease severity and how many truncating variations patients carried. This suggests that patients with biallelic truncation mutation are likely to have more severe phenotypes. However, there was no convincing evidence indicating that individuals with biallelic missense mutation would have milder or later presentation. On the other hand, due to the limited number of patients, the frequency of compound heterozygotes, and the lack of enzymatic studies, it is difficult to assess the precise relationship between genotype and phenotype. Furthermore, inter-allelic complementation complicated the predictions of potential genotype-phenotype correlations. Therefore, more cases are needed for further exploration.

With regard to the prognosis, most of our patients had full recovery after symptomatic and supportive treatment, and maintained normal growth and development, without further episodes during follow-up. According to the literature, only one case had neurological sequelae (Conboy et al., 2018). However,

there still were 6 patients who died of hypoglycemic crisis and serious metabolic acidosis during acute metabolic decompensation (Liu et al., 2019; Kilic et al., 2020; Wang et al., 2020a; Yang et al., 2020). These results suggest that *HMGCS2D* is a fatal, but treatable, hereditary metabolic disease. If we can diagnose it before onset, and then prevent those trigger factors like long-term fasting, and administrate oral glucose when patients have poor food intake, we may be able to prevent metabolic crises. However, patients cannot be diagnosed before disease onset through the current newborn screening program. We believe that the combination of rapid and accurate next-generation sequencing technology and biochemical screening may improve newborn *HMGCS2D* screening efficiency in the future (Luo et al., 2020).

CONCLUSION

In summary, mitochondrial *HMGCS2* deficiency is a rare ketone synthesis disorder. We have described clinical symptoms, biochemical features, clinical outcomes, and molecular analysis of 10 new Chinese patients. We have also expanded the *HMGCS2* mutational spectrum with 10 novel variants. The variation c.1201G > T/p.E401* is the most common, and may be a hot-spot mutation of the *HMGCS2* gene in Chinese patients. Through a literature review, we found that patients with biallelic truncation mutation appeared to show a more severe clinical condition.

Background: Pseudohypoaldosteronism (PHA) diseases are difficult to diagnose because symptoms are often non-specific and an in-depth pathogenesis study is still lacking.

Case Presentation: We present the case of a 19-day-old neonate who presented with unexplained recurrent hyperkalemia, hypovolemia and metabolic acidosis, whose parents did not have significant clinical disease characteristics. Whole-exome sequencing was performed to confirm the disease and genetic pattern of the neonate. Sanger sequencing was performed to identify the mutation sites. Secondary structure comparisons and 3D model construction were used to predict changes in protein structure. Two novel frameshift mutations in the *SCNN1B* gene were identified (c.1290delA and c.1348_1361del), which resulted in amino acid synthesis termination (p.Gln431ArgfsTer2 and p.Thr451AspfsTer6). Considering the clinical phenotype and genetic analysis, this case was finally identified as a PHA type I disease. Genetic analysis showed that the neonate suffered complex heterozygosity in the *SCNN1B* gene inherited from the parents, which is passed on in an autosomal recessive inheritance pattern. These two deleterious mutations resulted in an incomplete protein 3D structure.

Conclusions: Our results have confirmed the associations of mutations in the *SCNN1B* gene with recurrent hyperkalemia, which can cause severe PHA type I disease, meanwhile suggested clinical attention should be paid when persistent recurrent hyperkalemia is accompanied by these types of mutations.

Keywords: pseudohypoaldosteronism type I, whole-exome sequencing, *SCNN1B*, frameshift mutations, genetic pattern, rare disease

INTRODUCTION

Pseudohypoaldosteronism (PHA) is a severe disease first described by Cheek and Perry (1), characterized by congenital resistance to the action of aldosterone on epithelial tissue, failure to thrive, hyperkalemia, hypovolemia, and metabolic acidosis. PHAs can be divided into types I and II. PHA type I often harbors mutations in the *SCNN1A*, *SCNN1B*, and *SCNN1G* genes, which encode the epithelial sodium channel (ENaC) (2, 3). PHA type II is caused by mutations in the *WNK1* and *WNK4* genes, which encode lysine-deficient protein kinases. PHA type I results in excessive salt wasting despite very high plasma aldosterone and renin levels, whereas PHA type II leads to blood pressure disorder-related diseases (4–6). Molecular level research on PHA type I shows the *SCNN1A* (12p13), *SCNN1B* (16p12.2–p12.1), and *SCNN1G* (16p12) genes encoding the three homologous α , β , and γ subunits of ENaCs (7–10), which are membrane-bound ion channels that are selectively permeable to Na^+ ions. Changes in Na^+ concentration affect the movement of fluids and, consequently, fluid volume and blood pressure (11, 12). ENaC activity is modulated by the mineralocorticoid aldosterone, and the α , β , and γ subunits of ENaC are essential for transport to the membrane assembly of functional channels on the membrane; mutations in *SCNN1A*, *SCNN1B*, and *SCNN1G* lead to loss of ENaC activity (13–15).

Here, we report the case of a 19-day-old neonate presumptively diagnosed with PHA with two novel frameshift mutations in *SCNN1B* (c.1290delA and c.1348_1361del), which resulted in premature amino acid synthesis termination (p.Gln431ArgfsTer2 and p.Thr451AspfsTer6) by both two chromosomes. We also reviewed and analyzed the clinical features of the neonate to further clarify the correlation between the deletion region and the phenotype.

MATERIALS AND METHODS

Editorial Policies and Ethical Considerations

This study was agreed by the Research Ethical Review Committee, Beijing Children's Hospital Affiliated to Capital Medical University (approved protocol no.2017-k-81). Written informed consent was obtained from the individual(s), and minor(s)' legal guardian/next of kin, for the publication of any potentially identifiable images or data included in this article. All blood samples were obtained after written informed patient consent and were fully anonymized. The participants and legal guardian provided written informed consent to participate in this study.

Clinical Presentation

A 19-day-old neonate suffered an inexplicable electrolyte disturbance for 15 days and was admitted to the neonatal intensive care unit at the Beijing Children's Hospital with a history of poor feeding, hypothermia, lethargy, and bradycardia. She was born by cesarean section after a full-term pregnancy with a birth weight of 3,490 g (10–90th percentile) and lost 15% of her weight 5 days after birth. She was the first child of her parents, and

the mother had no perinatal problems. Neither of the parents had a family history of significant illness or unexplained death.

On physical examination, her weight and height were 3.09 kg (<3rd percentile) and 50.2 cm (3rd–10th percentile), respectively, and her head circumference was 34.1 cm (10–50th percentile). Routine examination showed a blood pressure of 73/39 mmHg, pulse rate of 148/min, respiratory rate of 44/min, and temperature of 37.2°C. The neonate was pale and lethargic and exhibited hypotonic extremities and severe dehydration. Her external genitals developed normally, and other physical examination results were within the normal range.

The initial serum laboratory examinations results were as follows: hyponatremia: sodium 111 mmol/L (normal range = 130–150 mmol/L), hyperkalemia: potassium 9.0 mmol/L (normal range = 3.5–5.5 mmol/L), hypochloremia: chloride 83.6 mmol/L (normal range = 98–108 mmol/L), urea nitrogen 4.2 mmol/L (normal range = 1.7–7.1 mmol/L), and creatinine 23 $\mu\text{mol/L}$ (normal range = 30–104 $\mu\text{mol/L}$). Arterial blood gas analysis revealed metabolic acidosis: pH = 7.227 (normal range = 7.251–7.429) and base excess: –14 mmol/L (normal range = –6–2). Plasma adrenocorticotrophic hormone < 5–11.9 pg/ml (normal range = 0–46 pg/ml), Plasma cortisol 1.27–9.28 $\mu\text{mol/dl}$ (normal range = 5–25 $\mu\text{mol/dl}$), Plasma testosterone < 20 ng/dl (normal range = 0–106.9), Plasma 17- α -hydroxyprogesterone 5.18 nmol/L (normal range = 0.31–38.1). Further laboratory studies subsequently revealed markedly increased plasma renin 5.36 ng/mL/h (normal range = 0.00–0.79 ng/mL/h), serum aldosterone 22.78 ng/dL (normal range = 5.9–17.4 ng/dL), and angiotensin II 398.7 pg/mL (normal range = 40.6–90.0 pg/mL). B-ultrasound of adrenal gland showed that the structure of adrenal gland was normal. Symptoms of hyperkalemia persisted during the treatment from day 1 to day 4 (**Figure 1**). Meanwhile, through differential diagnosis, we ruled out renal failure, hypovolemia: shock or dehydration, adrenocortical insufficiency: adrenal hemorrhage, adrenal hypoplasia, etc., congenital adrenal hyperplasia, potassium retention diuretics and other diseases. Based on these clinical tests, a presumptive diagnosis of PHA was made (**Table 1**), metabolic acidosis was corrected, and blood potassium was lowered using simultaneous high-salt milk feeding (1 g NaCl/day, 20–30 ml/feeding). Because the PHA disease was not confirmed, the type and genetic pattern was also unclear, accurate treatment could not be provided; therefore, whole-exome sequencing and Sanger sequencing were performed on the neonate and her parents who without typical PHA disease symptoms.

Genomic DNA Extraction

We obtained the peripheral blood of the neonate and her parents at Beijing Children's Hospital and extracted the DNA immediately using the QIAamp DNA Blood Mini Kit according to the manufacturer's instructions.

Whole-Exome Sequencing and Single Nucleotide Polymorphism Calling

Exome capture was performed using the Agilent SureSelect Human All Exon V6, according to the manufacturer's standard protocols. The Illumina HiSeq 2500 platform was used to

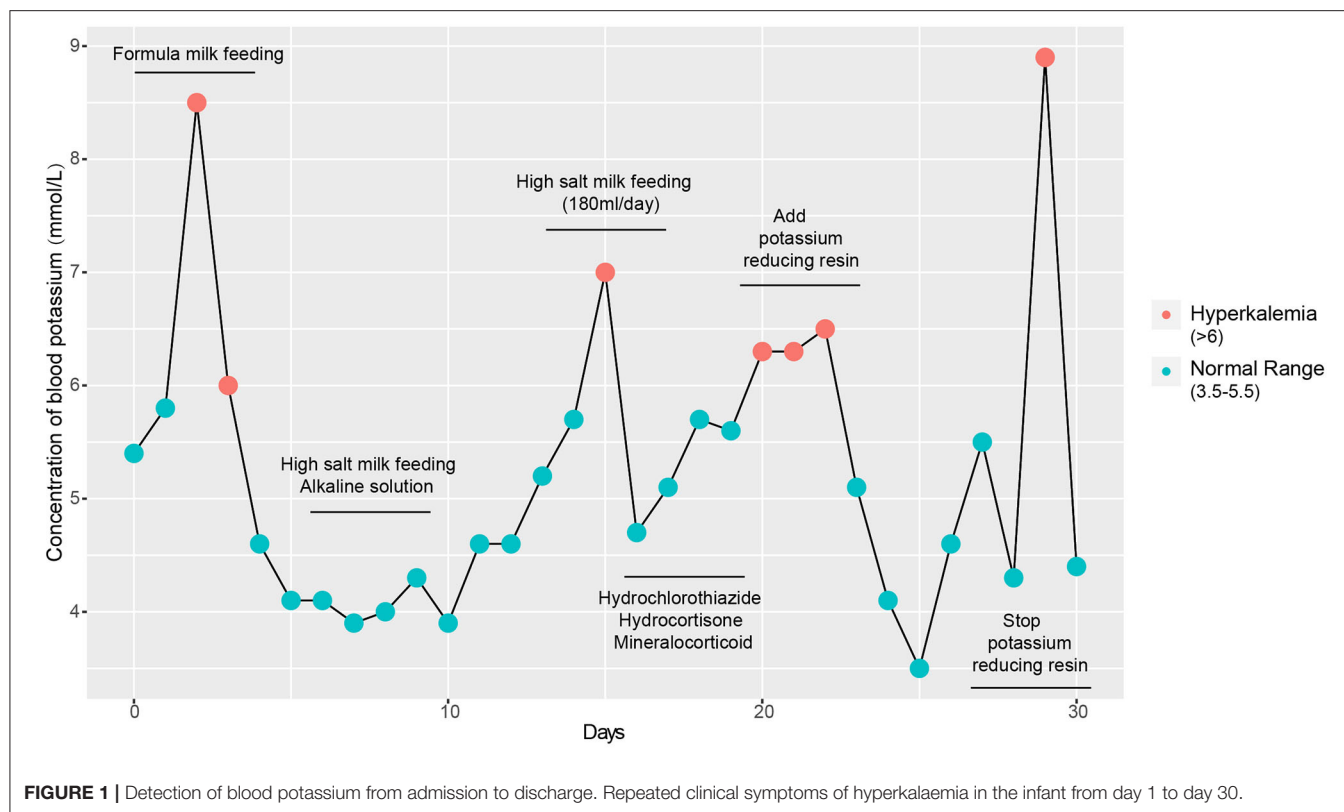

TABLE 1 | Differential diagnosis of the neonate.

Pathogeny	Diagnosis	The neonate
Excessive potassium intake	Intravenous infusion a large amount of potassium liquid	No
Renal potassium depletion disorder	Renal failure	No
	Hypovolemia: shock or dehydration	No
	Adrenocortical insufficiency: adrenal hemorrhage, adrenal hypoplasia, etc.	No
	Congenital adrenal hyperplasia	No
	Potassium retention diuretics	No
	Pseudohypoaldosteronism	Highly suspicious

detect the DNA sequence, and paired-end sequencing was conducted with a read length of 150 bp (16). More than 10 GB of clean sequence data and more than $100 \times$ read depth were obtained for each DNA sample. All individual sequence reads were aligned to the human reference genome (NCBI build GRH37/hg19) using the Burrows-Wheeler Aligner software (17). The genome analysis toolkit, SAMtools, and Picard tools were used for bioinformatic analysis, and SNPs and insertion-deletions (indels) were identified using the genome analysis toolkit (18, 19).

3D Modeling

Amino acid sequence alignment and the 3D structure of *SCNN1B* were constructed using Swiss-Model software (<https://swissmodel.expasy.org/>).

RESULTS

Mutation Analysis and Verification

In order to identify the PHA disease and the type of PHA, SNPs and indels in the *SCNN1A*, *SCNN1B*, *SCNN1G*, *WNK1*, and *WNK4* genes were investigated. As shown in **Table 2**, two novel frameshift mutations in *SCNN1B* (c.1290delA and c.1348_1361del) were revealed, both of which led to the production of the stop codon TGA. We further verified the two new mutations using Sanger sequencing (**Figure 2A**). Neither mutation had been described previously (<http://www.ncbi.nlm.nih.gov/projects/SNP>). Other candidate genes were also analyzed, but no significant pathogenic SNPs or indels were found (**Table 2**). Based on the molecular-level results, PHA type I was preliminarily identified.

FIGURE 2 | Mutation verification and protein 3D structure prediction. **(A)** Sanger sequencing demonstrated that c.1290delA was inherited from the mother. **(B)** Sanger sequencing demonstrated that c.1348_1361del was inherited from the father. **(C)** Genetic pattern analysis of compound heterozygotes. **(D)** Location of the mutation sites in the *SCNN1B* gene. **(E,F)** Amino acid sequence alignment indicated that both mutations caused early termination of amino acid synthesis (6wth.1.b refers to the amino acid sequence after mutation; Model_01 refers to the non-mutated amino acid sequence). **(G)** The 3D model predicted an incomplete ENaC structure after mutation.

Confirmation of Compound Heterozygosity and Genetic Pattern

Because the neonate’s parents do not have typical PHA disease characteristics, next, we explored the genetic patterns of these mutations. As shown in **Figures 2A–C**, c.1290delA was carried by her mother, whereas c.1348_1461del was carried by her father, and the neonate inherited these two frameshift mutations concurrently. Her parents possessed heterozygous mutations with a normal phenotype, indicating a recessive inheritance pattern (**Figure 2C**). Thereafter, we confirmed that these two mutations were distributed in different chromosomes in the neonate, so the translation of the *SCNN1B* gene was terminated prematurely in both chromosomes. Whole-exome sequencing results showed that c.1290delA occurred at chr16:23388505, whereas c.1348_1461del occurred at chr16:23388651, and the distance between these two mutations was 146 bp (**Figure 2D**). We then counted the number of reads covered in this range, there was no single read containing both mutations, all the reads covered from chr16:23388505 to chr16:23388651 had only one mutation, either c.1290delA or c.1348_1461del, which indicates that the two mutations occurred in different chromosomes. Based on these findings, the neonate suffered a “double-stop” compound heterozygous mutation in the *SCNN1B* gene, which led to no functional B-subunit protein of ENaC and severe and persistent electrolyte abnormalities.

Amino Acid Sequence Alignment and 3D Prediction of Protein Structure

Further, we want to know whether these two mutations will cause changes in the three-dimensional structure of the protein. We found that the two mutations at the amino acid level were p.Gln431ArgfsTer2 and p.Thr451AspfsTer6. After amino

acid sequence alignment, we found that these two frameshift mutations led to the early termination of amino acid synthesis (**Figures 2E,F**). We also found that both mutations led to an incomplete structure in the protein 3D prediction model (**Figure 2G**).

Follow Up and Outcome

After confirmation of recessive hereditary PHA type I using genetic analysis, the parents were asked to go back to the local hospital for treatment after a clear diagnosis, we recommend continuing oral potassium lowering resin (1–2g/kg/day) and high-salt milk feeding (1g NaCl/day, 20–30 ml/feeding) as therapeutic approach. Serum electrolytes returned to the normal range after initial parenteral hydration, oral sodium supplementation, and kayexalate usage; all clinical indicators were within the normal range after returning to the local hospital, but the development level was slightly slower than that of normal infants. At 3 months of age, the following measurements were obtained: weight 3.8 kg (normal range = 4.4–8.71 kg), height 55 cm (normal range = 54.2–67.5 cm), and head circumference 37 cm (normal range = 37.4–42.2 cm). At the age of 4 months, the infant returned to Beijing Children’s Hospital due to convulsions without obvious causes, respiratory infection symptoms, increased blood potassium level, decreased blood sodium level, and ventricular tachycardia. Subsequently, resuscitative efforts were unsuccessful and the infant died.

DISCUSSION

PHA is a mineralocorticoid resistance disease characterized by renal salt wasting, dehydration, and failure to thrive. PHA type

I typically presents in the neonatal period with severe salt-wasting crisis with hyponatraemia, hyperkalaemia, acidosis, and dehydration due to sodium loss through the kidneys, colon, sweat, and salivary glands (20, 21). Patients may also present with lethargy and failure to thrive. PHA type I is often recessively inherited, and genetic mutations cause manifold loss of function of ENaC protein subunits and sodium reabsorption disfunction (3, 22). There is no specific treatment for PHA type I, except for the potassium ion exchange resin.

We present a case of PHA type I identified using whole-exome sequencing, with two novel frameshift mutations in the *SCNN1B* gene, which resulted in severe hyperkalaemia, hyponatraemia, metabolic acidosis, moreover, the emergence of compound heterozygotes of this mutant type may lead to growth retardation and early neonatal mortality. These mutations were inherited from the parents, who did not exhibit typical PHA clinical symptoms. Although several cases of patients with PHA type I have previously been presented, and mutations such as c.1466 +1 G > A, c.1288delC, and c.1266-1G > C have been reported (9, 23–26). This neonate carried novel compound heterozygote mutations in the *SCNN1B* gene, both of which resulted in an abnormal stop codon.

The ENaC plays a critical role in cellular functions, such as Na⁺ and water balance, blood pressure stabilization, and response to aldosterone. As a result, mutations in ENaC genes generally produce clinical symptoms of failure to thrive, hypovolemia caused by sodium wasting, metabolic acidosis, and severe hyperkalaemia. c.1290delA and c.1348_1461del changed the reading frame, resulting in a completely different translation compared with the original (27, 28), and these two deletions lead to abnormal stop codons that were distributed in different chromosome. These two novel frameshift mutations led to p.Gln431ArgfsTer2 and p.Thr451AspfsTer6 (29). The advantage of our study is we established the mutations identified were inherited from both parents, who had novel frameshift mutations. The parents were not diagnosed with PHA because the mutation in the *SCNN1B* gene only occurred in one of the homologous chromosome. The other homologous chromosome had a *SCNN1B* gene with normal structure and function; therefore, the parents did not exhibit significant clinical symptoms. However, both of them carried different mutations in the *SCNN1B* gene, and their daughter inherited these mutations.

This case increased our understanding of phenotypes resulting from *SCNN1B* mutations. Our results highlight the need for

increased attention to parents or children with such genotypes in clinical practice.

Niemann–Pick disease is a relatively common lysosomal storage disease. Cholestatic liver disease is a typical clinical phenotype of Niemann–Pick disease in infancy. The diagnosis is traditionally based on Niemann–Pick cells in bone marrow smears or liver biopsies. Treatment for cholestatic liver disease mainly includes ursodeoxycholic acid and liver protection drugs. Here, we reported two cases of Niemann–Pick disease type C, diagnosed by genetic analysis during early infancy. Besides cholestatic jaundice, the two patients also exhibited signs of immune system hyperactivity, such as elevated immunoglobulins or multiple autoantibodies, which might require the application of glucocorticoids. In addition, three novel missense variants of the NPC1 gene were identified. The findings suggest that immune activation should be considered as a “new” clinical phenotype of lysosomal storage diseases.

INTRODUCTION

Lysosomal storage diseases (LSDs) comprise a group of more than 70 distinct genetic diseases. LSDs are characterized by the accumulation of undigested macromolecules in lysosomes of various body cells. Although these disorders are rare, they affect 1 in 5,000 live births, accounting for 14% of all inherited metabolic diseases. LSDs have similar clinical features despite different pathogenetic mechanisms (Rigante et al., 2017; Platt et al., 2018). Niemann–Pick disease is a relatively common autosomal recessive LSD. Clinical manifestations and pathogenic genes are mainly classified into types A, B, and C (Vanier, 2013). Niemann–Pick disease type C (NPC) is a progressive and fatal disorder caused by mutations in the NPC1 (OMIM 257220) or NPC2 (OMIM 607625) gene, which results in the intracellular accumulation of unesterified cholesterol. As cholesterol accumulates in cells, it affects the brain, liver, spleen, and lungs, leading to premature death. The estimated incidence of NPC is 1:100,000, with variable age of onset and clinical features (Vanier, 2010; Patterson et al., 2012; Geberhiwot et al., 2018). Perinatal manifestations of NPC often include splenomegaly, hepatomegaly, fetal ascites, or nonimmune fetal hydrops (Spiegel et al., 2009; Surmeli-Onay et al., 2013). Severe hepatic diseases, associated or not with pulmonary disease, are neonatal manifestations of NPC (Bjurulf et al., 2008; Griesse et al., 2010). In comparison with the adult period, cholestatic liver disease is a typical clinical phenotype in infants. However, some affected infants may also present hypotonia and developmental delay with little hepatic and pulmonary involvement (Vanier et al., 1988). Later in childhood and adulthood, patients can present a

progressive neurodegenerative disorder characterized by developmental delay, clumsiness, cataplexy, supranuclear gaze palsy, ataxia, dystonia, and progressive dementia (Vanier, 2010).

Autoimmune diseases are systemic diseases that affect approximately 5% of the population in western countries. They are characterized by chronic, systemic excessive immune activation and inflammation (Davidson and Diamond, 2001; Xiao et al., 2021). Many studies have reported an association between autoimmune phenomena and LSDs (Rigante et al., 2017). Recently, autoantibodies in NPC have been reported in several studies (Dimitriou et al., 2019; Chu et al., 2021). Herein, we reported two clinical cases of NPC in the form of cholestatic jaundice combined with immune activation in early infancy diagnosed by genetic analysis.

CASE PRESENTATION

Clinical Features

Two independent patients were recruited into this study after the parents signed the informed consent. Both patients presented early-onset jaundice, abnormal liver function, and hepatosplenomegaly, suggestive of cholestatic liver disease. In addition, both patients showed signs of the immune system hyperactivity, such as elevated levels of immunoglobulins.

Patient 1

A female patient (Patient 1) was born at term after an uneventful pregnancy by cesarean delivery, with a birth weight of 3,400 g (50–75th centile). The patient was breastfed and was the first child of a nonconsanguineous Chinese couple. The patient's mother had once miscarried before because of a bad pregnancy outcome. The father is healthy without any known comorbidity. The patient had developed progressive jaundice since the third day after birth. At 1.8 months, the patient was initially admitted to a local hospital, and hepatosplenomegaly was identified. After more than 1 month of conservative medical treatment, the patient developed yellowing of the skin and sclera, which slowly improved, while hepatosplenomegaly progressively worsened. Therefore, the patient was referred to Tongji Hospital at the age of 3.1 months. Malnutrition was documented based on a low body weight (4,400 g, < third centile). Physical examination revealed slight yellowing of the skin, increased respiratory rate, and moist rales of the lungs. The patient's liver was 3.5 cm below the right costal margin, while the spleen was 6.0 cm below the left costal margin.

Laboratory tests showed an elevation in the serum levels of alanine aminotransferase (ALT), aspartate aminotransferase (AST), total bilirubin (TBIL), direct bilirubin (DBIL), indirect bilirubin (IBIL), γ -glutamyl transferase (γ -GT), total bile acid (TBA), globulin (GLB), and alpha-fetoprotein (AFP). Blood routine test results, prothrombin time (PT), activated partial thromboplastin time (APTT), and international normalized ratio (INR) were normal. Blood amino acid spectrum analysis performed by tandem mass spectrometry (MS-MS) and urinary

gas chromatography-mass spectrometry (GC-MS) analysis was unremarkable. Infectious causes were also investigated. Serological markers of hepatotropic viruses, rubella virus, herpes simplex virus, Epstein-Barr virus, human immunodeficiency virus, syphilis, and toxoplasma were negative, but markers for cytomegalovirus and human parvovirus B19 were positive. Notably, immunological evaluation revealed an increased serum level of immunoglobulins tested, including IgA, IgG, and IgM. Antinuclear antibody was positive in the range of 1:3,200; moreover, anti-scl-70 antibody and IgM anticardiolipin antibody were also positive (Table 1).

Abdominal ultrasound revealed hepatosplenomegaly and uneven distribution of echogenic dots, and multiple hyperechoic and hypoechoic masses within the liver parenchyma. The maximum size of the masses was 20 × 12 mm. Subsequent liver magnetic resonance imaging (MRI) showed multiple abnormal signal foci of the liver, suggesting possible fatty infiltration within the liver mass. In addition, echocardiography indicated patent ductus arteriosus, while high-resolution chest computed tomography (CT) showed severe pulmonary infection. A liver biopsy under ultrasonic guidance was performed at the age of 3.3 months. Light microscopy examination of the collected liver tissue showed some vacuolated hepatocytes with positive periodic-acid-Schiff (PAS) staining. In contrast, immunohistochemistry examination indicated that a diagnosis of hepatoblastoma could not be completely excluded because of the limited size of the tissue sample. Electron microscopy revealed intrahepatic cholestasis, giant hepatocytes, and extramedullary hematopoiesis. The collected hepatocytes had a reduced rough endoplasmic reticulum, a fuzzy mitochondrial structure, and lipid deposits. Niemann-Pick cells were not found in the liver. The bone marrow biopsy found no abnormal cells.

The patient was treated with supportive medical treatment, including liver protection drugs, ursodeoxycholic acid (UDCA), supplementary fat-soluble vitamins, and antibiotics. After ruling out contraindications and obtaining informed parental consent, methylprednisolone was started at a low dose (1 mg/kg per day) since the patient had presented the activation of the immune system and severe pulmonary infection at the age of 3.7 months. Subsequently, the patient's clinical symptoms gradually improved. At 4 months, the patient was clinically stable and discharged. Biochemical parameters gradually improved and returned to the standard value (Table 1). At the age of 6.2 months, serum immune globulin also normalized. At the age of 9 months, the serum level of antinuclear antibodies was within a normal range. After the discontinuation of methylprednisolone at 12.4 months, there were no further abnormalities in these indicators. During the 29-month follow-up period, the patient never suffered from jaundice or pneumonia. There were no abnormalities in head MRIs or the Child Development Scale Assessment. The patient was last evaluated at 32 months. The patient's height was 91.5 cm (25–50th centile) and weight was 14.8 kg (50–75th centile). Her liver was 2.0 cm below the xiphoid process but not below the right costal margin, while the spleen was 5.0 cm below the left costal margin. The patient is still under clinical follow-up.

Patient 2

The second patient was also a female and was delivered at term after a protected pregnancy. She was born with a low birth weight of 1,960 g and was breastfed. The patient was the first child of nonconsanguineous and healthy parents of Chinese origin. The father's sister died of acute jaundice hepatitis at the age of 9 years. The patient had developed progressive jaundice since the first day after birth. At the age of 3.2 months, the patient began to develop epistaxis and cough. However, there was no improvement in her clinical symptoms after treatment with drugs for 1 week. At the age of 3.5 months, the patient was admitted to Wuhan Children's Hospital. On physical examination, severe yellowing of the skin and sclera was noticed. In addition, edema in both lower extremities and a few scattered needle-like bleeding spots were observed. The liver was 4.0 cm below the right costal margin, while the spleen was 4.0 cm below the left costal margin.

A biochemical exam revealed elevated AST, TBIL, DBIL, IBIL, alkaline phosphatase (ALP), TBA, and AFP levels. Blood routine test results showed hemoglobin level of 75 g/L (normal

range: 115–150 g/L) and platelet count of $94 \times 10^9/\text{L}$ (normal range: $125\text{--}350 \times 10^9/\text{L}$). The clotting tests revealed PT of 15.9 s (normal range: 10.2–13.4 s), APTT of 63.9 s (normal range: 25.7–39.0 s), and INR of 1.34 (normal range: 0.88–1.16). Tests for infectious causes, including hepatotropic viruses, Epstein-Barr virus, human immunodeficiency virus, and syphilis were all negative, while the test for cytomegalovirus was positive. Serum levels of the tested immunoglobulins were elevated (Table 1). At that time, autoantibodies were not tested because the doctor did not recognize the phenomenon of immune hyperactivity.

Abdominal ultrasound showed hepatomegaly 4.1 cm below the right costal margin, splenomegaly 4.7 cm below the left costal margin, and bilateral inguinal hernia. Echogenic dots were unevenly distributed. There were multiple hyperechoic masses within the liver parenchyma, and the size of the maximum mass was $6 \times 6 \text{ mm}$. Furthermore, no bile duct dysplasia was observed. The chest radiography revealed pulmonary infection. The head CT showed no significant abnormality.

Patient 2 received antibiotics, liver protection drugs, UDCA, and supplementary fat-soluble vitamins. However, jaundice was progressive, and there was no improvement in epistaxis, cough, or edema. After 3 days of medication, her parents gave up and refused further examination and treatment. The patient was referred to Tongji Hospital at the age of 3.9 months. Physical examination showed that her previous symptoms were worsening, and she developed anuria and lethargy. Regrettably, this patient was taken home by her parents after just a genetic test, and the parents refused any other examination and treatment, including bone marrow smears or liver biopsies. A short time later, the patient died at home.

Genetic Analysis

Genomic DNA of the patients and their parents was extracted from peripheral blood samples. Library preparation, custom-designed Medical Exome capture (MES, AmCare Genomic Lab), next-generation sequencing (PE 150Illumina, Inc), data alignment (Human GRCh37/hg19 assembly), and family genetic analyses were performed by in-house pipelines, with details described in previous studies (Wang et al., 2019; Li et al., 2020). Genetic diagnosis was confirmed for these two patients suspected of having NPC, and three novel missense variants (c.2816C > T, c.3749A > C, c.1820G > T) of the NPC1 gene were identified. Patient 1 carries compound heterozygous missense

TABLE 2 | Summary of NPC1 variants reported in this study.

Patient	cDNA	Protein	Chromosome position	Domain	Inheritance	gnomAD	Polyphen-2_HDIV Polyphen-2_HVAR	SIFT	PROVEAN	GERP++	Revel	ACMG
1	c.2816C > T	p.Pro939Leu	18:21,119,414	CTD	maternal	-	Possibly damaging	D	D	Conserved	D	VUS (PM2, PP3)
	c.3749A > C	p.Tyr1250Ser	18:21,113,324	C-terminal	paternal	-	Benign Probably damaging	D	D	Conserved	D	VUS (PM2, PP3)
2	c.3229C > T	p.Arg1077*	18:21,116,653	CTD	paternal	3.98*10 ⁻⁶	-	-	-	Conserved	-	LP (PVS1, PM2)
	c.1820G > T	p.Arg607Leu	18:21,125,051	MLD	maternal	-	Probably damaging	D	D	Conserved	D	VUS (PM2, PM3, PP3)

NM_000,271.5 for cDNA, and NP_000,262.2 for protein sequence. CTD, C-terminal domain; MLD, Middle luminal Domain; D, Damaging; VUS, variant of uncertain significance; LP, Likely pathogenic

cholesterol transferred by NPC2. The middle luminal domain (MLD) is also involved in the binding process. C-terminal domain (CTD) interacts with NTD to keep it in the proper orientation for receiving cholesterol during the export process (Cologna and Rosenhouse-Dantsker, 2019; Elghobashi-Meinhardt, 2020). Three novel variants reported in this study are located in highly conserved regions related to CTD and MLD, indicating their potential roles in maintaining the NPC1 protein function. Although the p.Pro939Leu carried by Patient 1 has not previously been reported, there are several other known pathogenic variants nearby (p.Ser940Leu, p.Asp948Asn, p.Val950Met), which indicates the importance of this region (Park et al., 2003; Skorpen et al., 2012; Abela et al., 2014; Reunert et al., 2016; Pipalia et al., 2017). The variant p.Tyr1250Ser is located downstream of CTD. There are also quite a few variants reported in this C-terminal region, such as p.Val1212Leu, p.Leu1213Phe, and p.Ser1249Gly (Yamamoto et al., 1999; Garver et al., 2010; Xiong et al., 2012), indicating that there may be a specific function of the C-terminal region. However, a further functional study is necessary to better understand the mechanism by which these variants affect the NPC1 function and/or structure.

Lysosome, a subcellular organelle responsible for digestion and recycling of different macromolecules, is necessary for many cellular processes (Ballabio and Bonifacio, 2020). Therefore, it is not surprising that LSDs can display different impairments in immune responses, such as inflammation, disrupted autophagy, and autoimmunity (Rigante et al., 2017). Nevertheless, it is uncertain whether an altered immune response directly contributes to pathogenesis in LSDs. LSDs can largely be divided into two categories, where some diseases are predisposed to immunosuppression, while others are prone to immune system hyperactivity (Castaneda et al., 2008). Gaucher disease (GD), the most common LSD, is associated with immunoglobulin abnormalities (Nguyen et al., 2020). Shoenfeld *et al.* analyzed the sera of 43 patients with GD to study the presence of autoantibodies against 14 autoantigens. The immunization of naive mice with a pool of purified anti-DNA antibodies from GD patients did not result in the induction of any experimental manifestation of systemic lupus erythematosus, suggesting that these autoantibodies were nonpathogenic (Shoenfeld et al., 1995). Also, a high incidence of autoantibodies or autoimmune disorders has been reported in patients with Fabry disease (Faggiano et al., 2006; Martinez et al., 2007; Katsumata et al., 2011). The phenomenon of neuroimmune responses in Niemann–Pick disease has been widely reported, concerning mainly inappropriate microglia activation (Ledesma et al., 2011; Pressey et al., 2012; Platt et al., 2016). Sideris *et al.* showed that Niemann–Pick disease type B could coexist with autoimmune pulmonary alveolar proteinosis in an 8-year-old girl (Sideris and Josephson, 2016). Recent studies have reported the rare association of Niemann–Pick disease type B and systemic lupus erythematosus in adult cases (Murgia et al., 2015; Baya et al., 2020). Furthermore, NPC has also been linked to inflammatory bowel disease (Jolliffe and Sarkany, 1983; Steven and Driver, 2005; Schwerd et al., 2017; Dike et al., 2019).

The clinical cases presented in this study are unique since the patients did not have any typical neurological symptoms at diagnosis but showed immune system hyperactivity in early infancy. In both patients, elevated immunoglobulins were noticed. In addition, there were multiple autoantibodies in the first patient. We excluded other possible factors that may cause immune activation. Before the immunoglobulin blood test, none of the patients were treated with any medications (e.g., gamma globulin) that may have affected the immune system. The first patient's mother was examined. There were no abnormalities in her immune function or symptoms of rheumatism, which ruled out the possibility of maternal antibody transmission through the placenta. However, we do not know whether the child may develop a secondary autoimmune disease, such as systemic lupus erythematosus, in the future.

NPC has no disease-specific treatment to modify the onset of neurologic progression or prolong lifespan. The disease usually progresses to premature death. Therefore, before the onset of neurological symptoms, treatment is essentially palliative and aims at alleviating specific symptoms (Geberhiwot et al., 2018; Matencio et al., 2020). The two infants included in this study mainly presented with cholestatic liver disease, which was treated with symptomatic support. In addition, given the presence of severe pneumonia and activation of immunity in the first patient, methylprednisolone, a common immunosuppressant drug, was used, and produced a good response. It indicates that methylprednisolone effectively treated the patient's immune system irregularities. However, we do not know yet whether this treatment would be suitable for other similar cases. Indeed, the limitation of our study is that it is difficult to draw any wider conclusions regarding these findings.

In conclusion, this study reported two unique cases that presented the typical clinical features of infantile NPC and immune system hyperactivity. Genetic analysis of these patients further confirmed the diagnosis of NPC, and three novel NPC1 variants were identified by exome sequencing. Our findings suggest that recognizing immune activation in LSDs is essential, and expand both the clinical phenotype and genetic mutation spectrum of NPC1.

DATA AVAILABILITY STATEMENT

The datasets for this article are not publicly available due to concerns regarding participant/patient anonymity. Requests to access the datasets should be directed to the corresponding authors.

ETHICS STATEMENT

The studies involving human participants were reviewed and approved by Medical Ethics Committee of Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology. Written informed consent to participate in this study was provided by the participants' legal guardian/next of kin.

AUTHOR CONTRIBUTIONS

FC organized the database and drafted the manuscript. SG performed data collection. SL, XL, HX, and ZH checked the data. LW and VZ carried out the genetic analyses. YY and SS followed up the patients. SS conceptualized and designed the study, and critically reviewed the manuscript. All authors

contributed to manuscript revision, and read and approved the submitted version.

ACKNOWLEDGMENTS

We thank all the research subjects for their support and cooperation.

(2022) Newborn Screening for
Mitochondrial Carnitine-Acylcarnitine
Cycle Disorders in Zhejiang
Province, China.
Front. Genet. 13:823687.
doi: 10.3389/fgene.2022.823687

Background: Disorders of mitochondrial carnitine-acylcarnitine cycle is a heterogeneous group of hereditary diseases of mitochondrial β -oxidation of fatty acids tested in NBS program in Zhejiang province, China. Large-scale studies reporting disorders of mitochondrial carnitine-acylcarnitine cycle among Chinese population in NBS are limited. The aim of this study was to explain the incidence and biochemical, clinical, and genetic characteristics of disorders of mitochondrial carnitine-acylcarnitine cycle in NBS.

Methods: From January 2009 to June 2021, 4,070,375 newborns were screened by tandem mass spectrometry. Newborns with elevated C0 levels and/or C0/(C16 + C18) ratios were identified as having CPT1D, whereas those with decreased C0 levels and/or C0/(C16 + C18) ratios and/or elevated C12-C18:1 level were identified as having CPT2D or CACTD. Suspected positive patients were further subjected to genetic analysis. All confirmed patients received biochemical and nutritional treatment, as well as follow-up sessions.

Results: Overall, 20 patients (12 with CPT1D, 4 with CPT2D, and 4 with CACTD) with disorders of mitochondrial carnitine-acylcarnitine cycle were diagnosed by NBS. The overall incidence of these disorders was one in 203,518 newborns. In total, 11 patients with CPT1D exhibited increased C0 levels and C0/(C16 + C18) ratios. In all patients of CPT2D, all long chain acyl-carnitines levels were elevated except for case 14 having normal C12 levels. In all patients with CACTD, all long chain acyl-carnitines levels were elevated except for case 17 having normal C12, C18, and C18:1 levels. Most patients with CPT1D were asymptomatic. Overall, two of 4 patients with CPT2D did not present any clinical symptom, but other two patients died. In 4 cases with CACTD, the disease was onset after birth, and

Abbreviations: CPT1, carnitine palmitoyltransferase 1; CPT2, carnitine palmitoyltransferase 2; CACT, carnitine-acylcarnitine translocase; CPT1D, carnitine palmitoyltransferase 1 deficiency; CPT2D, carnitine palmitoyltransferase 2 deficiency; CACTD, carnitine-acylcarnitine translocase deficiency; NBS, newborn screening; C0, free carnitine; C2, Acetylcarnitine; C3, Propionylcarnitine; C4, Butyrylcarnitine; C12, Lauroylcarnitine; C14, Myristoylcarnitine; C16, Palmitoylcarnitine; C16:1, Palmitoylcarnitine; C18, Octadecanoylcarnitine; C18:1, Oleoylcarnitine; MS/MS, tandem mass spectrometry; DBS, dried blood spot; NGS, next-generation sequencing; PCR, Polymerase chain reaction-restriction.

75% patients died. In total, 14 distinct mutations were identified in CPT1A gene, of which 11 were novel and c.1910C > A (p.S637T), c.740C > T (p.P247L), and c.1328T > C (p.L443P) were the most common mutations. Overall, 3 novel mutations were identified in CPT2 gene, and the most frequent mutation was c.1711C > A (p.P571T). The most common variant in SLC25A20 gene was c.199-10T > G.

Conclusion: Disorders of mitochondrial carnitine–acylcarnitine cycle can be detected by NBS, and the combined incidence of these disorders in newborns was rare in Zhejiang province, China. Most patients presented typical acylcarnitine profiles. Most patients with CPT1D presented normal growth and development, whereas those with CPT2D/CACTD exhibited a high mortality rate. Several novel CPT1A and CPT2 variants were identified, which expanded the variant spectrum.

Keywords: mitochondrial carnitine–acylcarnitine cycle disorders, carnitine palmitoyl transferase 2 deficiency, carnitine palmitoyltransferase 2 deficiency, carnitine–acylcarnitine translocase deficiency, newborn screening

INTRODUCTION

Carnitine cycle is essential for transporting long-chain fatty acids into the mitochondrial matrix for β -oxidation (Watkins et al., 2007). Mitochondrial carnitine–acylcarnitine cycle is an important component of carnitine cycle, which consists of carnitine palmitoyl-transferases 1 (CPT1), carnitine palmitoyl-transferases 2 (CPT2), and the transporter protein carnitine–acylcarnitine translocase (CACT), which can uptake fatty acyl-CoAs across the mitochondrial membrane (Lodhi and Semenkovich, 2014). First, CPT1 located on the outer mitochondrial membrane converts the long-chain acyl-CoAs to their acylcarnitine equivalents. Further, acyl-carnitines are transported into the mitochondrial matrix by CACT. In the end, acyl-carnitine is converted back to the acyl-CoA species and carnitine by CPT2 associated with the inner mitochondrial membrane (McGarry and Brown, 1997). CPT1 deficiency (CPT1D), CPT2 deficiency (CPT2D), and CACT deficiency (CACTD) are rare autosomal inherited recessive disorders, and the causative genes are CPT1A, CPT2, and SLC25A20, respectively (Wieser et al., 2003; Collins et al., 2010; Indiveri et al., 2011). Differences in the age of onset and clinical manifestations were observed in these disorders (Houten and Wanders, 2010). Late onset forms may present muscular symptoms such as myalgia, myoglobinuria, and muscle weakness during adolescence or adulthood. The condition can be triggered by fasting, illnesses, or high energy demand resulting in hypoketotic hypoglycaemia, hepatomegaly, cardiomyopathy, liver dysfunction, seizures, and sudden death at an early age. Disorders of mitochondrial carnitine–acylcarnitine cycle present different mortality and morbidity rates. In particular, CACTD was characterised with high mortality (Baruteau et al., 2014; Houten et al., 2016). Early detection and medical interventions can prevent individuals from metabolic decompensation and improve prognosis (Maguolo et al., 2020).

Infants with these diseases presented characteristic acylcarnitine profile are detectable by using tandem mass spectrometry (MS/MS), which has been widely implemented in NBS. With the application of MS/MS, the diagnosis of these

disorders through newborn screening has become easier (Wilcken et al., 2003). The combined incidence of disorders of mitochondrial carnitine–acylcarnitine cycle was thought to be rare, which is estimated to be 1:186,833 in mainland China, 1:250,000 to 1:666,667 in Australia, Germany, and <1:189,136 in the United States (Lindner et al., 2010; Deng et al., 2020). Disorders of mitochondrial carnitine–acylcarnitine cycle have great phenotypic variability and molecular heterogeneity. Herein, we present our over 12-years experience of NBS for the diagnosis and treatment of disorders of mitochondrial carnitine–acylcarnitine cycle in Zhejiang Province, China. The aim of this study was to determine the incidence and biochemical, clinical, and genetic characteristics of these disorders by NBS. With this study, the awareness about these rare disorders can be improved, and further implications of treatment can be considered.

MATERIALS AND METHODS

Study Population

From January 2009 to June 2021, 4,070,375 newborns were screened by MS/MS at Children's Hospital, Zhejiang University School of Medicine. Among 4,070,375 participants who were recruited in this study, 3,784,837 were normal-term infants, 276,482 were premature infants, and 9,056 were post-term infants. The ratio of male to female was 1.1:1. The Ethical Committee of Children's Hospital, Zhejiang University School of Medicine approved this research. The information sheet with consent information containing the explanation on the aim of this study was sent to participants and their parents and was signed by participants' parents.

NBS for Disorders of Mitochondrial Carnitine–Acylcarnitine Cycle

Dried blood spot (DBS) samples were randomly collected between 3 and 7 days after birth and delivered through cold-chain transportation to the NBS centre of Children's Hospital,

Zhejiang University School of Medicine within 3 days. Acylcarnitine profiles were assessed at our centre using NeoBase™ MS/MS reagent kits (PekinElmer, United States) according to the manufacturers' protocol. Newborns with elevated C0 levels and/or C0/(C16 + C18) ratios were identified to have CPT1D. Newborns with decreased C0 levels and/or C0/(C16 + C18) ratios and/or elevated C12-C18:1 level were identified to have CPT2D or CACTD. Newborns were subjected to further confirmatory tests if the initial screening value exceeded the diagnostic cut-off. Newborns were subjected to a repeated test if the initial screening value was equal to or exceeding the screening cut-off. If the second screening results were still positive, confirmatory detection tests were performed, including biochemical laboratory tests and genetic analysis.

Genetic Testing

Genomic DNA was extracted from patients. Genetic testing was performed by Genetic Diagnostic Laboratory at Children's Hospital, Zhejiang University School of Medicine (Hangzhou, Zhejiang, China). The target next-generation sequencing (NGS) was used on the probands with a target sequencing panel covering 306 known genes associated with inherited metabolic disorders. All potentially pathogenic mutations identified by NGS were further confirmed via Sanger sequencing. PolyPhen-2, PROVEAN, and Mutation Taster were used to predict the pathogenicity of the missense variants. The Structure stability analysis of novel missense variants were performed by Chimera version 1.15. The protein PDB number was entered in the Chimera software, and the three-level structure of protein was obtained. We selected the amino acid sequence and optimised the structure to find out whether the mutant amino acid triggers the atoms clash and contact. The three-dimensional structure of the protein was constructed after mutation, and the effect of mutation on protein stability was analysed.

Diagnosis and Follow-Up

Diagnosis was assessed by metabolic disease specialists based on the patients' free carnitine and acylcarnitine levels, genetic variations, as well as additional clinical symptoms. All confirmed patients were followed up in our hospital. Dietary guidance including more frequent feeding, avoiding fasting, limiting fat intake, and appropriate supplementation of L-carnitine were applied for the confirmed patients. The follow-up time was once every 3–6 months if the confirmed patients presented stable performances. Patients were regarded as lost to follow-up if the follow-up time exceeded over 3 months and the patient still did not return to the clinical centre. The monitoring items included physical and biochemical examinations; levels of free carnitine and acylcarnitine, blood glucose, lactic acid, and blood ammonia; and blood routine test.

RESULTS

Incidences Determined From NBS

In this study, 4,070,375 newborns were screened and 20 patients (12 with CPT1D, 4 with CPT2D, and 4 with CACTD) were

identified, with a total incidence of one in 203,518 live births. The incidence of CPT1D, CPT2D, and CACTD was 1:339,197, 1:1,017,593, 1:1,017,593, respectively. Among all the disorders of mitochondrial carnitine–acylcarnitine cycle, CPT1D was the most prevalent. There were two pairs of monozygotic twins among patients with CPT1D.

Initial Screening Results of Acylcarnitine Levels

Overall, 11 patients (91.7%) with CPT1D had increased C0 levels and C0/(C16 + C18) ratios. C0 levels and C0/(C16 + C18) ratios of case 12 were normal in initial screening accompanied with lower C12-C18:1 level. In these patients, the average C0 level was $125.1 \pm 61.68 \mu\text{mol/L}$ (range: 14.84–240.28 $\mu\text{mol/L}$) and C0/(C16 + C18) was 206.3 ± 278.5 (range: 25.59–1,007.27).

Overall, two of 4 patients with CPT2D had low C0 levels, and those of other two patients were normal. All long chain acylcarnitines levels were elevated except in case 14 with normal C12 levels. The C14, C16, C16:1, C18, and C18:1 levels were 1.59 ± 0.25 , 19.36 ± 2.33 , 1.69 ± 0.18 , 4.28 ± 0.74 , and $6.67 \pm 0.89 \mu\text{mol/L}$, respectively. The ratios of long-chain acylcarnitines to C0 were decreased and those to C2 and C3 were increased in all cases (C16 + C18:1)/C2, C14/C3, C16/C3, C16:1/C3, C18/C3, C18:1/C3, (C16 + C18:1)/C3, and C0/(C16 + C18) were, 3.6 ± 2.7 , 8.2 ± 2.55 , 89.36 ± 53.08 , 8.39 ± 5.25 , 23.89 ± 14.61 , 33.41 ± 21.43 , 122.8 ± 73.72 , and 0.51 ± 0.29 , respectively.

In total, three patients with CACTD had decreased C0 levels. ALL C0/(C16+C18) ratios were decreased. All long-chain acylcarnitines levels were elevated except in case 17 with normal C12, C18, and C18:1 levels. The C14, C16, and C16:1 levels were 1.33 ± 0.54 , 18.97 ± 8.5 , and $1.5 \pm 0.7 \mu\text{mol/L}$, respectively. All the ratios of long-chain acylcarnitines to C2 and C3 were increased except in case 17 with normal C18/C3 level. The (C16 + C18:1)/C2, C14/C3, C16/C3, C16:1/C3, C18/C3, C18:1/C3, (C16 + C18:1)/C3, and C0/(C16 + C18) were 2.84 ± 1.71 , 1.43 ± 0.45 , 20.52 ± 7.99 , 1.63 ± 0.51 , 3.57 ± 1.72 , 6.42 ± 4.09 , 26.9 ± 11.33 , and 0.38 ± 0.13 , respectively.

C14/C3, C16/C3, C16:1/C3, C18/C3, C18:1/C3, and (C16 + C18:1)/C3 ratios were higher in patients with CPT2D when compared with those with CACTD. The differences were statistically significant ($p = 0.038$, 0.042 , 0.042 , 0.032 , 0.048 , and 0.042 , respectively) (Table 1).

Initial Clinical Manifestations

The follow-up period of these patients lasted from 7 days to 4 years. Among 12 patients with CPT1D, 10 patients were asymptomatic. Case 2 presented clinical symptoms after birth, including hyperammonaemia and metabolic acidosis and passed away at 18 days-point. Follow-up data of case 1 were not available.

Patients 13 to 16 were identified as having CPT2D. Patient 13 died suddenly at 8 months at home with no available data. Patient 14 presented with poor feeding, poor response, and hypoglycaemia. Her condition deteriorated rapidly, and she died at 10 days after birth. No clinical symptoms were found in patients 15 and 16; however, patient 15 had incomplete right

bundle branch block in ECG, and patient 16 presented transient increase in alanine aminotransferase (ALT; 102 U/L) level.

Patients 17 to 20 were identified to have CACTD. All the patients had disease onset after birth. They presented feeding dysfunction, poor response, hypoglycaemia [1.9–3.2 mmol/L (normal range 3.6–6.1 mmol/L)], acidosis [1.8–17 mmol/L (normal range 0.5–1.6 mmol/L)], and hyperammonaemia [52–226 $\mu\text{mol/L}$ (normal range 9–30 $\mu\text{mol/L}$)]. After diet management, L-carnitine supplementation, and acidosis correction, the clinical presentations and biochemical results of case 17 became normal, and the data were good after 15-months follow-up. case 18 developed hepatic impairment, hepatomegaly, and cardiac hypertrophy; further, the parents stopped the treatment, and the infant died at the age of 2 months. The condition of cases 19 and 20 deteriorated rapidly, and they died at 7 days after birth (Table 2).

Genetic Findings

A total of 14 distinct mutations were identified in CPT1A gene; 85.72% (12/14) were missense, 7.14% (1/14) were deletion, and 7.14% (1/14) were splicing variants. Overall, 11 of these CPT1A variants were novel, and the other three were previously reported. The most frequent mutation was c.1910C > A (p.S637T), with an

allelic frequency of 16.67% (4/24). The relatively frequent mutations were c.740C > T (p.P247L) and c.1328T > C (p.L443P), and each of mutation was identified three times, with an allelic frequency of 12.5% (3/24). c.2125G > A (p.G709R) and c.1295C > T (p.P432L) were each identified twice. The remaining six mutations were identified only once.

A total of six distinct mutations were identified in CPT2 gene. Among which, 83.33% (4/6) were missense, and 16.67% (2/6) were frameshift variants. Overall, three of these CPT2 variants were novel. The most frequent mutation was c.1711C > A (p.P571T), with an allelic frequency of 37.5% (3/8). Each of the remaining five mutations were identified only once.

There were 4 distinct mutations in the SLC25A20 gene. All the mutations were previously reported. The most common variant was c.199-10T > G, which accounted for 62.6% (5/8). Each of the remaining three mutations was identified only once.

For all these novel missense variants, all were predicted to be potentially pathogenic by Polyphen-2, PROVEAN, and the MutationTaster predictor (Table 3). Structure stability analysis was performed using Chimera version 1.15. Atoms clash and contacts decreased structure stability. c.740C > T (p.P247L), c.1328T > C (p.L443P), c.1817G > A (p.R606H), c.1910C > A (p.S637T), c.2246G > A, (p.A749H). c.205G > A (p.V69M),

c.2125G > A (p.G709R), and (p.P432L). c.1054T > C (p.F352L) might cause 5, 5, 3, 1, 3, 7, 37, and one atom clash and contacts, respectively. No atom clash and contacts were caused by c.1295C > T (p.P432L), c.979C > T (p.H327T), and c.1131G > C (p.G377A). Atoms clash and contact are shown in yellow lines in **Figure 1**.

DISCUSSION

In this study, 20 patients with disorders of mitochondrial carnitine–acylcarnitine cycle were identified (12 with CPT1D, 4 with CPT2D, and 4 with CACTD) in approximately 4 million newborns in Zhejiang province, China between 2009 and 2021. The data revealed the largest series of cases with disorders of mitochondrial carnitine–acylcarnitine cycle detected by NBS in the Chinese Population. The incidence of newborns with disorders of mitochondrial carnitine–acylcarnitine cycle was 1:203,518 (CPT1D: 1:339,197; CPT2D: 1:1,017,593; and CACTD: 1:1,017,593) in Zhejiang province. CPT1D was the most common disorder of mitochondrial carnitine–acylcarnitine cycle. The incidence of these disorders in Taiwan was 1:263,523 (CPT1D: 1:790,567 and CPT2D/CACTD: 1:395,283) according to NBS

data in 2013 (Chien et al., 2013). Data from the largest nationwide cross-sectional study illustrated that the total incidence in mainland China was 1:236,655 (CPT1D: 1:546,128, CPT2D: 1:1,014,237, and CACTD: 1:709,996) (Deng et al., 2020). Incidence of these disorders in Australia, Germany, and the United States was 1:250,000 to 1:666,667 (Lindner et al., 2010). Disorders of mitochondrial carnitine–acylcarnitine cycle seem to be rare diseases in general population. The incidence of these disorders, especially that of CPT1D, in Zhejiang province seems to be higher than that reported in previous studies. This difference may be due to the awareness of these disorders, ethnic backgrounds, different cut-off values, recall criteria, and development of diagnostic methods. Previous reports revealed that these disorders may present normal acyl-carnitine levels at birth, resulting in false-negative cases (Dowsett et al., 2017). Case 12 with CPT1D was overlooked at the initial screening. Hence, the actual incidence may be higher than the reported data. A looser cut-off value can decrease false-negative cases but increase the false-positive cases. To handle these issues, a previous report revealed that they have developed second-tier molecular tests for these diseases (Lin et al., 2020).

NBS plays an important role in the early detection of deficiency in enzymes of mitochondrial carnitine–acylcarnitine

Reference sequence for CPT1A, CPT2, SLC25A20 are NM_001876.3, NM_000098.2, NM_000098.3 respectively. The previously unreported novel variants of this study are in boldface type. N/A: not available. PolyPhen-2: <http://genetics.bwh.harvard.edu/pph2/>, HVAR score ranges from 0 (neutral, N) to 1 (damaging, D), B: benign. PROVEAN: <http://provean.jcvi.org/index.php>, score ranges from ≤ -2.5 (deleterious, D) to > -2.5 (neutral, N). Mutation Taster: <http://www.mutationtaster.org/>, a score close to one indicates a high "security" of the prediction (P: polymorphism, D: disease causing).

Novel mutations are in boldface type.

cycle (Wilcken et al., 2003). Most patients with CPT1D presented increased C0 levels and C0/(C16 + C18) ratios and/or decreased long-chain acyl-carnitines levels. For instance, patient 12 with normal C0 levels and C0/(C16 + C18) ratios was overlooked at the initial screening and exhibited slight reduction of C12 to C18:1 level. Milder forms of CPT1D may present normal C0 levels and C0/(C16 + C18) ratios or slight changes can easily be missed by NBS (de Sain-van der Velden et al., 2013; Dowsett et al., 2017). Combining a lower C18:1 level with higher C0/(C16 + C18) ratios in plasma and high sensitivity and specificity for CPT1D could be found in a previous study (Heiner-Fokkema et al., 2017). The reduction in C18:1 level might be an important inducer of CPT1D, which is consistent with a previous study which reported nine patients with a low C18:1 level. The number of patients with low C18:1 level was more than that with low C12 to C16:1 level. Increased C12–C18:1 level (particularly C16 and C18:1) and/or decreased C0, C2 levels were the major characteristics in CACTD and CPT2D. Some patients had normal

concentrations of C12, C14, C16, C18, and C18:1. Elevation of (C16 + C18:1)/C2 ratios could reduce the false negative rate and improve the sensitivity (Sigauke et al., 2003; Edmondson et al., 2017; Tajima et al., 2017; Tang et al., 2019). However, this ratio sometimes may be normal (de Sain-van der Velden et al., 2013; Edmondson et al., 2017). The ratio of several long-chain acyl-carnitines to C3 like C14/C3, C16/C3, C18/C3, and (C16 + C18:1)/C3 can be used as better indices for CPT2D screening (Edmondson et al., 2017). In this study, it was observed that C14/C3, C16/C3, C16:1/C3, C18:1/C3, and (C16 + C18:1)/C3 ratios were increased in all patients with CACTD and CPT2D, which were significantly higher in CPT2D; this might be considered to distinguish between these two similar diseases. The results might be caused by very low concentrations of C3 levels in patients with CPT2D.

Patients with CPT1AD presented normal growth and development following a strict diet management and follow-up (Gan et al., 2021). CPT1D can be triggered by fasting or illnesses

and presented with hypoketotic hypoglycaemic episodes and hepatomegaly in the early period of life; few cases may die in neonatal period (Baruteau et al., 2014; Fohner et al., 2017). Several cases with mild cardiomegaly, heartbeat disorders, or distal renal tubular acidosis have been reported (Olpin et al., 2001; Yu et al., 2021). Most patients with CPT1D had no clinic symptoms and only one case presented with hyperammonaemia and metabolic acidosis and died in the early neonatal period. Additionally, data suggested that early diagnosis and proper treatment resulted in good prognosis in patients with CPT1D. It remains to be observed whether patients with CPT1D will present further clinical symptoms. Overall, three different phenotypes of CPT2D have myopathic, lethal neonatal, and severe infantile forms. The most common form of CPT2D is the myopathic form, and the symptoms in 70% cases of this form were presented during 0–12 years of ages. The most common clinical symptoms were

myalgia, myoglobinuria, and muscle weakness triggered by exercise and infection (Joshi et al., 2014; Joshi and Zierz, 2020). The severe infantile forms always presented hypoketotic hypoglycaemia, hepatomegaly, metabolic acidosis, cardiac manifestations, weakness, seizures, and sudden death (Sigauke et al., 2003). The lethal neonatal form is fatal, which causes death during the neonatal period (Isackson et al., 2008; Du et al., 2017). Overall, 4 CPT2D cases were detected in this study. One lethal neonatal form (patient 14) presented metabolic acidosis and hypoketotic hypoglycaemia and died soon in the neonatal period. One severe infantile form (patient 13) presented sudden death at 8 months at home without any available data. The two remaining cases (patients 15 and 16) were asymptomatic along with incomplete right and transient elevation of ALT, respectively. Critically ill patients with CACTD presented a severe phenotype in the neonatal time, including rapidly progressive condition and

a high fatality rate (Chen et al., 2020). Late onset form has been less common (Morris et al., 1998). In this study, the 4 cases with CACTD presented feeding dysfunction, poor response, hypoglycaemia, metabolic acidosis, hepatic impairment, hepatomegaly, and cardiac hypertrophy. In addition, two patients died in the early neonatal period, and 1 case died at 2 months after birth. Patient 17 survived. Although CACT deficiency diagnosed via NBS had a surely high mortality rate, early detection and treatment may save lives.

In general, more than 30 CPT1A pathogenic mutations have been reported (Tsuburaya et al., 2010; Gan et al., 2021). c.1436C > T (p.P479L) was the common mutation in northern Canada, Greenland, Colombia, and the native Alaskan population (Park et al., 2006). Moreover, c.2129G > A (p.G710E) was mainly detected in the US Alaskan and Hutterite populations, and a homozygous mutation might lead to severe clinical manifestations (Prasad et al., 2001; Prip-Buus et al., 2001). Hotspot mutations with CPT1D in the Chinese population have not yet been reported. c.1910C > A (p.S637T), c.740C > T (p.P247L), and c.1328T > C (p.L443P) presented highest occurring mutations in this study and might be the potential hotspot variants in Zhejiang province of South China.

Seventy pathogenic variants in CPT2 gene were reported and phenotype-genotype association was observed in CPT2D (Joshi et al., 2014). c.680C > T (p.P227L), c.1923_1935del, and c.983A > G (p.D328G) were thought to be correlated with lethal neonatal and severe infantile forms and generally not detected in patients with myopathic forms (Isackson et al., 2006; Isackson et al., 2008). Furthermore, the c.338C > T (p.S113L) mutation was detected in almost 70% patients with myopathic forms (Joshi et al., 2014; Fontaine et al., 2018). The c.338C > T (p.S113L) compound heterozygous patients were easily triggered by low temperature compared with c.338C > T (p.S113L) homozygous patients. Patients with truncating mutations were significantly easily triggered by fasting compared with those with missense mutations on both two alleles. The c.338C > T (p.S113L) mutation of CPT2 is a common variant in the Caucasian population, whereas c.1148T > A (p.F383Y) mutation is common in Japanese population (Yasuno et al., 2008). According to dataset, the most frequent mutation was c.1711C > A (p.P571T), which was previously reported in the northern China and might be the potential hotspot of CPT2D in Chinese population (Qian et al., 2017).

More than 40 SLC25A20 pathogenic mutations have been identified (Yan et al., 2017). Phenotype-genotype association in CACTD have been reported previously. The c.241G > A (G81R) mutation was associated with severe phenotype, whereas the c.955insC mutation was associated with a milder form in the Netherlands (IJlst et al., 2001). c.199-10T > G mutation was the most common in East Asia, which accounted for 83% of the variant alleles in Chinese population (Tang et al., 2019; Chen et al., 2020). The homozygous c.199-10T > G mutation was correlated with lethal neonatal form in Asian cases; two cases with homozygous c.199-10T > G mutation in our study were died early. c.199-10T > G mutation may cause premature protein truncation and translocate enzyme without activity which may explain the severe genotype of c.199-10T > G mutation (Hsu

et al., 2001). A compound heterozygous case with c.199-10T > G and c.1A > G (p.M1V) mutation died at 6 days after birth (Yan et al., 2017), whereas a case in our study with the same mutation survived. Early timely treatment is crucial for CACTD and may reverse the metabolic decompensation. This good prognosis of our case might have benefitted from early detection and early management after NBS.

This study identified 11 novel CPT1A variants and 3 novel CPT2 variants. Deletion (c.577delC (p.M194*)) and frameshift variants (c.988dupT (p.I332Hfs*2) and c.895-896insGGGCAGAGCTC (p.R303Gfs*6)) would result in truncated proteins which would potentially affect protein function. All novel missense variants were predicted as possibly pathogenic by bioinformatics analysis. We further predicted structure stability analysis of novel missense mutations. In addition to c.1295C > T (p.P432L), c.979C > T (p.H327T), and c.1131G > C (p.G377A), all missense variants might cause atom clash and contacts and decreased structure stability of protein resulting in a loss-of-function effect. Nevertheless, the pathogenicity of all these novel variants needs to be confirmed by further functional investigations.

CONCLUSION

In conclusion, disorders of mitochondrial carnitine-acylcarnitine cycle, with a rare combined incidence among newborns, were detected through NBS in Zhejiang, China. Most of the patients presented different typical acylcarnitine profiles. To be more specific, most patients with CPT1D presented normal growth and development, whereas those with CPT2D/CACTD had a high mortality rate. Overall, 11 novel CPT1A variants and 3 novel CPT2 variants were identified, which further expanded the mutational spectrum. All novel missense variants were predicted as possibly pathogenic by bioinformatics analysis. This study may help in enhancing overall awareness of disorders of mitochondrial carnitine-acylcarnitine cycle through clarifying the signification of early diagnosis and proper treatment on the prevention and recovery of patients.

DATA AVAILABILITY STATEMENT

The data presented in the study are deposited in the Figshare. The accession numbers were 10.6084/m9.figshare.18392345 and 10.6084/m9.figshare.18392426.

AUTHOR CONTRIBUTIONS

DZ performed the data analysis, drafted the initial manuscript, reviewed and revised the manuscript; YC assisted with data collection; XY revised the manuscript; ZH, JY, a followed the patients and collected the clinical data; HM, YZ performed the genetic tests, variats analysis; XH, BW designed and supervised

the study. All authors approved the final manuscript for submission and publication. These authors contributed equally to this work.

Congenital muscular dystrophy with early rigid spine, also known as the rigid spine with muscular dystrophy type 1 (RSMD1), is caused by *SEPN1* mutation. We investigated the clinical manifestations, pathological features, and genetic characteristics of 8 Chinese RSMD1 patients in order to improve diagnosis and management of the disease. Eight patients presented with delayed motor development, muscle weakness, hypotonia, and a myopathic face with high palatine arches. All patients could walk independently, though with poor running and jumping, and most had a rigid spine, lordosis, or scoliosis. The symptoms of respiratory involvement were present early, and upper respiratory tract infections and pneumonia often occurred. Five patients had severe pneumonia, pulmonary hypertension, and respiratory failure. Lung function tests showed variable restrictive ventilation dysfunction. Polysomnography suggested hypoxia and hypoventilation. The serum creatine kinase (CK) level was normal or mildly increased. Muscle biopsy indicated chronic myopathic changes and minicores. Muscle magnetic resonance imaging (MRI) showed diffuse fatty infiltration of the gluteus maximus and thigh muscle. *SEPN1* gene analysis revealed 16 compound heterozygous variants, 81.3% of which are unreported, including 7 exon 1 variants. Our study expands the spectrum of clinical and genetic findings in RSMD1 to improve diagnosis, management, and standards of care. *SEPN1* mutations in exon 1 are common and easily missed, and exon 1 should be carefully analyzed when RSMD1 is suspected, which will provide valuable genetic counseling for the family and useful information for future natural history studies and clinical trials.

Keywords: congenital muscular dystrophy with spinal rigidity, rigid spine with muscular dystrophy type 1, respiratory insufficiency, *SEPN1* gene, selenoprotein N

INTRODUCTION

Congenital muscular dystrophy with early rigid spine, also known as the rigid spine with muscular dystrophy type 1 (RSMD1), is caused by *SEPN1/SELENON* (MIM 606210) mutation. RSMD1 is characterized by slowly progressive muscle weakness, early-onset spinal rigidity, scoliosis, and progressive and potentially life-threatening respiratory insufficiency induced by diaphragm weakness (Koul et al., 2014).

In addition to RSMD1, *SEPN1* gene mutations also cause congenital fiber-type disproportion, a severe form of classic multiminiore myopathy, and desmin-related myopathy with Mallory body-like inclusions (Cagliani et al., 2011). Due to the clinical and genetic overlap between these four autosomal recessive conditions, there is an emerging idea that they are all manifestations of the same disease, namely, *SEPN1*-related myopathy (*SEPN1*-RM) (Scoto et al., 2011). However, there is no clear correlation between genotype and pathologic or genetic findings.

The *SEPN1* gene, located on chromosome 1p36.13, contains 13 exons and encodes selenoprotein N, encompassing transmembrane domain, EF-hand domain (Ca^{2+} -interacting region), thioredoxin domain, and SCUG motif (Chernorudskiy et al., 2020; Zhu et al., 2021). The underlying mechanisms of *SEPN1*-RM are unclear as the function of the selenoprotein N is incompletely understood. Selenoprotein N, an endoplasmic reticulum (ER) glycoprotein and an enzyme containing a selenium atom, has an established role in redox-based calcium hemostasis and protects muscle cells from oxidative damage and ER stress (Arbogast et al., 2009; Arbogast and Ferreira, 2010; Pozzer et al., 2019; Varone et al., 2019). Mutations in *SEPN1* lead to the absence or malfunction of selenoprotein N, and one study has suggested that some compounds effectively rescued the *SEPN1*-devoid cell phenotype *ex vivo* (Arbogast et al., 2009). However, the lack of natural history data, the complications of disease progression or prognosis determinants, and unclear phenotype-genotype correlations hinder the clinical trial implementation.

In this study, we investigated the clinical manifestations, pathological features, and genetic characteristics of 8 Chinese RSMD1 patients in order to improve the diagnosis and management of this disease.

MATERIALS AND METHODS

Clinical Studies

We studied eight patients with a clinical diagnosis of *SEPN1*-RM, performed a retrospective review of medical records, and carried out a prospective cohort study. Clinical and laboratory data, including motor development, family history, serum creatine kinase (CK) levels, pulmonary function test and polysomnography data, electrocardiography (ECG), ultrasound cardiography, and electromyography (EMG) findings, and muscle magnetic resonance imaging (MRI) were collected and analyzed based on the medical records provided by the attending physicians.

Pathological Studies

Skeletal muscle biopsies were performed on probands for pathological diagnosis. Muscle biopsies from the biceps brachii or quadriceps muscle were embedded, frozen in isopentane, and cooled in liquid nitrogen. Frozen sections (6 μm) were cut and processed for routine histological and immunohistochemical

staining. A Nikon Eclipse TE2000-S microscope was used to obtain images.

Genetic Analysis

Genomic DNA was extracted from peripheral blood leukocytes using standard protocols. The genomic DNA was first prepared as a DNA library, amplified, and then analyzed by next-generation sequencing (NGS) using a myopathy panel or whole-exon sequencing. After sequencing, the sequencing reads were mapped to the GRC37/hg19 human reference genome using Burrows-Wheeler Aligner software (version 0.59). Then the single-nucleotide variants (SNVs) and small insertions or deletions (InDels) were detected using the GATK UnifiedGenotyper (broadinstitute.org/). Finally, we filtered and selected the variants according to the minor allele frequency (MAF) with a cutoff value of <0.05 in multiple databases (such as 1000 Genome Project, dbSNP, HGMD, HapMap, and in-house Chinese local database). Variants' pathogenicity was evaluated using the variant-classification guidelines of the American College of Medical Genetics and Genomics (ACMG) (Richards et al., 2015) and determined based on the population frequency, phylogenetic conservation analysis, *in silico* prediction programs, and reporting in locus-specific databases. The candidate variants detected using NGS were verified in the probands and family members using Sanger sequencing. Exon 1 of *SEPN1* and its flanking intronic regions were amplified by polymerase chain reaction (PCR) and directly sequenced using Sanger sequencing. The primers of exon 1 are as follows: F- 5'-CTT GCGTTCGCGTGTA-3', R- 5'-ACTCGTCCATGCCCA TGTC-3'; F- 5'-GATCAGCCCCCTCTTGGCGTTC-3', R: CTCTGGATAGAGACCCCTCCAGTC-3'. The reference sequence NM_020451 of *SEPN1* was used.

RESULTS

In total, eight patients were clinically diagnosed with RSMD1, and *SEPN1* gene mutations were confirmed. The clinical features of these patients are summarized in **Tables 1, 2**.

Clinical Characteristics

Onset of Signs

The age of onset ranged from birth to 1 year old. Five patients (5/8, 62.5%) had a congenital presentation with hypotonia (5/5) and feeding difficulties (3/5). All seven patients presented with delayed motor milestones or gross motor difficulties, subdivided into the following categories: 5/8 (62.5%) poor or delayed head control (after 4 months of age), 4/8 (50.0%) delayed ability to sit unsupported (after 10 months of age), 4/8 (50.0%) delayed walking (after 18 months of age), and 8/8 (100%) difficulty in running or jumping, frequent falls, or easy fatigability.

Muscle Weakness and Functional Abilities

Four patients (4/8, 50.0%) presented with facial weakness, high palatine arches, and a nasal, high-pitched voice. All patients had

TABLE 1 | Clinical features of 8 RSMD1 patients.

Patient	Sex/age	Age of onset	Onset of symptoms	Maximum motor milestone	Contractures	Spinal deformities	CK level (U/L)	ECG	UCG	EMG	Muscle biopsy
1	F/9 y 3 m	Birth	Delayed motor milestones and weakness	Walking and running	Long finger flexor	Rigid spine and mild scoliosis	281	Normal (9 y)	Normal (9 y)	Myogenic	No significant pathological changes (1 y 2 m)
2	M/18 y	Birth	Delayed motor milestones and weakness	Walking	No	Rigid spine and scoliosis	<195	Sinus tachycardia (12 y)	Right ventricular enlargement, interventricular septal hypertrophy, pulmonary hypertension and mild tricuspid regurgitation (12 y); normal (18 y)	Myogenic	Myopathic, minicore (12 y)
3	F/11 y 9 m	<6 m	Delayed motor milestones	Walking	No	Rigid spine, scoliosis, and lordosis	<195	n/a	Mild enlargement of the right heart and mild pulmonary hypertension (6 y 8 m); normal (11 y)	No significant changes	n/a
4	F/12 y 4 m	Birth	Delayed motor milestones and weakness	Walking	No	Rigid spine and scoliosis	<195	Sinus tachycardia (8 y)	Normal (12 y)	No significant changes	n/a
5	F/8 y deceased	Birth	Delayed motor milestones and weakness	Walking and running	No	Rigid spine	<195	Sinus tachycardia (5 y)	Normal (8 y)	No significant changes	Myopathic, minicore (3 y)
6	M/13 y 8 m	1 y	Frequent falls and difficulty running	Walking and running	Elbow, Achilles tendon	Rigid spine, and mild scoliosis	664	n/a	Normal (13 y)	Myogenic	Myopathic, minicore (3 y)
7	F/13 y 5 m	<1 y	Delayed motor milestones and difficulty jumping	Walking	No	Scoliosis	<195	Sinus tachycardia (12 y)	Enlargement of right heart, decreased diastolic function of left ventricle, mild pulmonary hypertension, and mild tricuspid regurgitation (12 y)	Myogenic	n/a
8	F/7 y	<1 y	Delayed motor milestones	Walking, running	No	No	<195	Normal (7 y)	Normal (7 y)	n/a	n/a

F, female; M, male; y, year; m, month; CK, creatine kinase; ECG, electrocardiogram; UCG, ultrasound cardiography; EMG, electromyography; n/a, not available. The upper limit of the normal CK level is 195 U/L.

muscle weakness, especially axial weakness, in the neck flexors, abdominal muscles, and predominantly mild proximal limb muscles, with relatively well-preserved neck extensors. Deep-

tendon reflexes were invariably diminished or absent. All patients remained fully ambulant and were able to walk independently indoors and outdoors when last followed up.

TABLE 2 | Respiratory function of 8 *RSMD1* patients.

Patient	Lung function tests		Polysomnography						Severe pneumonia/Age	Respiratory insufficiency/Age	NIV/age
	Age	FVC (% predicted)	Age	Mean nocturnal SpO2 (%)	Minimum nocturnal SpO2 (%)	NH	AHI (/h)	OSAHS

y, year; m, month; FVC, forced vital capacity; NH, nocturnal hypoventilation; AHI, apnea-hypopnea index; h, hour; OSAHS, obstructive sleep apnea-hypopnea syndrome; NIV, noninvasive ventilation; n/a, not available.

Spine and Joint Deformity

Six patients (except patients 7 and 8) were first referred for rigid spines between 4 and 12 years old (mean age 6.8 years). In 6 patients, presentation with scoliosis was between 4 and 12 years of age (mean age 8.8 years); patient 3 presented lordosis at 6 years of age. Patient 6 showed contractures involving the elbow and Achilles tendon at 12 years old. After birth, the right ring finger, left pinky finger, and ring finger of patient 1 could not be straightened, and the contracture of the long finger flexor was more pronounced at the age of 1 year old.

Respiratory and Cardiac Involvement

The symptoms of respiratory involvement were present in all patients. They often had upper respiratory tract infections, five (5/8, 62.5%) were susceptible to pneumonia, and three (3/8, 37.5%) had severe pneumonia between the ages of 5 and 7 years.

The respiratory function data of 8 patients are summarized in **Table 2**. Forced vital capacity (FVC) data were available, and all had predicted FVC values (FVC%) below 80%. Pulmonary function tests suggested mild (in patient 1), moderate (in patients 2 and 6), and severe (patients 3, 4, 5, and 7) restrictive ventilation dysfunction. Polysomnography indicated variable hypoxia and nocturnal hypoventilation in all patients (see **Table 2**), and three (3/8) showed low oxygen saturation, apnea, and a high apnea-hypopnea index (AHI), suggestive of obstructive sleep apnea-hypopnea syndrome (OSAHS). Five patients had varying degrees of respiratory insufficiency from

5 to 12 years old (mean age 8.2 years; median 7), requiring nocturnal noninvasive ventilation (NIV) at a mean age of 9.2 years (median 9.5). After NIV treatment, all patients slept well at night, the symptoms of hypoxia and hypoventilation improved, and oxygen saturation at night improved significantly compared with before. Patient 6 declined regular respiratory follow-up and nocturnal NIV, and died at 8 years old. Patients 1 and 8 did not receive NIV in the first decade.

All patients underwent cardiac assessment. Three (3/8) had sinus tachycardia without abnormal electrocardiogram. Although right ventricular enlargement and mild pulmonary hypertension secondary to respiratory insufficiency were observed in the echocardiogram of three patients (3/8, 37.5%), their cardiac function improved after the active non-invasive respiratory support. A normal echocardiogram was obtained for the remaining 5 patients.

Survival

Patient 6 declined regular nocturnal NIV and died from respiratory failure at the age of 8 years because of severe pneumonia.

Auxiliary Tests

Serum CK levels were normal or mildly increased in all patients (see **Table 1**). EMG revealed myogenic changes in 4/8 patients, and no significant changes were found in 3/8 patients.

Muscle MRI

Muscle MRI of probands 1, 3, 4, and 6 showed diffuse fatty infiltration of the gluteus maximus and thigh muscle (**Figure 1**).

FIGURE 1 | Muscle MRI of RSMD1 patients. Arrows showed the gluteus maximus and thigh. C: control.

All the four patients exhibited fatty infiltration and atrophy of the gluteus maximus, and the adductor magnus was severely affected in patients 4 and 6. The semimembranosus was severely atrophic and absent in patient 1. Several muscles were preserved and mildly affected, including the gracilis, semitendinosus, rectus femoris and tibialis anterior, and tibialis posterior muscles in the lower leg (patients 1 and 6).

Muscle Pathology

Muscle biopsy was performed in patients 1, 2, 5, and 6. Most (patients 2, 5, and 6) indicated chronic myopathic changes with fiber size variation, mild atrophic and regenerative fibers, internalized nuclei, and a mild increase in endomysial connective tissue (see **Figure 2**). NADH staining showed that minicores present small areas of reduced oxidative enzyme

reactivity. No significant changes in patient 1 were observed, and the lesions were minimal.

Genetic Analysis

Genomic sequencing revealed 16 compound heterozygous variants (13 unreported, 81.3%) of the *SEPN1* gene (**Figure 3; Table 3**), and all tested parents of probands were healthy heterozygous carriers. We observed a cluster of variants in exons 1 (7/16, 43.8%), 10 (2/16, 12.5%), and 11 (3/16, 18.8%) (**Figure 3A**). Exon 1, which included the high GC sequence, harbored the largest number of mutations and was the most frequent variable sequence in our cohort. The types of *SEPN1* mutations mainly included missense (6/16, 37.5%), deletion (5/16, 31.3%), insertion (2/16, 12.5%), duplication (2/16, 12.5%), and insertion–duplication (1/16, 6.2%) (**Figure 3B**).

FIGURE 2 | Muscle biopsy of RSMD1 patients: **(A–E)** hematoxylin and eosin (H&E) staining, **(F–J)** modified Gomori Trichrome (MGT) staining, and **(K–O)** β -nicotinamide-adenine dinucleotide (NADH) staining. Arrows showed minicore changes.

The mutations mainly affected the transmembrane domain and thioredoxin (Trx) domain (encompassing the SCUG motif) of selenoprotein N. Ten mutations (62.5%) result in nonsense variants and are predicted to produce truncated proteins. Most missense mutations (5/6, 83.3%) mainly affect the Trx domain, including the SCUG motif (encoding the selenoprotein N putative catalytic site), a variant (c.1384T>A), and causing a loss of selenocysteine (Sec).

DISCUSSION

In this study, we clinically and genetically analyzed a cohort of 8 Chinese RSMD1 patients in detail to improve our understanding of the disease, extend the disease phenotypic spectrum, and facilitate diagnosis and management of the disease. In agreement with previous studies (Scoto et al., 2011), we characterized the clinical phenotype of RSMD1 patients with delayed motor milestones, slowly progressive muscle weakness, spinal rigidity, and progressive and potentially life-threatening respiratory insufficiency.

Although all our patients had a congenital onset, they fully remained ambulant with poor running and jumping, and none needed a wheelchair for an outdoor activity. This suggests that clinical severity is independent of the age at its onset. Axial weakness was generally present with an early onset but often neglected. Since the patients showed preserved limb strength and ambulation, they rarely complained of axial weakness. The muscular disease was suspected when scoliosis and respiratory insufficiency were detected at the end of the first decade.

Joint contractures were not significant in our patients, with only two cases of long finger flexors, elbow, and Achilles tendon. As reported, the contractures most commonly affected the Achilles tendons and elbow, and less frequently the long finger flexors (Scoto et al., 2011). However, in contrast to contractures, spinal rigidity was a presenting feature and a significantly progressive factor in our cohort. *SEPN1*-RM predominantly manifests as cervico-dorsal spinal rigidity that differs from the rigid spine in myopathies caused by mutations in *LMNA* (Quijano-Roy et al., 2008), *EMD* (Kubo et al., 1998), *COL6* (Bönnemann, 2011), or *RYR1* (Bharucha-Goebel et al., 2013). Our patients presented a rigid spine at a mean age of 6.8 years and developed scoliosis at a mean age of 8.8 years, earlier than the reported age of 10 years (Scoto et al., 2011).

Pulmonary function tests showed abnormal FVC values, and PSG suggested variable hypoxia and nocturnal hypoventilation in our patients. In our patients, respiratory insufficiency was found at a mean age of 8.2 years, requiring nocturnal NIV at a mean age of 9.2 years, which was earlier than the reported age of 13 years (Villar-Quiles et al., 2020). Due to obvious diaphragmatic weakness in patients with RSMD1, sleep-related respiratory disorders are likely to occur, which will eventually lead to respiratory insufficiency (Cagliani et al., 2011). In our cohort, pulmonary hypertension secondary to respiratory insufficiency improved with nocturnal NIV, and there was no clear progressive deterioration of the respiratory function with good oxygen saturation at night. FVC values are reported to be essentially stable after the 2nd decade of life following the introduction of NIV (Scoto et al., 2011). In our cohort, one patient who refused NIV died of respiratory failure. The respiratory function declines systematically from the end of the third decade, and early NIV

FIGURE 3 | (A) Schematic localization of the variants identified in the *SEPN1* gene. ATG: initiation codon. EF-hand domain: Ca²⁺-interacting region. SECIS: selenocysteine insertion sequence. SRE: selenocysteine redefinition element. TAG, TGA: termination codon. TM domain: transmembrane domain. Trx domain: thioredoxin domain, encompassing SCUG motif. UTR: untranslated region. **(B)** The types of *SEPN1* variants. **(C)** Mean depth of coverage in *SEPN1* exons and genome by next-generation sequencing (<https://gnomad.broadinstitute.org>).

may initially stabilize the respiratory muscle strength (Caggiano et al., 2017). Respiratory involvement might be aggravated by spinal deformities, especially scoliosis. Indeed, one study reported that one-third of patients had a spinal fusion at a mean age of 13.9 years, with good tolerance and no deterioration of motor or respiratory function after surgery (Scoto et al., 2011). Therefore, it is important to improve the prognosis by managing scoliosis and respiratory insufficiency.

Muscle MRI in our patients revealed the involvement of the gluteus maximus and adductor magnus, and the lower leg was mildly affected. The semimembranosus is reportedly the most

abnormal muscle in all *SEPN1*-RM patients (Flanigan et al., 2000). However, it was present in patient 1 but not in some RSMD1 patients (Mercuri et al., 2010). A distinct radiological pattern in *SEPN1*-RM with predominant axial and cervical muscle involvement, severe wasting of sternocleidomastoid muscles, and dramatic atrophy of semimembranosus, with relative preservation of the rectus femoris, long adductor, and gracilis, has been reported (Hankiewicz et al., 2015). This information might be useful for diagnosis even in very young patients or those with mild disease. We found no clear correlation between histopathological findings and clinical

features. Muscle biopsy indicated chronic myopathic changes and minicores, as previously described (Scoto et al., 2011; Villar-Quiles et al., 2020), and the age and site of biopsy correlated with the histopathological variability. Muscle biopsy is recommended at the school age to promote diagnosis.

In our study, exon 1 harbored the highest number of mutations. Mutations in *SEPN1* are distributed along with the whole gene, except for exon 3. GC-rich exon 1 has been reported as a major hotspot, although it is poorly or not covered by NGS panels (see **Figure 3C**). Hence, mutations in exon 1 of *SEPN1* are easily missed by NGS, and NGS data should be re-analyzed, or the detection of exon 1 using Sanger sequencing should be performed. Moreover, the first *SEPN1* copy number variation (c.(872+1_873-1)(1602+1_1603-1) del), a large out-of-frame deletion affecting exons 7 to 12, was identified (Villar-Quiles et al., 2020). Mutations in the *SEPN1* 3' UTR selenocysteine insertion sequence (SECIS), an untranslated cis element necessary for selenocysteine integration, were also found (Villar-Quiles et al., 2020). All these findings highlight the need to search for *SEPN1* copy number variations and mutations in SECIS, particularly when only one *SEPN1* pathogenic variant has been detected.

Most *SEPN1* mutations in our cohort were null mutations producing truncated proteins prone to nonsense-mediated

decay (NMD). As reported, all mutations located around or in the sequence encoding the potential catalytic site (SCUG motif) were missense. The codon UGA encoding selenocysteine is located in exon 10 (c. 1384_1386); UGA is usually a termination codon, which causes coding termination, but selenoprotein N is unique. The SECIS located in the 3'UTR of the mRNA and the selenocysteine redefinition element (SRE) downstream of the UGA jointly mediate the selenocysteine insertion into the selenoprotein N polypeptide chain (Moghadaszadeh et al., 2013). Mutations in the codon UGA encoding selenocysteine, SECIS, and SRE can reduce the insertion efficiency of selenocysteine, reduce the level of mRNA, and ultimately affect the synthesis and expression of selenoprotein N (Maiti et al., 2009). We also detected mutations in the EF-hand domain-encoding sequence. We did not observe a clear genotype–phenotype correlation. Biallelic null mutations may be associated with higher disease severity, which is the only genotype–phenotype correlation that has been proposed (Villar-Quiles et al., 2020).

Selenoprotein N, an endoplasmic reticulum glycoprotein, is a member of an enzyme family containing one selenium atom that binds covalently to form selenocysteine in the catalytic region (Castets et al., 2012). Selenoprotein N participates in redox reactions (Moghadaszadeh et al.,

2013) and calcium homeostasis (Lescure et al., 2009), protects cells from the oxidative stress (Arbogast and Ferreira, 2010), and plays a role in early embryonic development, cell proliferation, and regeneration (Castets et al., 2009). Excessive oxidative damage induces dysfunction and degradation of muscle fibers, which is considered a primary pathophysiological mechanism of *SEPN1*-RM (Varone et al., 2019). Selenoprotein N is required for calcium transients between the ER-mitochondria, thereby controlling mitochondrial bioenergetics. The mutation of *SEPN1* leads to impaired ER-mitochondria contacts and decreased ATP levels in muscle cells (Filipe et al., 2021). The antioxidant N-acetylcysteine has been identified as an effective protective agent against oxidative stress-induced cell death (Arbogast and Ferreira, 2010) and should be considered in future clinical trials. Multidisciplinary management should be provided to patients, including physical rehabilitation and nursing, cardiovascular and respiratory management, nutritional support, orthopedic surgery, and psychological care. We recommend yearly follow-up, including respiratory and cardiac evaluations and spine surveillance. Regular pulmonary function tests and PSG are recommended for all patients, and NIV should be used as soon as nocturnal hypoventilation or respiratory failure is detected.

In summary, our study expands the spectrum of clinical and genetic findings in RSMD1 and provides valuable genetic counseling for the families. The findings will contribute to improving diagnosis, management, and standards of care, and provide useful information on future natural history studies and clinical trials.

The Presence of Vacuolated Kupffer
Cells Raises a Clinical Suspicion of
Niemann-Pick Disease Type C in
Neonatal Cholestasis.
Front. Genet. 13:867413.
doi: 10.3389/fgene.2022.867413

Early diagnosis of Niemann-Pick disease type C (NP-C) in neonatal cholestasis is still challenging because splenomegaly is non-specific and oxysterol profiling studies also have a relatively low specificity. This study explores a method for identifying infants with a high clinical suspicion of NP-C in neonatal cholestasis. We reviewed the clinical findings of 9 neonatal cholestatic infants with NP-C genetically diagnosed between January 2015 and December 2020. Seven underwent liver biopsy at ages ranging from 35 to 112 d. Foam cells were only detected in 2 (28.6%, 2/7) liver tissues obtained beyond 3 months of age. However, vacuolated Kupffer cells were detected in all 7 liver tissues. Their significance was explored by using 168 neonatal cholestatic infants, who underwent genetic tests and liver biopsy between January 2018 and December 2020. Of them, 26 detected vacuolated Kupffer cells. Six (23.1%, 6/26) were diagnosed as NP-C, comparing to none of the 142 neonatal cholestatic infants without vacuolated Kupffer cells ($\chi^2 = 33.983$, $p < 0.001$). The ratio of positive diagnosis of NP-C was 31.6% (6/19) in neonatal cholestatic infants with both vacuolated Kupffer cells and splenomegaly. Therefore, we conclude that the presence of vacuolated Kupffer cells can raise a high clinical suspicion of NP-C in neonatal cholestatic infants, especially in those with splenomegaly.

Keywords: neonatal cholestasis, infant, Niemann-Pick disease type C, Kupffer cell, diagnosis

INTRODUCTION

Niemann-Pick disease type C (NP-C) is a rare progressive and life limiting lysosomal storage disorder. It results from compound heterozygous or homozygous pathogenic variants in either of the two genes: *NPC1* or *NPC2* (Carstea et al., 1993; Vanier et al., 1996). Nearly 95% of cases are caused by *NPC1* deficiency, with approximately 5% caused by *NPC2* deficiency (Jahnova et al., 2014). It is classified as visceral-neurodegenerative form (early-infantile), neurodegenerative form (late-infantile and juvenile), and psychiatric-neurodegenerative form (adult) (Patterson, 2000; Geberhiwot et al., 2018). Primary manifestations are age dependent. In early infancy, clinical manifestations are predominantly visceral, with cholestasis and hepatosplenomegaly (Patterson, 2000). Cholestasis in the majority spontaneously resolves after 3–4 months of age, while splenomegaly persists and neurological symptoms develop with age (Evans et al., 2017; Geberhiwot et al., 2018). The early diagnosis is the key for reduction of organ damage since a medical treatment is available now (Pineda et al., 2018).

Newborn screening for NP-C still has not been developed. Splenomegaly in neonatal cholestatic infants raises a clinical suspicion of NP-C (Geberhiwot et al., 2018). Two plasma oxysterols, 7-ketocholesterol (7 KC) and cholestane-3 β ,5 α ,6 β -triol (C-triol), are biomarkers for aiding diagnosis (Mazzacuva et al., 2016; Maekawa et al., 2020). Genetic tests can lead to a definite diagnosis. However, early diagnosing of NP-C is still challenging because splenomegaly is non-specific (Mazzacuva et al., 2016; Maekawa et al., 2020) and oxysterol profiling studies also have a relatively low specificity for NP-C in neonatal cholestasis (Polo et al., 2016; Degtyareva et al., 2019). Genetic tests are usually ordered if an inherited disorder is suspected. Therefore, an alternative is necessary for early identification of infants with a clinical suspicion of NP-C in neonatal cholestasis.

This study summarized the clinical findings of 9 NP-C infants presenting as neonatal cholestasis, and unexpectedly found that vacuolated Kupffer cells were detected in all liver tissues obtained in the early disease course. We also explored the significance of vacuolated Kupffer cells on early detection of infants with a high suspicion of NP-C in neonatal cholestasis.

METHODS

Patients and Definitions

This study enrolled neonatal cholestatic infants (onset <3 months of age) diagnosed as NP-C who were referred to the Children's Hospital of Fudan University between January 2015 and December 2020. The diagnosis of NP-C is established if *NPC1* or *NPC2* biallelic pathogenic/likely pathogenic variants are identified. Cholestasis is defined as follows (Togawa et al., 2016): serum direct bilirubin (DB) > 20.0% of total bilirubin (TB) if TB > 85.5 μ mol/L; or DB > 17.1 μ mol/L if TB < 85.5 μ mol/L. Hepatomegaly and splenomegaly were diagnosed by ultrasonography.

To explore the significance of vacuolated Kupffer cells, this study also enrolled 168 consecutive infants with neonatal cholestasis, who underwent both genetic tests and liver biopsy, between January 2018 and December 2020. Following a work-up for neonatal cholestasis as described previously (Liu et al., 2010), surgical, infectious, parenteral nutrition, endocrinological, and drug-induced causes were excluded.

The study was approved by the ethics committees of the Children's Hospital, Fudan University and conducted in full compliance with medical ethics standards. Informed consent had been obtained from the parents/guardians during the admission. Clinical data were collected from their medical records.

Genetic Testing

Genetic testing was performed in the Translational Center of Children's Hospital of Fudan University. Genomic DNA was extracted from peripheral blood. *NPC1* variants (NM_000271) and *NPC2* variants (NM_006432) were screened by NGS, including panel, medical exome, and whole exome sequencing. The procedures of sequencing, data analyses, and variation

Novel pathogenic or likely pathogenic variants are shown in bold font.

classification were described previously (Wang et al., 2016; Qiu et al., 2017; Zhang et al., 2020). Variant pathogenicity was assessed according to the American College of Medical Genetics and Genomics (ACMG) standards and guidelines (Richards et al., 2015).

Histologic Studies

Liver tissues were obtained by needle biopsy or intraoperative wedge biopsy. Liver tissues sections were stained by hematoxylin and eosin (HE), periodic acid-schiff (PAS), anti-CD68 (GENE, Shanghai, China), etc.

Smears of bone marrow aspirations were Wright's stained.

Statistical Analysis

Statistical analysis was performed using SPSS Inc. version 17.0 software (University of Chicago, Chicago, IL). Difference among ratios was tested by Chi-square test using Fisher's exact value. Comparison of two medians was done by nonparametric Mann-Whitney test. $p < 0.05$ was considered significant.

RESULTS

Molecular Findings

A total of 9 neonatal cholestatic infants, including 4 boys and 5 girls, were finally diagnosed as NP-C for harboring biallelic pathogenic or likely pathogenic variants in *NPC1* (Table 1). No infant was found to harbor biallelic pathogenic variants in *NPC2*. Sixteen distinct *NPC1* variants were identified, including 10 known disease-causing variants and 6 novel variants (4 frameshift indels and 2 missense variants) absented from the Genome Aggregation Database (GnomAD). The 2 novel missense variants, c.1024T > C (p.W342R) and c.3254A > C (p.Y1085S), were predicted to be disease causing and damaging by MutationTaster, Polyphen-2, and SIFT. Both were rated as likely pathogenic variants, while the 4 novel frameshift indels as pathogenic variants according to the ACMG standards and guidelines.

Clinical Findings

The 9 NP-C infants came from 9 distinct nonconsanguineous families. Jaundice and hepatosplenomegaly were identified in

FIGURE 1 | Histologic studies of bone marrow aspirations and liver tissues obtained from NP-C patients presenting as neonatal cholestasis. Vacuolated Kupffer cells (black arrow) are observed in CD68 staining sections from liver tissues of all 7 NP-C infants (P1 ~ P7), but not in control (a neonatal cholestatic infant with unknown cause). Foam cells (red arrow) are observed in HE and PAS sections of P6 and P7 when vacuolated Kupffer cells with enlarged sizes become obvious. BM, bone marrow aspiration; LS, liver specimens; P, patient.

all 9 patients (**Table 2**). Six exhibited acholic stools. Seven, but not patient (P) 3 and P7, were classified into cholestasis with high serum γ -glutamyl transpeptidase (GGT >100U/L). Aspartate aminotransferase (AST) was elevated in all 9 patients, and the ratios of AST to alanine aminotransferase (ALT) ranged from 2.1 to 7.5. Hypoglycemia (blood glucose levels <3.0 mmol/L) was present in 4 patients (P5, P6, P8, and P9) after fasting for 3 h.

P1 ~ P7 underwent liver biopsy. Foam cells were only detected in HE staining sections of P6 and P7, but vacuolated Kupffer cells were detected in CD68 staining sections from all 7 liver tissues (**Figure 1**). Vacuolated Kupffer cells were scattered in P1 and P2, whose liver tissues were obtained at the age of 35 and 36 d, respectively. More vacuolated Kupffer cells were identified in P3 and P4 at the age of 49 and 63 d, respectively. Most Kupffer cells

detected lipid vacuoles in P5 at 89 d of age, and a few had enlarged sizes. Vacuolated Kupffer cells with enlarged sizes became obvious in P6 and P7 at the age of 110 and 112 d, respectively.

Bone marrow aspiration was performed in P1, P3, P5, and P6 at ages ranging from 42 to 113 d, but no foam cell was observed (**Figure 1**).

Significance of Vacuolated Kupffer Cells

Of the 168 enrolled neonatal cholestatic infants, 26 detected vacuolated Kupffer cells, including 19 with splenomegaly (**Table 3**). Six of the 26 infants (P1 ~ P5, and P7) were diagnosed as NP-C, comparing to none of the 142 infants without vacuolated Kupffer cells (6/26 vs. 0/142, $\chi^2 = 33.983$, $p < 0.001$). The ratio of positive diagnosis of NP-C was 23.1% (6/26) in neonatal cholestatic infants with vacuolated Kupffer

TABLE 3 | Basic information of the 168 neonatal cholestatic infants with unexplained causes.

	With vacuolated Kupffer cells (n = 26)	Without vacuolated Kupffer cells (n = 142)

cells, and it could increase to 31.6% (6/19) in neonatal cholestatic infants with both vacuolated Kupffer cells and splenomegaly.

DISCUSSION

The diagnosis of NP-C is often delayed in neonatal cholestasis. The measurement of biochemical markers, such as plasm oxysterols, is recommended for early detection of NP-C (Vanier et al., 2016; Geberhiwot et al., 2018), while liver biopsy is now rarely needed (Geberhiwot et al., 2018; Patterson, 2000). Disappointingly, oxysterol screening has a relatively low specificity on distinguishing NP-C from other causes in neonatal cholestasis (Polo et al., 2016; Degtyareva et al., 2019). The NP-C infants with neonatal cholestasis usually still have liver biopsy done for etiologic studies because clinical manifestations are non-specific in the early disease course (Yerushalmi et al., 2002; Evans et al., 2017). Liver foam cells, a typical light microscopic feature of NP-C, can raise a high clinical suspicion of NP-C, but are detectable in only 37–50% NP-C children (Kelly et al., 1993; Rodrigues et al., 2006). In this study, liver foam cells were detected in 2 (28.6%) NP-C infants beyond 3 months of age.

Differentiated from liver foam cells, vacuolated Kupffer cells were detected in all 7 NP-C infants who underwent liver biopsy at age ranging from 35 to 112 d. Abundant vacuolated Kupffer cells were detected at age 89 d and a few had enlarged sizes. When vacuolated Kupffer cells with enlarged sizes became obvious, liver foam cells were observed. A previous study also found that liver foam cells were negative in the early disease course and developed with age (Yerushalmi et al., 2002). These indicate that vacuolated Kupffer cells can evolve into liver foam cells. NP-C was finally diagnosed in 23.1% of neonatal cholestatic infants with vacuolated Kupffer cells, but none of those without vacuolated Kupffer cells. Hence, the presence of vacuolated Kupffer cells raises a clinical suspicion of NP-C in neonatal cholestatic infants, especially in those with splenomegaly, while their absence excludes a possibility of NP-C.

Demonstration of foam cells in bone marrow adds to clinical suspicion of NP-C (Kelly et al., 1993; Geberhiwot et al., 2018), but it can be negative in early infancy (Rodrigues et al., 2006). It is believed that foam cells may become apparent in bone marrow as the disease evolves. In the

current study, foam cells were not identified in all 4 bone marrow samples obtained within 4 months of age. Therefore, the diagnosis of NP-C may be missed if early bone marrow aspiration is only relied on. It challenges the importance of bone marrow aspiration for the diagnosis of NP-C in younger infants with neonatal cholestasis.

NP-C infants usually present as neonatal cholestasis with high GGT (Woś et al., 2016; Yamada et al., 2019), but in some instances as neonatal cholestasis with low GGT (Evans et al., 2017). In the current study, we found 2 NP-C infants presented as neonatal cholestasis with low GGT (<100U/L). Furthermore, 4 NP-C infants were found to have fasting hypoglycemia. The reasons of hypoglycemia are still unclear. It may be associated with mitochondrial dysfunction which has been demonstrated in fibroblasts derived from NP-C patients (Woś et al., 2016). Therefore, blood glucose should be routinely monitored in NP-C infants presenting as neonatal cholestasis.

CONCLUSION

This study reports the molecular and clinical findings of 9 neonatal cholestatic infants diagnosed as NP-C. Vacuolated Kupffer cells are detected in all 7 NP-C infants who underwent liver biopsy in early disease course. The presence of vacuolated Kupffer cells raises a clinical suspicion of NP-C in neonatal cholestatic infants, especially in those with splenomegaly.

TMEM199-Congenital Disorder of
Glycosylation With Novel Phenotype
and Genotype in a Chinese Boy.
Front. Genet. 13:833495.
doi: 10.3389/fgene.2022.833495

Background: TMEM199-congenital disorder of glycosylation (TMEM199-CDG) is a rare autosomal recessive inherited disease characterized by chronically elevated serum transaminase, decreased serum ceruloplasmin, steatosis and/or fibrosis, *TMEM199* mutation, reduced level of TMEM199 protein, and abnormal protein glycosylation.

Methods: The information of a Chinese patient with TMEM199-CDG in the Children's Hospital of Fudan University was reviewed. The patient's clinical, pathological, and molecular features were obtained by clinical data study, liver biopsy, immunohistochemistry, and molecular genetic analysis.

Results: A 4-year-old Chinese boy presented with hypertransaminasemia, hypercholesterolemia, elevated alkaline phosphatase, decreased serum ceruloplasmin and serum copper level, and coagulopathy since birth. To the best of our knowledge, novel findings included strabismus, cirrhosis by liver biopsy, reduced expression of TMEM199 by immunohistochemistry, and a frameshift variant of c.128delA/p.Lys43Argfs*25 in the *TMEM199* gene.

Conclusion: This case added to the phenotypic and genotypic spectrum of TMEM199-CDG.

Keywords: congenital disorders of glycosylation, TMEM199-CDG, inherited metabolic disease, liver disease, mutation

INTRODUCTION

Congenital disorder of glycosylation (CDG) is an emerging group of metabolic diseases with autosomal recessive inheritance. One or more glycosylation enzyme defects lead to the abnormal glycosylation of protein or lipid in CDG, resulting in corresponding clinical symptoms (Yarema and Bertozzi, 2001; Jaeken, 2013). Common manifestations include dysmorphic features; diarrhea or malnutrition; abnormalities in the liver, coagulation, gland, and immune and nervous system; psychomotor disability; language retardation; ataxia; eye abnormalities; spinal or joint impairment; and cardiac disorders. Given the diversity of clinical performance, definitive diagnosis of CDG is difficult. With the development of whole-exome sequencing (WES), more than 140 CDG types have been identified. As a new subtype discovered in recent years, TMEM199-CDG (OMIM: 616829) is characterized by isolated or predominant liver involvement, which is different from most CDGs associated with multiple organ dysfunction (Marques-da-Silva et al., 2017). To date, only seven cases

of TMEM199-CDG have been reported worldwide (Jansen et al., 2016; Vajro et al., 2018). The patients presented with cryptogenic elevated alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase, creatine kinase, total cholesterol, low-density lipoprotein cholesterol, and decreased serum ceruloplasmin. Liver biopsies revealed steatosis and/or fibrosis, and an ultrastructure of dilation and vesiculation of the Golgi and/or endoplasmic reticulum (ER). Several mutation sites of *TMEM199* were found by sequencing. Western blot confirmed reduced or undetectable levels of TMEM199 protein. Glycosylation analysis results were consistent with the type II CDG pattern.

Herein, we reported a Chinese boy with TMEM199-CDG, presenting with abnormal liver function, strabismus, and mild psychomotor delay. The liver biopsy showed steatosis, severe fibrosis as cirrhosis at stage 4, and reduced expression of TMEM199 by immunohistochemistry. WES revealed two compound heterozygous variants, c.20C > A mutation and c.128delA deletion in *TMEM199* exon 1, of which the latter had not been previously reported. Treatments with bicyclic alcohol, zinc sulfate, and penicillamine yielded no effect, while no significant progression in the course of the disease was observed after 1-year follow-up. To the best of our knowledge, he is the first Chinese patient described with TMEM199-CDG who carried a novel phenotype and genotype, which might expand the understanding of this rare disease.

MATERIALS AND METHODS

Patient

The information of a Chinese pediatric patient with TMEM199-CDG in the Children's Hospital of Fudan University was reviewed. Clinical, pathological, and molecular features of the patient were assessed by clinical manifestations, laboratory investigations, liver biopsy, immunohistochemistry, and molecular genetic analysis. This study conformed to the provisions of the institutional ethics committee and the Declaration of Helsinki (as revised in 2013). The patient's parents shared all procedures including treatment and signed the written informed consent. The written informed consent was obtained for publication of any potentially identifiable images or data included in this article.

Liver Biopsy

The specimen was obtained from core-needle biopsy, fixed in 10% buffered formalin, dehydrated in graded concentrations of ethyl alcohol, and embedded in paraffin. Then it underwent routine staining for hematoxylin and eosin (HE), and histochemical special staining for periodic acid-Schiff (PAS) with and without diastase, Masson, reticulin, copper, and iron.

Immunohistochemistry

Additional 4- μ m sections were deparaffinized, rehydrated, and pretreated with 3% H₂O₂ to eliminate endogenous peroxidase activity. Moreover, they were treated with EDTA (pH 9) or citrate buffer (pH 6) for heat-mediated antigen retrieval before

commencing with the immunohistochemical staining protocol. The primary antibodies used included CK7 (clone MX053, ready-to-use solution), CK19 (clone MX054, ready-to-use solution), CD68 (clone MX075, ready-to-use solution), CD163 (clone MX081, ready-to-use solution), CD3 (clone MX036, ready-to-use solution), and CD8 (clone C8/144B, ready-to-use solution), which were purchased from <http://www.maxim.com.cn> (Fuzhou, China). In addition to the series of conventional antibodies, a rabbit polyclonal antibody against TMEM199 (purchased from <http://www.abcam.cn>, product code: ab121907) with a 1:50 dilution was utilized. The sections were incubated overnight at 4°C, followed by incubating with a general secondary antibody for 1 h at room temperature. Finally, the sections were developed with DAB and counterstained with hematoxylin. A normal liver sample (donated by a surgical patient) was prepared as the positive control, while omitting the first antibody as the negative control.

Molecular Genetic Analysis

Genetic testing was performed by Running Gene Inc (<http://www.mono-mz.com/auth>, Beijing, China). EDTA-anticoagulated whole blood specimens were collected from the patient and his parents. DNA was isolated from peripheral blood using the DNA Isolation Kit (Blood DNA Kit V2, CW2553). Concentrations were determined on a Qubit fluorometer (Invitrogen, Q33216) using the Qubit dsDNA HS Assay Kit (Invitrogen, Q32851). Agarose gel (1%) electrophoresis was performed for the quality control. A total of 1 μ g isolated DNA was sheared using the following parameters: duty cycle 10%, intensity 5, cycles per burst 200, and time six cycles per 60 s. This step was performed using a Bioruptor UCD-200 (Diagenode). All samples were sheared very consistently, and the size distribution peak was around 200 bp. In total, 3 μ l of the sheared DNA was electrophoresed in a 2% agarose gel to confirm the presence of fragments of the desired size range. The multiplex ligation-dependent probe amplification assay (MLPA) was performed using the *ATP7B* MLPA kit (SALSA MLPA Probemix P098-D1, MRC-Holland, the Netherlands) (Chen et al., 2019). However, MLPA analysis excluded copy number variations in *ATP7B*. Then IDT-WES was performed to dig for potential genetic abnormalities. DNA libraries were prepared using the KAPA Library Preparation Kit (Kapa Biosystems, KR0453) following the manufacturer's instructions. The procedure comprised three standard steps: end-repair of fragmented DNA, A-tailing, adapter ligation, and amplification. Purifications between steps were carried out using Agencourt AMPure XP beads. The libraries were estimated using the Qubit dsDNA HS Assay kit (Invitrogen, Q32851). Hybridization of pooled libraries to the capture probes and removal of non-hybridized library molecules were carried out according to the SeqCap hybrid Mix system. DNA libraries were sequenced using the Illumina novaseq platform (Illumina, San Diego, United States) as paired-end 200-bp reads. For data analysis, adapters and low-quality sequences were removed to obtain clean and basic data. Genome Analysis Toolkit (GATK) (<https://gatk.broadinstitute.org>) was used for variation calling to summarize single-nucleotide variants (SNVs) and indels. ANNOVAR software and Enliven® Variants Annotation

Interpretation System were employed for annotation and interpretation. Data were aligned against the Human Gene Mutation Database (HGMD) Professional (<http://www.hgmd.cf.ac.uk>), 1,000 Genome Database (www.1000genomes.org), Genome Aggregation Database (gnomAD) (<https://gnomad.broadinstitute.org>), dbSNP152 (<https://www.ncbi.nlm.nih.gov/snp>), and Exome Aggregation Consortium (ExAC) (<http://exac.broadinstitute.org>). The variants were filtered out only with a population frequency of <5% in 1,000 genomes and <2% in gnomAD. Damage prediction of the genetic variants was conducted by Combined Annotation-Dependent Depletion (CADD) (<https://cadd.gs.washington.edu>) for scoring and mutation significance cutoff (MSC) (<https://lab.rockefeller.edu/casanova/MSC>) for further comparison. The MSC server was applied to CADD, PolyPhen 2 (<http://genetics.bwh.harvard.edu/pph2>) and SIFT (https://sift.bii.a-star.edu.sg/www/SIFT_indels2.html), with a confidence interval of 99% and database source of HGMD and ClinVar (<https://www.ncbi.nlm.nih.gov/clinvar>). Genomics England PanelApp (<https://panelapp.genomicsengland.co.uk>), a crowdsourcing tool, was utilized for analysis based on variant–disease and gene–disease associations. Human Phenotype Ontology (HPO) (<https://hpo.jax.org>), Online Mendelian Inheritance in Man (OMIM) (<https://www.omim.org>), and HGMD database were used to match the phenotype descriptions with variant and gene prioritization results. According to the American College of Medical Genetics and Genomics (ACMG) guidelines, genetic variants were classified as pathogenic, likely pathogenic, variants of uncertain significance (VUS), likely benign, and benign. Thereafter, two pathogenic variants of *TMEM199* were identified with the transcript of NM_152464.1, which was validated by using Sanger sequencing. The pathogenicity of amino acid changes caused by gene mutations was predicted using MutationTaster (<http://www.mutationtaster.org>). We conducted protein modeling using the SWISS-model (<https://www.swissmodel.expasy.org>) with a UniProtKB code Q8N511, and the mutated structures were analyzed and visualized using PyMol (<http://www.pymol.org>).

RESULTS

Clinical History

The patient was born to healthy non-consanguineous parents as the second child of the family, whose older sister was healthy. At the age of 1 month, the patient was hospitalized for jaundice. During a routine blood test, remarkably elevated aspartate aminotransferase (253.0 IU/L, reference range 0–40 IU/L), γ -glutamyl transferase (540.0 IU/L, reference range 7–50 IU/L) and total bilirubin (303.8 μ mol/L, reference range 5.1–17.1 μ mol/L), and decreased globulin (9.6 g/L, reference range 20–30 g/L) and ceruloplasmin (0.04 g/L, reference range 0.22–0.58 g/L) were noticed. The patient was discharged after jaundice was treated. However, the hypertransaminasemia, hypercholesterolemia, elevated alkaline phosphatase, decreased serum ceruloplasmin and serum copper level, and coagulopathy persisted during the approximate 4-year follow-up.

Then the 4-year-old boy with abnormal liver function since birth was admitted to our in-patient department. Physical examination showed that his height was 108 cm (87th percentile by the WHO standard) and weight was 19 kg (88th percentile). Ocular strabismus was present, while the Kayser–Fleischer ring was absent. The liver was located 3 cm below the right costal and 4 cm below the xiphoid process, with a soft texture. The examination of the skin, abdomen, and nervous system showed no abnormalities. Abdominal ultrasonography indicated that the echogenicity of the liver was inhomogeneous, showing mild fatty liver manifestation. Cranial magnetic resonance imaging revealed that the anterior part of the right ventricle was slightly plentiful, and part of the sinus mucosa was thickened. The patient was assessed as having a mild intellectual disability by the development screening test (DST). The measured intellectual age was below his actual 51 months, showing 36 months in exercise, 27 months in social adaptation, and 36 months in intelligence. The majority of liver enzymes were elevated, including alanine aminotransferase (58.80 IU/L, reference range 0–40 IU/L), aspartate aminotransferase (123.20 IU/L, reference range 0–40 IU/L), alkaline phosphatase (1296.00 IU/L, reference range 42–383 IU/L), and creatine kinase isoenzyme (30.8 IU/L, reference range 0–30 IU/L). The lipid profile revealed increased total cholesterol (7.92 mmol/L, reference range 3.1–5.2 mmol/L), high-density lipoprotein cholesterol (1.61 mmol/L, reference range 0.91–2.05 mmol/L), and low-density lipoprotein cholesterol (5.72 mmol/L, reference range 1.30–3.90 mmol/L). Serum ceruloplasmin (0.04 g/L, reference range 0.22–0.58 g/L) and serum copper (2.80 μ mol/L, reference range 10.99–21.98 μ mol/L) levels were decreased. Transferrin (2.7 g/L, reference range 2.5–4.3 g/L) and ferritin (48.02 ng/ml, reference range 30–400 ng/ml) levels were normal. With the exception of prolonged activated partial thromboplastin time (46.6 s, reference range 28.0–44.5 s), increased D-dimer (0.57 mg/L, reference range 0–0.3 mg/L) and decreased fibrinogen (1.43 g/L, reference range 2–4 g/L), other coagulation indicators were normal. **Table 1** summarizes the predominant laboratory investigations of the patient in different phases. Subsequently, the patient was treated with bicyclic alcohol, zinc sulfate, and penicillamine for 1 year. To date, there has been no significant improvement or disease progression during the surveillance period. The follow-up showed elevated serum transaminases, alkaline phosphatase, and lipid profiles, and persistent low ceruloplasmin.

Liver Biopsy

Liver biopsy showed that the architecture of liver lobules was disordered, and pseudo-lobule was formed (**Figure 1A**). High power exhibited ground-glass-like hepatic cells, with a lightly stained cytoplasm and clear cell membrane, and vesicular steatosis, which were more evident in the portal area, rather than the regions around the central vein (**Figure 1B**). Infiltration of few lymphocytes in the portal area was also observed (**Figure 1C**). PAS staining identified small vacuoles in partial hepatocytes (**Figure 1D**), while PAS with diastase, copper, and iron staining were negative. The hyperplastic fibrous tissue in the

portal area separated liver lobules, formatting bridging-like fibrosis and pseudo-lobules, which was highlighted by Masson staining (**Figure 1E**). The preserved reticular scaffold structure was displayed by reticulin staining. It presented cirrhosis with stage 4 assessment according to the Scheuer histopathologic scoring system (Scheuer, 1991).

Immunohistochemistry

Immunohistochemical staining of CK7 and CK19 showed mild hyperplasia of bile ducts along the margins of pseudo-lobules (**Figure 1F**). Slightly proliferated Kupffer cells in hepatic sinusoids were indicated by CD68 and CD163 staining, and lymphocytes infiltrating in the portal area were detected by CD3 and CD8 staining. It was worth noting that the expression of TMEM199 was reduced in this index patient sample (**Figure 1G**), compared with the normal liver sample

(donated by a surgical patient), which displayed a cytoplasmic positive pattern in hepatic and bile duct cells (**Figure 1H**).

Molecular Genetic Analysis

With a suspected diagnosis of Wilson disease according to the clinical manifestation, a multi-gene panel was screened. However, the absence of *ATP7B* mutation and normal DNA copy number variant (CNV) ruled out Wilson disease. Thereafter, two compound heterozygous variations, c.20C > A and c.128delA, were found in *TMEM199* gene exon 1 (**Figure 2A**) by WES. The c.20C > A was inherited from the healthy father, leading to a change of alanine to glutamate at amino acid position 7 (p.Ala7Glu), which was reported in the HGMD (Jansen et al., 2016). The c.128delA as a deletion mutation was inherited from the healthy mother, which caused a frameshift with an early termination (p.Lys43Argfs*25), which was not reported in the HGMD. The amino acid residue of the splice-

site mutation (p.Ala7Glu) was conserved across various species, while the frameshift mutation (p.Lys43Argfs*25) was not conserved (**Figure 2B**). The CADD score of c.20C > A and c.128delA was 14.560 and 11.410 respectively, both predicted as a high impact by MSC. Both mutations of c.20C > A (functional test PS3 + absent from controls PM2 + homozygous variants and distribution in trans PM3.Strong + phenotype match PP4) and c.128delA (frameshift variant with LOF PVS1 + absent from controls PM2 + phenotype match PP4) were evaluated to be pathogenic according to the guideline of the ACMG. The nomenclature of variants was based on the recommendations of the Human Genome Variation Society (HGVS, <http://www.hgvs.org/varnomen>). Wild-type and mutated TMEM199 were modeled by PyMol (<http://www.pymol.org>) which showed no effect of Ala7Glu residue change on the polar contact with them around amino acid Arg53 (**Figure 2C**). Spatial conformation of the frameshift mutation (p.Lys43Argfs*25) predicted by protein modeling showed that the amino acid at position 43 moved backward 25 positions and then terminated, resulting in protein truncation, which contained a loss of the Vam12 domain (**Figure 2D**). **Figure 2E** illustrates the TMEM199 protein domains, location of amino acid changes of the reported variants so far.

DISCUSSION

CDGs are clinically and genetically heterogeneous disorders sharing a primary defect of glycosylation. Mandato et al. (2006) detected aberrant glycosylation of transferrin (Tf) by electrospray ionization mass spectrometry (ESI-MS) in four children with cryptogenic chronic hypertransaminasemia and/or liver steatosis and fibrosis, leading to the discovery of a new type of CDG-X with unknown disease-causing genetic alterations. With the development of WES, researchers found two cases of CDG-X and one unrelated case with *TMEM199* heterozygous mutations (Vajro et al., 2018). In addition,

Jansen et al. (2016) confirmed that the abnormal glycosylation of serum protein was caused by Golgi homeostasis defects, and mutations at different sites in the *TMEM199* gene were found in four patients. Two heterozygous mutations in *TMEM199* were detected in our patient with the abnormal liver function since birth. Based on the mutations of the *TMEM199* gene, all the eight patients were diagnosed with TMEM199-CDG. The main features of the eight patients are listed in **Table 2**.

The eight patients with TMEM199-CDG included seven Europeans (originating from Greece and Italy) and one Chinese. There were six male and two female patients, with an age range of 2–41 years, four of whom were two pairs of siblings. Seven patients had the disease onset since early childhood. Intellectual disability or mild language retardation was found in three patients, among whom one also presented with hypotonia, while one Chinese patient also presented with strabismus. All patients reported to date presented high fluctuating levels of alanine aminotransferase (23–437 IU/L, reference range 0–40 IU/L), aspartate aminotransferase (31–746 IU/L, reference range 0–40 IU/L), and alkaline phosphatase (132–3990 IU/L, reference range 42–383 IU/L). Total cholesterol (5.3–9.3 mmol/L, reference range 3.1–5.2 mmol/L) and low-density lipoprotein cholesterol (1.16–7.17 mmol/L, reference range 1.30–3.90 mmol/L) were elevated in seven patients, while high-density lipoprotein cholesterol (1.01–3.03 mmol/L, reference range 0.91–2.05 mmol/L) was normal or slightly increased in four patients. Low levels of serum ceruloplasmin (0.03–0.24 g/L, reference range 0.22–0.58 g/L) and serum copper (2.80–8.60 μ mol/L, reference range 10.99–21.98 μ mol/L) were found. The coagulation function was normal, close to borderline or slightly weakened in six patients. These findings indicate that TMEM199-CDG mainly affects the liver, and nervous and muscular systems may be involved as well.

Liver biopsies were performed in six patients, four of whom showed various degrees of steatosis and periportal fibrosis, and two only showed steatosis. Among them, one patient underwent the

assessment of the ultrastructural characteristics of hepatocytes using a transmission electron microscope. Diffuse and severe vacuolization were observed to most likely derive from the rough ER, smooth ER, and/or Golgi apparatus (Jansen et al., 2016). Unlike the mild or minimal fibrosis manifested in European patients, the liver biopsy of the Chinese patient presented cirrhosis with bridging-like fibrosis and pseudo-lobule formation, which was assessed as stage 4 according to the Scheuer histopathologic scoring system (Scheuer, 1991). The presentation of cirrhosis in early childhood indicates that the severity of liver impairment caused by TMEM199-CDG may require more attention and early intervention.

WES demonstrated heterozygous *TMEM199* mutations in five patients and homozygous *TMEM199* mutations in three patients, including c.13-14delTT (p.Ser4Serfs*30), c.20C > A (p.Ala7Glu), c.40G > C (p.Ala14Pro), c.92G > C (p.Arg31Pro), c.128delA (p.Lys43Argfs*25), and c.376-1G > A (p.?) (Figure 2E). *TMEM199* (NM_152464.1, ENST00000292114) is located on chromosome 17 (chr17:26,684,604–26,690,705), containing six exons encoding a protein of 208 amino acids. The encoded TMEM199 (previously known as C17orf32), a transmembrane protein, is mainly located in the endoplasmic reticulum–Golgi apparatus intermediate compartment (ERGIC) and is involved in Golgi homeostasis. Moreover, as a human homolog of yeast Vma12p, TMEM199 participates in the formation of V-ATPase, which is the proton pump in the process of vesicle acidification via the secretory pathway (Miles et al., 2017). The homeostasis of Golgi apparatus cannot be maintained in TMEM199 deficiency due to the pH imbalance, leading to the abnormal glycosylation of serum proteins, which is closely related to the clinical manifestations of liver dysfunction in patients with TMEM199-CDG. In previously reported patients, glycosylation and functional studies showed aberrant N- and O-glycosylation as a type II CDG pattern, and deficient incorporation of galactose and sialic acid as seen in other Golgi homeostasis defects, which was confirmed by metabolic labeling and restored by lentiviral transduction with wild-type TMEM199 (Jansen et al., 2016; Vajro et al., 2018). Hence, the hepatic phenotype with abnormal glycosylation is considered to be resulted from TMEM199 deficiency. Glycosylation defects and the abnormal protein function of the Chinese patient need to be determined in future studies. Additionally, the expression level of TMEM199 in the Chinese patient’s liver specimen detected by immunohistochemical staining was lower than normal control, which was consistent with the reduced or unmeasurable level of TMEM199 protein in skin fibroblasts detected using the Western blot in the European patients (Jansen et al., 2016; Vajro et al., 2018). The TMEM199 antibody (ab121907) is designed with a recombinant fragment corresponding to human TMEM199 amino acids at positions 7–143. Therefore, the unique c.128delA (p.Lys43Argfs*25) in *TMEM199* exon 1 in our patient caused a frameshift with an early termination, which was mainly responsible for the weak immunohistochemical signal.

Treatment and prognosis were reported in five patients, two of whom did not receive any medication. Despite the 2 years of carbamazepine usage for attention deficit starting at age 6, no other drugs were given to a Greek patient (Jansen et al., 2016). Vitamin D usage for 1 year starting at age 4 and penicillamine usage for 6 months starting at age 5 were reported in an Italian patient (Vajro et al., 2018), while the Chinese patient in the

present study was given bicyclic alcohol, zinc sulfate, and penicillamine for 1 year initiating at age 4. However, it seemed that medical treatments had no definite effect on improving the liver function of these patients. Nevertheless, the previous patients were reported to have no deterioration over several decades, and the Chinese patient presented no significant disease progression during 1-year follow-up. Therefore, there was a view that TMEM199-CDG had a more favorable course to avoid worries of the patients and their parents and unnecessary repeated blood sampling (Vajro et al., 2018). As far as our case is concerned, the early emergence of cirrhosis makes the outcome of the disease not too optimistic; more cohort observations are needed to verify our findings.

CONCLUSION

This report expands the phenotypic and genotypic spectra of TMEM199-CDG by presenting the first Chinese patient carrying strabismus, severe fibrosis, reduced expression of TMEM199, and a novel truncating mutation. Like the previously reported patients, this Chinese boy was monitored, without significant disease progression. But the appearance of cirrhosis in early childhood needs to be paid attention to, and more cases will help better understand the unclear course of this rare condition.

DATA AVAILABILITY STATEMENT

The data presented in this study is included in the article/Supplementary Material. The DNA datasets are not readily

available due to privacy restrictions, further inquiries should be directed to the corresponding authors.

ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the Children's Hospital of Fudan University. (2022) Establishment of Cutoff Values
for Newborn Screening of Six
Lysosomal Storage Disorders by
Tandem Mass Spectrometry.
Front. Pediatr. 10:814461.
doi: 10.3389/fped.2022.814461

Objective: Lysosomal storage disorders (LSDs) are becoming increasingly important in newborn screening, and tandem mass spectrometry (MS/MS) is widely used in newborn screening for LSDs through measurement of enzymatic activities in dried blood spots (DBSs). Overall, the determination of the cutoff value is important in such screening, and different laboratories have different methods of determining this value; most do not use a fixed cutoff value but rather calculate the corresponding batch cutoff value based on each batch of experimental data. In this study, we used MS/MS to screen for LSDs and sought to find an appropriate method to establish the cutoff value for LSD screening.

Methods: A total of 38,945 samples from newborn blood tablets collected from various maternity hospitals in six cities in Shandong province, including Jinan, Dezhou, Heze, Linyi, Weifang, and Zibo, were tested using a Waters Xevo TQD tandem mass spectrometer; the experimental data were analyzed with MassLynx V4.1. The laboratory used 30% of the median GLA enzyme activity and 20% of the median ABG, ASM, GALC, IDUA, and GAA enzyme activities in every test as the cutoff values for that batch of experiments.

Results: There were 254 suspicious positives in the initial screening test, including one case of Gaucher disease, one of Niemann-Pick disease, 47 of Krabbe disease, four of MPS-I, 21 of Fabry disease, and 180 of Pompe disease. After genetic screening, 11 children were diagnosed, including three with Pompe disease, three with Fabry disease, and five with Krabbe disease. In addition, the enzyme activity cutoff value of this experiment showed seasonal variation, which was initially believed to be related to the ambient temperature, such as the effect of ambient temperature on the human body or the temperature when the blood tablets dried naturally.

Conclusion: Overall, MS/MS can be used in LSD screening, and using different cutoff values in each batch of experiments is feasible. The ambient temperature might be a reason why the enzyme activity cutoff value has seasonal variation. More samples are needed to develop a method of determining cutoff values in laboratories.

Keywords: lysosomal storage disorders, newborn screening, cut-off value, tandem (hybrid) mass spectrometry, diagnose

INTRODUCTION

Lysosomal storage disorders (LSDs) are a group of rare genetic metabolic diseases, and it is found that early treatment can lead to the optimal clinical effect (1). Some research finds that there is approximately one LSD case among ~7,700 newborns (2). Therefore, newborn screening for LSDs is increasingly important.

Lysosomes are organelles with monolayer membrane cystic structures containing a variety of hydrolytic enzyme substances that decompose many substances. Approximately 60 enzymes are involved in lysosomal catabolism (1). LSDs occur when some of these enzymes or other lysosomal proteins cannot perform their functions. Moreover, LSDs are believed to occur due to genetic variation (3). Indeed, mutation can lead to deficiency in certain lysosomal enzymes, which causes the corresponding substrates in the cells to be stored without being degraded, causing cell metabolism disorders and organ dysfunction (4). Nevertheless, some nonenzymatic lysosomal and nonlysosomal proteins related to lysosomal activity are considered to only represent a small component, and such accumulation might begin early in embryonic development (5). Currently, LSDs comprise more than 50 genetic metabolic disorders. Most of these disorders are inherited in an autosomal recessive manner with a small portion being X-chromosome linked (1). Lysosomal diseases can be classified in many ways, the most common of which is based on the nature of the accumulated substrate. For example, the corresponding enzymes in MPS-I, Fabry, Gaucher, Krabbe, Niemann-Pick, and Pompe diseases are IDUA, GLA, ABG, GALC, ASM, and GAA, respectively. However, some research in Chinese populations shows that the most common LSD in China is MPS-II (6).

The first disease screened for in neonates using dried blood tablets was phenylketonuria (PKU); the detection method reveals whether a neonate lacks phenylalanine hydroxylase by assessing the amount of the enzyme present (7). Previous studies find that the enzymatic activities of several lysosomal enzymes are retained in dried blood spots (DBSs) used for neonatal disease screening (8). Therefore, DBS testing can be used in the screening of LSDs. Tandem mass spectrometry (MS/MS) is currently the most common screening method for DBSs, and it can quantitatively assess lysosomal enzyme activity.

The gold standard for any test is the positive predictive value (PPV), which is the ratio of true positives to test positives (10). However, the determination of this value is difficult for LSD screening experiments because it is difficult to determine whether newborns who screen as positive truly have the disorder. First, some gene mutations lead to late-onset LSDs, such as late-onset Pompe disease, which would delay the determination of true positives (9). Second, LSDs are considered rare diseases, and the incidence of some is one in tens of or even hundreds of thousands (the incidence of MPS-VII could be <1 in 300,000) (11). Thus, a laboratory needs sufficiently large experimental data to prove the PPV. Based on the above, the false negative and positive rates are significant for NBS screening laboratories; determination of the cutoff value is also important. According

to some research, most laboratories do not use a fixed enzyme activity cutoff value, but generally use the multiple or percentage of the median or mean of the enzyme activity of a test batch with unique cutoff values for each batch (7). According to the research of [Burlina et al. (12)], using 30% of the median GLA enzyme activity and 20% of the median of the other enzyme activities in each test as cutoff values would result in recalls that neither miss positive cases nor recall too many healthy children. For the first time, we used this method to determine cutoff values, such that the cutoff value could be flexibly adjusted according to the test situation to prevent excessive false positive or negative detection. Furthermore, a stable cutoff value would render data analysis relatively straightforward and allow screening results to be more comparable between studies. In this study, we sought to determine a fixed cutoff value.

This study summarizes 38,945 LSD screening data points, including MPS-I, Fabry, Gaucher, Krabbe, Niemann-Pick, and Pompe disease data obtained by MS/MS, from the Newborn Disease Screening Laboratory in Jinan City. We also verified the test method and the method used to establish the cutoff value.

METHODS

The main technique used for this project was MS/MS, which can determine the activity of six lysosomal enzymes in newborns, allowing for the risk of six LSDs to be assessed.

Instrumentation

A tandem mass spectrometer (*Waters Xevo TOD*) and incubation shaker (*Thermo MB100-4A*) were utilized in this study.

Reagents

A screening kit for six LSDs (NeoLSD MS/MS Kit, PerkinElmer) was used in this study.

Procedure

The samples used in this experiment were DBSs of newborns (age between 27 h and 7 days), which were sent to the Jinan Newborn Disease Screening Center from various maternity hospitals in six cities in Shandong province, including Jinan, Dezhou, Heze, Linyi, Weifang, and Zibo; informed consent was obtained from the parents. The collected dried blood tablets were stored under low-temperature drying conditions. Every week, the experimenter randomly selected ~700 continuous samples from the screening samples for that week, which was convenient for associating newborn information with LSD data for LSD detection. Moreover, we conducted a reexamination of the original blood film of the positive samples in the previous batch of experiments as well as a call-up test for suspected positive cases.

The dried blood tablets were hole-punched into 96-well plates with one hole-punched sample per dried blood tablet. Each 96-well plate included two blank wells (BL), two sets of DBS quality controls (C1, C2, C3), and 88 samples. After adding 30 μ l of reaction mixture containing buffer, six substrates, and six internal standards, the plates were covered with an aluminum

foil microplate sealing membrane and incubated on a shaker (400 rpm) for more than 18 h at 37°C. After incubation, the microplates were cooled to room temperature, and 100 µl of quencher (a mixture of methanol and NeoLSD extract with a volume ratio of 50:50) was added to stop the reaction; the samples were repeatedly pipetted up and down 10 times with pipette tips to ensure that the blood spot solution was completely mixed with the quencher. Then, all the liquid in the microplates was transferred to deep 96-well plates, and 400 µl of NeoLSD extract (ethyl acetate) and 200 µl of ultrapure water were added to each well with repeated blowing 20 times using a pipette tip. The aluminum foil microplates were sealed and centrifuged for 5 min at 2,500 rpm, after which 50 µl of the supernatant was pipetted into a U-shaped microplate. This step was conducted carefully to avoid collecting any of the lower water layers. The liquid in the microplate was blown dry using nitrogen. After the reagent was completely volatilized, 100 µl of flow solvent was added, the sealing film was attached, and the mixture was shaken at low speed for 10 min prior to analysis.

The analysts checked whether the quality control and total ion chromatogram (TIC) were normal and uploaded them to the Anaconda system to analyze the resulting data. For cutoff value establishment, the laboratory initially established the value based on the research of Burlina et al. (12), in which the cutoff value of GLA enzyme activity was 30% of the median activity in each test, and 20% of the median of IDUA, ABG, ASM, GALC, and GAA enzyme activities in each test was used as the cutoff values for these enzymes. If the first screening result was positive, the analysts performed a reexamination of the original DBS. Then, if the results of both tests were positive, the center recalled the newborns for a second blood sampling and DBS test. Finally, if the results of reexamination were positive, the child underwent DNA tests based on the doctors' judgment.

RESULTS

Summary of Screening Experimental Results

There were a total of 38,945 newborns who were screened for six LSDs by MS/MS using DBSs. If the results of the first newborn screening were positive, the original DBS was used for a second test. The newborns with two positives in screening were recalled to collect a new DBS for analysis. If the results of the review were positive, doctors combined the children's physical signs and genetic test results as confirmation of the diagnosis. **Table 1** shows the summary of the positives in the initial screening, positives in the original DBS reviews, positives in the second DBS reviews and confirmed number of cases. For all DBSs in LSD screening, there were 402 positives in the initial test, and 254 samples were still positive based on the original DBS review. Among them, GAA had the highest positive rate. For the children who were still positive in the original DBS reviews, the NBS center recalled them and collected a second DBS for testing. Finally, the children were subjected to genetic screening, and three children were diagnosed with Pompe disease, three were diagnosed with

TABLE 1 | The rate of screening positive, review positive, and confirmed disorders in LSD newborn screening (due to lack of reagents, not all the initial screening positives on July 22 and July 27, 2020, were followed up).

Enzyme/LSD	ABG	ASM	GALC	IDUA	GLA	GAA	Total
Positives in initial screening	12	1	71	5	34	279	402
Positives in second original DBS review	1	1	47	4	21	180	254
Suspected cases	0	0	5	0	3	3	11

The type of gene sequence variation in nine suspected cases was "uncertain significance" but with a persistent decrease in enzyme activity as well as signs.

TABLE 2 | Genetic site information and enzyme activity in the screening experiment in confirmed cases.

Number	Disease	Enzyme	Genetic results	Screening result
1	Fabry	GLA	c.1019G > C	0.3 (2.54)
2	Fabry	GLA	c.1286-7del	2.12 (2.74)
3	Fabry	GLA	c.454T > C	0.48 (2.56)
4	Pompe	GAA	c.859-2A > T c.2065G > A	0.42 (1.73)
5	Pompe	GAA	c.752C > T c.761C > T	0.61 (1.92)
6	Pompe	GAA	c.752-761delins c.1757C > T	0.4 (1.72)
7	Krabbe	GALC	c.1901T > C c.2041G > A	0.33 (0.93)
8	Krabbe	GALC	c.1901T > C c.1901T > C	0.52 (0.92)
9	Krabbe	GALC	c.1901T > C c.1901T > C	0.45 (0.87)
10	Krabbe	GALC	c.1204G > A c.1535G > T	0.21 (0.7)
11	Krabbe	GALC	c.1901T > C c.1671-14G > A	0.35 (0.61)

In the "screening result" column, the parentheses are cutoff values for the batch of experiments.

Fabry disease, and five were diagnosed with Krabbe disease (**Table 2**). Additionally, the genetic results revealed five Pompe disease carriers, two Fabry disease carriers, and three Krabbe disease carriers.

Cutoff Value

ABG, ASM, GALC, IDUA, and GAA are lysosomal enzymes with reduced activity in Gaucher disease, Niemann-Pick disease, Krabbe disease, MPS-I, and Pompe disease, respectively. Thus, we decided to use 30% of the median enzyme activity of GLA in each experiment as the cutoff value for Fabry disease; the cutoff values for the other five diseases were 20% of the median enzyme activity. To determine the fixed cutoff value, the cutoff values for all experiments from August 2019 to June 2021 were

FIGURE 1 | Summary of the cutoff value for 38,945 screening samples. **(A)** In this chart, the abscissa is the date of the experiment, and the ordinate is the cutoff value of six lysosomal enzymes. The orange, gray, yellow, blue, green, and navy blue lines represent ABG, ASM, GALC, IDUA, GLA, and GAA, respectively. The overall trend of the six lysosomal enzymes was first an increase and then a decrease followed by another increase, finally showing a downward trend. Among them, the increasing trends of ABG and GLA were obvious though the changes in ASM, IDUA, GAA, and GALC were not significant. **(B)** In this chart, the abscissa is six lysosomal enzymes, and the ordinate is the average monthly cutoff value. Differently colored bars represent different months. For all six lysosomal enzymes, the average cutoff values were the lowest in July and highest in November, December, January, or February.

summarized (**Figure 1**). Activities of ABG and GLA lysosomal enzymes changed significantly over time, peaked in November 2019 and December 2020, and decreased to a minimum in July 2020. In contrast, the other four lysosomal enzymes did not show a significant seasonal change (**Figure 1A**). **Figure 1B** compares the monthly average cutoff values after statistical analysis of the data during the experiment. All six lysosomal enzymes showed the lowest activity in July, whereas the highest activity appeared in November, December, January, or February.

DISCUSSION

It is necessary to promote newborn screening for LSDs. In Europe, the United States, Taiwan, and many other countries, this screening has been ongoing for a long time (12). MS/MS, a high-throughput screening method, can detect enzyme activity by measuring the number of related products of the reaction (13). Moreover, the application of MS/MS to disease screening is common in neonatal disease-screening laboratories; it was first used to screen for PKU. In this study, MS/MS was mainly used to analyze the activity of IDUA, ABG, ASM, GALC, GLA, and GAA, which are reduced in MPS-I, Gaucher disease, Niemann-Pick disease, Krabbe disease, Fabry disease, and Pompe disease, respectively. Among these 38,945 samples, three children were diagnosed with Pompe disease, three with Fabry disease, and five with Krabbe disease through genetic screening. The total incidence of LSDs was nearly 1/3,000 though some research shows that the rate of these diseases is 1/6,000–7,000 (2). This discrepancy might be due to the inclusion of carriers in screen-positive specimens, and the enzyme activity of carriers would also be reduced. More samples are needed to verify the disease incidence in Shandong. The positive rate in Pompe disease was highest among the six diseases in the screening experiment, but the number of diagnosed children was not the largest either due to the effect on screening results of reduced enzyme activity in carriers or because current cutoff value establishment methods are not suitable for Pompe disease; more samples are needed to clarify this. On the other hand, there were no confirmed cases of Gaucher disease, Niemann-Pick disease, or MPS-I among any of the test samples. The incidence of Gaucher disease has strong regional and ethnic differences; it is relatively common in Eastern Europe (14), and the incidence is $\sim 1/500,000$ to $1,000,000$ (15). Similarly, Niemann-Pick disease has the lowest incidence in China, and it is mainly found in the Middle East, Western Europe, North America, and other countries, which may be why no confirmed cases of these two diseases were found in this study. Although some research shows that MPS is common in China, there were no confirmed cases in this study. This result might be because MPS with a relatively high incidence in China would be type II or type IVA (16), but the main MPS type analyzed in this study was MPS-I. Therefore, research on MPS-II and MPS-IV marker screening tests is needed.

We sought to determine a fixed cutoff value of the LSD screening experiment for this laboratory. However, lysosomal

enzyme activity cutoff values differed according to the month. In fact, lysosomal enzyme activity cutoff values were lowest in July and August and highest in December and January. This situation made it difficult to establish a fixed cutoff value. We attempted to explore the reasons for this, and we initially thought changes in temperature to be a factor. The main principle of this experiment was to detect the activity of lysosomal enzymes in DBSs, and enzyme activity appears to be affected by temperature (17). This effect might be divided into the effect of low or high temperatures, but the main difference between these two conditions is that high temperatures would completely inactivate enzymes and low temperatures would not (18). This research was conducted in Shandong, China, and July and August are the 2 months with the highest average temperature in this region. Moreover, all six lysosomal enzymes showed low activity, which might be affected by high temperature. Conversely, low temperature would not inactivate an enzyme but cause a dormant state with activity being restored when the temperature returns to a suitable one (19). The results of this experiment are in accordance with this idea. All six lysosomal enzyme activities were highest in December and January, when the temperature was lowest in the 1-year test. This result might be because a relatively low ambient temperature would provide low-temperature storage conditions for lysosomal enzymes, which would better retain the enzyme activity. This is in accordance with the change in enzyme activity. Therefore, the change in the cutoff value might be related to the change in temperature. This experiment was carried out in a laboratory environment with constant temperature and humidity, and the blood tablets were transported to the laboratory through a cold chain. Nonetheless, the effect of different outdoor temperatures on enzyme activity in the human body and blood tablets at room temperature drying after collection might also cause changes in enzyme activity. In summary, using a fixed cutoff value leads to an increase in false positives in winter and false negatives in summer. However, more samples are required to further verify the effectiveness of the cutoff value establishment method. Although the incidence of lysosomal storage disease is 1 in 7,000 to 8,000, the incidence of each single disease is relatively low; for example, the incidence of Pompe disease is ~ 1 in 40,000 (20).

Overall, MS/MS is feasible for screening LSDs. In this research, the highest initial screening positive rate was for Pompe disease (GAA), and there were eight children with suspected related gene mutation among the 38,945 newborns in the newborn screening test of LSDs but only three confirmed cases with two causative sites were detected. Moreover, we found that the lysosomal enzyme activity cutoff value exhibited seasonal variation, and we suggest that the main reason for this is the effect of seasonal temperature on enzyme activity. Therefore, it is optimal to change the cutoff value for each test batch. According to the current experimental data, the cutoff value establishment method was feasible, but the high rate of positivity in Pompe disease screening might reflect that this cutoff value establishment method is not suitable for screening for Pompe disease in this laboratory. More samples

are needed. Overall, 11 children with suspected mutations were successfully screened in this study. However, due to the low disease incidence, more samples are needed for further verification. Furthermore, as LSDs with high incidence in China are different from those in other countries, new markers need to be further studied to improve screening of LSDs in the Chinese population.

Background: Methylmalonic acidemia (MMA) can display many clinical manifestations, among which acute lymphoblastic leukemia (ALL) has not been reported, and congenital heart disease (CHD) is also rare.

Case presentation: We report an MMA case with ALL and CHD in a 5.5-year-old girl. With developmental delay and local brain atrophy in MRI, she was diagnosed with cerebral palsy at 9 months old. Rehabilitation was performed since then. This time she was admitted to hospital because of weakness and widespread bleeding spots. ALL-L2 (pre-B-cell) was confirmed by bone marrow morphology and immunophenotyping. Echocardiography showed patent foramen ovale. The girl was treated with VDLD and CAML chemotherapy, during which she developed seizures, edema and renal insufficiency. Decrease of muscle strength was also found in physical examination. Screening for inherited metabolic disorders showed significantly elevated levels of methylmalonate-2, acetylcarnitine (C2), propionylcarnitine (C3), C3/C2 and homocysteine. Gene analysis revealed a compound heterozygous mutation in *MMACHC* (NM_015,560): c.80A > G (p.Gln27Arg) and c.609G > A (p.Trp203*). CblC type MMA was diagnosed. Intramuscular injection of cyanocobalamin and intravenous L-carnitine treatment were applied. The edema vanished gradually, and chemotherapy of small dosage of vindesine was given intermittently when condition permitted. 2 months later, muscle strength of both lower limbs were significantly improved to nearly grade 5. The levels of methylmalonic acid and homocysteine were improved.

Conclusion: Metabolic disease screening and gene analysis are very necessary for diseases with complex clinical symptoms. ALL can be a rare manifestation for MMA.

Synopsis: We report a case of methylmalonic acidemia with acute lymphoblastic leukemia and congenital heart disease, which uncovered the importance of genetic testing and metabolic diseases screening in patients with multiple systemic organ involvement.

Keywords: methylmalonic acidemia, acute lymphoblastic leukemia, congenital heart diseases, homocysteinemia, genetic analysis

INTRODUCTION

Methylmalonic acidemia (MMA) is an autosomal recessive disorder of methylmalonate and cobalamin (cbl; vitamin B12) metabolism first reported in 1967. Two main forms and different subtypes of the disease were identified based on enzymic and metabolic abnormalities: methylmalonyl-CoA mutase (MCM) defects, caused by mutation in *MUT* gene, including MUT^0 and MUT^- type; and synthesis and dysfunction of adenosylcobalamin (AdoCbl) and methylcobalamin (MeCbl), associated with mutation in *MMAA*, *MMAB*, *MMCHC*, *MMADHC*, *LMBRD1*, *HCFC1*, and *ABCD4* gene, including cblA, cblB, cblC, cblD, cblF, cblX, and cblJ type (Zhou et al., 2018). According to clinical and biochemical characteristics, MMA can also be classified into two phenotypes: isolated MMA, including *cblA*, *cblB*, *cblH*, and *MUT* deficiencies; and combined MMA, where the levels of both methylmalonic acid and homocysteine elevate, such as *cblC*, *cblD*, and *cblF* deficiencies (Watkins and Rosenblatt, 2013).

Abnormal accumulation of toxic metabolites can cause multisystem damages, including kidney, heart, eye, skin and nervous system, as well as gastrointestinal system and immune system. Symptoms may occur before 1 year of age or in early infancy (early-onset MMA), and may also appear between the ages of 4 and 14, even in adulthood (late-onset MMA). Clinical presentations are relatively non-specific, such as lethargy, seizures, developmental delay, hypotonia, movement disorders, feeding difficulties and vomiting (Zhou et al., 2018). Hematological disorders have been reported in some cases, such as megaloblastic anemia, neutropenia or pancytopenia. Cardiovascular changes have also been observed in few cases, such as cardiomyopathy and arrhythmias.

In this study, we reported a combined MMA (cblC type) case in a 5.5-year-old girl, with rare complications -- acute lymphoblastic leukemia (ALL) and patent foramen ovale (PFO). To our knowledge, no such complication has ever been described.

CASE PRESENTATION

The patient was a 5.5-year-old girl, whose primary symptom was developmental retardation—unable to crawl at 9 months. With no history of intrauterine infection or postnatal asphyxia, the girl was diagnosed with cerebral palsy by local hospital based on brain MRI changes. After receiving aggressive rehabilitation, she was barely able to walk without help until nearly 3 years old.

In January 2021, the girl was brought into hospital again because of weakness and widespread bleeding spots for 1 week. Pale lips and face, petechiae in skins and edema in eyelids were observed in physical examination. Blood routine examination showed severe anemia (hemoglobin of 53 g/L), moderate thrombocytopenia (platelets of $22 \times 10^9/L$), with normal white blood cell count ($6.53 \times 10^9/L$). Liver function, kidney function and myocardial enzyme tests were all normal. Proteinuria (+) was detected, and 24-hour urine protein was 0.38 g. Echocardiography showed patent foramina ovale of 3.4 mm. In

order to find out the reason of hematological abnormalities, bone marrow puncture was performed. Morphology and immunophenotyping confirmed the diagnosis of ALL-L2 (pre-B-cell). Ph-like ALL gene analysis showed positive mutated *IKZF1* gene, lower expression of *CRLF2* gene and positive mutated *WT1* gene. No abnormal karyotype was found in chromosome analysis. VDL regimen (vindesine, daunorubicin, L-asparaginase and prednisone) was used as induction chemotherapy. Complete remission (CR) was achieved 15 days later, with the mutated *IKZF1* gene turning negative.

Treatment for leukemia continued for 2 months, when the girl developed vomiting, abdominal pain, distension and muscle tension during the early intensive CAML chemotherapy (cyclophosphamide, cytarabine, mercaptopurine and pegaspargase). Severe acute pancreatitis was diagnosed based on elevated serum amylase, lipase and characteristic abdominal CT changes. At same time, she showed recurrent attack of generalized seizures. Ambulatory electroencephalogram revealed lateralized periodic epileptic discharges in the left brain, and partial discharges from the left back side. Brain magnetic resonance imaging (MRI) showed encephalomalacia and gliosis in the left frontal and parietal lobe and basal ganglia, with regional brain atrophy, and abnormal signals in the left lateral ventricle and semiovale region (Figure 1). She also showed edema, hypertension, increased urinary protein (+++, 2.035 g/24 h) and hematuria (blood test +++, RBCs 25.52/HP). Chemotherapy was halted to deal with pancreatitis, seizures and renal injury. After her condition improved, the girl was discharged with prescriptions of oral levetiracetam, nifedipine, prednisone and furosemide.

1 month later, she showed gradually aggravated edema, hypertension, renal dysfunction, oliguria (about 200ml/24 h) and three episodes of seizures. Physical examination results at this admission were: BP 133/102 mmHg, severe edema in both eyelids and lower limbs, pale lips and face, and decrease of muscle strength (grade 3 in upper limbs, grade 2 in lower limbs), with normal muscle tone. Massive proteinuria (++++, 2.255 g/24 h) and hematuria (blood test +++, RBCs 38.42/HPF) was detected. Peripheral blood test results were: WBC of $8.26 \times 10^9/L$ ($4-10 \times 10^9/L$), Neutrophil of $6.24 \times 10^9/L$ ($1.8-6.3 \times 10^9/L$), hemoglobin of 85 g/L (110–140 g/L), platelets of $65 \times 10^9/L$ ($100-300 \times 10^9/L$), albumin of 28.9 g/L (40–55 g/L), lactic dehydrogenase (LDH) of 2963 U/L (120–250 U/L), urea of 14.36 mmol/L (2.85–7.14 mmol/L) and creatinine of 88 $\mu\text{mol/L}$ (59–104 $\mu\text{mol/L}$). Calculated creatinine clearance (Ccr) was 36 ml/min. Based on these results, the girl was diagnosed with CKD(G3b).

Considering the early-onset of symptoms and multisystem involvement, screening for metabolic diseases was performed. Results are: methylmalonic acid-2 of 8.68 $\mu\text{mol/L}$ (0.2–3.6 $\mu\text{mol/L}$), serum homocysteine of >50 $\mu\text{mol/L}$ (4.44–13.56 $\mu\text{mol/L}$), free carnitine of 177.194 $\mu\text{mol/L}$ (10–60 $\mu\text{mol/L}$), acetylcarnitine (C2) of 58.959 $\mu\text{mol/L}$ (6–30 $\mu\text{mol/L}$), propionylcarnitine (C3) of 17.561 $\mu\text{mol/L}$ (0.5–4 $\mu\text{mol/L}$), and C3/C2 of 0.298 (0.04–0.25). MMA was suspected, whole exome sequencing (WES) was performed, and detected mutations was verified by Sanger

FIGURE 1 | Brain MRI images. **(A,B,D)** Brain atrophy was found in Transverse T1 and T2 weighted image and Sagittal T1 weighted image (the red arrow); Sulci fissure widened and deepened in Transverse T1 and T2 weighted image (the green arrow); **(C)** High signal in white matter near to bilateral periventricular in FLAIR sequence (the yellow arrow).

sequencing. The proband had a compound heterozygous mutation in MMACHC gene, c.80A > G (p.Gln27Arg) in exon 1 inherited from her mother, and c.609G > A (p.Trp203*) in exon 4 [reference sequence: NM_015560] from father (**Figure 2**). c.609G > A (p.Trp203*) is a nonsense mutation, which is expected to change the 203rd amino acid of encoded protein from Trp to stop codon, causing the encoded protein to be truncated and lose its normal function. As was reported in several literatures, this mutation is a hot mutation in Chinese patients with methylmalonic acidemia and homocystinemia. In the gnomAD database, the frequency of this variation in East Asian population is 0.0005562. c.80A > G (p.gln27arg) is a missense mutation, which is expected to change the 27th amino acid of the encoded protein from Gln to ARG. The frequency of this mutation in gnomAD database is 0.0001669 in East Asian population. Considering the ACMG score, both variants are pathogenic.

The final diagnosis was determined as combined methylmalonic acidemia and homocystinemia (cblC type), secondary nephrotic syndrome (nephritis type), secondary hypertension (level 2), and chronic kidney disease (C3b). Vitamin B12 (cyanocobalamin; 1mg, twice-weekly) and L-carnitine (1000 mg, IV, qd) were given, together with oral antiepileptic drug, antihypertensive agents, diuretics and

prednisone. When condition permitted, a low dose of vindesine (1.5 mg, IV) was administered intermittently for chemotherapy. About 1 week later, the edema vanished gradually. After 2 months of treatment of vitamin B12 and L-carnitine, the muscle strength of both lower limbs were significantly improved to nearly grade 5. In the following 3 months, the girl was treated with Chimeric Antigen Receptor T-Cell Immunotherapy (CAR-T) twice. After reinfusion of her own T cells, there was no abnormality in bone penetration, MRD and fusion gene. Then she received sequential treatment of CD19 and CD22, and 3 times of VDL chemotherapy. Now the girl receives intramuscular injection of cyanocobalamin twice a week, oral administration of L-carnitine and folic acid tablets. The levels of methylmalonic acid and homocysteine were improved.

DISCUSSION

Methylmalonic acid is the metabolite of methylmalonyl-CoA in the catabolism of branched chain amino acids (isoleucine, methionine, threonine and valine), odd-chain fatty acids, gut-derived propionate and cholesterol. In order to enter the

FIGURE 2 | The family pedigree showing the mutations detected in *MMACHC*. **(A)** The pedigree of the family with MMA. The arrow indicates the proband; her parents have no signs of MMA. **(B)** The mutations detected in the family. The proband has both mutations, while the c. 80A >G mutation was only detected in her mother and the c. 609G > A mutation was only detected in her father.

tricarboxylic acid cycle, methylmalonyl-CoA is reversibly isomerised to succinyl-CoA, which process is catalyzed by mitochondrial enzyme methylmalonyl-CoA mutase and requires adenosylcobalamin (AdoCbl) as an essential cofactor (Froese et al., 2015; Hu et al., 2018). Children with cblC type MMA have defects in *MMACHC* gene, whose coding proteins is related with the synthesis of AdoCbl and methylcobalamin (MeCbl) (Bassila et al., 2017). MeCbl is the coenzyme of methyltetrahydrofolate-homocysteine methyltransferase, also known as methionine synthase (MS), located in the cytoplasm, catalyzing the methylation of homocysteine to methionine. Low levels of AdoCbl and MeCbl in cblC type patients cause abnormal accumulation of metabolites such as methylmalonate, methylcitrate and 3-hydroxybutyric acid, decreased serum methionine, and reduced activity of succinic dehydrogenase. As a result, mitochondrial energy metabolism was affected, and multiple symptoms appear (Bassila et al., 2017).

In China, most of *MMACHC* mutations are located in exons 3 and 4, and C. 609G > A (P.w203x) is the most common. In this case, clinical manifestations include cerebral palsy, developmental delay, epilepsy, hypertension, proteinuria, chronic renal insufficiency; laboratory findings showed elevated methylmalonic acid-2, acetyl carnitine, propionyl carnitine in blood and urine; genetic testing revealed a compound heterozygous mutation in *MMACHC* gene [c. 80A > G (P.q27r, from her mother) and c. 609G > A (P.w203x, from her father)], which has been reported in MMA cases before (Hu et al., 2018; Wang et al., 2019). Clinical features, laboratory findings and genetic testing all support the diagnosis of cblC-type MMA.

The diagnosis of MMA mainly depends on examination of blood acylcarnitine profile and urinary organic acids, characterized by remarkably increased blood C3, C3/C2 ratio and relatively high concentrations of methylmalonic acid and methyl citrate in urine (Keyfi et al., 2016). Genetic analysis is helpful for the classification of MMA (Chandler and Venditti, 2005). According to responses to vitamin B12, MMA can be divided into two sub-type: Vitamin B12 responsive and vitamin

B12 unresponsive. B12 responsive ones are mostly caused by deficiency of coenzyme synthesis (Froese et al., 2009), while unresponsive ones are mostly caused by deficiency of mutase (Pela et al., 2006). Once MMA was suspected or diagnosed, initial treatments must be performed without delay. Basic principle of treatment is to reduce the production of methylmalonic acid and its bypass metabolites, and to accelerate their clearance. For acute management, treatments are stabilizing the patient, restricting protein intake, providing enough calories, and administering drugs including L-carnitine, vitamin B12 (preferably hydroxocobalamin), biotin, sodium phenylbutyrate and arginine. For long-term management, vitamin B12 responsive MMA patients should be treated with vitamin B12 (1mg, IM, once or twice a week), followed by other oral drugs including vitamin B6, betaine, folic acid, L-carnitine, and sometimes methionine. If concentration of C3 and urinary methylmalonic acid are at appropriate levels, highly restricted diet may not necessarily be taken (Ribas et al., 2010). For vitamin B12 unresponsive cases, specialized amino acid formulations (containing minimal to no isoleucine, methionine, threonine, and proline, etc.) should be used, and nutritional intervention, such as strict restriction on the intake of natural protein and supplements, should be applied. L-carnitine is effective for both types of MMA because of its ability of promoting the excretion of both methylmalonic acid and C3 (Ribas et al., 2010). After diagnosis, the case was treated with intramuscular injection of vitamin B12 (1mg, twice a week), supplemented by L-carnitine (1g/day). The clinical course should be classified as early-onset: developmental delays in gross movement, brain atrophy in cerebral MR images, and seizures. The results of metabolic screening and genetic analysis confirmed the diagnosis. Symptoms improved significantly after vitamin B12 administration, so we speculate this case to be an early-onset and vitamin B12 responsive one.

B-acute lymphoblastic leukemia (B-ALL) is the most prevalent childhood hematological malignancy, whose development is a complex process of multiple gene mutations, involving fusion mutations in early-stage and collaborative genes mutations in

Abbreviation: PAH, pulmonary arterial hypertension; ASD, atrial septal defect; VSD, ventricular septal defect; PDA, patent ductus arteriosus; NM, not mentioned; CBL, hydroxocobalamin; CAR, carnitine; PR, protein restriction. BET, betaine. F, folic acid.

late-stage. In particular, gene mutations associated with B cell development play an increasingly important role in the pathogenesis of B-ALL (Pui et al., 2015).

We conducted a literature review about congenital hematological disease and cardiac disease in MMA. We searched for keywords “Hematological”, “Cardiovascular”, “heart”, “blood” and “child” in all fields in PubMed and Web of Science, and screening out original articles focusing on cardiovascular disease and hematological disease in MMA. This section was summarized in **Tables 1, 2**.

In summary, (Nogueira et al., 2008; Wang et al., 2010; Fischer et al., 2014; Liu et al., 2018; Wang et al., 2019; He et al., 2020a; He et al., 2020b; Kang et al., 2020; Wang et al., 2021), anemia is the most common blood system damage of MMA (**Table 1**), the incidence of which is 21.4–83.3%. Other hematological complications include granulocytopenia, thrombocytopenia, pancytopenia and hemolytic uremia.

The protein encoded by *MMACHC* is mainly involved in the biological synthesis of AdoCbl and MeCbl (Bassila et al., 2017), and then affects the levels of methylmalonyl-coA mutase (MUT) and MMA, and also affects the activity of methionine synthase (MTR). MTR C. 2756 mutation has been reported to be positively correlated with the occurrence of ALL in Asian population in former studies (Yu et al., 2010), but its mechanism is still unclear.

Among the 14 methionine-dependent tumor lines tested by Watkins (Watkins, 1998), reduced methionine synthase function and reduced MeCbl and AdoCbl synthesis was observed only in MeWo LC1 melanoma cell lines. It was later proved that the decreased expression of *MMACHC* in MeWo LC1 was caused by methylation of CpG island at the end

of the corresponding gene 5. Recent studies have shown that in some cbIC patients, specific mutations in *PRDX1*, a contiguous gene of *MMACHC*, lead to secondary epigenetic mutations that affect methylation of the *MMACHC* promoter and expression of *MMACHC* (Guéant et al., 2017, 2018). Both MeWo LC1 human melanoma cell line and cbIC patient-derived cells have reduced AdoCbl and MeCbl synthesis, decreased intracellular cobalamin concentration, and impaired activity of these two cobalamin-dependent enzymes (Loewy et al., 2009). These similarities open up the possibilities to clarify whether there is a common mechanism of methionine dependence in cbIC patient-derived cells and MeWo LC1 cell lines (Loewy et al., 2009).

The child suffered from methylmalonic acidemia, which leads to decreased expression of *MMACHC* gene, decreased intracellular cobalamin concentration, decreased activities of AdoCbl and MeCbl, two cobalamin-dependent enzymes, and increased levels of methionine and homocysteine, resulting in changes in blood microenvironment. Many syndromes can have complications of leukemia, of which the possible reason may be microenvironment changes caused by chromosomal, genetic and metabolic abnormalities. Simultaneous MMA and leukemia may be associated with abnormal amino acid levels and changes in blood microenvironment, or may be related to the genetic variation of *MMACHC* and MTR C. 2756 and the subsequent decrease of MTR activity. Further studies are needed to determine whether these changes lead to acute lymphoblastic leukemia. While, perhaps the presence of both ALL and cbIC methylmalonic acidemia in this case may also be a coincidence.

In MMA cases combined with heart disease (**Table 1**), (Andersson et al., 1999; Heinemann et al., 2001; Tomaske

TABLE 2 | Case reports of MMA complicated with cardiovascular diseases.

NO.	References	Year	Sex	At diagnosis age	MMA-type	MMACHC mutation	Types of heart disease	Mean Hey (umol/L)	Mean urine MMA (mmol/mol cr)	Treatment	Outcome

Abbreviation: PAH, pulmonary arterial hypertension; ASD, atrial septal defect; VSD, ventricular septal defect; PDA, patent ductus arteriosus; NM, not mentioned CBL, hydroxocobalamin; CAR, carnitine; PR, protein restriction. ↑, larger than the reference value. CBL, hydroxocobalamin; PR, protein restriction; CYS, cystadane; ASA, aspirin; CAR, carnitine; F, folic acid.

et al., 2001; De Bie et al., 2009; Profitlich et al., 2009), cardiomyopathy(1.2–2.9%) and pulmonary hypertension (0.9–1.7%) were more common (Andersson et al., 1999; Heinemann et al., 2001; Tomaske et al., 2001; De Bie et al.,

2009; Profitlich et al., 2009; Prada et al., 2011; Kido et al., 2017; Liu et al., 2017; De Simone et al., 2018; Wen et al., 2020; Zhang et al., 2020). While mitral valve prolapse, mild mitral regurgitation, focal left ventricular uncompacting, atrial septal defect, ventricular

septal defect, patent ductus arteriosus and pulmonary artery stenosis were also reported (Table 2).

A study suggested that MTR polymorphisms (rs1770449 and rs1050993) may be associated with the risk of CHDs and modified the relation between maternal folate intake and CHDs (Deng et al., 2019). Three independent case-control studies in a total of 2,340 patients with CHD and 2,270 controls suggested that two regulatory variants of MTR, 2186T.G and +905G.A were associated with increased risk of CHD (Zhao et al., 2014). Patent foramen ovale, a secondary atrial septal defect, was detected in this case by echocardiography. We speculate that the main cause of this patent foramen ovale was MMA combined with homocysteine. The structural defects of heart in cblC MMA patients may be related to the increase of metabolites such as methionine, s-adenosine methionine and s-adenosine homocysteine, or the lack of methionine synthase.

This case was unable to crawl at 9 months old, and was diagnosed with cerebral palsy based on brain atrophy in brain MRI. Gestational age and birth weight were normal, and no history of postnatal asphyxia, hypoxia, hyperbilirubin encephalopathy, and intrauterine infections were found. Seizures occurred during chemotherapy, and the results of EEG suggested epilepsy. Therefore, when a patient showed cerebral palsy and epilepsy with no common causes, screening for metabolic diseases should be performed to exclude metabolic diseases.

CONCLUSION

1. Metabolic screening and genetic analysis are necessary for cases with multiple system involvement.
2. Cerebral palsy may have multiple causes, and genetic metabolic diseases should be taken into consideration apart from common causes such as preterm birth, low weight, history of postnatal asphyxia, and hypoxia, neonatal hyperbilirubin encephalopathy and intrauterine infection.
3. MMA and homocysteinemia should be considered in the differential diagnosis of congenital cardiac defects. Routine and regular cardiovascular assessments should be performed in patients with MMA to identify cases with cardiac structural defect and cases with risks of thromboembolism and stroke.
4. The lack of specific clinical manifestations causes difficulties in MMA diagnosis. Physicians, especially pediatricians in high-prevalence areas, should raise awareness for the diseases, screen

high-risk patients timely and perform blood carnitines and urine organic acids analysis, so as to make early diagnosis and treatments, and improve prognosis of the disease.

DATA AVAILABILITY STATEMENT

The datasets for this article are not publicly available due to concerns regarding participant/patient anonymity. Requests to access the datasets should be directed to the corresponding author.

ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the First Hospital of China Medical University. Written informed consent to participate in this study was provided by the participants' legal guardian/next of kin.

AUTHOR CONTRIBUTIONS

JZ, SW, and XZ were responsible for the acquisition of clinical information and drafted the manuscript. BZ analysed the patient data and edited manuscript. YL assisted in developing figures and images for the manuscript. HJ was responsible for acquisition of the clinical information and reviewed the manuscript. All authors approved the manuscript for submission.

FUNDING

This work was supported by the National Natural Science Foundation of China (Grant No. 81300130) and Liaoning Province Livelihood Science and Technology project (Grant No. 10300008). The role of funders was to sponsor the multiplex ligation-dependent probe amplification analysis for this case.

ACKNOWLEDGMENTS

We wish to thank the patients and their families for participating in this study, without whom none of this would be possible.

Case Report: Cystinosis in a Chinese Child With a Novel CTNS Pathogenic Variant

Yu-Jia Guan^{1,2,3}, Yan-Nan Guo^{3,4*}, Wen-Tao Peng^{1,2,3} and Li-Li Liu^{1,2,3}

¹ Department of Nursing, West China Second University Hospital, Sichuan University, Chengdu, China, ² West China School of Nursing, Sichuan University, Chengdu, China, ³ Key Laboratory of Birth Defects and Related Diseases of Women and Children (Sichuan University), Ministry of Education, Chengdu, China, ⁴ Department of Pediatrics, West China Second University Hospital, Sichuan University, Chengdu, China

Objective: To report a rare case of cystinosis with a novel CTNS pathogenic variant in the Chinese population.

Methods: Retrospective analysis of the clinical manifestations, laboratory results, and gene detection data of a child with cystinosis.

Results: A Chinese Zang ethnic girl could not stand or walk until 3 years old, with additional symptoms including a loss of appetite. Since then, the girl gradually exhibited “X” leg, double wrist joints, a bilateral ankle deformity, and rickets. At the age of 9 years, the girl was hospitalized. Laboratory testing showed that her blood phosphorus, blood calcium and blood potassium levels were significantly decreased. At the same time, the girl’s urine glucose and urine protein were positive, although her fasting blood glucose, glycosylated hemoglobin, and 75 g glucose tolerance were not significantly abnormal. Further, blood gas analysis showed metabolic acidosis. These symptoms corresponded to Fanconi syndrome. Gene analysis showed that there was a homozygous pathogenic variant c.140 ≤ 5G > A (p.?) in the CTNS gene, which was a small variation in the intron region. To our knowledge, this is the first report of the rare variant.

Conclusion: Attention should be paid to the differential diagnosis of cystinosis by gene analysis in children whose clinical manifestations include exercise dysplasia, renal damage, or multiple organ damage (including bone, thyroid, etc) and who cannot be firmly diagnosed for the time being.

Cystinosis in a Chinese Child With a
Novel CTNS Pathogenic Variant.
Front. Pediatr. 10:860990.
doi: 10.3389/fped.2022.860990

INTRODUCTION

Cystinosis is an extremely rare autosomal recessive metabolic disease which is caused by the lack of L-cystine transporters on the lysosomal membrane resulted from the pathogenic variant of CTNS. This defect in lysosomal membrane transport leads to cystine accumulation, which eventually causes multiple organ dysfunction, including the eyes, kidneys, nerves, heart, and endocrine gland, amongst others. Until now, the majority of reported Cystinosis cases have occurred in Europe and the United States. The incidence of cystinosis in the general population is within the range

of 1:260,000–1:115,000 (1, 2), which varies greatly in different regions. It should be noted that the relevant data in China are still incomplete.

In recent years, some progress has been made in the study of the disease in developed countries. However, relatively few reviews or case reports from China have been published (3–6). Furthermore, cases of cystinosis in children are particularly rare, which may be related to the low incidence of the disease and also the understanding of the disease. Timely findings, accurate diagnosis, and extensive reporting will be helpful to increase awareness of this disease. Meanwhile, early diagnosis and early treatment have an important impact on the prognosis of the disease, and can help to reduce or delay the occurrence of complications and prolong the patient's life. In this paper, the clinical manifestations, laboratory results, and gene detection data of a child with cystinosis diagnosed in West China Second Hospital of Sichuan University were reported (see below). The clinical characteristics, diagnosis and treatment strategies were discussed.

CASE PRESENTATION

The patient was a 9-year-old girl who was the second child of non-consanguineous parents from the Zang ethnic minority group, Sichuan Province, China. Her mother was not exposed to or used alcohol, tobacco, or drugs during her pregnancy. She was carried full-term and had a normal vaginal delivery, although her birth weight and body length could not be provided by her family. She was breastfed after birth with supplementary foods added when appropriate. At the age of 1, the child began to crawl and sit by herself, which was not something her family paid particular attention to. However, by the age of 3, she could not stand or walk. Her mobility issues were accompanied by a poor diet, which mainly consisted of formula milk. The child's upper limb movement and cognitive and intellectual development were not significantly abnormal compared to children of the same age. Vitamin D and lysine were prescribed for her initial treatment in the outpatient department of a local hospital. At the age of 4 years, she could walk independently and appeared "X" leg. This patient was diagnosed with Fanconi syndrome, which based on renal tubular acidosis, vitamin D deficiency, growth retardation, normocytic anemia and the decreased serum phosphorus and calcium level during her first hospitalization, and diagnosed with bronchitis and hypocalcemia. Then she was treated with sodium dihydrogen phosphate, disodium hydrogen phosphate, sodium citrate + potassium citrate, vitamin D, and calcium.

After her symptoms were alleviated, it was suggested that she continue to take the above drugs after discharge and be followed up with the outpatient service. However, the child neither went to the clinic for follow-up on time, nor took medicine strictly according to the doctor's advice. Her family members admitted that they forgot occasionally and thought it was not such a serious problem. Their poor compliance may be related to distance from hospitals, lack of time, and family cultural background, concept and other reasons.

About 4 years later, at 8 years and 9 months old, the girl experienced fatigue and her hands were bent and claw-like. These symptoms were accompanied by pain, and at this time her family members independently decided to discontinue her medication. One month later, she presented with a paroxysmal dull ache in her hypogastrium, dizziness and headaches, and occasionally felt nauseous when eating greasy foods, soreness when exercised. She had occasional soft coughs, without polydipsia, urorrhagia, and so on.

At the age of 9, she was hospitalized in West China Second University Hospital of Sichuan University. The anthropometric evaluation showed that her stature (bodyweight 18 Kg, height 108 cm) was lower than the 3rd percentile of height and weight for individuals of the same age and sex, and also that her subcutaneous fat was thin. A Pectus carinatum brace was fitted. Upon testing, it was found that her blood phosphorus (1.07 mmol/L), blood calcium (1.72 mmol/L), and blood potassium (3.4 mmol/L) levels were significantly decreased. And it was found that her hemoglobin level (88 g/L) was decreased, while both of the level of Mean Corpuscular Volume (MCV) and the level of mean corpuscular hemoglobin (MCH) were within the normal range. This indicated that the patient can be diagnosed with normocytic anemia.

Meanwhile, laboratory tests showed a decreased Vitamin D (both 25-OH-D and 1.25-OH-D) level (9.6 ng/ml), an increased alkaline phosphatase level (575 U/L), significantly increased blood urea nitrogen level (6.98 mmol/L) and creatine level (163 μ mol/L). Urine sugar (3 +) and urine protein (2 +) were positive. Her levels of free carnitine (6.1 μ mol/L), citrulline (44.86 μ mol/L), glucose (75 g) tolerance, glycosylated hemoglobin, fasting blood glucose, and thyroid function were normal. Blood gas analysis showed metabolic acidosis and anion gap. Renal ultrasound image (**Figure 1**) showed slightly enhanced parenchymal echo in both kidneys.

The child's clinical symptoms included abnormal motor development for 6 years, with bone deformity, "X" legs, chicken chest, double wrist joints, bilateral ankle joint deformity, and other changes in her left bone and distal radius, ulna distal osteoporosis, including the decreased bone mineral density detected by bone densitometry of child via Quantitative Ultrasound Bone Densitometry (QUS), and left radius and distal ulna rickets. The child had rickets and hypophosphatemia in the past. A diagnosis of Fanconi syndrome was the preliminary clinical consideration. In addition, according to Schwartz formula, the Epidermal Growth Factor Receptor (eGFR) of the patient was 20.17 mL/(min 1.73 m²), indicating that the child was in chronic kidney diseases (stage IV) and did not meet the criteria for dialysis, so dialysis treatment was not performed for the time being. At the same time, we informed the patient's family that the patient was about to enter chronic kidney diseases (stage V), and preparations before dialysis should be made, including indwelling central venous catheterization for hemodialysis and peritoneal dialysis.

The patient suffered from renal tubular acidosis, hypokalemia, hypocalcemia and hypophosphatemia since childhood. The examination after admission showed that urine sugar (3 +) and urine protein (2 +) were positive, while glucose (75 g) tolerance,

FIGURE 1 | Renal ultrasound image.

FIGURE 2 | CTNS mutation Sanger analysis results for the patient involved in this study. Polymerase chain reaction (PCR) and Sanger was performed in our test.

glycosylated hemoglobin and fasting blood glucose were normal. In addition, α 1-microglobulin, β 2-microglobulin and other proteins in urine that reflect the reabsorption function of renal tubules were increased. Therefore, the patient was considered to have renal tubular injury, which can lead to electrolyte disturbance, renal diabetes, and partial tubular proteinuria.

Meanwhile, considering the renal tubular injury, the decrease of serum calcium/phosphorus concentration/level and the increase of parathyroxine levels (945.8 pg/ml), the secondary hyperparathyropathy could be diagnosed. Furthermore, the girl had abdominal pain for more than 3 months prior to hospitalization. A CT scan showed slightly blurred mesenteric

fat space, multiple enlarged lymph nodes in the abdominal cavity were identified, thus mesenteric lymphadenitis was considered.

During hospitalization, the girl appeared tetany repeatedly, manifested as flexion and rigidity of the limbs as well as chicken claw-like hands accompanied by pain, and the lowest blood calcium level was 1.68 mmol/L. Calcium carbonate was then supplemented intravenously and oral calcium zinc gluconate and ossified triol were added. As citrate would combine with free calcium ions, which could further decrease blood calcium levels, the administration of citrate was stopped.

The girl underwent ophthalmologic examination in West China Fourth Hospital of Sichuan University. The conjunctiva, cornea, iris, lens, retina, intraocular pressure, and diopter were normal, no binocular corneal crystalline was found, and there was no visual field defect.

On the premise of informed consent, the whole exome sequencing (WES) of this girl was conducted. We decided to perform WES analysis because the initial onset age of the patient was early, accompanied by multiple organ system damage, and the treatment effect of oral sodium and potassium citrate mixture for renal tubular acidosis was not good. Meanwhile, the renal function of this patient showed progressive decline. The progression of renal tubular dysfunction, followed by glomerular involvement and renal decompensation, led us to strongly suspect that the patient had a mono-genetic inherited related renal tubule dysfunction.

Gene analysis showed that there was a homozygous pathogenic variant $c.140 \leq 5G > A$ (p.?) in the patient's CTNS gene (**Figure 2**). This was a small variation in the intron region, found for the first time. Notably, such a variant has not been reported in the literature and is rare in the population. Combined with the results of genetic examination, the diagnosis of cystinosis was made.

Although the child was in a serious condition, her parents asked for her to be discharged after 6 days of hospitalization. Research shows that hypophosphatemia and hypocalcemia in Fanconi syndrome and proximal renal tubular acidosis can be exacerbated by vitamin D deficiency, and the resulting tetany and obvious bone pain. And the above clinical symptoms can be effectively alleviated by the treatment with sodium hydrogen phosphate and sodium phosphate disodium buffer solution and active vitamin D.

After discharge, the parents were guided to supervise the girl to use drugs according to doctor's prescriptions (to take orally sodium dihydrogen phosphate, disodium hydrogen phosphate, lysine inositol vitamin B12, lysine calcium hydrogen phosphate tablets, calcitriol soft capsules, ferrous succinate tablets and vitamin C, and to recheck regularly).

The girl was asked to limit the intake of high protein foods, and return to the hospital if there was any discomfort. Twenty-eight days after the discharge, her family received the gene report results and were advised to carry out the related gene detection. Unfortunately, her family refused to carry out genetic testing. We used network follow-up to remind her family members to take her to the local hospital for urine review to monitor kidney function, but the patient did not follow up strictly according to the doctor's advice.

DISCUSSION

Up to date, most of the reported cases of cystinosis have occurred in Europe and the United States, with much less cases of cystinosis reported in Asia. Specifically, one case in Japan (7), 6 cases in Thailand (4 families involved) (8), 2 cases in India (9), and 21 cases in China have been reported (**Table 1**) (3, 5, 6, 10–13). The Chinese cases included 10 Mainland families (including 13 patients with CTNS homozygous mistranslation variant N323K, $c.681 G > A$ (p.E227E), $c.477C > G$ (p.S159R), $c.274C > T$ (p.Q92X), $c.680A > T$ (p.E227V) and CTNS pathogenic variant of (IVS6+1, del G and IVS8-1, and del GT), or with a deletion of $c.18_21del$ GACT, (p.T7FfsX7)), and 5 Taiwanese families (including 8 patients with CTNS homozygous mistranslation variant N323K, $753G > A$ (W138X), exon 11 (IVS11+2T > C), 1178A-G (K280R) or mutation 57-kb deletion cystinosis).

At present, the known types of gene pathogenic variant include insertion, deletion, repetition, translocation, point variant, splice site variant, promoter variant, and genome rearrangement of CTNS gene sites. Here we report a new homozygous variant of the CTNS gene. The pathogenic variant site was Intron4 position on chr17:3550821 chromosome, and the protein level of reference transcript was NM 004937.3: $c.140+5G > A$ (p.?). The variation is a small variation in the intron region, which has not been reported in the literature as this variant is rare in the population. The variation cannot be found in the ESP6500siv2 ALL, 1000g2015aug ALL, EXAC, gnomAD, and dbSNP147 databases. Unfortunately, the family members of the child refused to undergo genetic testing, and as such, we could not determine whether other members of the family had similar variations.

Also, among the cases reported in China, only Yong-jia Yang's report clarified ethnic groups of cystinosis patients, in which a Chinese Han family was affected.

Compared with adults, there are very few reports on cystinosis in children in China. However, in recent years, scholars are increasingly paying attention to cystinosis in children. Based on the duration of presented symptoms and the severity of renal involvement, Cystinosis can be divided into infant type (also known as kidney type), juvenile type (also known as intermediate type), and ophthalmopathy type, of which infant type is the most common and most serious, typically characterized by kidney involvement as the first symptom (14). In our report, the patient belongs to infant type, manifested as involvement of multiple organs such as kidney, bone, and thyroid. The girl began to develop symptoms at the age of 3 and was first diagnosed with Fanconi syndrome at the age of 4. At the age of 9, she was hospitalized due to the aggravation of the symptoms. At this time, following gene detection, she was diagnosed with cystinosis and chronic kidney disease. It took 5 years from the initial visit to the final diagnosis for this case. This may be related to the low medical cooperation of the patient's family members, characterized by irregular medical treatment, poor medication compliance, etc. There are also other factors, including the rarity of the cases, economic conditions, limit of diagnosis, and treatment technologies as well as the concept of medical behavior of the patient and her family members. In recent

	2	–	–	9 years	–	–	Binocular corneal crystalline	Kidney failure (ESRD) and received allografts	Began cysteamine treatment until transplantation at ages 19.8 and 26.4 years. Obstructive nephropathy with progressive graft failure at age 26.4 years and was treated for vulvar condyloma and carcinoma <i>in situ</i> of cervix
Thoene et al. (13)	1	–	8 years and 1 months	–	1308C > G (N323K)	Nephropathic	Binocular corneal crystalline	Proteinuria, At age 12 her creatinine clearance had fallen to 67 mL/min/1.73 m ² and her proteinuria had increased to 3.2 g/day	–
	2	–	5 years and 8 months	–	1308C > G (N323K)	Nephropathic	Binocular corneal crystalline	Proteinuria, At age 12 9/12 her daily protein excretion is 2.7 g and creatinine clearance 18 mL/min/1.73 m ²	–
	3	Unknown	7 years	13 years	753G > A (W138X), exon 11 (IVS11+2T > C)	Intermediate	Binocular corneal crystalline	Kidney failure (ESRD)	Renal transplant at age 15
	4		5 years	11 years	753G > A (W138X), exon 11 (IVS11+2T > C)	Intermediate	Binocular corneal crystalline	Kidney failure (ESRD)	Renal transplant at age 14
	5		16 years	18 years	753G > A (W138X), exon 11 (IVS11+2T > C)	Intermediate	Binocular corneal crystalline, moderate hypertension, minimal photophobia, thyroid gland is slightly enlarged	Proteinuria, creatinine clearance has declined to 42 mL/min/1.73 m ²	–
	6		12 years	25 years	57-kb deletion, 1178A-G (K280R)	Intermediate	Binocular corneal crystalline	ERSD	Hemodialysis and renal transplant at age 30 at age 43, the serum creatinine was 1.4 mg/dL
Ma et al. (4)	1	–	2 years	–	c.696C > G(p.323 N > K)	Nephropathic	Binocular corneal crystalline, growth retardation, rickets	Tubular dysfunction	It is only mentioned that supportive treatment and specific treatment can be used

years, with the development of economy and the progress of diagnosis and treatment technologies, gene detection technology has gradually become popularized in China, which has greatly enriched the means of diagnosis and treatment and improved the level of treatment.

At present, on the premise of combining clinical manifestations and laboratory results, there are three methods to assist in the diagnosis of suspected cystinosis patients: (1) Using mass spectrometer liquid chromatography to detect the level of cystine in blood leukocytes. This method has high sensitivity and specificity, and can monitor the therapeutic effect. However, as the requirements for instruments and testers are high, it cannot be easily conducted in a clinic. (2) Most patients can be diagnosed by gene detection, although the price is relatively high. (3) Using a slit lamp to detect characteristic corneal cystine crystallization is simple and economical; however, the scope of application is narrow: it is only suitable for patients with eye symptoms and cannot monitor the therapeutic effect.

Therefore, the corresponding medical testing methods can be selected based on the local medical conditions and the clinical manifestation type of the patient in question. At present, some cases of cystinosis in China have been analyzed by gene analysis, with the number of such cases increasing in recent years (3, 5, 6, 10–13). Gene diagnosis is beneficial to the diagnosis and analysis of cystinosis, and it is also an area for development in the future (15).

Some studies have pointed out that, the cases diagnosed may only be part of the actual cases because of the difficulty of diagnosis, such that some patients may not be able to be diagnosed (16). If patients with cystinosis cannot be diagnosed in time, they will not be treated in time, meanwhile the genetic information and clinical data of this population will be missing. From this case, it can be seen that the treatment compliance of the child and her families is not high. Thus, medical and nursing staff need to work to improve the treatment compliance of children and their families.

Health outcomes can be improved through health education and the improvement of drug research and treatment methods, such as developing sustained-release capsules to reduce the frequency of drug taking (17), and informing children and their families of the serious consequences of drug withdrawal through real cases examples.

At present, mercaptamine bitartrate, a drug that can specifically reduce cystine in lysosomes, is the preferred treatment for nephropathic cystinosis. The drug was transported to lysozyme by lysosomal membrane PQLC2 vector by forming cysteamine cysteine binding molecule with cystine in lysozyme. Early medication can effectively improve the growth and

development, delay the occurrence of end-stage renal disease, but cannot prevent the progress of the disease. A new cysteamine preparation with delayed release simplifies the administration schedule, but still cannot cure cystinosis disease. Mercaptamine bitartrate is widely used in developed countries, but has not yet been introduced into China, which limits our research on this disease.

In the future, therapeutic research may be carried out based on CTNS-carrying stem cell transplantation, which has been successfully carried out in mouse model. Hematopoietic stem cell transplantation and gene editing technology are possible choices to cure the diseases (18).

As our understanding has developed, cystinosis has gradually become a treatable rare disease. Going forward, it is very important to improve the awareness by timely reporting of the disease and to adopt the behavior of actively seeking medical treatment. Early detection and early treatment can reduce and delay the occurrence of complications and improve the prognosis of patients with cystinosis.

PC Splice-Site Variant c.1825+5G>A
Caused Intron Retention in a Patient
With Pyruvate Carboxylase Deficiency:
A Case Report.

Front. Pediatr. 10:825515.

doi: 10.3389/fped.2022.825515

Background: Pyruvate carboxylase deficiency (PCD; MIM#266150) is a rare autosomal recessive disorder characterized by a wide range of clinical features, including delayed neurodevelopment, elevated pyruvate levels, lactic acidosis, elevated ketone levels, and hyperammonemia. The pyruvate carboxylase (PC) gene was identified to be the disease-causing gene for PCD. A novel homozygous splice variant in the PC gene was identified in a Chinese boy, but the pathogenicity is still unclear. The objective of the present study was to determine the effect of this splice-site variant by reverse transcription analysis.

Methods: We reported the clinical course of a 20-month-old Chinese pediatric patient who was diagnosed with PCD using whole-exome sequencing (WES). The effects of the variant on mRNA splicing were analyzed through the transcript analysis *in vivo*.

Results: The results of metabolic blood and urine screening suggested PCD by employing tandem mass spectrometry. WES revealed a novel homozygous splice-site variant (c.1825+5G>A) in the PC gene. *in vivo* transcript analysis indicated that the splice-site variant caused the retention of 192 bp of the intron.

Conclusion: Thus, c.1825+5G>A was established as a pathogenic variant, thereby enriching the mutational spectrum of the PC gene and providing a basis for the genetic diagnosis of PCD.

Keywords: pyruvate carboxylase deficiency, c.1825+5G>A, PC gene, splice-site variant, pathogenic variant

INTRODUCTION

Pyruvate carboxylase deficiency (PCD; MIM# 266150) is a rare autosomal recessive inherited disorder with an estimated prevalence of 1:250,000. It results from the insufficient activity of pyruvate carboxylase (PC), a mitochondrial matrix enzyme, which converts pyruvate to oxaloacetic acid, thereby facilitating gluconeogenesis and energy production (1, 2). Low activity of PC causes the accumulation of pyruvate, which is subsequently converted into lactate in the

plasma by the enzyme lactate dehydrogenase. This eventually elevates plasma lactic acid levels. The decreased production of oxaloacetate decreases gluconeogenesis, thereby promoting hypoglycemia and preventing the liver from oxidizing pyruvate and fatty acid-derived acetyl-CoA (2). This increases the acetyl-CoA pool, resulting in hepatic ketone body synthesis or ketoacidosis (2). It also affects the tricarboxylic acid (TCA) cycle and impairs the synthesis of aspartic acid, which consequently affects the urea cycle and the related biosynthetic pathways, thereby causing hyperammonemia. Another relevant role of PC activity involves astrocytes where the TCA cycle provides α -ketoglutarate as a precursor for the production of the neurotransmitter, glutamate (1–3).

Pyruvate carboxylase deficiency is associated with variants in the PC gene and is typically characterized by delayed development, recurrent seizures, elevated pyruvate levels, and lactic acidosis (3). PCD manifests in three main clinical forms: types A, B, and C. The infantile-onset form (type-A) manifests several months after birth; it is characterized by hypotonia, failure to thrive, delayed development, and lactic acidemia, followed by infection, diarrhea, and other symptoms, which eventually result in mortality during infancy or early childhood (4, 5). The neonatal-onset form (type-B) is usually characterized by severe lactic acidosis, hyperammonemia, and mortality within the first 3 months of life (6–8). The late-onset form (type C) presents with normal or mildly delayed neurological development and episodic metabolic acidosis (9, 10). To date, only 33 cases of PCD have been reported, and none of them are from the Chinese population. Here, we report the presence of a novel PC splice-site variant (c.1825+5G>A) in a 20-month-old Chinese boy and validate that the association of the variant is associated with abnormal PC mRNA processing, leading to intron retention.

MATERIALS AND METHODS

Patient

The proband was a 20-month-old boy who was transferred to Xijing Hospital after presenting with delayed neurodevelopment and recurrent lactic acidosis. The patient was the first child of healthy consanguineous Chinese parents, with no significant family history. The child was born at full-term with normal weight, length, and head circumference. At the age of 3 months, the patient presented with bilateral eyelid clonus seizures, lasting from 30 s to 1 min, and was completely controlled by the oral administration of levetiracetam. At the age of 9 months, the patient presented with severe lactic acidosis with failure to thrive, tachypnea, and lethargy after 2 days of upper respiratory symptoms. Laboratory investigations during the acute episode revealed a plasma pH of 6.96 and the plasma levels of lactate, ammonia, and glucose, and alanine and citrulline levels to be 7.95 mmol/L, 93.77 μ mol/L (limit: < 40 mmol/L), 6.1 mmol/L, 715 μ mol/L (normal range: 90–450 μ mol/L), and 69.18 μ mol/L (normal range: 5.5–45 μ mol/L), respectively. The levels of lactate and ketones were also elevated in urine. MRI of the patient's brain revealed abnormal signal shadows in the white matter near the triangle of the bilateral

lateral ventricles. Abdominal ultrasound indicated the absence of hepatomegaly. After intravenous administration of bicarbonate and hemodialysis, the patient's serum pH returned to normal. The patient subsequently presented with five additional episodes of lactate acidosis, which were treated with intensive fluid therapy; however, the patient's plasma lactic acid and ammonia levels remained elevated at 3.7–12 mmol/L and 36.25–93.77 μ mol/L, respectively. The patient was slightly hypotonic, and his developmental milestones corresponded to those observed at 12 months of age. He could walk with support and pronounce approximately two words. Following diagnosis, the patient was administered biotin, aspartate, carnitine, thiamine, and citrate. At the age of 34 months, following one week of respiratory symptoms, the child developed severe metabolic acidosis. Despite treatment with dialysis, the patient's condition continued to deteriorate, with lactic acid levels increasing from 7.7 to 23.4 mmol/L, eventually followed by death.

Whole-Exome Sequencing for Mutation Screening

To identify the gene responsible for the patient's clinical presentation, peripheral blood was collected from the patient and sent to Running Gene, Inc. (Beijing, China) for whole-exome sequencing (WES). Briefly, DNA was isolated and fragmented to build a DNA library by using the KAPA Library Preparation Kit (Illumina, Inc., San Diego, USA). Then, the library was sequenced using an Illumina HiSeq4000 platform (Illumina, San Diego, USA) using a 150-bp paired-end read according to the standard manual. The sequencing data was filtered and aligned with the human reference genome (GRCh37/hg19) by using the BWA Aligner (<https://bio-bwa.sourceforge.net/>), and variants were annotated by ANNOVAR (annovar.openbioinformatics.org/en/latest/). The exclusion of variants with minor allele frequency (MAF) >1% according to the gnomAD database (<https://gnomad.broadinstitute.org/>) and/or the 1000 Genomes Project database (<https://www.genome.gov/27528684/1000-genomes-project>), as well as *in silico* pathogenicity predictions for missense variants (SIFT: <http://sift.jcvi.org>, PolyPhen2: <http://genetics.bwh.harvard.edu/pph2>, MutationTaster: <http://www.mutationtaster.org>, FATHMM: <http://fathmm.biocompute.org.uk>, and CADD: <http://cadd.gs.washington.edu>) and splice-site variants (Varseak: <https://varseak.bio/>, splice AI: <https://spliceailookup.broadinstitute.org/>, dbSCSNV_ADA and dbSCSNV_RF: <https://sites.google.com/site/jpopgen/dbNSFP>). Variants were classified as: pathogenic, likely pathogenic, benign, likely benign and VUS, according to American College of Medical Genetics (ACMG) guidelines. A candidate causal gene mutation was identified and confirmed using Sanger sequencing.

Transcript Analysis *in vivo*

Total RNA was extracted from the peripheral blood of the proband, his parents, and a healthy volunteer. Peripheral blood was collected in the PAXgene Blood RNA tube (BD Biosciences). RNA was isolated from the PAXgene Blood RNA kit (BD Biosciences) and then reverse-transcribed into cDNA

FIGURE 1 | Partial sequence chromatograms of pyruvate carboxylase (PC). The red arrows represent the mutation site. Index: homozygous splice-site variant c.1825+5G>A; father and mother: heterozygous splice-site variant c.1825+5G>A.

by using PrimeScript RT Master Mix (Takara). The target sequence was amplified from cDNA by PCR. The primer of the amplification is forward GCCCAAAGCTGTTGCACTAC and reverse AAGTCATCCCAGACATGGAATC. PCR products were separated on 1.5% agarose and sequenced with an ABI 3130 genetic analyzer (Applied Biosystems). Generated next-generation sequencing (NGS) library using the PCR product was sequenced by Illumina HiSeq4000 platform. PCR products were separated on 1.5% agarose and sequenced with an ABI 3730XL DNA analyzer (Applied Biosystems).

RESULTS

Genetic Findings

Exome sequence analysis revealed that the patient was homozygous for a specific variant (c.1825+5G>A) in the PC gene (NM_022172), and Sanger sequencing confirmed that both parents were heterozygous carriers of the variant (Figure 1). The variant was not found in either the Genome Aggregation Database (gnomAD) or 1000 Genomes database. According to the American College of Medical Genetics and Genomics (ACMG) guidelines (11), the pathogenicity of c.1825+5G>A was unclear. However, *in silico* prediction of the variant's effects, using four different algorithms (Varseek, splice AI, dbSNV_ADA, and dbSNV_RF), consistently predicted that the variant would affect splicing (Table 1).

PC mRNA Expression *in vivo*

Agarose gel electrophoresis of RT-PCR-amplified genes showed that the band corresponding to that of the proband (mut) was larger than that of the control (wt) (Figure 2A). This indicates that the complementary DNA (cDNA) of the proband may have abnormal splicing. The cDNA amplification products of the proband, his parents, and healthy control were subjected to NGS. The results indicated that the proband cDNA retained a part of intron 13 (homozygous), and both the parents retained a part of intron 13 (heterozygous) (Figure 2B). Sanger sequencing indicated that the variant c.1825+5G>A caused aberrant splicing compared with that observed in the healthy control, resulting in the retention of the 192 bp intron 13 in the proband sample. Since the abnormal bands of his parents were too weak to be analyzed using the Sanger sequence, their sequencing results were similar to that of the control (Figures 2C,D). Eventually, the variant c.1825+5G>A was rated as pathogenic, based on the ACMG guidelines.

DISCUSSION

Pyruvate carboxylase deficiency is a rare neurometabolic disorder. Among the 34 cases reported to date, 10, including the proband of the present study, studies were born to consanguineous parents. The patient's symptoms first presented in the third month of his life and included

TABLE 1 | Summary of clinical findings of the proband.

	Proband			
Age of onset	3 months			
Clinical findings	Lactic acidosis	Developmental delay	Seziures	Recurrent metabolic neoacidosis
Laboratory	pH 6.96	Lactate 7.95	Ammonia 93.77 μmol/L	
	Plasma glucose 6.1	Alanine levels 715 μmol/L	Cit levels 69.18 μmol/L	
	Urinary organic acids:	elevated lactate and ketones		
MRI	Both abnormal signal shadows of the white matter near the triangle of bilateral lateral ventricles

	dbscSNV_RF	0.9499 (range [0,1])		
Time of diagnosis	At the age of 20-month-old			
Prognosis	At the age of 34 months, the child died of severe metabolic acidosis			

delayed development, recurrent seizures, elevated pyruvate levels, lactic acidosis, hyperammonemia, and elevated ketone levels, which were consistent with the typical characteristics of type-A PCD (4). Among the eight patients that have been reported with type A PCD, two patients developed epilepsy, experiencing infantile spasms and tonic seizures.

The symptoms were controlled by using a combination of multiple epilepsy drugs. However, the patient in the current study experienced a mild seizure, with the only form of attack of clonic seizure, which was well controlled with levetiracetam. Lactic acidemia and hyperammonemia seemed to respond to treatment with aspartate, biotin, carnitine, and thiamine. However, for the remaining conditions, anaplerotic therapy did not seem to affect disease progression. Despite medical interventions, episodes of severe acidosis with lethargy still occurred in the proband, following a respiratory tract infection. Eventually, the proband died during early childhood similar to the outcomes of other patients with type A PCD.

Here, we reported the identification, via WES analysis, of a novel PC splice-site variant. This variant was homozygous in the 20-month-old study patient and was inherited from close relative parents, who carried the heterozygous mutation at the same site. Notably, the variant was not found in the Genome Aggregation Database (gnomAD). *in silico* prediction of the variant's effects, using four different algorithms (Varseak, splice AI, dbSNV_ADA, and dbSNV_RF), consistently indicated that the variant affected PC mRNA splicing. Thus, the splice-site variant could explain the proband phenotype. To determine the effect of this PC splice-site variant, total RNA isolated from venous blood was transcribed into cDNA *in vivo*. Sanger sequencing analysis of the cDNA revealed that the splice-site variant could cause the retention of 192 bp of intron 13. The pathogenicity of the splice-site variant was classified as like-pathogenic (PS3+PM2+PP4), according to the ACMG guidelines (11). After comprehensive consideration of the clinical manifestations, genetic analysis, and cDNA sequencing results, the c.1825+5G>A variant was identified as the cause of the patient's PCD.

The PC gene maps to 11q13.2 and includes 20 coding exons as well as four non-coding codons (12). Biallelic variants in the PC gene are associated with PCD. According to the Human Genome Mutation Database and other studies, approximately 44 causative variants (**Supplementary Table 1**), including nonsense, missense, splicing, insertion/deletion, and frameshift mutations, have been identified in 33 PCD-affected individuals. Genotype/phenotype correlations in both the fatal PCD forms (types A and B) are unclear. Theoretically, the presence of at least one truncating mutation in the PC gene should generate more severe clinical phenotypes. The current proband carried biallelic mutations and presented as type A PCD. However, one case that was similar to our patient was homozygous for splice-site variant c.321+1G>T and was diagnosed with type-B PCD (13), while another case with biallelic missense mutation 506G>A also presented with type-B PCD (14). Thus, the correlation between genotypes and clinical phenotypes certainly requires further investigation.

For the differential diagnosis of PCD, practitioners should focus on identifying other hereditary metabolic diseases that cause hyperlactatemia and abnormal neurodevelopment, such as carbohydrate metabolic diseases, including type-I glycogen accumulation syndrome (GSD1) (15), pyruvate dehydrogenase complex deficiency (PDHCD) (16), hereditary

fructose intolerance (17), and the fructose-1,6-bisphosphatase deficiency (1,6-FBD) (18). These disorders can be distinguished based on the fact that hypoglycemia and hepatomegaly are common in type I glycogen accumulation syndrome and fructose-1,6-bisphosphatase deficiency but not in PCD, where these effects are only seen in individuals with the type B form. In addition, while PDHCD and PCD have identical clinical manifestations, blood ketone bodies are not detectable in PDHCD.

To the best of our knowledge, this is the first case to be reported among the Chinese population (4–9, 13, 14, 16, 19–21). The patient had 6-times higher metabolic acidosis, accompanied by increased levels of lactic acid, blood ammonia, and pyruvate. Due to insufficient knowledge, it was not accurately clearly diagnosed in the early stages. Further, patients manifesting similar clinical characteristics need to be evaluated for PCD, and PC tests can be further confirmed.

In summary, we report the identification of a novel splice-site variant (c.1825+5G>A) in the PC gene of a Chinese boy with type-A PCD. In addition, we confirmed the variant's pathogenicity, which involves an alteration in mRNA splicing. This report enriches the mutational spectrum of the PC gene and provides a basis for the genetic diagnosis of PCD.

doi: 10.3389/fped.2022.812408

Leigh syndrome is a neurodegenerative disorder that presents with fluctuation and stepwise deterioration, such as neurodevelopmental delay and regression, dysarthria, dysphagia, hypotonia, dystonia, tremor, spasticity, epilepsy, and respiratory problems. The syndrome characteristically presents symmetric necrotizing lesions in the basal ganglia, brainstem, cerebellum, thalamus, and spinal cord on cranial magnetic resonance imaging. To date, more than 85 genes are known to be associated with Leigh syndrome. Here, we present a rare case of a child who developed Leigh syndrome due to pathogenic variants of *NDUFAF6*, which encodes an assembly factor of complex I, a respiratory chain subunit. A targeted next-generation sequencing analysis related to mitochondrial disease revealed a missense variant (NM_152416.4:c.371T > C; p.Ile124Thr) and a frameshift variant (NM_152416.4:c.233_242del; p.Leu78Glnfs*10) inherited biparentally. The proband underwent physical therapy and nutrient cocktail therapy, but his physical impairment gradually worsened.

Keywords: Leigh syndrome, mitochondrial disease, *NDUFAF6*, complex I deficiency, neurodegenerative disorder

INTRODUCTION

Mitochondrial disease is a common inherited metabolic disorder that is clinically and genetically heterogeneous and occurs in approximately 10–25 cases per 100,000 individuals, many of which are childhood-onset usually by the age of 3 years (1). Mitochondria are present in all cells except erythrocytes and, given that mitochondria are responsible for oxidative phosphorylation and ATP synthesis, mitochondrial disease exhibits diverse phenotypes depending on the affected organs. Mitochondrial dysfunction leads to multiple system disorder, manifesting a progressive course with high morbidity and mortality (2). Mitochondrial disease is a genetic disorder resulting from pathogenic variants of mitochondrial DNA (mtDNA) and nuclear DNA (nDNA) associated with mitochondrial function. The mtDNA consists of 37 genes and encodes 13 proteins, and over 1,000 nuclear genes encode proteins related to mitochondrial function (3).

The most common mitochondrial disease that occurs during childhood is Leigh syndrome, with a prevalence of approximately 2.5 cases per 100,000 individuals (4). Most cases of Leigh

syndrome occur in childhood and rarely in adolescence or early adulthood. Leigh syndrome is a neurodegenerative disorder, with characteristic symmetric, necrotizing lesions in the basal ganglia, brainstem, cerebellum, thalamus, and spinal cord on cranial magnetic resonance imaging (MRI). The phenotypes of Leigh syndrome include neurological symptoms showing fluctuation and stepwise deterioration, such as neurodevelopmental delay and regression, dysarthria, dysphagia, hypotonia, dystonia, tremor, spasticity, epilepsy, and respiratory problems. Other non-neurologic symptoms include cardiac abnormalities, hepatorenal anomalies, anemia, and gastrointestinal symptoms such as constipation and vomiting (5). More than 85 genes are related to Leigh syndrome including mtDNA and nDNA, and genes related to complex I (NADH: ubiquinone oxidoreductase) deficiency are the most common causes. Approximately 75–80% of cases of Leigh syndrome are caused by pathogenic nDNA variants and more than half of the nDNA genes are related to complex I. *NDUFAF6* (NADH: ubiquinone oxidoreductase complex assembly factor 6) is one of them, and *NDUFAF6* is one of the major genes that cause reduced complex I activity by mitochondrial respiratory chain complex defect. Biallelic missense variants of *NDUFAF6* are known to cause Leigh syndrome.

Here, we present a rare case of a child who developed Leigh syndrome due to pathogenic variants of *NDUFAF6* on chromosome 8, which encodes an assembly factor of complex I, a respiratory chain subunit. A targeted next-generation sequencing study (NGS) enabled rapid genetic confirmation and avoided invasive diagnostic procedures such as skeletal muscle biopsy and skin fibroblast cell culture.

CASE PRESENTATION

A 56-month-old boy was referred to a rehabilitation clinic due to left hand clumsiness and frequent falling. The symptoms gradually began around the age of 3 years and slowly progressed. The patient had been born after an uncomplicated 40-week gestation with a birth weight of 3.07 kg. There were no perinatal problems and no specific family history of interest. There was no psychomotor developmental abnormalities prior to the onset of symptoms. The patient was brought to the primary clinic at 55 months due to language developmental delay, with simplified sentences and inaccurate pronunciation. In the evaluation, the patient's overall comprehension and language expression level was measured around 56–60 months, and his consonant accuracy was evaluated at approximately 87% in the pronunciation intelligibility assessment. The patient also presented with weakened tongue movement, simplification of middle consonants, and simplification of liquid consonants. In the psychoeducational profile-revised (PEP-R) evaluation, the overall developmental level was 64–65 months, and the other domains were above the normal ranges, except for fine motor function, which was below the average of 52–54 months. During the examination, the patient presented poor bimanual

manipulation, with left hand clumsiness and slight weakness of the right ankle dorsiflexion; the patient was referred to a tertiary medical center.

Clinical Assessment

During the physical examination, the patient presented with dystonic and ataxic movements on the left side and clumsy movements of both hands. Weakness in ankle dorsiflexion involving both sides and spastic hypertonia in the left upper and lower extremities were observed. The strength of both ankle dorsiflexors was 3/5, and the strength of the other muscles was 5/5. The patient had difficulty jumping on both feet and stair-climbing and descending. Poor balance with one-leg standing with eyes open was also observed. The patient could independently walk but had tip-toeing and limping gait patterns. In the functional assessment, the balance evaluation using the Berg balance scale (BBS) revealed a poor standing balance of 36/56. The total score on the gross motor function measure-88 (GMFM-88) was 81.82%. The Beery-Buktenica developmental test of visual motor integration (6th edition) revealed a normal range of visual motor function of 99 (47%) with impaired motor coordination ability of 73 (4%).

Neuroimaging and Laboratory Tests

Due to a suspected brain pathology, an MRI of the head was performed, revealing abnormal signals in the bilateral putamen, with slight volume reduction and partial necrosis. The MRI revealed high signal intensity on T2- and diffusion-weighted images, an apparent diffusion coefficient (ADC), and fluid-attenuated inversion recovery (FLAIR) images with low signal intensity on T1-weighted images in the bilateral putamen (**Figure 1**). MR angiography showed normal cerebral vessels. To differentiate diseases that could show lesions of symmetric basal ganglia, we also performed MR spectroscopy, detecting normal N-acetylaspartate, choline, and creatine levels, and increased lipid and lactate levels (**Figure 2**). The high lactate peak would indicate acute mitochondrial dysfunction and with clinical features, we determined that there was a possibility of mitochondrial encephalopathy, especially Leigh syndrome. The laboratory test revealed a lactic acid level of 2.45 mmol/L (range, 0.50–2.20 mmol/L) and a creatine phosphokinase level of 287 U/L (range, 0–250 U/L). In the urine organic acid test, a slight increase was observed in tiglylglycine levels to 0.4 mmol/mol creatine (range, 0–0.2 mmol/mol creatine). The other laboratory test results, including serum aspartate aminotransferase, alanine aminotransferase, amino acid analysis, and acylcarnitine were all within normal ranges.

Cytogenetic and Molecular Analyses

We performed a mitochondrial DNA sequencing test and targeted NGS analysis of a multi-gene panel related to the mitochondrial disease. Informed consent from the patient's guardian was collected. Libraries were prepared with the IlluminaTM Truseq DNA kit, and sequencing was performed using the IlluminaTM Nextseq platform. The

FIGURE 1 | Brain MRI showing high signal intensity on T2-weighted imaging (**A**, axial, **B**, coronal) and diffusion-weighted imaging (**C**), apparent diffusion coefficient (**D**), and fluid-attenuated inversion recovery (**E**) images with low signal intensity on T1-weighted imaging (**F**) in the bilateral putamen. Arrowheads indicate the lesions.

whole mtDNA test revealed a normal mtDNA sequence. The NGS test revealed two heterozygous variants of *NDUFA6* in the different exons, identifying a missense variant (NM_152416.4:c.371T > C; p.Ile124Thr) and a frameshift variant (NM_152416.4:c.233_242del; p.Leu78Glnfs*10), which were validated by Sanger sequencing. No other significant variants were found. The missense variant c.371T > C has been previously reported to cause Leigh syndrome, while the c.233_242del variant has not been reported (6–8). The missense variant c.371T > C was classified as a likely pathogenic variant and the frameshift variant (c.233_242del) was classified as a pathogenic variant by American College of Medical Genetics and Genomics (ACMG) Classification Standards and Guidelines for Genetic Variations. *In silico* prediction for the missense variant, SIFT predicted as deleterious (score: 0.05), PolyPhen-2 as benign (score 0.255), and MutationTaster as disease causing (probability: 0.99). For the frameshift variant, MutationTaster predicted as disease causing (probability: 1). To identify these compound heterozygous variants, we performed targeted gene sequencing of the parents, which

revealed that the c.371T > C variant was inherited from the mother while the c.233_242del variant was inherited from the father (**Figure 3**). Finally, the proband was diagnosed with Leigh syndrome caused by biallelic pathogenic variants of *NDUFA6*, inherited biparentally.

Clinical Progressions

After the diagnosis, the patient continued physiotherapy and occupational therapy while undergoing nutrient cocktail therapy. He was prescribed 10 mg of biotin, 500 mg of thiamine, 100 mg of Coenzyme Q10, and 100 mg of L-carnitine per day. However, worsening and improvement of spastic dystonia and balance impairment were repeated and his gait instability gradually worsened.

Five months after the first visit and at the age of 61 months, the patient's BBS dropped from 36/56 to 11/56, and his GMFM-88 score worsened from 81.82 to 58.33%. He required support from two hands for walking and for transitioning from sitting to standing. He was unable to maintain an upright

FIGURE 2 | Brain MR spectroscopy showing increased lipid and lactate in the lesions. Normal patterns outside lesions (A), elevated lipids (white arrow) (B), and elevated lactate in both putamen (arrowhead) (C,D).

sitting or standing position and showed poor sitting balance. A symmetric tonic neck reflex appeared, and a hand-foot crawling pattern was observed.

DISCUSSION

We have reported a proband with biallelic pathogenic variants, c.371T > C and c.233_242del in *NDUFAF6*, who showed the typical phenotype of Leigh syndrome. The proband presented Leigh syndrome-appropriate clinical features, brain MRI and MR spectroscopy findings, and genetic confirmation. However, the serum biomarkers

showing oxidative phosphorylation impairment such as lactate, pyruvate, creatine kinase, amino acid, acylcarnitine, and organic acid revealed no disease-specific findings. The patient underwent rehabilitation therapy and nutrient cocktail therapy, but his physical impairment rapidly worsened.

NDUFAF6 is an assembly factor of NADH-ubiquinone oxidoreductase (complex 1) and plays an important role in complex 1 maturation and activity. *NDUFAF6* is a 38 kDa protein, consists of 333 amino acids, and is involved in the assembly of complex I in early stages, playing a role in regulating and stabilizing the complex I subunit MT-ND1. Defects in *NDUFAF6* isoform 1 can disrupt complex I assembly by causing

FIGURE 3 | (A) Pedigree of the family. Arrow indicates the proband. **(B)** Chromatographs of *NDUFAF6*. The proband had a missense variant (c.371T > C) from the mother and a frameshift variant (c.233_242del) from the father.

Homozygous; Variants for which clinical features were not described [Khoda et al. (6)]—four patients: c.226T > C, c.805C > G; c.206A > T, c.371T > C; c.371T > C, 805C > G; 820A > G, Lee et al. (22)—two patients: c.265G > A, c.233_231del; c.874-2A > C, c.820A > G].

rapid proteolysis of the newly formed ND1 subunit, adversely affecting mitochondrial function (9, 10). Biallelic pathogenic variants cause Leigh syndrome, and 16 variants have been reported in 20 patients to date (Table 1 and Figure 4). Among them, the most variants have been reported in exon 2, and 2 variants have also been reported in exons 3 and 5. All children with *NDUFAF6*-related Leigh syndrome show necrotic lesions in the symmetric basal ganglia, dystonia, and neurological regression. Characteristically, *NDUFAF6*-related Leigh syndrome tends to show normal or slight higher serum lactate, and our proband also showed lactate close to the normal range, revealing little diagnostic value for Leigh syndrome.

In a cohort study of 166 patients with Leigh syndrome, 8 had pathogenic variants of *NDUFAF6*. As a result of the analysis, mtDNA variants were associated with high mortality, and patients with *NDUFAF6* variants had better outcomes than those with other nDNA gene variants showing lower mortality and longer motor function preservation (11). However, not all patients with *NDUFAF6*-related Leigh syndrome show mild phenotypes, and the genotype does not appear to predict the prognosis sufficiently, given that there are patients with early disease onset with severe symptoms who have the same variants (12). Our proband showed normal psychomotor development with uneventful medical history until the age of 3, and symptoms developed gradually. At 55 months, he showed mild motor impairment, but from then on, he showed rapid deterioration. Since there is no report on long term functional prognosis in the *NDUFAF6*-related Leigh syndrome, additional reports will be helpful for prognosis prediction.

Mitochondrial disease is difficult to diagnose due to the diverse clinical features. Previously, tissue biopsy was often performed for diagnosis by histochemical and biochemical analysis. With the recent development of NGS technology, there have been numerous cases that relied on genetic tests. In addition, cases previously diagnosed with probable or uncertain mitochondrial disease have more frequently been genetically confirmed. As a

result, overall diagnostic success has risen from less than 20% to more than 60% (1). In particular, given that 75–80% of cases of childhood-onset mitochondrial disease occur due to the pathogenic variant of nDNA, the NGS test increases the diagnosis success (13). In a study conducted in 2015, patients who were ultimately diagnosed with mitochondrial disease had met an average of 8.19 physicians before being confirmed, and 70% of the patients had undergone invasive muscle biopsy. Rapid diagnosis without invasive tests has been made possible with the advances in genetic diagnostic technology, including whole exome sequencing and whole genome sequencing (14).

Treatment for Leigh syndrome has no clear evidence, but cocktails of nutritional dietary supplements, such as antioxidants, vitamins, coenzyme Q10, and nitric acid precursors have been widely used (15). Given that Leigh syndrome is genetically heterogeneous, early intervention with tailored therapy according to the genotype rather than treatment according to the phenomenon will be an important treatment direction in the future. In terms of rehabilitation, exercise prescription including aerobic exercise training is often performed for patients with mitochondrial disease with gait disturbance, imbalance, frequent falling, fatigue, and exercise intolerance. In general, excessive physical activity is not recommended, and physiotherapy is contraindicated for patients with cardiac involvement. Physiotherapy is also not recommended for those with acute illness, severe fatigue, and a generally deconditioned status because of the expected excessive energy demand in addition to the body's energy demands (16). However, there was a report that oxygen utilization, exercise tolerance, and quality of life were better for the group who continued exercise training than for the group who did not (17). Therefore, rehabilitation therapy should be determined individually. Our patient underwent rehabilitation therapy because his general condition was not poor and did not correspond to discontinuation; however, his physical function gradually deteriorated.

CONCLUSION

We report a rare genetic disorder: *NDUFAF6*-related Leigh syndrome resulting from biallelic pathogenic variants, c.371T > C and c.233_242del in *NDUFAF6*. The proband showed typical Leigh syndrome features, and his physical impairment gradually worsened despite several therapies. This case report is distinguished from those previously reported in that we describe in detail the clinical features, including the developmental evaluation and clinical progressions.

Isolated methylmalonic acidemia (MMA) is an inherited organic acid metabolic disorder in an autosomal recessive manner, caused by mutations in the methylmalonyl coenzyme A mutase gene, and the isolated MMA patients often suffer from multi-organ damage. The present study aimed to profile the differential proteome of serum between isolated MAA patients and healthy control. The *in vivo* proteome of isolated MAA patients and healthy subjects was detected by an isobaric tag for relative and absolute quantitation (iTRAQ). A total of 94 differentially expressed proteins (DEPs) were identified between MMA patients and healthy control, including 58 upregulated and 36 downregulated DEPs in MMA patients. Among them, the most significantly upregulated proteins were CRP and immunoglobulins, and the top five most significantly downregulated proteins were all different types of immunoglobulins in MMA patients. GO analysis showed that these DEPs were mainly enriched in immune-related function and membrane protein-related function. KEGG revealed that these DEPs were mainly enriched in lysosome and cholesterol metabolism pathways. Also, these DEPs were predicted to contribute to lipid metabolic diseases. We addressed the proteomes of isolated MMA patients and identified DEPs. Our study expands our current understanding of MMA, and the DEPs could be valuable for designing alternative therapies to alleviate MMA symptoms.

KEYWORDS

methylmalonic acidemia, iTRAQ, differential proteome, cholesterol metabolism, immunoglobulins, methylmalonyl coenzyme A mutase

Introduction

Methylmalonic acidemia (MMA) is an inherited organic acid metabolic disorder in an autosomal recessive manner. According to the biochemical manifestation, MMA can be classified into two common types: isolated MMA and MMA combined with homocysteinemia (Manoli and Venditti, 2005). Isolated MMA is mostly caused by mutations in the methylmalonyl coenzyme A mutase (MCM) gene (*MUT*) (Han et al., 2017), and a few cases have been shown to be the result of other gene mutations, such as *MMAA*, *MCEE*, and others (He et al., 2020). MMA usually resulted in various clinical symptoms, including severe metabolic acidosis, thrombocytopenia, hyperammonemia, ketosis and ketonuria, developmental delay, neutropenia, and hyperglycinemia (Manoli and Venditti, 2005). Clinical diagnosis of MMA relies upon specialized metabolic testing. Definitive diagnosis of MMA relies on the analysis of organic acids in plasma and/or urine by gas-liquid chromatography and mass spectrometry; the concentration of methylmalonic acid is greatly increased in the plasma, urine, and cerebrospinal fluid of affected individuals (Manoli et al., 1993). Based on complex and comprehensive clinical diagnosis, the abnormal production of metabolites in MMA patients has been relatively clear, but proteomic changes in MMA patients are rarely reported.

Isolated MMA patients with mutations in the *MUT* gene are usually severely ill with poor prognosis, high early mortality, and high lifelong morbidity (Jiang et al., 2020; Liang et al., 2021). The age of death in children with isolated MMA was 2 years, ranging from 5 days to 15 years, and 40% of individuals died and the overall mortality rate was 36%, with all deaths occurring during or after the acute metabolic crisis (Dionisi-Vici et al., 2006). The primary treatment for patients with isolated MMA is dietary restriction of propyl amino acid and carnitine supplementation. Despite treatment, the metabolite profile of the patients with isolated MMA remains abnormal, and the prognosis is still poor. Although several hypotheses have been proposed, the pathologic mechanism of abnormal protein expression in progressive isolated MMA systemic injury remains to be elucidated.

Recently, the characterization of MMA with homocystinuria and cobalamin deficiency type C (cblC) proteome in fibroblasts found that the downregulated proteins were mainly enriched in cellular detoxification (Hannibal et al., 2011). Also, the proteome in circulating lymphocytes in cblC patients has been demonstrated (Caterino et al., 2015). However, the proteomic characteristics of isolated MMA patients are still unclear. The present study investigated the proteome of serum isolated from three isolated MMA patients with *MUT* treated with a multi-drug combination. These three patients still have abnormal levels of metabolites although receiving treatment. This study of the proteome in isolated MMA patients was performed using the isobaric tag for relative and absolute quantitation (iTRAQ) analysis. Proteome identification helped bridge the gap

between the role of *MUT* gene products and the clinical manifestations of MMA defects in humans.

Materials and methods

Ethics statement

This project was approved by the Ethical Committee of The Sixth Affiliated Hospital of Sun Yat-sen University and adhered to the World Medical Association's Declaration of Helsinki (WMADH 2008). In this study, MMA analysis was performed with written informed consent from guardians of each pediatric patient, following the approval of The Sixth Affiliated Hospital of Sun Yat-sen University.

Patient selection

The serum for three MMA patients and three healthy subjects from The Sixth Affiliated Hospital of Sun Yat-sen University was collected. Genotypes of MMA donors are listed in Table 1; the virulence gene of three MMA patients is *mut* gene. Clinical diagnosis of MMA patients relies upon specialized metabolic testing, which is performed by the Genetic Metabolic Disease Detection Laboratory of the Sixth Affiliated Hospital of Sun Yat-sen University. Table 2 listed the detailed clinical features of MMA patients determined by gas-liquid chromatography and mass spectrometry and also listed the detail of laboratory biochemical parameters. Serum from normal control and patients with confirmed MMA were subjected to iTRAQ assay for investigating the differentially expressed proteins (DEPs). Moreover, to verify the clinical characteristics of candidate DEPs, we subsequently collected the clinical biochemical data from 14 MMA patients and 15 non-MMA and uninfected patients. These 29 samples were in addition to those analyzed in the iTRAQ experiment. The information of these 29 samples is shown in Supplementary Table S1. All frozen tissue samples in liquid nitrogen were stored at -80°C .

Protein extraction and isobaric tag for relative and absolute quantitation labeling

Frozen serum samples were extracted by using RIPA lysis buffer (Elabscience, China) and subsequently homogenized by sonication (Scientz) on ice. The homogenate was cleared using centrifugation at 12,000 rpm for 15 min at 4°C . The major proteins of albumin and IgG were removed using ProteoExtract™ Albumin Removal Kit (Cat. No.:122640, MERCK). After that, the protein concentrations of supernatants were determined by Pierce BCA Protein Assay

Kit. Subsequently, 20 μg of each sample was taken and tested by SDS-PAGE. The qualified protein sample entered the iTRAQ labeling stage. Total protein (150 μg) from each sample solution was mixed with 200 μl of 8 mol/L urea in Nanosep Centrifugal Devices (PALL, United Kingdom) and centrifuged at 14,000 g at 20°C for 20 min. All following centrifugation steps were performed applying the same conditions allowing maximal concentration. Samples were incubated in 20 μl of 50 mmol/L

iodoacetamide for 30 min in the dark to block reduced cysteine residues followed by centrifugation, and the liquid at the bottom was discarded. The Tris-HCl (pH 8.0) was added to every tube, centrifuged at 12,000 rpm for 10 min, and the solution was discarded at the bottom. Then, 200 μl of 100 mmol/L triethylammonium bicarbonate (TEAB) buffer was added to tubes and centrifuged twice. The solution was subjected to proteolytic digestion (1:50) overnight at 37°C. The digests of

peptides were collected by centrifugation following iTRAQ labeling.

Each iTRAQ-label reagent (AB Sciex, United States) was dissolved in 70 μ l of isopropanol. The digested-peptide samples were dissolved in 30 μ l TEAB buffer (200 mM). Next, the iTRAQ-label reagent was added to the respective peptide mixture for 2 h. The labeling reaction was quenched by the addition of 100 μ l of MilliQ water, and six labeled samples were then pooled into one sample according to the manufacturer's instructions. After pooling, the samples were evaporated by vacuum concentration to remove excess water, TEAB, and isopropanol.

One-dimensional high-pH reversed-phase chromatography separation

The freeze-dried samples were dissolved in 100 μ l of mobile phase A (10 nM ammonium formate, 5% acetonitrile, pH 10.0). Peptide separation was performed on a Thermo UltiMate 3000 UHPLC, and the chromatographic column was purchased from Agilent (ZORBAX Extended-C18, 2.1). The detection wavelength was UV 215 nm, and the flow rate was 0.3 ml/min. Mobile phase B (10 nM ammonium formate, 90% acetonitrile, and pH 10.0) separation gradient was linear from 5 to 38% in 80 min. One tube was collected every 1 min within the gradient range, and a total of 16 tubes of elution solution were collected, centrifuged, and dried for LC-MS analysis.

Liquid chromatography tandem mass spectrometry analysis and data reorganization

The LC-MS/MS analysis was conducted by Wininnovate Bio (China). Briefly, the lyophilized peptide fractions were re-suspended in 0.1% formic acid and then loaded into a nanoViper C18 (3 μ m, 100 \AA) trap column, and online chromatography separation was performed on the Easy nLC 1200 system (ThermoFisher, United States). The trapping and desalting procedure was carried out with a volume of 20 μ l 100% solvent A (0.1% formic acid). Then, an elution gradient of 5–38% solvent B (80% acetonitrile, 0.1% formic acid) at a flow rate of 300 nl/min (0–50 min, 5–38% B; 60–60 min, 38–100% B) in 60 min was used on an analytical column (50 μ m \times 15 cm C18-3 μ m 100 \AA). The data-dependent acquisition (DDA) mass spectrum techniques were used to acquire tandem mass spectrometry (MS) data on a ThermoFisher Q Exactive mass spectrometer (ThermoFisher, United States) fitted with a Nano Flex ion source. Data were acquired using an ion spray voltage of 1.9 kV, and an interface heater temperature of 275°C. The MS was operated with FULL-MS scans. For DDA, survey scans were acquired in 250 ms and up to 20 product ion scans (50 ms) were

collected. Normalized collision energy (NCE) was set to 30 eV. Only spectra with a charge state of 2–4 were selected for fragmentation by higher-energy collision energy. Dynamic exclusion was set for 25 s. The proteomic raw data have been deposited on PRIDE Archive (<https://www.ebi.ac.uk/pride/archive>) with the project accession: PXD034075.

Data reorganization

The MS/MS data were analyzed for protein identification and quantification using the Proteome discoverer (v2.1.0.81). The local false discovery rate was 1.0% after searching against the Human protein database with a maximum of two missed cleavages and one missed termini cleavage. The following settings were selected: oxidation (M), acetylation (Protein N-term), deamidation (NQ), Pyro-glu from E, Pyro-glu from Q for variable modifications as well as carbamidomethylation (C), iTRAQ8plex (N-term), and iTRAQ8plex (K) for fixed modifications. Precursor and fragment mass tolerance were set to 10 ppm and 0.05 Da, respectively. A full list of proteins identified and relatively quantified by iTRAQ is shown in [Supplementary Table S4](#). A full list of peptide groups identified and relatively quantified by iTRAQ is shown in [Supplementary Table S5](#).

Statistical analysis of isobaric tags for relative and absolute quantitation data

DEPs were screened by t-test of the “*limma*” R package, and proteins with *p*-value < 0.05 and fold change (FC) \geq 1.2 were considered DEPs.

Functional annotation

For functional annotation, the proteomic data were normalized, and then the protein expression of each sample was analyzed for differences to screen the DEPs using a t-test provided by the “*limma*” R package. The screening criterion of DEPs was that fold change (FC) \geq 1.2 and the *p*-value < 0.05, between the two groups. Next, cluster analysis, principal component analysis (PCA), and partial least squares discrimination analysis (PLS-DA) were performed on DEPs, and they were referred to the Gene Ontology (GO) and Kyoto Encyclopedia of Genes and Genomes (KEGG) database, among which the “*ggplot2*” R package was used for volcano plots, heatmap, and PCA. The “*ropls*” R package was used for PLS-DA. For gene set enrichment analysis (GSEA), the whole genome was ranked from the largest to smallest based on the logFC of DEPs and matched to the KEGG pathway database, to draw a GSEA plot. A protein–protein interaction (PPI) network was constructed by Cytoscape version 3.6.1 using DEPs.

(C) Partial least-squares discriminant analysis (PLS-DA) diagram of six samples based on all proteins. Oval indicates the 95% confidence intervals.

Results

Quantitative proteomic profiling of serum of patients with isolated methylmalonic acidemia by isobaric tags for relative and absolute quantitation labeling

Serum of patients with isolated MMA and healthy donors was subjected to proteomic analysis to elucidate proteomic changes. A total of 10306 peptides were identified, of which 9722 were uniquely mapped to known sequences of our iTRAQ proteomic results. Moreover, we identified 770 proteins whose average molecular weight was between 24 and 80 kDa (Figure 1A). PCA and PLS-DA analysis showed an obvious separation in the control group and mut group with the 95% confidence intervals, implicating that proteins were significantly separated (Figures 1B,C). Therefore, these data were used for further analysis.

Differential proteomics analysis

To search for MMA-induced specific proteins, proteome differential analysis was performed. As shown in the volcano plot, MMA induction upregulated the expression of 58 proteins and downregulated the expression of 36 proteins (Figure 2A). MMA and control groups were analyzed by the heatmap overview showing a good separation between the two groups, as well as confirmed by the PLS-DA (Figures 2B,C). All the details of DEPs are listed in Supplementary Table S2, compared with the control group, the most significantly upregulated proteins were C-reactive protein (CRP), immunoglobulin, collagen alpha-2 (XI) chain (COL11A2), GTP-binding protein SAR1a (SAR1A), and dipeptidyl peptidase 1 (CTSC), and the top five most significantly downregulated proteins were all immunoglobulins, followed by apolipoprotein (APO), tubulin beta chain (TUBB), and cholesteryl ester transfer protein (CETP).

FIGURE 4

DEPs associated with lipid metabolic diseases. Disease enrichment analysis of identified DEPs. The left is the name of the disease, the right represents enrichment, and the size of the solid circle indicates the number of genes; the color of the solid circle indicates the $-\log_{10}$ (p-value) of enrichment.

Functional analysis of differentially expressed proteins

To further explore the potential functions of DEPs, GO, and KEGG predictions were performed. GO functional analysis showed that DEPs were mainly related to immune function (such as neutrophil-mediated immunity, neutrophil activation, neutrophil degranulation, neutrophil activation involved in immune response) and membrane protein function (such as vesicle lumen, cytoplasmic vesicle lumen, collagen-containing extracellular matrix) (Figure 3A). The KEGG pathway analysis showed that six DEPs were significantly enriched in the lysosome, including CTSC, tartrate-resistant acid phosphatase type 5 (ACP5), lysosomal protective protein (CTSA), cathepsin B (CTSB), prosaposin (PSAP), and tripeptidyl-peptidase 1 (TPP1), these six DEPs were downregulated in MMA patients (Figure 3B, Supplementary Figure S1). Also, four DEPs were significantly enriched in cholesterol metabolism, including APOE, APOC2, APOB, CETP, and these four DEPs were downregulated in MMA patients (Figure 3B, Supplementary Figure S2). We also found that the classical immune pathway of the NOD-like receptor pathway was also significantly enriched by these DEPs. Moreover, we used GSEA to further explore the potential function of DEPs, consistent with the KEGG results, the lysosome pathway was also observed in the GSEA-plot with the top five significant enrichment pathways, as well as an autoimmune disease pathway of systemic lupus erythematosus

(Figure 3C). These results suggested that the disease progression of MMA may be involved not only in immune disorders but also related to abnormal lysosomal function and cholesterol metabolism.

Differentially expressed proteins associated with lipid metabolic diseases

Furthermore, we predicted the relationship between DEPs and human disease. As shown in Figure 4, the diseases most significantly associated with these DEPs were as follows: congenital disorders of lipid/glycolipid metabolism, lipid metabolism phenotypes, LDL cholesterol, lipoprotein-associated phospholipase A2 activity and mass, and HDL cholesterol. In addition, other diseases related to lipid metabolism were also predicted, such as triglycerides and cholesterol total. These results imply that DEPs are widely involved in lipid-abnormal metabolic diseases.

Protein–protein interaction network analysis

Subsequently, we interrogated the interaction relationship of these DEPs. The UNIPROT_ACCESSION of DEPs was input in Cytoscape, the data were retrieved from the HPIDB database to

FIGURE 5 Protein–protein interaction network. DEPs interaction network diagram. The green circles represent proteins, and the red arrows point to target proteins (target proteins of DEPs), and the corresponding ones are source proteins (DEPs).

FIGURE 6 CRP was positively correlated with MMA. (A) Levels of CRP in serum of 14 MMA patients and 15 non-MMA (uninfected) patients. (B) Correlation analysis of serum CRP and MMA. (C) Correlation analysis of serum CRP and methylcitric acid.

plot the protein interaction network, and the results as shown in Figure 5. APOE is not only a target of itself but also a target protein of other APO family members. TPP1, which is significantly downregulated in MMA patients, is mainly a target protein of BCAR1, while the downregulated protein of TUBB interacts with multiple DEPs at the same time. Interestingly, both APO and TPP1 have been reported to be involved in lipid metabolism (Ghosh et al., 2017). It follows that there is a tight interaction relationship between the DEPs, which may co-act together on MMA progression, and this contribution may be related to lipid metabolism.

C-reactive protein was positively correlated with methylmalonic acidemia

To explore the reliability of the proteomic data, we expanded the sample size. We compared the levels of CRP in the serum of 14 MMA patients and 15 non-MMA (uninfected) patients, these values were in a range (MMA: 0.5–23.09; non-MMA: 0.5–2.41) consistent with the finding in serum levels of CRP (MMA: < 0.5, 0.91; no-MMA: < 0.5, 0.52) in serum of Table 2 and Supplementary Table S3. The results showed that CRP levels were significantly up-regulated in MMA patients compared with

those of non-MMA patients (Figure 6A). Further analysis showed that serum CRP levels were significantly positively correlated with MMA levels and methylcitric acid levels in MMA patients (Figures 6B,C). In fact, we have also analyzed the correlation between CRP content and patient age, gender, C3, C0, and other indicators, but no correlation was found. Together, these results support our proteomic data and suggest a positive correlation between CRP and MMA. The CRP validation is consistent with clinical metadata shown for the patients and thus gives confidence to the iTRAQ dataset as a whole.

Discussion

Isolated MMA is an inborn error of metabolism caused by the impaired isomerization of L-MCM to succinyl-CoA mutase. Normally, methylmalonic acid is the product of odd-chain fatty acids, some branched-chain amino acids, and cholesterol *via* the catabolic pathway of the propionyl coenzyme A to Krebs cycle (Richard et al., 2006). *MUT* gene mutations prevent the proper breakdown of these molecules, leading to the accumulation of a large number of compounds in the tissue that eventually form the pathologic characteristics of MMA. Considering Since the fact that the clinical diagnosis of MMA relies on metabolite detection, at present, the alteration of the metabolome caused by mutations in the *MUT* gene has been greatly recognized. In this study, we characterized the protein expression profiles of three isolated MMA patients and three healthy controls by iTRAQ technology in an attempt to connect the relationship between *MUT* mutations and abnormal protein expression at the global level in MMA patients.

In our study, a total of 94 DEPs were identified between MMA patients and healthy control, including 58 up-regulated and 36 down-regulated DEPs in MMA patients. Among them, compared with the control group, the most significantly up-regulated proteins were CRP and immunoglobulins, and the top five most significantly down-regulated proteins were all different types of immunoglobulins. Immunoglobulins appear repeatedly in the differential protein expression profiles of MMA patients and healthy control, which emphasizes that the immune environment may be strongly altered in MMA patients. This is consistent with the clinical outcome of MMA patients. Wong et al. (1992) reported that the population of B-lymphocytes was aggressively diminished and the ratio of CD4/CD8 was reversed in MMA infants which were regarded as having severe immunodeficiency. Altun et al. (2021) also proved that immunoglobulins and various immune cell types (including memory B cells, recent thymic emigrants, and Naïve helper T cells) exhibit marked defects. Importantly, intravenous administration of immunoglobulin has a dramatic rescue effect on the adverse clinical manifestations of MMA (Aikoh et al., 1997). Abnormal metabolism of MMA is located in mitochondria and leads to the failure of the citric acid cycle

and affects the mitochondria function (Forny et al., 2021). It is reported that mitochondrial function determines individual B-cell fates, as well as their immunoglobulins (Jang et al., 2015). Therefore, immunoglobulins may be a potential idea to reverse-interrogate the consequences of *MUT* mutations in MMA patients.

In addition, CRP is massively elevated in the plasma of patients with MMA, and we speculate that there may be a point of association. It is generally agreed that CRP is highly conserved and is part of innate immune function, and occurs locally in inflamed or damaged tissues. As part of inflammation, elevated CRP is associated with cardiovascular disease, which is well-established by the Centers for Disease Control and the American Heart (Black et al., 2004). Wang et al. (2020) demonstrated that cardiovascular disease was strongly associated with mitochondria-derived MMA. Thus, the inflammatory response may be responsible for the accumulation of CRP protein in MMA serum. However, Del Giudice and Gangestad, (2018) proposed a new theory that CRP may exist in the absence of inflammation and have a net anti-inflammatory effect. In this case, elevated CRP indicates that the body is investing in protecting, preserving, and/or repairing somatic tissue. Depending on the state of the organism, maintenance may translate into responses including inflammation or tolerance. We conjecture that the currently recognized function of CRP may be only the tip of the iceberg and that the increase of CRP in MMA patients may be either a mechanism of clearance of damaged mitochondria or an unknown one. Collectively, CRP is one of the ways to understand the pathological mechanism of MMA.

Moreover, we found significant enrichment of DEPs in cholesterol metabolism pathways and lipid-related diseases. Similar results were found in zebrafish, where cobalamin C (cblC) deficiency caused by mutations in MMA resulted in deregulated expression of genes involved in cholesterol metabolism as demonstrated by Sloan et al. (2020). This can be explained by the physiological function of MCM enzymes. The MCM enzyme is encoded by the *MUT* gene and is also required for the degradation of a variety of amino acids, odd-chain fatty acids, and cholesterol (Keyfi et al., 2016). Thus, MMA patients with *MUT* mutations have abnormal cholesterol metabolic pathways. In addition, Manoli and Venditti (2005) reviewed that the major secondary complications of MMA include mental retardation, metabolic stroke, progressive impairment of renal function, pancreatitis, acrodermatitis-enteropathica-like lesions, and functional immune impairment. Interestingly, the occurrence of these diseases is associated with cholesterol or lipid abnormalities. For example, studies have shown that abnormal mutations in cholesterol biosynthetic genes are a possible cause of intellectual disability (Besnard et al., 2019). Mental retardation is also accompanied by a significant accumulation of lipids (Elmahgoub et al., 2009). The total cholesterol levels and incidence of severe acute pancreatitis

present a U-shaped relationship (Hong et al., 2020). Therefore, the disease predicted by DEPs may be similar to the complications of MMA, with the common denominator of abnormal cholesterol or lipid metabolism. Summarily, cholesterol metabolism may be one of the important bridges between communicating *MUT* gene mutations and MMA disease.

The CRP validation is consistent with clinical metadata shown for the patients and thus gives confidence to the iTRAQ dataset as a whole. However, the clinical validation of only one DEP also limits the generalizability of the results of this study to a certain extent. Therefore, in the further continuation, we will continue to explore the expression patterns and functions of four DEPs, including two upregulated DEPs (CTSC and SARA) and two downregulated DEPs (lactotransferrin and CETP) in MMA patients compared with healthy control. As mentioned in the results, DEPs associated with lipid metabolic diseases, which prompted us to examine the relationship between lipid-related DEPs and MMA progression. Therefore, CTSC (Rufinatscha et al., 2017), SARA (Sane et al., 2019), lactotransferrin (Kovacic et al., 2014), and CETP (Trinder et al., 2021) were selected for future validation due to their significant *p*-value and their correlation with lipid metabolism. We expect to provide more theoretical bases and evidence for clinical determination.

In conclusion, the present study characterized the protein expression profile of isolated MMA patients with *MUT* mutation and identified DEPs compared with healthy controls. These DEPs were mainly enriched in GO entries associated with an immune function such as neutrophil-mediated immunity, neutrophil activation, neutrophil degranulation, neutrophil activation involved in immune response, and membrane protein function. KEGG revealed that these DEPs were mainly enriched in lysosome and cholesterol metabolism pathways. Moreover, these DEPs contributed to lipid metabolic diseases. The DEPs and their pathways may be useful targets for new therapies to alleviate disease symptoms, importantly, candidate DEPs, such as CRP and immunoglobulins, and are associated with specific pathways were can be measured by routine tests (already available) and thus implemented in a clinical setting.

Data availability statement

The data presented in this study are deposited in the repository, accession number: PXD034075 (PRIDE Archive, <https://www.ebi.ac.uk/pride/archive>). The other data found in the article/Supplementary Material.

Ethics statement

The studies involving human participants were reviewed and approved by the Ethics Committee of the Sixth Affiliated Hospital of Sun Yat sen University (Ethics Committee Batch no. 2019ZSLYEC-105). Written informed consent to participate in this study was provided by the participant's legal guardian/next of kin.

Advantages of publishing in Frontiers

OPEN ACCESS

Articles are free to read
for greatest visibility
and readership

FAST PUBLICATION

Around 90 days
from submission
to decision

HIGH QUALITY PEER-REVIEW

Rigorous, collaborative,
and constructive
peer-review

TRANSPARENT PEER-REVIEW

Editors and reviewers
acknowledged by name
on published articles

Frontiers

Avenue du Tribunal-Fédéral 34
1005 Lausanne | Switzerland

Contact us: frontiersin.org/about/contact

REPRODUCIBILITY OF RESEARCH

Support open data
and methods to enhance
research reproducibility

DIGITAL PUBLISHING

Articles designed
for optimal readership
across devices

FOLLOW US

@frontiersin

IMPACT METRICS

Advanced article metrics
track visibility across
digital media

EXTENSIVE PROMOTION

Marketing
and promotion
of impactful research

LOOP RESEARCH NETWORK

Our network
increases your
article's readership
