About Frontiers

Frontiers is more than just an open access publisher of scholarly articles: it is a pioneering approach to the world of academia, radically improving the way scholarly research is managed. The grand vision of Frontiers is a world where all people have an equal opportunity to seek, share and generate knowledge. Frontiers provides immediate and permanent online open access to all its publications, but this alone is not enough to realize our grand goals.

Frontiers journal series

The Frontiers journal series is a multi-tier and interdisciplinary set of open-access, online journals, promising a paradigm shift from the current review, selection and dissemination processes in academic publishing. All Frontiers journals are driven by researchers for researchers; therefore, they constitute a service to the scholarly community. At the same time, the *Frontiers journal series* operates on a revolutionary invention, the tiered publishing system, initially addressing specific communities of scholars, and gradually climbing up to broader public understanding, thus serving the interests of the lay society, too.

Dedication to quality

Each Frontiers article is a landmark of the highest quality, thanks to genuinely collaborative interactions between authors and review editors, who include some of the world's best academicians. Research must be certified by peers before entering a stream of knowledge that may eventually reach the public - and shape society; therefore, Frontiers only applies the most rigorous and unbiased reviews. Frontiers revolutionizes research publishing by freely delivering the most outstanding research, evaluated with no bias from both the academic and social point of view. By applying the most advanced information technologies, Frontiers is catapulting scholarly publishing into a new generation.

What are Frontiers Research Topics?

Frontiers Research Topics are very popular trademarks of the *Frontiers journals series*: they are collections of at least ten articles, all centered on a particular subject. With their unique mix of varied contributions from Original Research to Review Articles, Frontiers Research Topics unify the most influential researchers, the latest key findings and historical advances in a hot research area.

Find out more on how to host your own Frontiers Research Topic or contribute to one as an author by contacting the Frontiers editorial office: frontiersin.org/about/contact

Brain organoids for addressing COVID-19 challenge

Jin Yu^{1*†}, Kailun Wang^{2†} and Dalin Zheng^{1†}

¹Department of Hematology, Panzhihua Central Hospital, Panzhihua, Sichuan, China, ²Department of Emergency, Panzhihua Central Hospital, Panzhihua, Sichuan, China

COVID-19 is a systemic disease involving multiple organs, and clinically, patients have symptoms of neurological damage to varying degrees. However, we do not have a clear understanding of the relationship between neurological manifestations and viral infection due to the limitations of current *in vitro* study models. Brain organoids, formed by the differentiation of stem cells under 3D culture conditions, can mimic the structure of tiny cell clusters with neurodevelopmental features in different patients. The paper reviewed the history of brain organoids development, the study of the mechanism of viral infection, the inflammatory response associated with neurological damage, the detection of antiviral drugs, and combined microarray technology to affirm the status of the brain organoid models in the study of COVID-19. In addition, our study continuously improved the model in combination with emerging technologies, to lay a theoretical foundation for clinical application and academic research.

KEYWORDS

brain organoids, COVID-19, organoids-on-a-chips, translational medicine, 3D culture

Introduction

The pandemic of COVID-19 has resulted in 635,538,583 confirmed cases and 6,594,050 deaths worldwide as of 31 October 2022, according to the World Health Organization.¹ Almost 30–40% of patients have predominantly neurological symptoms such as headaches, strokes, and hyposmia (Gasmi et al., 2021). The construction of preclinical models to obtain first-hand information on possible mechanisms of viral infection between COVID-19 and neurological manifestations is of great urgency.

Common models for pathogen research include common two-dimensional (2D) cell and animal models. The models for COVID-19 include A549, Calu-3, Human neural progenitor cells-based 2D cells and mouse-based rodents, and even non-human primates such as rhesus monkeys, which may be efficient in studying possible mechanisms of viral infection and treatment (Blanco et al., 2020; Zhou et al., 2020). The 2D unit, which is the main model for current studies, also has some non-negligible

¹ <https://worldometers.info/coronavirus>

problems. (1) Vulnerability to disturbances in the signal dynamics in the petri dish, which is detrimental to nerve cell growth. (2) Human nerve cells can show characteristic changes such as myelin formation and electrophysiology, while 2D cells lack these properties (Dehaene and Spelke, 2015). (3) 2D cultures emphasize individual cells, whereas the advanced functions of the brain are achieved through synaptic connections, and the regulatory functions of various glial cells cannot be presented in 2D cultures (Silbereis et al., 2016); Animal models are more widely used in the study of neurological disorders and altered consciousness, but again, there are some problems. (1) Not only has the human cerebral cortex evolved many more neurons than other mammals, but it has also formed functional structures such as the sulcus gyrus. More importantly, it has thinking activities not found in lower species (Herculano, 2009); (2) some medications may cause severe neurological damage and even death in patients due to drug accumulation during diseases treatment, but the aforementioned phenomena were not observed in preclinical animal models (Giandomenico and Lancaster, 2017). Given the above limitations of the models, we had to look for new *in vitro* research models, and therefore, we focused on organoids.

An organoid is an organ-like structure formed by the aggregation of stem cells in three-dimensional (three-dimensional, 3D) culture, containing cell types specific to the source organ that can reproduce a variety of functions such as secretion, filtration and even partial neural activity, according to the source organ function. Therefore, it displays the physiological functional structure of real organs *in vitro*, which then has great potential for replacing cell and animal testing (Sato et al., 2009; Lancaster et al., 2013; Lancaster and Knoblich, 2014). In the surge of COVID-19, organoids are contributing to host-pathogen interactions, to the study of differences in viral tropism of individual cells, and the kinetics of viral replication, especially in neurological infections, as organovir states “we want to bring organoids for virology to the next level.”² Therefore, brain organoids play an essential role in the molecular pathology of virus-invading cells and the development of therapeutic drugs, and related research is in full swing (Table 1).

As a disease involving multiple systems throughout the body, a single brain organoid only statically reflects the pathological changes following direct viral action on specific cells. Moreover, since the human body is a dynamic and balanced system integrating multiple organs and a physiological microenvironment, how to combine the organ-like model of viral infection with existing equipment to realize the interaction between each organ and the microenvironment to study COVID-19 remains a concern. Therefore, we introduced the organoid-on-chips technology, which is a micro-physiological system built on a chip with microfluidics as its core,

through the cross-fertilization of physics, chemistry, biology, materials science, engineering, micro-electro-mechanics and medicine, and other multidisciplinary science and technology fields (Reardon, 2015; Park et al., 2019). Organoid-on-chips technology is included in organ-on-chips technology, which replaces 2D cells with organoids and uses microfluidics to construct a unified whole *in vitro* to represent multiple organoids, biofluids, mechanical signals, and functional tissue interfaces (Wang et al., 2022). The use of this model allows for a more comprehensive understanding of the association between viruses and neurological manifestations based on existing findings, providing a new platform for discovering potential targets and developing effective treatments.

The chronicles of brain organoids

Research on brain organoids dates back to 1907 when Harrison (1907) discovered that isolated sponge cells had the potential to spontaneously re-form organoids. Over the next century, many teams gradually progressed through 2D to 3D culture of embryoid and potential stem cells (potential stem cells, PSC) from experimental animals until a ROCK inhibitor sustaining human embryonic stem cells (human embryonic stem cells, hESC) passaging allowed hESC to survive through multiple passages (Martin, 1981; Thomson et al., 1998; Watanabe et al., 2005, 2007). Yoshiki, by adjusting the initial conditions of patterning factors and then the tissue will order folding and assembly spontaneously, generated a mammalian brain without external instructions in the Petri dish, unveiling the possibility for a variety of other systems to be studied while demonstrating the organoid as an *in vitro* model (Eiraku et al., 2008). Since then, many teams have continued to improve on culture protocol construction, culture identification, drug efficacy and toxicology testing, making organoids a hot spot in basic life science research, clinical disease simulation and new drug development (Eiraku et al., 2011; Lancaster et al., 2013; Sakaguchi et al., 2015; Watanabe et al., 2017; Mansour et al., 2018; Tao et al., 2018; Pellegrini et al., 2020; Popova et al., 2021).

The pathogenesis of COVID-19 in brain organoids

COVID-19 is an infection induced by the synaptic protein on the envelope of the severe acute respiratory syndrome virus 2 (The severe acute respiratory syndrome virus 2, SARS-CoV-2), which enters the host cells along with receptors/co-receptors on the surface of the host cell membrane and other cofactors. Angiotensin-Converting Enzyme 2 (Angiotensin-Converting Enzyme 2, ACE2), transmembrane serine protease 2 (transmembrane serine protease 2, TMPRSS2), neomycin trichothecene 1 (neomycin trichothecene 1, NRP1) and

TABLE 1 Applications of brain organoids in virus.

Brain regions	Cell types	Patterning factors	Age of organoids when assayed	Virus type used	Infection details	References
Dorsal /ventral forebrain	Hipsc/ESC	Y27632, CHIR99021, SB431542, GM-CSF, A-83-01,LDN193189,dorsomorphin,WNT3A, IWR1e,XAV-939,SHH,SAG,NT3	35 days	ZIKV-MR776	Infected microglia-containing organoids are indicated by the significant morphological abnormalities and cell detachment.	Xu et al., 2021
Cerebral cortex(early-stage)	Human H9 ES (WA09)	bFGF,Noggin,BMP-4,VEGF, hLIF, Y27632, CHIR99021, SB431542, GM-CSF, Cyc A/SNH,BDNF,GDNF.	10 days	ZIKV-H/PF/2013	Organoids incubated with a virus inoculum are exhibited in time-dependent growth attenuation and significantly smaller	Krenn et al., 2021
Cerebral cortex	Hipsc	bFGF,Noggin,BMP-4,VEGF, hLIF, Y27632, CHIR99021, SB431542, GM-CSF, Cyc A/SNH,BDNF,GDNF.	14 days	ZIKV-H/PF/2013	Brain organoids are inoculated with ZIKV to induce a prominent change in organoid structure.	Pettke et al., 2020
Cerebral cortex	Hips	human recombinant FGF and EGF,	14 days	HIV-1 strain NLYU2	Both infected and uninfected microglia continued to infiltrate into the hBORGs	Dos Reis et al., 2020
Cerebral cortex	Hipsc	bFGF, Y27632	15 days	HSV-1 strain F	Cerebral organoids are infected with different titer of HSV-1 in the culture medium for three day.	Qiao et al., 2020
Neocortical /forebrain	hiPSC lines (73 -56010 -01 SA and 73 -56010 -02)	bFGF, Y27632, CHIR99021, SB431542, LDN193189	12 weeks	HSV -1 strain KOS	Brain organoids are infected for 2 h, and then the inoculum is removed.	Abrahamson et al., 2020
Neocortical /forebrain	iPSCs	FGF,EGF, Y27632, CHIR99021, SB431542, LDN193189	12 weeks	HCMV strain TB40/E	The inocula of cerebral organoids are removed after 2h and then analyzed at days 3 and 5 post infection	Sison et al., 2019
ventricular/subventricular zone	AG14048 iPSCs	bFGF,Noggin,BMP-4,VEGF, hLIF, Y27632, CHIR99021, SB431542, GM-CSF, Cyc A/SNH,BDNF,GDNF.	> 9 weeks	HCMV strains Towne	Brain organoids are exposed to virus for 24 h, and then medium is replaced.	Brown et al., 2019
Forebrain	HNSC.100	bFGF,Noggin,BMP-4,VEGF, hLIF, Y27632, CHIR99021, SB431542, GM-CSF, Cyc A/SNH,BDNF,GDNF.	> 6 weeks	DENV-1 (Hawaiian strain)	Direct injection of the virus strain	Yoon et al., 2017

ZIKA, zika virus; HIV, human immunodeficiency virus; HSV, herpes simplex virus; HCMV, human cytomegalovirus; HIPSC, human induced pluripotent stem cells.

furin/furin-like proteases are common receptor components, and the broad spectrum of ACE2 receptor hosts establishes its status as the primary receptor for neurological infections (Liu Z. R. et al., 2020).

The mechanism of COVID-19 based on ACE2 receptor in brain organoids

When comparing the distribution of ACE2 in different *in vitro* models, the expression of ACE2 in neurons and astrocytes in brain organoid was significantly higher than that in 2d cultures, so a rational choice of *in vitro* models is a prerequisite for achieving the reliability of the study results. COVID-19 selectively infects astrocytes and radial glial progenitor cells in brain organoids, but there are also differences in infection rates between the two: nearly 50% in the former compared to 30% in the latter (Chen et al., 2020). In addition to the above-mentioned cells, it has been suggested that the virus is more plexiform celophilic, but the detailed mechanism relies on Jacob et al. (2020) showing infection rates of up to 20% in choroid plexus-like organs with COVID-19 are accompanied by a large number of transcribed genes downregulated. Genes related to cytokines and vascular remodeling were upregulated, whereas genes related to ion channels and intercellular junctions were downregulated. Similarly, Pellegrini and Lancaster (2021) further found that IL-6 produced by the virus through intrinsic immunity and C3 and C4 production by the complement system led to both studies. Both results suggested that ACE2-expressing choroid plexus epithelial cells are the main pathogenic mechanism of viral infection in brain organoids as the blood-brain barrier is disrupted by the recruitment of inflammatory factors (Sunngak et al., 2020).

However, ACE2 expression is lower in the neuronal cells, which make up the majority of brain cells, and the virus has a different proclivity for these cells (Qi et al., 2020). Some studies pointed out that the virus does not infect neurons, but several studies also concluded that the virus affects the upregulation of metabolism-related pathways such as cell division and the formation of a hypoxic environment at the foci of infection; or causes stress and direct damage to neurons by altering the distribution of Tau proteins in neurons and hyperphosphorylation (Song et al., 2020; McMahon et al., 2021); The above studies mentioned that viral infection interferes with metabolic processes, leading to changes in the microenvironment between normal and infected cells. The aforementioned studies suggest that viral infection interferes with metabolic processes, thereby affecting the survival of pericytes which constitute the neurovascular brain. Interestingly, viral mRNA may be 50-fold higher in pericyte-containing organoids, which act as a center of viral replication. In contrast, in controls without pericytes, no SARS-CoV-2 fragments are detected, which may be related to the

fact that pericytes promote astrocyte maturation and mediate viral infection of cells (Ramani et al., 2020). Furthermore, it has been proposed that infection causes corresponding neurological symptoms such as headache and dizziness by rapidly decreasing the number of excitatory synapses of cortical neurons in brain organoids (Wang L. et al., 2021). In addition to the ACE2-mediated direct infection of neuronal cells described above, the nasal cavity, consisting of the sieve plate and olfactory epithelium, establishes a contact with the nerve center, and the severe acute respiratory syndrome virus infection of the nervous system via this pathway also provides new inspiration, that is, whether COVID-19 can also invade the nervous system along this pathway? (Baig et al., 2020) The expression level of ACE2, the key to viral invasion, correlates with the time of organoid culture. Bullen et al. (2021) notes that brain ACE2 expression was highest in organoids at 9 weeks, while McMahon et al. (2021) found that organoids cultured *in vitro* for 180 days had viral titers that could be diluted to 10^2 PFU due to the wide distribution of ACE2 and that the amount of ACE2 was not constant. As the virus replicates in neuronal cells, ACE2 expression increases accordingly, which warns us that ACE2 mRNA levels do not represent ACE2 protein expression (Wang L. et al., 2021); it is worth mentioning that ACE2 expression levels also change if patients have comorbidities such as chronic diseases like hypertension and neurodegenerative diseases like Alzheimer's disease (Cantuti et al., 2020).

The mechanism of COVID-19 based on other receptor in brain organoids

Most of the aforementioned studies on nerve cell infection by COVID-19 have focused on ACE2, which is less expressed in olfactory cells. And the higher viral infection may be attributed to the high expression of the NRP1 co-receptor, which promotes viral interaction with a small number of ACE2 receptors to enhance viral entry into host cells when ACE2, TMPRSS2, and NRP1 are present together, but does not promote infection when only NRP1 is expressed. Meanwhile, the role of NRP1 depends on florin cleavage of the viral S protein to form a specific c-terminal sequence that promotes viral invasion of neuronal cells (Andrews et al., 2021). Similarly, in human cortical organoids, no significant ACE2 expression was observed in astrocytes, while in virus-infected cells, CD147 and DPP4 co-receptor expression were significantly higher in virus-infected cells, and the rate of viral infection also varied with the amount of co-receptor expression. Interestingly, co-receptors also induce an inflammatory gliosis-like injury (Wang et al., 2020). It has also been suggested that T lymphocytes with low levels of ACE2 expression are also susceptible to infection, which may be associated with CD147 receptor molecule-mediated endocytosis on the surface of T cells. Further studies are still

needed to address whether it is another potential target for viral invasion (Blanco et al., 2020).

The mechanism of inflammation of COVID-19 in brain organoids

There is also controversy regarding the neuroinflammation induced by viral infection via the aforementioned receptors (or targets). Some studies have pointed out that infection does not cause the production of neuroinflammation such as interferon (interferon, IFN; McMahon et al., 2021). But others have pointed out that low levels of IFN I and III with elevated chemokines and high expression of IL-6 are key to the development of neuroinflammatory symptoms, even more importantly, infected astrocytes are involved in neuroinflammation through upregulation of inflammation-related genes such as IFIT1, IFI44, and ISG15, and that genotoxic stress activation leads to nearly 20% apoptosis (Ramani et al., 2020). Inflammatory factors such as IL-1 β , IL-6, chemokine ligand 5, and chemokine ligand 10 are significantly upregulated, compromising the integrity of the blood-brain barrier (blood-brain barrier, BBB). Local hypoxia produces an inflammatory response, which in turn lowers the threshold for tissue damage and thus exacerbates neurological damage, and these findings further expand our understanding of the pathogenic mechanisms of COVID-19 (Blanco et al., 2020).

Screening therapeutic regimens of brain organoids in COVID-19

With an understanding of the pathogenesis of COVID-19, drug selection and vaccine development become particularly important in treatment and prevention. We all know that antiviral drugs generally take 8–12 years to develop, and even after hitting the market, they can be withdrawn at any time due to issues of efficiency, quality, targeting, and safety issues; Vaccines involve phase IV clinical trials and require constant adaptation to cope with the high variability of the virus, and as Feinberg says, “This is a world where we’re going to see infectious diseases we’ve never seen before, and we need to get really good at developing vaccines against them quickly.”³ And the time to market for vaccines is usually longer than for drugs, taking about 8–18 years. The urgent need to develop antiviral drugs and vaccines that use brain-based organs continues to be explained by the wide range of people involved in COVID-19, the high mortality rate, and the poor prognosis.

Given that ACE2 is a major molecule mediating infection, Monteil et al. (2020) attempted to inhibit viral infection by

blocking the ACE2 receptor, and they used human recombinant soluble ACE2 (hrsACE2, human recombinant soluble ACE2) to treat virus-infected vascular and kidney organoids. They found that the rate of virus infection in vascular organoids was reduced by about 5-fold before and after the use of hrsACE2, while the effect was even more dramatic in renal organoids, even decreasing by nearly 1,000-fold. Since ACE2 is widely distributed in multiple tissues, including the brain, can hrsACE2 achieve the same anti-infective effect in infected brain organoids? In addition, in brain organoids with TMPRSS2 receptor expression, the serine protease inhibitor Camostat Mesilate, blocks viral S protein-mediated infection (Hoffmann et al., 2020). The EK1 peptide, an inhibitor of stinging proteins, inhibits endocytosis mediated by the binding of viral stinging proteins to cellular receptors at 40 μ M, thereby inhibiting viral infection by interfering with the cell fusion process (Blanco et al., 2020). Not only are there drugs targeting each receptor molecule but the monoclonal antibody tocilizumab to ACE2 is also very effective and inhibits viral infection of the organoid even at 100-fold dilution (Song et al., 2020). Lv et al. (2021) found that using SARS-CoV-2 infected lung and small intestine organoids, including imatinib, mescaline, quinacrine hydrochloride and chloroquine, could inhibit virus invasion. Moreover, the effective concentration of mycophenolic acid in the four drugs could even be as low as 0.15 μ M, and the animal model also verified the experimental results, enlightening us whether SARS-CoV-2 can first infect the lung, then there was a relay station for virus replication and transmission, and eventually led to brain infection through blood circulation remains to be further investigated. Sofosbuvir, an Food and Drug Administration-approved anti-hepatitis C drug, was used to prevent infection-induced neurotoxic changes because of its high homology to SARS-CoV-2 in terms of base arrangement. Mesci et al. (2020) chose 20 μ M of Sofosbuvir to treat brain organoids infected with the virus and found that the drug significantly reduced virus replication and nerve cell death in brain organoids.

The applications of COVID-19 in brain organoid-on-a-chip

Brain organoids reproduce, to some extent, some of the structures and functions of the human nervous system, but the lack of vascular endothelial cells and immune cells exposes us to the deficiencies of this model in simulating the host's inability to initiate intrinsic and adaptive immune response after the pathogenic attack; simultaneously, the formation of neuronal networks in the brain is dependent on the regulation of physicochemical factors, and most existing protocols include chemical signals such as neurotrophic factors and hormones sequentially to induce nerve cell differentiation, migration and maturation, and eventually brain organogenesis (Yu et al., 2022).

³ <https://www.statnews.com>

Without including physical signals in the culture. This may result in problems such as difficulties in the simulation and control of organoid tissues whose structure and function are not equivalent to the source tissue's physical signals, including mechanical, electromagnetic, and optical signals. Additionally, because of challenges with modeling and control, organoids are often only maintained in static culture systems, even though both the growth of nerve cells and the production of myelin depend on the presence of physical signals (Ryan et al., 2021). However, more importantly, fluids are crucial in order to meet the high metabolic demands during organoid culture and to avoid inefficient ways of oxygen uptake and nutrient supply in static culture systems, such as passive diffusion of nutrient supply only. In a study of COVID-19 infection of the intestine, the expression of ACE2 increased significantly with the combination of physical signals such as fluid shear and mechanical peristalsis, laying the model basis for further studies (Bein et al., 2021).

The organic combination of developmental biology, bioengineering, and 3D stem cell culture technology to form a micro-processed cell culture device, the organ chip, depends on how to introduce and precisely regulate the physicochemical factors at the right time during each stage of model construction. Therefore, the existing organoid models can have a high match with the source tissues. It simplifies the major anatomical structures of the target organ and takes the corresponding cells for co-culture with novel materials and a controlled microfluidic environment, forming a model with high fidelity. The model is widely used, especially in alveolar epithelial cells, endothelial cells, fluid, air-fluid interface, and air sac structures on both sides that deform with respiratory movements together constitute the lung organ-on-a-chip, and then infection with the COVID-19 can better simulate the virus transmission process along the respiratory tract (Thacker et al., 2021). Since organoids composed of multiple cells produce coordinated mechanical activity in terms of traction and fluid shear that is significantly different from that of organoids formed by individual cells on chip. Combining organoids containing multiple differentiated cells with microfluidic systems to form organoids on a chip allows the construction of *in vitro* models with more significant advantages (Guo et al., 2021; Zhang et al., 2021).

For the current status of the COVID-19 pandemic, organoid microarrays have become the first choice in studying the potential pathogenesis of the virus. The lung respiratory membrane and blood-brain barrier communicate through the microfluidic chip. Interestingly, unlike the virus that directly infects brain organoids to destroy the integrity of the BBB, in this experiment, the virus first infects alveolar organoids on the chip and activates immune cells in the lung to trigger systemic inflammation, leading to brain endothelial damage and BBB dysfunction, validating the theory that COVID-19 is a multisystem infection. At the same time, this study mimics

pathological changes in the viral host after infection at the organ level, which is difficult to achieve in other *in vitro* models (Wang P. et al., 2021). Moreover, even CD4 + T cells in the intestine of necrotizing enterocolitis (NEC, necrotizing enterocolitis) mice induce NEC-associated brain injury by releasing IFN- γ in brain organoids via blood circulation (Zhou et al., 2021). All these studies showed the obvious limitations of single brain organoids in studying systemic diseases, highlighting the need for multi-class organ microfluidic chips as an experimental research vehicle (Figure 1).

Challenges and future prospect

Traditional *in vitro* models such as 2D cells and experimental animals have been more successful in the study of pathogens. However, for infections where 2D cells cannot mimic host-pathogen interactions and the host spectrum is limited to humans and cannot be performed in animal models, organoids have leaped to be a better choice under their homology with the source host and their high genetic and phenotypic match. Current studies on COVID-19 infected organoids have focused on the lung, especially when screening drugs using this model, not only have clinical therapeutic doses of certain drugs failed to achieve inhibition of viral infection in lung organoids but even shown experimentally from experiments in 2D cellular and animal models (Si et al., 2021). Although some patients with clinically significant neurological symptoms of COVID-19, most of whom patients exhibit neuroinflammation caused by a storm of inflammatory factors. Building a research system targeting brain organoids to demonstrate infection-induced immune responses and interactions between multiple organs to address these questions. The formation of a brain-organoid-on-a-chip, an automated platform by co-culture with mesenchymal and immune cells and other advanced approaches, in addition to fluidly connecting different organs into a whole, inspired us to build a “multi organoids-on-chips” to achieve the goal of immune response and the study of COVID-19 from a multi-organoids level (Skardal et al., 2017). In February 2022, the U.S. FDA formally approved the cold agglutinin syndrome drug Enjaymo for autoimmune demyelinating diseases based on preclinical efficacy data from human organoids, demonstrating that we can achieve the goal of “old drugs, new uses” by relying only on organoid models and providing clinical efficacy evidence for new drug indications.⁴ In addition to studying infection mechanisms and treatment options, the brain organoids on a chip can also be used to study the long-term effects of environmental factors such as nicotine that predispose to neurological disorders (Wang et al., 2018). And the use of organoid microarrays in vaccine research includes a significant

⁴ <https://www.pharmacytimes.com>

FIGURE 1

Schematic illustration of *in vitro* human organoid models for COVID-19 research. **(A)** COVID-19, clinically presents a wide spectrum of neurological complications, such as dizziness, headache, impaired consciousness (Blanco et al., 2020). Brain organoids are derived from human stem cells and aggregated with patterning factors addition *in vitro* (Chen et al., 2021). With fluid flow, stretch, and tissue interface to mimic cellular microenvironment on a bioengineered microfluidic cell culture device, recapitulating the brain organoid-on-a-chip (Park et al., 2019). **(B)** Integrating brain organoid and other organoids with other approaches like multi-omics, biosensors, 3D bioprinting, and artificial intelligence to generate multi-organoid-on-chips to provide new pathway for virus, which physiologically relevant model systems can be applied to study SARS-CoV-2 virus transmission, pathogenesis and tropism, host-virus interactions, immune responses, and screen preclinical drugs and vaccine (Sang et al., 2021; Wang et al., 2022).

increase in B-cell differentiation and specific IgG antibody production in tonsil organoids infected with live attenuated influenza vaccine and triple vaccine against measles, mumps, and rubella (Wagar et al., 2021); In contrast, lymphoid follicle organoids formed by B and T lymphocytes in human blood

are similar to tonsil organoids in terms of cytokine secretion and immunoglobulin production after influenza vaccination. And with the addition of antigen-presenting cells, they can also be used to test immune responses induced by vaccines and adjuvants (Goyal et al., 2021). To research viral and

vaccine effectiveness in real-time and combat the formation of mutant virus strains, brain organoid microarrays are therefore a valuable tool.

In terms of the current problems with brain organoids, the duration of brain organoids culture varies from weeks to months, with material selection, culture protocols, virus titers, and duration of infection effects varying between research teams (Yi et al., 2020; Zhu et al., 2022). Moreover, the affinity of viruses for brain organoids varies depending on the growth stage, and most organoids formed during culture are currently used only for studies related to the early stages of neurodevelopment, whereas the extended culture time allows brain organoids to have a broader scope of application, especially in the study of pathogenic infections, degenerative diseases. In addition, brain damage caused by mid-to late-stage chronic diseases, and the communication between nerve cells and the connections established at each synapse is also crucial for the reproduction of functions (Sidhaye and Knoblich, 2020). How to mimic viral recruitment of immune cells and initiate immune responses to clear viruses when combined with other pathogens to form a complex infection. And the use of specific hydrogels instead of animal-derived matrix gels can reduce the variability introduced by the compositions and batches (Liu H. T. et al., 2020). Since culture protocols vary from lab to lab and the culture period and size of organoids vary, it is also possible to separate organoids of a certain size by setting traps on microcolumn arrays to obtain uniformly sized organoids (Zhu et al., 2017). Currently, technologies such as multi-omics analysis, artificial intelligence, 3D bioprinting and biosensor provide new ways to efficiently study virus-induced diseases, and the combination of brain organoids with these approaches ultimately allows for study the virus transmission, host-virus interaction, immune responses, and the development of new therapies and vaccines

(Yin et al., 2021). It is believed that with the improvement of culture technology and further research on viruses, organoid models can continuously provide new clinical ideas in the field of pathogen research, which is expected to solve the bottlenecks and troubles of clinical diseases and provide better application prospects for the development of academic research and translational medicine.

Introduction: Previous studies support modular organization of locomotor circuitry contributing to the activation of muscles in a spatially and temporally organized manner during locomotion. Human spinal circuitry may reorganize after spinal cord injury; however, it is unclear if reorganization of spinal circuitry post-injury affects the modular organization. Here we characterize the modular synergy organization of locomotor muscle activity expressed during assisted stepping in subjects with complete and incomplete spinal cord injury (SCI) of varying chronicity, before any explicit training regimen. We also investigated whether the synergy characteristics changed in two subjects who achieved independent walking after training with spinal cord epidural stimulation.

Methods: To capture synergy structures during stepping, individuals with SCI were stepped on a body-weight supported treadmill with manual facilitation, while electromyography (EMGs) were recorded from bilateral leg muscles. EMGs were analyzed using non-negative matrix factorization (NMF) and independent component analysis (ICA) to identify synergy patterns. Synergy patterns from the SCI subjects were compared across different clinical characteristics and to non-disabled subjects (NDs).

Results: Results for both NMF and ICA indicated that the subjects with SCI were similar among themselves, but expressed a greater variability in the number of synergies for criterion variance capture compared to NDs, and weaker correlation to NDs. ICA yielded a greater number of muscle synergies than NMF. Further, the clinical characteristics of SCI subjects and chronicity did not predict any significant differences in the spatial synergy structures despite any neuroplastic changes. Further, post-training synergies did not become closer to ND synergies in two individuals.

Discussion: These findings suggest fundamental differences between motor modules expressed in SCIs and NDs, as well as a striking level of spatial and temporal synergy stability in motor modules in the SCI population, absent the application of specific interventions.

Introduction

Locomotion requires complex coordination of muscles in the body. It is a general consensus that the central nervous system (CNS) often controls the coordination by activating groups of muscles via networks of interneurons in the spinal cord, rather than controlling each of the muscles individually (Bernstein, 1967; Lundberg et al., 1987; Bizzi et al., 1995, 2000; McCrea and Rybak, 2008; Giszter, 2015). It has been suggested that descending signals combined with reflexes and local excitatory and inhibitory interactions of spinal circuitry dynamically select appropriate muscle synergies and behavior from the available repertoire (McCrea, 1992; Kargo and Giszter, 2000; Hart and Giszter, 2004; Cappellini et al., 2006; Krouchev et al., 2006; Ivanenko et al., 2007, 2013; Dominici et al., 2011; Fox et al., 2013; Yang et al., 2019; Sylos-Labini et al., 2020). Spinal interneurons that organize synergy patterns have been identified in frogs, mice and primates (Hart and Giszter, 2010; Takei and Seki, 2010; Levine et al., 2014; Takei et al., 2017), and intraspinal stimulation similarly revealed modular recruitment in animal models (Bizzi et al., 1991; Giszter et al., 1993; Mussa-Ivaldi et al., 1994; Tresch and Bizzi, 1999; Caggiano et al., 2016; Yaron et al., 2020). Further, modular organization of the spinal network is likely determined early in development and refined with experience (Dominici et al., 2011; Yang et al., 2019). Combined, these studies support modular organization of the spinal networks across species.

Muscle synergies are observed during locomotion in healthy individuals and following CNS injury. It is reported that people with complete and incomplete spinal cord injury (SCI) exhibited muscle synergies during treadmill walking (Ivanenko et al., 2013). The patterns of muscle weighting from individuals with motor-incomplete SCI resembled the normal pattern; however, the patterns from individuals with motor-complete SCI did not, indicating that the severity of the injury impacted the weighting in synergies (Ivanenko et al., 2013). In ambulatory individuals with incomplete SCI, fewer synergy modules and altered patterns of synergies were identified both in adults (Hayes et al., 2014; Perez-Nombela et al., 2017) and in pediatric populations (Fox et al., 2013), compared to non-disabled individuals. Danner et al. (2015) reported that

step-like, synergistic electromyography (EMG) patterns in the leg muscles were induced by unpatterned epidural electrical stimulation in individuals with motor-complete SCI while supine, suggesting modular organization of the spinal circuitry can be expressed in this population even with unusual or altered feedback. In people post-stroke, fewer synergy modules were identified during walking as a result of merging of the modules observed in non-disabled individuals (Clark et al., 2010). These studies investigated the organization of modules when some supraspinal inputs are partially or completely lost after CNS injury. However, we know rather little about the synergies exhibited by the residual spinal locomotor circuitry (which is known to undergo anatomical and functional reorganization in both humans (Hiersemenzel et al., 2000; Schindler-Ivens and Shields, 2000; Beauparlant et al., 2013; Tseng and Shields, 2013) and animal models (de Leon et al., 1998, 1999; Rossignol et al., 1999, 2008; Pearson, 2000; Rossignol, 2006; Cote et al., 2012; Houle and Côté, 2013; Takeoka et al., 2014; Asboth et al., 2018), after motor-complete severe SCI, and with varying chronicity and neurological injury level. Interestingly, in rats, complete spinal transection occurring at different ages (neonate vs. adult) affords similar synergy patterns, that are nonetheless slightly different from intact adult synergy patterns, despite different experience and influences of descending pathways (Yang et al., 2019).

To better understand the modular organization of the locomotor network in the absence of voluntary stepping ability and its changes following the recovery of walking in humans, we here characterize the modular structure of the locomotor network expressed by the human spinal cord after SCI, and relate the modular structures to healthy patterns. We also explore if chronicity of the injury that allows extensive neuroplastic changes of the spinal circuitry affects the modular organization of the locomotor circuitry. Further, we examine whether clinical characteristics, such as the severity and neurological level of SCI, affect the modular organization. Finally, we asked whether and how the synergy characteristics changed when the subjects achieved walking after locomotor training with spinal cord epidural stimulation (scES, $n = 2$). Using non-negative matrix factorization (NMF) and independent component analysis (ICA), we investigate synergy

profiles of leg muscle activity observed during stepping with manual facilitation and body weight support in people with SCI and non-disabled individuals. Our study provides information regarding the spatial and temporal profile of muscle synergies in a large sampling of people with SCI with varying clinical characteristics, prior to any systematic locomotor training, and demonstrates several consistent synergy structures despite these variations. Further, we show that the training with neuromodulation (scES) does not lead to the normalization of synergy patterns in the absence of neuromodulation, even though the individuals achieved independent walking with scES.

Materials and methods

Subjects

Eighty individuals were included in this study, consisting of two groups: 73 individuals with SCI (SCI group) and 7 non-disabled individuals (ND group). The SCI group (age 33.94 ± 12.92 years, YSI 4.30 ± 4.34 years, median YSI 3.0 years, IQR = 3.07 years) included 54 individuals with no motor function below the lesion (AIS A $n = 34$, AIS B $n = 20$), and 19 with an impaired motor function below the lesion (AIS C $n = 13$, AIS D $n = 6$). [Table 1](#) and [Supplementary Table 1](#) summarize the demographic and clinical characteristics of the subjects in the SCI group. All individuals in the SCI group were non-ambulatory, except 2 AIS D participants (D11 and D43) who ambulated with a walker. Removing these 2 ambulatory subjects from the data analysis did not affect any of the statistical findings presented here, and their modular patterns were similar to non-ambulatory subjects. We also present the data from two subjects (B23 and B30) who achieved independent walking in the presence of epidural stimulation following locomotor training with task-specific stimulation. The ND group (age 26.84 ± 3.57 years) had no diagnosis of neural injury and served as a control group to understand the characteristics of the modular organization of locomotor circuitry in the absence of spinal cord injury. The experimental protocol was approved by Institutional Review Board at the University of Louisville.

Data collection

Both ND and SCI groups stepped on the treadmill using partial body weight support. During stepping, surface EMG was recorded at 2,000 Hz using a custom-written LabView program (National Instruments, Austin, TX). EMGs from the soleus (SOL), medial gastrocnemius (MG), tibialis anterior (TA), medial hamstring (MH), vastus lateral (VL), rectus femoris (RF), and adductor magnus (AD) muscles were recorded bilaterally using bipolar surface electrodes with fixed inter-electrode distance (Motion Lab Systems, Baton Rouge, LA).

Vertical ground reaction force (70 SCIs, 7 NDs) or foot switch data (3 SCIs) were also collected and used to identify the swing and stance phases of the step cycle. For post-training data ($n = 2$), the EMG data without epidural stimulation during treadmill walking with minimal assistance and body weight support were analyzed. Individuals in the ND group walked on the treadmill at varying speeds with body weight load (BWL), and EMGs during 1.07–1.34 meters/second (m/s) with 100% BWL were included in the analysis of the motor module. Individuals in the SCI group stepped on a body-weight supported treadmill with manual facilitation. Manual facilitation provided stepping-related sensory cues and helped optimize body kinematics. Step speed and percentage BWL were selected for each subject to produce the optimal kinematic pattern and muscle activation with manual facilitation. Foot switches with four sensors on each side were attached to the shoe insole to detect foot contact with the treadmill during stepping. Vertical ground reaction force data were acquired at a frequency of 100 Hz from the treadmill instrumented with pressure sensors (Zebris Medical GmbH, Germany).

Data processing and analysis of motor module

Each channel of EMG signals was high-pass filtered at 40 Hz using a zero-lag fourth-order Butterworth filter, demeaned and rectified. The EMG signals were then low-pass filtered at 4 Hz using a zero lag, fourth-order Butterworth filter ([Clark et al., 2010](#)). Subsequently, the EMG from each muscle was normalized to its peak value from the gait cycle and time-interpolated over individual gait cycles on a time base with 100 points ([Chvatal and Ting, 2012](#); [Hayes et al., 2014](#)) in order to allow comparisons between subjects. Motor modules were calculated based on the EMG traces of concatenated steps of ≥ 10 step cycles to capture step-to-step variability ([Clark et al., 2010](#)). In NDs, 10–19 steps were analyzed (13.29 ± 3.64 steps), and in SCIs, 10–34 steps were analyzed (18.03 ± 6.07 steps). After the EMG processing, motor modules during stepping were extracted separately for left and right leg muscles in each subject using three analysis methods: spatially-fixed non-negative matrix factorization (SF-NMF), temporally-fixed non-negative matrix factorization (TF-NMF), and independent component analysis (ICA). The number of modules required to account for $\geq 90\%$ of the total variability in the EMG (VAF) was identified using each analysis ([Clark et al., 2010](#)).

Non-negative matrix factorization (NMF)

For both SF- and TF-NMF, the number of modules required to account for $\geq 90\%$ of the total variability in the EMG (total VAF) was identified in each subject ([Clark et al., 2010](#)) using a custom-written MATLAB program. SF-NMF analysis was used to test the hypothesis that muscle synergies during stepping have

TABLE 1 Clinical characteristics of SCI subjects.

	Age (years)	Gender	YSI	NLI
AIS A (N = 34)	33.94 ± 11.72	26 male, 8 female	5.23 ± 5.59	Cervical = 16, Thoracic = 18
AIS B (N = 20)	32.30 ± 11.61	16 male, 4 female	3.26 ± 1.83	Cervical = 14, Thoracic = 5 Lumbar = 1
AIS C (N = 13)	34.46 ± 13.30	9 male, 4 female	4.13 ± 2.93	Cervical = 9, Thoracic = 4

YSI, years since injury, NLI, neurological level of injury.

fixed spatial patterns and varying temporal patterns (Safavynia and Ting, 2012). To identify spatially-fixed synergy patterns, the EMG data were structured in $m \times t$ matrices, where m is the number of muscles recorded from each leg, and t is the concatenated steps (100 points per cycle \times number of step cycles). Then, the NMF algorithm was applied to the matrix, which generated spatially-fixed muscle weightings W ($m \times n$ matrix) and temporally-varying muscle recruitment pattern C ($n \times t$ matrix).

TF-NMF analysis yielded motor module descriptions used to explore the hypothesis that muscle synergies during stepping have fixed temporal patterns and varying spatial patterns (Safavynia and Ting, 2012). To identify temporally-fixed synergy patterns, the EMG data were structured in $s \times r$ matrices, where s is the number of time points, and r is the number of muscles \times step cycles. When the NMF algorithm was applied to the matrix, temporally-fixed muscle recruitment pattern C ($s \times n$ matrix) and spatially-varying muscle weightings W ($n \times r$ matrix) were generated (Ivanenko et al., 2003; Safavynia and Ting, 2012).

Independent component analysis (ICA)

Independent component analysis was used to extract mutually independent synergy components from EMG data (Bell and Sejnowski, 1995; Hart and Giszter, 2004; Dominici et al., 2011; Yang et al., 2019). The value of ICA is to detect weakly excited synergies using information rather than variance (Yang et al., 2019). As many components as input muscles are extracted on the basis of minimal information of components. However, ICA is very sensitive to information content and the original sampling and filtering of EMG. It has been very effective with intramuscular recordings (Kargo and Nitz, 2003; Hart and Giszter, 2004; Krouchev et al., 2006; Yang et al., 2019) though often also effective in surface EMG (Cappellini et al., 2006). Here, we tested ICA to explore if it added valuable information to the variance-based analyses. ICA always provides as many modules as muscles, which can then be examined for variance contributions. ICA was performed using the code from Giszter lab (adapted from Makeig's EEGLab; (McCrea, 1992; Makeig et al., 1997; Cappellini et al., 2006; Krouchev et al., 2006; Ivanenko et al., 2013; Yang et al., 2019). To be consistent with the synergy selection criterion in NMF analyses, the number of motor modules was identified based on the cumulative VAF $\geq 90\%$. In addition, to find a breakpoint or an "elbow" in the ICA VAF, a piecewise linear regression was performed using

a piecewise regression function in OriginPro (Version 2021, OriginLab Corporation, Northampton, MA, USA).

Grouping of motor modules

The temporal and spatial characteristics of motor modules in NDs and SCIs were examined by grouping motor modules from each participant. Modules were grouped based on the muscle weighting and recruitment patterns with a high correlation coefficient (Pearson $r \geq 0.7$). We did not set the ND patterns as a reference due to the possibility that the common synergy patterns in SCIs differ from those of NDs. Modules identified by SF-NMF were grouped based on the correlation of spatial patterns, whereas modules from TF-NMF were grouped based on the correlation of temporal patterns.

Analysis of post-training data

In the individuals who achieved voluntary walking post-training, we further compared their pre-training and post-training (no stimulation) data. Six out of 7 muscles (RE, VL, MH, TA, MG, and SOL) were in common between pre-training data and post-training data. Therefore, 7 AIS B participants were randomly selected to define muscle synergies for non-ambulatory SCIs using NMF analyses (SF and TF-NMF). Further, muscle synergies from 6 muscles were defined in all NDs ($n = 7$) using NMF analyses. We quantified the similarity of the sets of synergies in pre- and post-training in 2 subjects with those of NDs and a cohort of AIS B SCI individuals in free order, by calculating an inner product column similarity measure using the matcorr and matperm function in MATLAB (from EEGLab; (Makeig et al., 1997; Godlove et al., 2016; Yang et al., 2019). Ratios of the correlation for each pre- and post-training module were calculated by dividing its correlation to ND group mean synergy by its correlation to SCI group mean synergy. The ratio of greater than 1 indicates that the module exhibits greater similarity to the NDs than to the SCIs, and less than 1 indicates the module exhibits greater similarity to the SCIs than to the NDs.

Statistical analysis

For descriptive and inferential statistics, the clinical characteristics, such as NLI and chronicity of injury (YSI),

were further categorized to determine the effects of clinical characteristics on the number and profile of motor modules. NLI was categorized into upper cervical (C1-C4), lower cervical (C5-C8), upper thoracic (T1-T6), and lower thoracic (T7-T12) lesions. Categorization of thoracic lesions was based on the potential impact of the autonomic dysfunction present in subjects with T6 injury and above on the modular organization and spinal plasticity. A subject with a lumbar lesion ($n = 1$) was not categorized. YSI was categorized into 5 subgroups: ≤ 1 year, 1-2 years, 2-5 years, 5-10 years, and ≥ 10 years, to compare the effects of chronicity of the injury on motor modules. Group differences in the number of modules across synergy extraction methods in the SCIs were analyzed using a 3-way ANOVA or MANOVA (SPSS, Version 26.0. IBM Corp., Armonk, NY). A repeated-measures ANOVA was used to compare the number of modules identified by the 3 analyses. Wilcoxon signed-rank test and paired t -test were used to compare the number of modules found bilaterally in NDs and SCIs, respectively. The significance level was set at 0.05, and *post hoc* comparisons were performed using Bonferroni correction. The comparisons of the muscle weighting and recruitment patterns among individuals were conducted using a Pearson correlation. Data are presented as mean \pm standard deviation (SD).

Results

We analyzed data recorded from non-disabled individuals (NDs, $N = 7$) and SCI subjects (SCIs, $N = 73$; clinical characteristics in [Table 1](#) and [Supplementary Figure 1](#)). Of those SCIs, 71 were non-ambulatory, while 2 American Spinal Injury Association Impairment Scale (AIS) D subjects were ambulatory with a walker. None were subject to any in-house locomotor training prior to the testing. Consistent with previous findings, subjects with motor-complete and incomplete SCI showed patterns of rhythmic leg muscle activity during stepping with manual facilitation ([Dietz et al., 1995](#); [Dobkin et al., 1995](#)), allowing extraction of muscle synergies ([Supplementary Figure 1](#)). Fifty-one SCI subjects demonstrated irregular activity or inactivity in at least one muscle during stepping. Note that in both NMF and ICA these “noise patterns” were segregated by the synergy separation algorithms and account for the fractions of ungrouped synergies excluded. They are thus not a confound in our data. In addition, individuals with SCI showed greater step-to-step variability in vertical ground reaction force during stepping. The standard deviation of vertical ground reaction force was $5.21 \pm 3.58\%$ BWL on average (range 1.74-30.18%) in SCIs, whereas in NDs, the standard deviation of vertical ground reaction force was $3.35 \pm 0.83\%$ BWL on average (range 2.01-4.85%).

Characteristics of stepping in individuals with SCI

We first examined if there was a specific set of step parameters that produced optimal stepping patterns with manual facilitation in individuals with SCI, and if the parameters differed depending on the clinical characteristics. The step speed and % body weight load (% BWL) were related to categorizations by AIS, years since injury (YSI), and neurological level of injury (NLI), and are shown in [Supplementary Figure 2](#). A three-way MANOVA using AIS, YSI, and NLI indicated a significant interaction among the three factors on speed and % BWL, $F(4, 74) = 3.71$, $p = 0.008$. However, neither of the clinical characteristics individually had a significant effect on the step speed and % BWL (AIS $p = 0.08$; YSI $p = 0.08$; NLI $p = 0.39$). *Post hoc* analysis using Kruskal-Wallis tests also indicated that the AIS, YSI, and NLI had no significant effects on speed or % BWL in our subjects (all $p > 0.1$).

Number of motor modules from SF-NMF, TF-NMF, and ICA

We used spatially-fixed NMF (SF-NMF), temporally-fixed NMF (TF-NMF), and ICA to extract synergy patterns. These yielded varying numbers of motor modules to reliably reconstruct $\geq 90\%$ variances accounted for (VAF) in the stepping EMG patterns in the NDs and SCIs. In all ND subjects, the SF-NMF and TF-NMF resulted in 3 modules to explain $\geq 90\%$ VAF in each leg ([Figures 1A,B](#)), whereas the ICA identified 4-6 modules to explain $\geq 90\%$ VAF ([Figure 1C](#)). Four modules were identified in 1 leg, 5 modules in 4 legs (4 individuals), and 6 modules in 9 legs (6 individuals). A repeated-measures ANOVA indicated that different modular analyses resulted in a significant difference in the number of modules in NDs detected, $F(2, 26) = 221$, $p < 0.001$ ([Figure 1D](#)). *Post hoc* comparison indicated that the number of modules from ICA was significantly greater than those from SF and TF-NMF analyses (Bonferroni $p < 0.001$; [Figure 1D](#)).

The number of motor modules was also compared between left and right legs to examine potential laterality or “sidedness” revealed by the analysis of motor modules. While all 7 NDs had the same number of modules bilaterally from both SF-NMF and TF-NMF ([Figures 1E,F](#), respectively), in ICA, only 43% had the same number of modules bilaterally ([Figure 1G](#)). However, the number of motor modules extracted from ICA was not statistically different bilaterally (Wilcoxon signed rank test, $Z = 0.80$, $p = 0.38$).

Subjects in the SCI group exhibited a wider range of the number of motor modules, compared to NDs, needed to explain $\geq 90\%$ VAF in all analyses. SF-NMF analysis led

FIGURE 1

Cumulative percentage variability accounted for (%VAF) and the number of modules extracted by SF-NMF, TF-NMF, and ICA in NDs and SCIs. (A–G) indicates VAF and the number of modules in NDs ($N = 7$, 14 legs), and (H–N) indicates SCI data ($N = 73$, 146 legs). (A–C) %VAF (group mean + SD) for left (L) and right (R) legs from SF-NMF (A), TF-NMF (B), and ICA (C) in NDs. The horizontal red line indicates 90%. ICA required a greater number of modules to explain 90% VAF in EMGs. (D) Comparison of the number of modules explaining $\geq 90\%$ VAF in the EMG all three analyses in NDs (left and right pooled). Each dot indicates an individual data point. SF- and TF-NMF identified 3 modules in all NDs, whereas ICA identified 4 modules in 1 leg (1 individual), 5 modules in 4 legs (4 individuals), 6 modules in 9 legs (6 individuals). ICA yielded a significantly greater number of modules compared to SF and TF-NMF to explain $\geq 90\%$ VAF in NDs ($p < 0.001$). (E–G) The number of left and right modules in NDs, identified by SF-NMF (E), TF-NMF (F), and ICA (G). Each line represents left-right pair for each subject. Thicker lines represent a greater prevalence of the pair. All subjects had 3 modules bilaterally from SF- and TF-NMF, whereas only 3 ND subjects had the same number of modules (Bizzi et al., 2000) bilaterally in ICA. The number of modules between left and right legs was not statistically different. (H–J) %VAF (group mean + SD) for left (L) and right (R) legs from SF-NMF (H), TF-NMF (I), and ICA (J) in SCIs. Similar to the NDs, ICA required a greater number of modules to explain 90% VAF in SCIs. (K) Comparison of the number of modules explaining $\geq 90\%$ VAF in the EMG all three analyses in SCIs. SF-NMF yielded 2 modules in 32 legs (25 individuals), 3 modules in 97 legs (64 individuals), and 4 modules in 17 legs (16 individuals). TF-NMF yielded 2 modules in 19 legs (15 individuals), 3 modules in 85 legs (56 individuals), 4 modules in 35 legs (29 individuals), and 5 modules in 7 legs (7 individuals). ICA yielded 3 modules in 1 leg (1 individual), 4 modules in 7 legs (6 individuals), 5 modules in 44 legs (36 individuals), 6 modules in 92 legs (61 individuals) and 7 modules in 2 legs (2 individuals). ICA resulted in a significantly greater number of modules than SF- and TF-NMF in SCIs, and TF-NMF resulted in a greater number of modules than SF-NMF ($p < 0.001$). (L–N) The number of left and right modules in SCIs, identified by SF-NMF (L), TF-NMF (M), and ICA (N). Each line represents left-right pair for each subject, and thicker lines represent a greater frequency of the pair. The number of modules between left and right legs was not statistically different.

to 2–4 modules (mean 2.90 ± 0.57 , Figure 1H), and TF-NMF led to 2–5 modules (mean 3.21 ± 0.73 ; Figure 1I). SF-NMF identified 2 modules in 34% of SCIs, 3 modules in 88%, and 4 modules in 22%. In TF-NMF, 2 modules were found 21% of SCIs, 3 modules in 77%, 4 modules in 40%, and 5 modules in 10%. Similar to the NDs, the

ICA in the SCIs indicated a greater number of modules, resulting in 3–7 modules (mean 5.59 ± 0.64 ; Figure 1J). Three modules were identified in 1% of SCIs, 4 modules in 8%, 5 modules in 49%, 6 modules in 84%, and 7 modules in 3%. A repeated-measures ANOVA again indicated that different modular analyses resulted in a significantly

different number of modules in SCIs, $F(2,286) = 1382.40$, $p < 0.001$ (Figure 1K). *Post hoc* comparison indicated that the number of modules from all 3 analyses was significantly different from each other (Bonferroni $p < 0.001$; Figure 1K). Results from NDs and SCIs together indicated that the ICA resulted in a greater number of modules compared to SF- and TF-NMF. This was consistent with ICA capturing weaker activated modules in the information-based analyses and likely richer drive structure, but the reduced number of recorded muscles and the surface EMG signal properties made these highly granular ICA results less informative than in other studies. Thus, subsequent analyses described here are focused on NMF.

The cumulative percentage VAF (% VAF) from SF- and TF-NMF demonstrated a clear “elbow” or breakpoint to determine the number of motor modules both in the NDs (Figures 1A,B) and SCIs (Figures 1H,I); however, cumulative% VAF found from ICA did not show the same characteristics (Figures 1C,J), and breakpoints were relatively poorly defined. Fuller and detailed comparison of NMF and ICA method for these data are in Supplementary material (Supplementary Results).

While some bilateral asymmetry is usually assumed *a priori* in SCIs, we directly compared the number of modules for the left and right leg in SCIs (Figures 1L–N). Forty-one SCI (56%) in SF-NMF, 37 SCIs (51%) in TF-NMF, and 39 SCIs (53%) in ICA had the same number of modules bilaterally. Paired *t*-tests indicated no significant laterality and associated bilateral asymmetry in the number of modules in the SCIs ($df = 72$, $t = 0.17$, $p = 0.87$ for SF-NMF; $df = 72$, $t = -0.3$, $p = 0.77$ for TF-NMF; $df = 72$, $t = -0.29$, $p = 0.77$ for ICA).

While the results of the left-right comparison indicated no sidedness, significant bilateral asymmetry may be present in the NDs and SCIs, absent systematic laterality, if the population sidedness was randomly sorted. Thus, we sorted the legs in each subject by fewer vs. more modules, i.e., regardless of the left or right, and tested if bilateral asymmetry was present and statistically significant in NDs and SCIs. When the number of modules between legs that had fewer vs. more modules was compared, there was no asymmetry in NDs ($Z = 1.80$, $p = 0.13$). However, in the SCI group, results indeed indicated significant bilateral asymmetry for SF-NMF (paired *t*-test, $t = -7.31$, $d.f. = 72$, $p < 0.001$) and for TF-NMF ($t = -7.71$, $d.f. = 72$, $p < 0.001$). Similarly, in ICA, there was also a significant bilateral asymmetry in SCIs ($t = -6.95$, $d.f. = 72$, $p < 0.001$). Thus, SCI resulted in significant bilateral asymmetry in the spinal circuitry that led to significant differences in motor modules between sides during stepping, but no laterality was observable. Lack of any systematic laterality allowed pooling of left and right legs into a single group for several of the subsequent analyses examining muscle weightings (spatial) and recruitment (temporal) patterns of motor modules.

Clinical characteristics do not determine the number of motor modules

We examined if the clinical characteristics, including AIS, NLI, and YSI influenced the number of motor modules in individuals with SCI. Supplementary Figure 4 represents the percentage distribution of each number of modules across AIS (Supplementary Figure 4A), NLI (upper and lower cervical or thoracic level; Supplementary Figure 4B), and YSI (≤ 1 year, 1–2 years, 2–5 years, 5–10 years, ≥ 10 years; Supplementary Figure 4C), respectively. Three-way MANOVAs tested the effects of clinical characteristics on the left and right number of modules (separately) assessed from each of the analyses. Results for SF-NMF indicated no significant interaction among the three clinical characteristics, $F(4, 74) = 0.86$, $p = 0.50$, nor were main effects significant, $F(6, 74) = 1.44$, $p = 0.21$; $F(8, 74) = 0.95$, $p = 0.49$; $F(8, 74) = 1.34$, $p = 0.23$, respectively. Results for TF-NMF and ICA were similar, indicating that there were no significant interactions and no main effects of the clinical characteristics on the number of left and right modules, similar to the finding of clinical characteristics being unrelated to functional measures of %BWL and walking speed.

Characteristics of motor modules identified by SF-NMF in NDs and SCIs

Spatially-fixed non-negative matrix factorization identified 3 modules in NDs and 2–4 modules in SCIs. In NDs, all the synergy patterns had a within-group correlation coefficient of ≥ 0.7 when cross-correlated and grouped; therefore, no patterns were excluded. However, in SCIs, 88.2–92.2% of the spatial pattern showed a correlation coefficient of ≥ 0.7 . Further details on the excluded patterns are found in Supplementary material (Supplementary Results).

The spatial and temporal patterns obtained from SF-NMF are presented in Figure 2. Spatial (synergy muscle weight) matching of modules extracted by SF-NMF resulted in a low variance in spatial patterns but greater variance in temporal patterns. Even though most muscles were active in more than 1 module, they were predominantly active in one module, as indicated by their weightings in the spatial pattern. We classified SCI subjects' leg modularity by the number of modules capturing 90% VAF and examined the resulting groups of synergies in 2-module, 3-module, and 4-module patterns. In NDs, only 3-module patterns were identified.

In the 3-module pattern for NDs, Module 1 (M1) was characterized by SOL and MG activity during the mid-late stance, Module 2 (M2) was characterized by TA, VL, RF, and AD activity during the early stance and early and late swing, and Module 3 (M3) was characterized by MH, VL, and AD activity during the swing-to-stance transition (Figure 2A).

FIGURE 2

Spatial and temporal pattern identified by SF-NMF in NDs and SCIs. (A) ND 3-module pattern. (B–D) SCI 2-, 3-, and 4-module patterns. The correlations between the ND and SCI 3-module patterns were weak to moderate. Pearson r for M1 was 0.60 for the spatial patterns and 0.65 for the temporal patterns. For M2, Pearson r was 0.78 for spatial patterns and 0.03 for temporal patterns. For M3, Pearson r was 0.61 and 0.35 for spatial and temporal patterns, respectively. Bar graphs for spatial patterns indicate the group mean + SD. Temporal patterns are also indicated by group mean + SD. SOL, soleus; MG, medial gastrocnemius; TA, tibialis anterior; MH, medial hamstring; VL, vastus lateralis; RF, rectus femoris; AD, adductor.

In SCIs, all spatial and temporal profiles of motor modules looked somewhat different from those of NDs. In SCI 2-module patterns, each module was predominantly tied to stance or swing, with M1 active during the stance comprising SOL, MG, and TA activity and M2 active during the early stance and swing phases comprising MH, VL, RF, and AD activity (Figure 2B). In SCI 3-module patterns, while the spatial and temporal patterns of M1 appeared similar to the 2-module M1, we found that M2 and M3 diverged from the spatial pattern of the 2-module M2. During late stance in M2 in this case, VL and RF were active (M2), while MH and AD were active in M3 in late swing (M3; Figure 2C). In the SCI 4-module pattern (Figure 2D), the spatial and temporal patterns of M1, M2, and M3 appeared similar to those in the SCI 3-module patterns, and an M4

pattern appeared to have diverged from the 3-module M2. The correlation between the 3-module patterns of the NDs and SCIs was moderate (see Figure 2 legend for details). The differences in the temporal and spatial patterns between NDs and SCIs here indicate clear differences of synergy, e.g., coactivation of antagonistic ankle muscles during the stance phase occurs in the SCIs.

Characteristics of motor modules identified by TF-NMF in NDs and SCIs

Temporal matching in the modules extracted by TF-NMF resulted in a lower variance in temporal patterns and a greater

variance in spatial patterns. Only 3 modules were identified by TF-NMF in all NDs. M1 was active during the mid-late stance with SOL and MG activity, M2 was active during the early swing and swing-to-stance transition with TA, MH, VL, RF, and AD activity, and M3 was active during the early stance and early and late swing phases with TA activity (**Figure 3A**).

Modules identified by TF-NMF in SCIs further revealed differences in the modular organization, also identifying more (Lundberg et al., 1987; Bizzi et al., 1995, 2000; McCrea and Rybak, 2008) module patterns (**Figures 3B–D**). In correlating temporal patterns, 88.6–91.4% of temporal patterns showed a correlation coefficient of ≥ 0.7 (further details in **Supplementary material (Supplementary Results)**). In 2-module patterns, while temporal patterns indicated a synergy during stance (M1) and swing phase (M2), the associated spatial patterns did not show any clear distinction in muscle activation for each (**Figure 3B**). In 3-module patterns, M1 was characterized by SOL and MG activity during the early-mid stance, M2 by VL, RF, and AD activity during the stance-to-swing transition, and M3 by MH and AD activity during late swing (**Figure 3C**). The correlation coefficients between the ND and SCI 3-module patterns were only weak to moderate. In 4-module patterns, M1 and M4 appeared to have diverged from the M1 in 2- and 3-module temporal patterns (**Figure 3D**). In 5-module patterns, while temporal patterns indicated peaks in different phases of stepping, spatial patterns again lacked clear distinctions in muscle activity (**Figure 3E**). Interestingly, in 4- and 5-module patterns, the M1 temporal patterns resembled the M1 of NDs, although the spatial pattern from TF-NMF did not show any similarity.

Correlation of motor modules identified by SF- and TF-NMF

In order to investigate if different strategies of identifying synergy patterns lead to different patterns of motor modules, we examined (for both SF- and TF-NMF analyses) the correlations between the within-method average temporal and spatial patterns of motor modules in NDs. M1 and M2 identified by both the two analyses in ND demonstrated a high correlation among subjects. For M1 of SF-NMF and TF-NMF, Pearson r for both temporal and spatial patterns were 1.00, and for M2, Pearson r for the spatial patterns was 0.78, and the temporal patterns 0.80. However, for M3, the correlation was weak; the correlation coefficient for the spatial patterns was 0.16, and the temporal patterns 0.42. These results indicate that while M1 and M2 in NDs were commonly identified as synergy patterns during stepping regardless of whether the spatial or temporal pattern was fixed, the patterns of M3 were more specific to the analysis method in ND.

We next compared correlations between the SF-NMF and TF-NMF methods. In SCIs, temporal and spatial patterns derived from SF-NMF and TF-NMF were compared within each of the 2-, 3-, and 4-module groups. In the SCI 2-module patterns, both M1 and M2 were highly correlated between SF- and TF-NMF methods. The correlation for M1 spatial patterns was 0.79, and temporal patterns 0.88. The correlation for M2 spatial patterns was 0.75, and temporal patterns 0.92. The SCI 3-module patterns also showed a high correlation between SF and TF-NMF. In M1, the correlation for spatial patterns was 0.97, and the temporal pattern was 1.00. The correlations for M2 spatial and temporal patterns were 0.97 and 0.96, respectively. Further, the correlation for M3 spatial patterns was 0.86, and temporal patterns 0.95. In SCI 4-module patterns, the correlation for M1 spatial patterns was 0.63, and temporal patterns 0.55. The correlation for M2 spatial patterns was 0.78, and temporal patterns 0.75. For M3, the correlation for the spatial patterns was 0.98, and the temporal pattern was 0.96. However, for M4, the correlation for the spatial and temporal patterns was -0.24 and -0.18 , respectively. These results in the SCI group suggest that the modules identified in 2- and 3-module patterns were reliably identified regardless of whether the spatial or temporal pattern was fixed. However, the M4 pattern identified in the richer, 4-module pattern in SCI was more specific to the analysis method. The data as a whole support repeatable synergies and activation patterns across individuals in the untreated SCI population.

Characteristics of motor modules across clinical characteristics using three modules

While the number and shape of synergy modules extracted based on $\geq 90\%$ VAF criterion provided valuable information on the characteristics of the modular organization of stepping circuitry in NDs and SCIs, the variations in module number resulting made it difficult to compare the motor modules across all SCI subjects. Thus, we proceeded to run a version of the NMF analysis using a 3-modules analysis on all subjects. This allowed us to further examine the effects of NLI, AIS, and chronicity of injury on the characteristics of motor modules.

The spatial and temporal patterns identified by the added 3-module SF- and TF-NMF analyses were mostly similar across AIS (SF-NMF modules in **Figure 4**, TF-NMF modules in **Supplementary Figure 6**). The majority of the spatial and temporal profiles of each AIS subgroup also demonstrated moderate to strong correlation with each other (**Supplementary Table 2**). Results also indicated that the spatial and temporal profiles of the subgroups showed a weak or (for temporal) even negative correlation to ND synergies, except in spatial patterns of M1 and M2 from SF-NMF (cf. **Figures 2A, 3A, 4** and **Table 2**) and temporal pattern of M3 from TF-NMF (cf. **Figures 2A, 3A**

FIGURE 3

Spatial and temporal patterns identified by TF-NMF in NDs and SCIs. (A) ND 3-module pattern. (B–E) SCI 2-, 3-, 4-, and 5-module patterns. The correlations between the ND and SCI ND 3-module patterns were: for M1, temporal pattern $r = 0.79$ and spatial pattern $r = 0.82$; for M2, temporal pattern $r = -0.30$ and spatial pattern $r = 0.75$; for M3, temporal pattern $r = 0.83$ and spatial pattern $r = 0.25$.

and [Supplementary Figure 6, Supplementary Table 2](#)). Further, the correlations of the patterns between NDs and AIS C and D subjects were similar to the correlations between NDs and ASI A and B subjects, indicating functional supraspinal control of leg muscles does not lead to stepping synergy patterns that better resemble those of NDs.

The spatial and temporal patterns from SF-NMF and TF-NMF were also mostly similar across SCIs with different NLI ([Figure 5](#) and [Supplementary Figure 7](#)) and varying chronicity of SCI ([Supplementary Figure 8](#)). The majority of comparisons between modules across neurological levels of injury ([Supplementary Table 3](#)) and chronicity

TABLE 2 Correlation of SF-NMF 3-module patterns among ND and AIS groups.

Bold text indicates a strong correlation ($r \geq 0.7$). Asterisk indicates statistical significance ($p < 0.05$).

(Supplementary Table 4) indicated strong correlations in spatial and temporal patterns among the subgroups of SCIs, but weak correlations to those of NDs. These findings indicate that the plasticity occurring in the spinal cord circuitry after SCI and the NLI do not strongly affect the modular structure expressed in pattern generation during stepping in this SCI population.

Characteristics of motor modules using 6 muscles in NDs and SCIs

Two subjects (B23 and B30) achieved independent walking in the presence of scES following locomotor training with task-specific stimulation. In order to examine synergy patterns in those two subjects with 6 EMGs (RE, VL, MH, TA, MG, and SOL) collected post-training, we performed the NMF analysis with 6 muscles in the non-ambulatory AIS B SCI subjects ($n = 7$, randomly selected) and NDs ($n = 7$). The number of motor modules extracted from 6 muscles varied from 2 to 4 in NDs and SCIs. In NDs, SF-NMF resulted in 2 modules (2 legs in 2 individuals) and 3 modules (12 legs in 7 individuals, Figures 6, 7 ND group), whereas TF-NMF resulted in 3 modules to explain $\geq 90\%$ VAF in all individuals (14 legs). The spatial and temporal patterns of three-module synergy were consistent with those extracted from 7 muscles. In SCIs (7 AIS B subjects), SF-NMF yielded 3 modules in 6 individuals (11 legs' data) and 2 modules in 2 individuals (3 legs' data; Figures 6, 7, SCI group), and TF-NMF yielded 3 modules in all individuals (12 legs' data), 2 modules in 2 individuals (2 legs' data, 1 in each individual).

Characteristics of motor modules post-training in two successfully rehabilitated AIS B individuals

Post-training, the subject B23 walked on the treadmill at 0.13 m/s and 70% BWL, and B30 walked at 0.72 m/s and 65% BWL, respectively. Twelve concatenated steps from B23 and 36 steps from B30 were analyzed. The number of motor modules was mostly similar pre-training and post-training in both subjects. For B23, SF-NMF using 6 muscles led to 3 modules to explain $\geq 90\%$ VAF pre- and post-training, and TF-NMF led to 4 modules pre- and post-training both legs. For B30, SF-NMF yielded 2 modules to explain $\geq 90\%$ VAF pre- and post-training, and TF-NMF produced 3 modules pre-training and 2 modules post-training for both legs.

Training changed both temporal and spatial synergy patterns. In B23, despite the consistency in the number of modules to explain $\geq 90\%$ VAF pre- and post-training, temporal and spatial patterns of muscle synergies changed (Figures 6, 7). Further, bilateral symmetry increased both for the spatial and temporal patterns. For example, pre-training, Pearson r for the left-right spatial pattern correlation of the three-module patterns ranged 0.15–0.86, and temporal correlation ranged 0.32–0.81 from SF-NMF. Post-training, Pearson r for left-right spatial pattern correlation ranged 0.88–0.92, and temporal pattern correlation ranged 0.75–0.95. In B30, temporal and spatial patterns obtained from SF-NMF were similar pre- and post-training. However, the patterns from TF-NMF had a reduction in motor modules. Bilateral symmetry remained

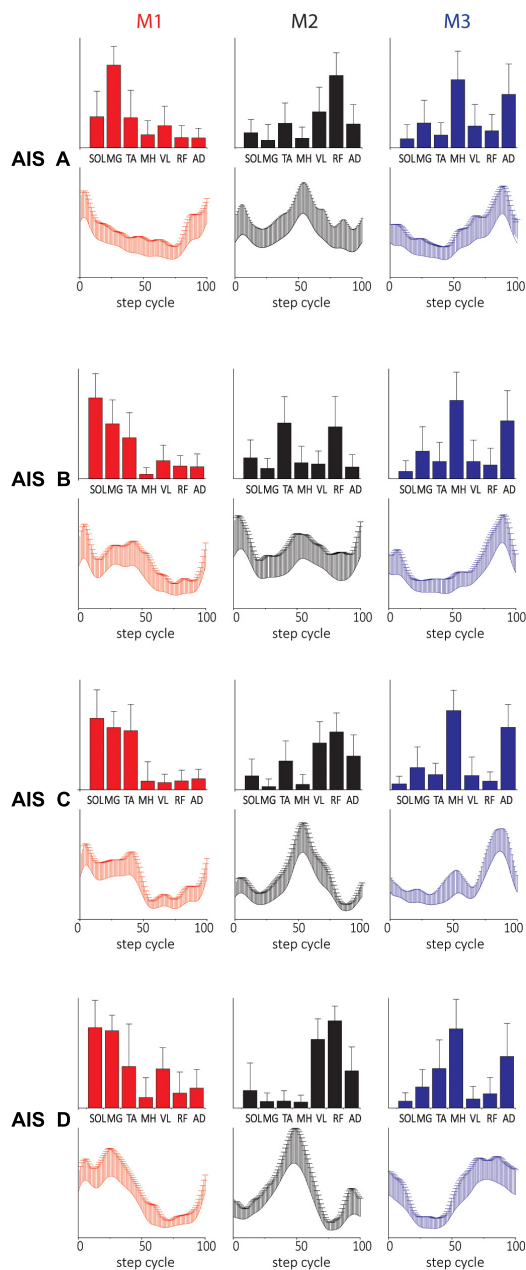

FIGURE 4

consistently high in B30 pre- and post-training. Pre-training, Pearson r for the left-right spatial pattern correlation of the two-module pattern was 0.99 and 1, and temporal correlation was 0.93 and 0.96 from SF-NMF. Post-training, Pearson r for left-right spatial pattern correlation was 0.97 and 1, and temporal pattern correlation was 0.93 and 0.94. While some of the motor modules changed, the synergy patterns did not exhibit greater

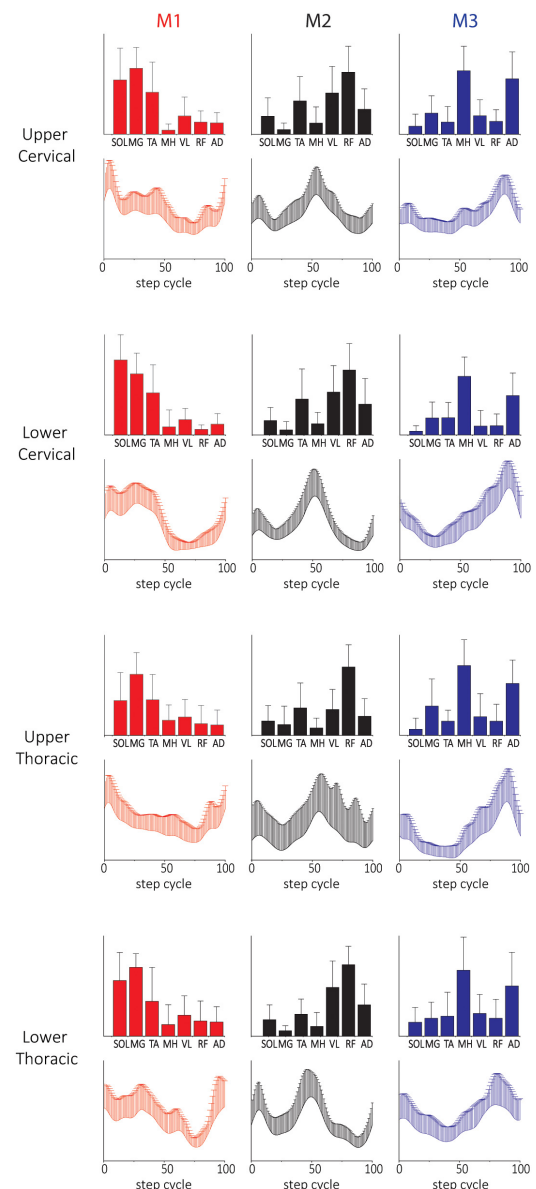

FIGURE 5

similarity to the ND patterns ([Figures 6, 7](#), scatterplots on the bottom), indicating that the recovery of walking function is not dependent on normalized synergy patterns.

Discussion

In this study, we have characterized the modular structure of the locomotor network that the spinal cord is capable of

producing. We identified modularity in response to the step-related sensory feedback received during assisted stepping in subjects with severe SCI, and able-bodied locomotion (NDs). We also compared clinical characteristics, such as AIS, NLI, and YSI to modular control of locomotion and constituent muscle synergies. In addition, we analyzed the changes in synergy patterns in two individuals who achieved independent walking overground with scES, following step training with epidural stimulation (Angeli et al., 2018). Synergy patterns identified by ICA in SCIs mostly presented as single muscle-level synergies, and the NMF analyses were better suited to identify consistent synergy structure for the surface EMGs collected here. Our results indicated that the numbers of synergy patterns identified in SCIs were more variable than those in NDs. Further, neither the severity of the injury, the expected strength of supraspinal inputs, nor the post-injury time available for neuroplastic changes of the spinal circuitry was related to differences in the synergy structures in the SCIs. The synergy modules extracted by SF- and TF-NMF were largely similar within each group (NDs, SCIs). We demonstrated a highly consistent 3-module synergy pattern capturing $\geq 90\%$ VAF in the ND group in NMF analyses within which M1 and M2 were highly similar but M3 could show more variation with analysis method (SF vs. TF). The SCI synergy characteristics are discussed in detail below. Lastly, our results in two successfully rehabilitated individuals indicated no discernable patterns that were consistent between them, indicating that the recovery of walking function with epidural stimulation is not dependent on the normalization of the spinal generated synergy patterns. This may be due to the fact that independent walking is only achieved during the combination of epidural stimulation and the subject's intention to walk, and thus may depend highly on neuromodulation and supraspinal controls. Nonetheless, small changes observed in the synergy patterns without stimulation indicate that the interneuronal network that generates synergy patterns in the lumbosacral spinal cord undergoes some changes during the locomotor training and scES, and these changes may also contribute to the recovery.

In the SCI group, SF- and TF-NMF identified 2-5 modules required for $\geq 90\%$ VAF capture in stepping EMG. Subjects with 2-module synergy patterns, showed a peak of each during the stance or swing phase, similar to the patterns identified during stepping in neonates (Dominici et al., 2011). This resemblance suggests that the expression of the 2-module pattern may be related a collapse of synergies to a de-differentiated pattern caused by insufficient supraspinal control of the locomotor circuitry and compromised propriospinal and proprioceptive control. The spatial and temporal profiles of 3-, 4- and 5-module patterns showed some correlation between healthy modules and SCI modules, but also the SCI coactivation of antagonistic muscles (e.g., SOL, MG, and TA). When taken together, the data suggest that following SCI, even non-collapsed motor modules are expressed differently in some way from healthy

modules. These findings further illustrate that the modular control of the locomotor circuitry either reverts to a more primitive structure as suggested by Yang, Logan (Yang et al., 2019), or else alternatively becomes tuned to or reorganized by the feedback controllers or specific biomechanical task requirements following SCI. For example, while commonly considered maladaptive, the coactivation of ankle muscles shown during stepping may be advantageous for tasks such as transfers or limb stabilization in SCIs (Lee et al., 2020).

Interestingly, we found that the synergy structures remained largely stable across AIS, YSI, and NLI. Ivanenko et al. (2003) reported that the motor modules identified from subjects with AIS C and D exhibited greater similarities to modules of NDs. This is inconsistent with our findings, as in 3-module patterns, spatial and temporal patterns of AIS C and D subjects showed a stronger correlation with those of AIS A and B subjects, rather than with those of NDs. This inconsistency may be due to the fact that the subjects in Ivanenko et al. (2003) underwent daily sessions of body weight-supported treadmill training for 1-3 months prior to the recording of leg muscle activity. In contrast, our subjects were untrained in any specific way prior to testing, except for the data from two participants (B23 and B30) presented after training. The training sessions might have helped guide the Ivanenko's SCI subjects to achieve synergy patterns closer to the healthy modules in AIS C and D subjects (Ivanenko et al., 2003). Further, our results of post-training synergies in two subjects indicate that the synergies sometimes do not strongly correlate with either SCIs or NDs (B23) or else change little and still correlate more to SCI (B30). These results suggest that the propriospinal contribution to the activation of synergies in these subjects post-training with scES is not adequate to normalize the synergy patterns even though the circuitry is capable of generating independent walking when additional excitation is provided to the spinal cord below the lesion. Alternatively, or in addition, it may be that specific supraspinal input is required for the generation of synergies similar to the NDs. Our new data also suggest that the step training combined with neuromodulation in spinal cord injured subjects may re-organize spinal circuitry differently compared to the locomotor training alone.

Our data suggest that AIS is not predictive of the modular control of the locomotor circuitry in response to afferent inputs following SCI. While AIS classification is a widely used diagnostic and classification tool in individuals with SCI, here and elsewhere, it is limited in capturing physiological and functional changes and classifying residual functions and potential for recovery following SCI (Steeves et al., 2007; Krishna et al., 2014; Kirshblum et al., 2021). Further, examining YSI also indicated stronger correlations among groups with different time frames since the injury, suggesting a striking level of stability in motor modules and in the core locomotor circuitry in SCIs over time, despite the reorganization of the spinal cord circuitry clearly occurring after injury (de Leon et al., 1998, 1999; Rossignol et al., 1999, 2008; Hiersemenzel et al., 2000; Pearson,

FIGURE 6

Temporal synergy patterns from SF-NMF using 6 muscles in NDs, SCIs, and two successfully rehabilitated individuals (B23 and B30). Each panel shows temporal patterns from SF-NMF grouped by the number of modules that explain $\geq 90\%$ variance in the EMG from 6 muscles of each leg. In the 2-module patterns of ND and SCI groups, each line represents a temporal synergy pattern from a leg. The 3-module patterns of ND and SCI groups represent group mean + SD. The scatterplots on the bottom represent the ratio of the maximum absolute correlation of each module. The ratio of greater than 1 indicates that the module exhibits greater similarity to the NDs than to the SCIs. See section "Materials and methods" for further details.

2000; Schindler-Ivens and Shields, 2000; Rossignol, 2006; Cote et al., 2012; Beuparlant et al., 2013; Houle and Côté, 2013; Tseng and Shields, 2013; Takeoka et al., 2014; Asboth et al., 2018) and regardless of rehabilitation status. This is consistent with findings in the rodent SCI model (Yang et al., 2019), but it contrasts with the previous findings in people post-stroke during upper extremity tasks (Cheung et al., 2012). There, synergy patterns of upper extremity muscles were directly related to the chronicity of stroke (Cheung et al., 2012). Further, a strong correlation among patterns of NLI categories also indicated that the modular control of leg muscles is not strongly influenced by the level of disruption of intersegmental coupling

between arms and legs (Bergmans et al., 1973; Miller et al., 1975; English and Lennard, 1982; Muzii et al., 1984; Wannier et al., 2001; Donker et al., 2002). This result also indicates that the autonomic dysfunction present in subjects with T6 injury or above does not influence the modular control nor the plasticity of the locomotor circuitry modularity expression following injury.

Populations with different neuropathologies possess different impairments of modular control of locomotor circuitry. Types of descending inputs lost or disrupted may affect the manifestation of motor modules differently. Individuals post-stroke showed a reduced number and

FIGURE 7

Spatial synergy patterns from SF-NMF using 6 muscles in NDs, SCIs, and two successfully rehabilitated individuals (B23 and B30). Each panel shows spatial patterns from SF-NMF grouped by the number of modules that explain $\geq 90\%$ variance. In the 2-module patterns of the ND and SCI groups, each bar represents a spatial synergy pattern from a leg. The 3-module patterns of ND and SCI groups represent group mean \pm SD. The scatterplots on the bottom represent the ratio of the maximum absolute correlation of each module between the ND and SCI group mean synergies (2- or 3-modules) in B23 (3 modules) or B30 (2 modules). The ratio of greater than 1 indicates that the module exhibits greater similarity to the NDs than to the SCIs.

complexity of modules (Clark et al., 2010; Kautz et al., 2011; Routson et al., 2014) due to merging of motor modules (Clark et al., 2010), suggesting that cortical lesion leads to the inability to independently activate each module (Clark et al., 2010; Safavynia et al., 2011). Similarly, in people with Parkinson's disease, fewer motor modules were identified compared to healthy subjects, and temporal patterns were altered while some spatial synergy patterns were unaffected (Rodriguez et al., 2013). Individuals with cerebellar lesions showed similar numbers of modules to healthy subjects with an altered duration of muscle activation in the temporal pattern (Martino et al., 2015). While some of our results showed similarities to the

previous findings regarding fewer motor modules compared to healthy subjects (Fox et al., 2013; Hayes et al., 2014; Danner et al., 2015; Perez-Nombela et al., 2017), we also identified similar and greater complexities in motor modules in some SCI subjects. These differences may be attributable to the ambulatory capabilities of individuals with SCI tested and the conditions in which the locomotor patterns were induced. The supraspinal control of the locomotor circuitry and the use of assistive devices may together contribute to a constrained and simplified modular expression (Fox et al., 2013; Hayes et al., 2014; Perez-Nombela et al., 2017). The varying number of motor modules, as well as altered temporal and spatial

patterns in the SCI subjects in our study, suggests that the loss of supraspinal inputs in the SCI subjects has extensive effects on spinal rhythm and pattern generation circuitry, and that these deficits of the modular control are not easily characterized by the commonly used clinical characteristics such as YSI, AIS, and NLI.

Our results on laterality illustrated that there was asymmetry in the number of modules, but, unsurprisingly, no inherent sidedness. While exploring bilateral symmetry of synergy patterns was not within the scope of this study, the rhythm and pattern generation between the two sides are clearly not independent of each other based on simulation and experimental investigations of the locomotor central pattern generator (Lanuza et al., 2004; Rybak et al., 2006, 2015; Crone et al., 2008; McCreary and Rybak, 2008; Dougherty et al., 2013; Hagglund et al., 2013; MacLellan et al., 2014; Ha and Dougherty, 2018; Dougherty and Ha, 2019). Further, greater bilateral symmetry in post-training synergies in one of the subjects (B30) may indicate that the recovery of bilateral symmetry is associated with the recovery of walking with neuromodulation. Future work may explore whether and how the synergy characteristics expressed on one side influence the synergy characteristics on the other side in the SCI stepping systems.

In SCI subjects, despite findings from Ivanenko et al. (2003), it is still unclear whether rehabilitation strategies can improve the modular control of locomotor circuitry across the range of SCI population and/or lead to modular characteristics more similar to NDs. Our data here, when combined with the earlier Ivanenko study, suggest that treatment modalities and rehabilitation combinations may have major impacts on this. Post-stroke, both merging and fractionation of muscle synergies during walking were observed over the course of therapy (Hashiguchi et al., 2016), and both spatial and temporal patterns of modularity can become similar to the healthy pattern after gait training (Routson et al., 2013). In SCI rats, electrical stimulation of motoneuron pools that mimics the spatiotemporal activation of muscle synergies seen during locomotion in healthy rats could improve weight-bearing ability and quality of locomotion (Wenger et al., 2016). As innovative techniques such as epidural and transcutaneous electrical stimulation combined with gait training and pharmacotherapy develop, it will be crucial to further investigate how these neuromodulatory techniques impact modular control of locomotor circuitry and generation of synergy patterns. It is of particular interest whether features of spinal-generated modular patterns, e.g., the number of modules or specific synergy patterns, serve as constraints or predictors for functional improvement.

There are two competing ways to think of the origins of synergies in locomotion: In the first locomotion synergies are relatively fluid and may be emergent from the combined influences of load and kinematic feedback systems of spinal

cord operating as an ensemble under, or separated from descending control; in the second locomotion synergies may be evolutionarily pre-determined and have spinal structural bases, but be actively adjusted or augmented through reflex and descending control in voluntary tasks. Given the range of SCI subjects tested pre-training, we believe our data are consistent with a common core infrastructure of synergies, expressed in all SCI subjects despite their wide variations in condition. However, it remains conceivable that if the complex and technically difficult experiment were to be performed in which the initial untrained SCI kinematics and loading in stepping were somehow precisely matched to some variant of identical ND kinematics and loading, the patterns in stepping and the synergy production of each would converge to identical outputs. In the absence of such a technical tour de force experiment, we favor the hypothesis of a common synergy infrastructure in spinal cord across all SCI subjects, modified in intact individuals through voluntary and other descending controls of spinal cord. It is noteworthy that both perspectives on synergy origins expect that some SCI subjects will achieve good stepping and weight support after extensive training, as described in Grasso et al. (2004) where detailed kinematics and EMG analyses were combined with the modular EMG organization presented in Ivanenko et al. (2003). Presumably, this training outcome must build on and further engage the consistent synergy patterns described here in the non-ambulatory initial conditions.

The purpose of manual facilitation during stepping was to provide stepping-related sensory feedback that provides excitation to the spinal circuitry that is otherwise silent, and to optimize body kinematics. Further, in the SCIs, step speed and percent BWL were selected for each subject to produce the optimal stepping pattern and muscle activation with manual facilitation. However, the excitation that the selected step speed and BWL provided to the spinal cord may not be identical to the excitation in NDs, who did not require manual facilitation during stepping.

In conclusion, we demonstrated that SCI synergy patterns expressed were mostly stable across different severities of injury, strength of supraspinal inputs (AIS grade), and length of time, and also largely similar among SCI subjects, though differing from NDs. Further, the recovery of walking function following spinal cord epidural stimulation and locomotor training does not lead to the normalization of synergy patterns during stepping without the scES in two AIS B subjects. We believe that our findings provide a basis for future investigations of neural and biomechanical mechanisms underlying the modular organization of locomotor circuitry and constraints on plastic changes, and gait symmetry during training in people with SCI. In addition, the consistent synergy patterns in the SCI subjects and their variations from healthy patterns must impact the design and assessment of future rehabilitation strategies.

Data availability statement

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

Ethics statement

The studies involving human participants were reviewed and approved by the Institutional Review Board at the University of Louisville. The patients/participants provided their written informed consent to participate in this study.

Author contributions

SYS and CAA designed research. SJH and CAA collected the data. SYS, SFG, and CAA analyzed the data. SFG helped design and data analysis. SYS, SFG, and CAA wrote the manuscript. All authors contributed to the article and approved the submitted version.

Funding

This work was funded by National Institutes of Health (MPI P01 NS016333 to SJH, MPI R01 NS049209 to SJH, P30 RR031159 to SJH, MPI R01NS104194 to SFG), this work was also funded by the Leona M. and Harry B. Helmsley Charitable Trust, and the Craig H. Neilsen Foundation.

Introduction: Ferroptosis-related gene (FRG) signature is important for assessing novel therapeutic approaches and prognosis in glioma. We trained a deep learning network for determining FRG signatures using multiparametric magnetic resonance imaging (MRI).

Methods: FRGs of patients with glioma were acquired from public databases. FRG-related risk score stratifying prognosis was developed from The Cancer Genome Atlas (TCGA) and validated using the Chinese Glioma Genome Atlas. Multiparametric MRI-derived glioma images and the corresponding genomic information were obtained for 122 cases from TCGA and The Cancer Imaging Archive. The deep learning network was trained using 3D-Resnet, and threefold cross-validation was performed to evaluate the predictive performance.

Results: The FRG-related risk score was associated with poor clinicopathological features and had a high predictive value for glioma prognosis. Based on the FRG-related risk score, patients with glioma were successfully classified into two subgroups (28 and 94 in the high- and low-risk groups, respectively). The deep learning networks TC (enhancing tumor and non-enhancing portion of the tumor core) mask achieved an average cross-validation accuracy of 0.842 and an average AUC of 0.781, while the deep learning networks WT (whole tumor and peritumoral edema) mask achieved an average cross-validation accuracy of 0.825 and an average AUC of 0.781.

Discussion: Our findings indicate that FRG signature is a prognostic indicator of glioma. In addition, we developed a deep learning network

that has high classification accuracy in automatically determining FRG signatures, which may be an important step toward the clinical translation of novel therapeutic approaches and prognosis of glioma.

glioma, ferroptosis, prognosis, MRI, deep learning network

1 Introduction

Glioma, the most common primary brain tumor in adults, is highly invasive and resistant to various combination therapies such as surgery, radiotherapy, and chemotherapy (Zhou et al., 2022). In particular, glioblastoma multiforme, which is the most malignant type of central nervous system (CNS) tumor, has a median survival <16 months, and this has not improved substantially with modern medical advances (Ma et al., 2018). Glioma recurrence, progression, and metastasis are the three primary challenges that lead to treatment failure. Previous studies have shown that glioma, as a highly complex and heterogeneous tumor, involves multiple pathways, the immune microenvironment, and metabolic reprogramming during its development and progression (Gao et al., 2022). Recently, molecular markers related to the prognosis and treatment of gliomas have been actively explored. For example, isocitrate dehydrogenase (IDH) and 1P/19q have been confirmed to be associated with the prognosis of glioma. In addition, there are new drugs targeting epidermal growth factor receptor (EGFR) and mammalian target of rapamycin (mTOR) for the treatment of gliomas (Deluche et al., 2019; Heinzen et al., 2019; Hu et al., 2022). Unfortunately, there are still many gaps in the prognostic assessment and treatment of gliomas; therefore, the identification of new markers remains imperative.

Ferroptosis is a form of regulated cell death triggered by lipid peroxidation that differs from other genetic, biochemical, and morphological forms of cell death (Dixon et al., 2012). The mechanism of ferroptosis involves several redox-inducing compounds (e.g., erastin and RSL3) and ferroptosis inhibitors (e.g., ferrostatin-1 and liproxstatin-1). Importantly, some cancer cells that are resistant to compounds targeting traditional cell death processes are susceptible to RSL3- and erastin-induced ferroptosis, indicating that ferroptosis induction may be an encouraging therapeutic strategy for gliomas (Hangauer et al., 2017). Previous studies have indicated that ferroptosis-related gene (FRG) signatures are associated with tumor immune features and have potential for prognosis prediction and immunotherapy assessment in gliomas (Hu et al., 2021; Wan et al., 2021). Thus, it is crucial to accurately predict FRG-related risk to plan an effective curative treatment.

Convolutional neural networks (CNNs) are a form of deep learning widely applied for image processing and cover an extensive range of disciplines, such as molecular profiles and genomic mutations in gliomas (Liu et al., 2021). Even though several hurdles exist for clinical implementation (Chang K. et al., 2018; Chang P. et al., 2018), these image signal intensity-based CNNs did not enable the incorporation of information from the tumor 3D voxel, which may cause data leakage problems. Moreover, the existing methodologies require extensive manual preprocessing, presegmentation, or multicontrast acquisitions, which limit their clinical merits. To mitigate these limitations, in the present study, we developed a fully automated and highly accurate deep learning 3D network and further performed this non-invasive method to determine the FRGs signature.

2 Materials and methods

2.1 Data collection

mRNA expression data and clinical information in glioma from three public databases (Ceccarelli et al., 2016), The Cancer Genome Atlas (TCGA),¹ Chinese Glioma Genome Atlas (CGGA),² and Genotype-Tissue Expression (GTEx),³ were used in this study. After data filtration, five available datasets, namely CGGA_693, CGGA_325, TCGA_LGG, TCGA_GBM, and GTEx, were chosen for further analyses. Among these datasets, TCGA_LGG and TCGA_GBM were assigned to the training cohort, whereas CGGA-693 and CGGA-325 were assigned to the validation cohort. Differential gene expression (DGE) analysis was conducted based on the GTEx dataset.

Gene transcription levels were normalized as fragments per kilobase million (FPKM) and further transformed to log2 (FPKM+1) for downstream analysis. A batch correction per subclass was applied using R packages “limma” and “sva.” A total of 323 ferroptosis-related genes, including drivers, suppressors,

¹ <https://tcga-data.nci.nih.gov>

² <http://www.cgga.org.cn/>

³ <http://xenabrowser.net>

and marker regulators, were obtained from the FerrDb database (Zhou and Bao, 2020)⁴.

2.2 Construction of the FRG-related risk score

DGE analysis was conducted using the R package “limma” between tumor and normal tissue samples, and $FDR < 0.05$ and $|\log FC| > 1$ was set as the threshold. Univariate Cox regression was used for the analysis of independent prognostic factors, and $P < 0.05$ was set as the significance threshold. The intersection of the genes, based on the results of DGE and univariate Cox regression analyses, was mapped using the R package “Venn” and described as FRGs for further analysis.

The defined FRGs were subjected to least absolute shrinkage and selection operator (LASSO) Cox regression, which is a classical dimension-reduction approach to screen for independent prognostic factors. The FRG-related risk score was constructed based on the LASSO weighting coefficients of the final selected genes using the following formula:

$$\sum_{i=1}^n (Coef_i \times x_i),$$

where $Coef_i$ represents the coefficients and x_i is the FPKM value of each FRG.

2.3 FRG-related risk score stratification

We used the R package “survminer” to classify the FRG-related risk scores into low- and high-risk groups. The survival rate differences among the stratified groups were compared using Kaplan–Meier (KM) analysis along with log-rank tests. Time-dependent receiver operating characteristic (tROC) curves were used to assess the efficiency of the FRG-related risk score in prognostic prediction.

To compare the clinicopathological and molecular characteristics between the low- and high-risk groups, Chi-square or Student’s *t*-tests were used. Statistical significance was set at $P < 0.05$.

2.4 Gene ontology and Kyoto encyclopedia of genes and genomes

A functional annotation of differentially expressed genes was used to visualize gene ontology (GO) and Kyoto Encyclopedia of Genes and Genomes (KEGG) results using the R package “ClusterProfiler,” to further explore their functional correlation.

2.5 Imaging acquisition and preprocessing

This study used multiparametric magnetic resonance (MR) images obtained from The Cancer Imaging Archive (TCIA) (Bakas et al., 2017).⁵ Preoperative MR images of each patient with glioma were obtained from T1-weighted (T1WI), T2-weighted (T2WI), fluid-attenuated inversion recovery (FLAIR), and T1 contrast-enhanced (T1CE) images.

A total of 122 patient samples were analyzed, representing all matched cases (according to shared barcodes) of glioma in TCGA and TCIA, of which 28 and 94 were partitioned into the high-risk and low-risk groups, respectively. The multiparametric MR images were preprocessed using the Cancer Imaging Phenomics Toolkit open-source software (CaPTk v.1.9.0) (Pati et al., 2020).⁶ The acquired Digital Imaging and Communications in Medicine (DICOM) images were converted to Neuroimaging Informatics Technology Initiative (NIfTI) images and reoriented to the right-most, anterior-most, inferior-most (RAI) coordinate system. Based on the SRI atlas, it was coregistered and resampled to a spatial resolution of $1 \text{ mm} \times 1 \text{ mm} \times 1 \text{ mm}$ (Rohlfing et al., 2010). The anatomical images were bias-corrected and skull-stripped after high-resolution reconstruction. After removing the outlier pixels that did not fall in the 99.9% percentile of the image histogram, the intensities of the images were converted into a background range of 0–255. Automated segmentation was performed using the DeepMedic module (Kamnitsas et al., 2017) and was approved or adjusted when necessary by a board-certified neuroradiologist (Lu) through CaPTk to determine the tumoral subregions of the TC (enhancing tumor and non-enhancing portion of the tumor core) and WT (whole tumor and peritumoral edema) (Figure 1).

2.6 Network details

We used the network architecture shown in Figure 2, a classification network trained on T1WI, T1CE, T2WI, and FLAIR based on TC and WT mask images, respectively. It is a CNN classifier for predicting high- and low-risk FRG-related signatures. The network framework is derived from the classical ResNet50, which contains an initial part (stage0), a residual learning part (stage1–stage4), and a fully connected part (AvgPool3d+Reshape+FC).

The residual learning part (stage1–stage4) comprises three, four, six, and three residual blocks, respectively. The residual blocks employed here are the Conv Block (Block1) and Identity Block (Block2). The Conv Block has inconsistent input

FIGURE 1

Ground truth whole-tumor masks. Red voxels represent non-enhancing tumor core; yellow voxels, enhancing tumor; and green voxels, peritumoral edema.

and output dimensions, requiring the addition of a 1×1 convolution and Batch Normalization (BN) at the location of the shortcut path to stretch the channels and make the dimensions consistent before the summation operation. The Identity Block (Block2) has consistent input and output dimensions, allowing for straightforward addition. The output of the residual learning part was transformed into data dimensions by AvgPool3d and reshape operations and used as the input of the FC.

2.6.1 Network implementation and cross-validation

To ensure the reliability of the network implementation, threefold cross-validation was performed on data from 122 patients (28 high-risk and 94 low-risk groups), and the dataset was randomly divided into threefolds. The data from these threefolds were alternated between the two training sets and one validation set to obtain three prediction models, and the average performance of these three models was calculated. The input images were T1WI, T1CE, T2WI, and FLAIR images cropped by the TC/WT mask to obtain the data with $96 \times 96 \times 96$ pixels. During network training, we performed random flip operations on the input images for data enhancement. The Cross Entropy Loss was chosen as the loss function of the network. The network

learning rate was set to 10^{-4} , the batch size was 8, and the maximum number of epochs was 70. Our pipeline was written in Pytorch, and all experiments were performed on a workstation with an Intel Xeon CPU E5-2630 and NVIDIA Tesla V100 GPU.

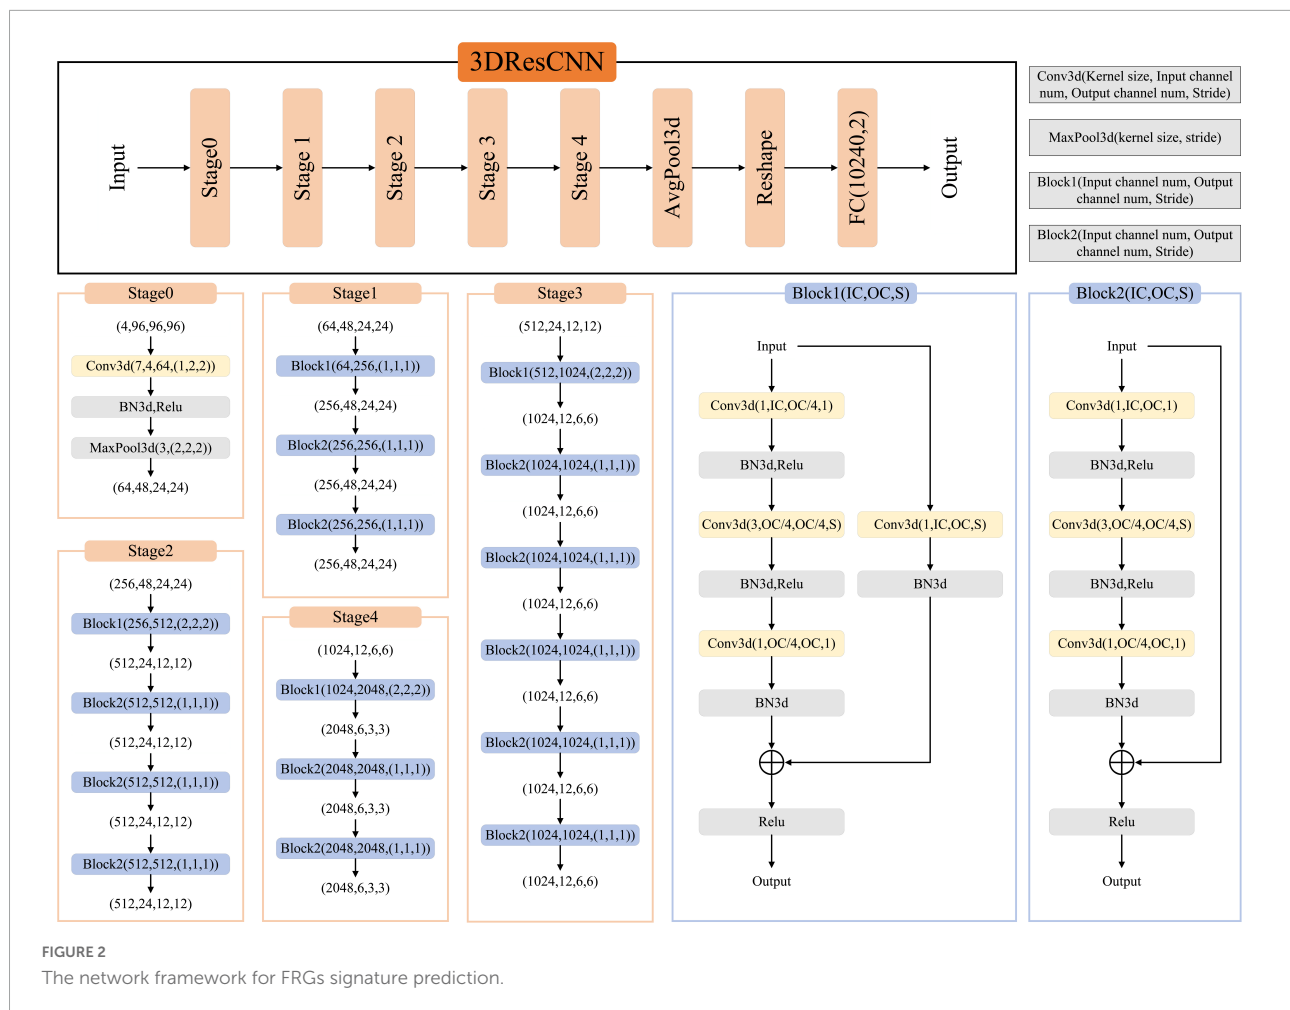

2.7 Network assessment

The diagnostic efficiency was assessed by receiver operating characteristic (ROC) using all predictions across folds of the cross-validation, and the area under the curve (AUC), accuracy (ACC), sensitivity, and specificity were calculated. Besides, we used the precision, recall, and F1 score to assess the signature classification performance of the FRGs. The F1 score was calculated by combining the precision and recall.

3 Results

3.1 Landscape of FRGs

A flowchart describing our study's analytical procedure is presented ([Supplementary Figure 1](#)). The TCGA cohort

containing 270 ferroptosis-related genes was obtained after removing some of the low-expression ferroptosis-related genes. After DGE analysis between tumor and normal tissue samples, 99 genes were retained (Figure 3). In addition, Cox regression analysis identified 221 genes as independent prognostic factors. Taking the intersection of predicted genes, 80 genes described as FRGs, including 53 up-regulated genes and 27 down-regulated genes, were enrolled (Supplementary Figure 2). Upregulation and downregulation of gene expression were also plotted as heatmaps and compared with the corresponding control (Figure 4).

Least absolute shrinkage and selection operator Cox regression analysis was conducted on 80 FRGs and identified 23 genes associated with the prognosis of glioma: 12 driven genes (*NOX1*, *NCOA4*, *ALOX12*, *ALOX15B*, *ZEB1*, *HMOX1*, *TGFBRI*, *IDH1*, *PEX12*, *MYCN*, *SMG9*, and *SLC39A7*) and 12 suppressor genes (*SCD*, *NFS1*, *SQSTM1*, *CD44*, *RRM2*, *GDF15*, *PARP4*, *PARP14*, *KIF20A*, *ETV4*, *LCN2*, and *HMOX1*), among which *HMOX1* is both a driver and a suppressor gene. The LASSO coefficient profiles of candidate genes are shown in

Figure 5. The FRG-related risk score was calculated according to the LASSO weighting coefficients of the final selected genes.

3.2 FRG-related risk score in prognosis

We determined the optimal cut-off using the “surv_cutpoint” function of the “survminer” R package (Supplementary Figure 3). Patients with FRG-related risk scores were further divided into high- and low-risk groups (Supplementary Figure 4).

Kaplan–Meier survival analysis showed that the survival probability was significantly worse in the high-risk group than in the low-risk group in the training and validation cohorts ($P < 0.001$) (Figure 6). tROC curve analysis showed that the development of the risk score in the present study exhibited good predictive effectiveness, which was indicated by 0.899, 0.917, and 0.930 for 1-, 2-, and 3-year AUC, respectively, in the training cohort and 0.765, 0.834, and 0.826 for 1-, 2-, and 3-year AUC, respectively, in the validation cohort (Figure 7).

FIGURE 3
Volcano plot of differential gene expression analysis between tumor and normal tissues.

3.3 Association of FRG-related risk score with clinicopathological and molecular characteristics

There were significant differences in FRG-related risk scores among patients in age ($P < 0.001$), grade ($P < 0.001$), IDH status ($P < 0.001$), MGMT promoter ($P < 0.001$), and 1p/19q codeletion ($P < 0.001$), but no significant differences were observed in sex ($P = 0.912$) (Figure 8).

In addition, patients in the high-risk group had higher grade, older age, wild-type IDH, 1p/19q non-codeletion, and MGMT promoter unmethylation ($P < 0.001$), but had no significant differences in sex (Table 1).

3.4 Analysis of biological properties and pathways related to the gene signatures

Gene ontology and KEGG analyses were used to annotate the intersection genes after risk differential analysis, (Figure 9). The biological processes (BPs) involved included the following: Cellular iron ion homeostasis, iron ion homeostasis, cellular transition metal ion homeostasis, transition metal ion homeostasis, response to metal ion, response to iron ion, regulation of protein serine/threonine kinase activity, cellular response to metal ion, cellular response to chemical stress, and cellular response to inorganic substance (Figure 9A). The

Training cohort

Validation cohort

FIGURE 6

Survival analysis shows survival probability curves in the training and validation cohort.

most abundant cellular component (CC) terminology included autolysosome, secondary lysosome, basal plasma membrane, basal part of cell, secretory granule membrane, and endocytic vesicle membrane (Figure 9A). The most abundant molecule function (MF) terms were ferric iron binding, ferrous iron

binding, iron ion binding (Figure 9A). KEGG pathway analysis revealed that ferroptosis, Mineral absorption, HIF-1 signaling pathway, MicroRNAs in cancer, Hepatocellular carcinoma, and Glutathione metabolism were the most abundant pathways (Figure 9B).

Association between the FRGs and other clinicopathological characteristics (A, age; B, sex; C, grade; D, IDH status; E, MGMT promoter status; and F, 1p/19q codeletion) in the training cohort.

3.5 Network performance in determining FRG signatures

The cross-validation average ACC of 3DResCNN (network [TC-mask]) reached 0.842 (0.900, 0.850, and 0.775 for Fold1, Fold2, and Fold3, respectively), the average F1 score was

0.843 (0.900, 0.844, and 0.784 for Fold1, Fold2, and Fold3, respectively), and the average AUC was 0.781 (0.827, 0.767, and 0.750 for Fold1, Fold2, and Fold3, respectively).

The cross-validation average ACC of 3DResCNN [network (WT-mask)] reached 0.825 (0.925, 0.800 and 0.750 for Fold1, Fold2, Fold3, respectively), the average F1 score was 0.830

TABLE 1 Characteristics of patients in low- and high-risk groups in the training cohort.

Characteristic	High-risk (N = 145)	Low-risk (N = 418)	P-value
Grade:			<0.001
G2	0 (0.00%)	212 (50.7%)	
G3	40 (27.6%)	196 (46.9%)	
G4	105 (72.4%)	10 (2.39%)	
Age (year)	61.0 (53.0, 70.0)	39.0 (32.0, 51.0)	<0.001
Sex:			0.912
Female	61 (42.1%)	180 (43.1%)	
Male	84 (57.9%)	238 (56.9%)	
IDH status:			<0.001
Mutant	1 (0.69%)	369 (88.3%)	
Wildtype	144 (99.3%)	49 (11.7%)	
1p/19q codeletion:			<0.001
Codel	0 (0.00%)	149 (35.6%)

Methylated	63 (43.4%)	356 (85.2%)	
Un-methylated	82 (56.6%)	62 (14.8%)	

(0.923, 0.810 and 0.757 for Fold1, Fold2, Fold3, respectively), and the average AUC was 0.781 (0.842, 0.800, and 0.700 for Fold1, Fold2, Fold3, respectively). The specific results of

3DResCNN in terms of the threefold respective and average metrics are shown in [Table 2](#).

The network (TC mask) showed a similar performance to the network (WT mask), and the summary ROC curves for the network (TC mask and WT mask) are shown in [Supplementary Figure 5](#).

4 Discussion

Evidence suggests that ferroptosis plays a crucial role in tumor initiation, progression, and evolution ([Dixon et al., 2012](#)). Several investigations have indicated that the risk score generated by ferroptosis is associated with the clinicopathological features of gliomas, which can independently predict patient prognosis ([Zhuo et al., 2020](#); [Hu et al., 2021](#); [Wan et al., 2021](#)). In addition, ferroptosis may affect immune cell infiltration in the glioma microenvironment ([Hu et al., 2021](#); [Wan et al., 2021](#)). Bioimaging is an essential tool for the non-invasive diagnosis of gliomas. Indeed, combined with multiple imaging modalities, multiparametric MR imaging enables effective expansion of the feature pool, which would provide more information. Previous studies have indicated that multiparametric MR-based deep learning has diagnostic performance in the differentiation of glioma mimicking encephalitis ([Wu et al., 2021](#)), classification of IDH mutation status ([Bangalore Yogananda et al., 2020](#)), discrimination of pseudoprogression and true progression ([Lee et al., 2020](#)), and determination of molecular subtype in gliomas ([Li et al., 2022](#)). For these reasons, we developed a deep learning 3D network

and further applied this non-invasive method to assess FRG signatures.

The results of GO and KEGG analysis showed the main enrichment pathways of intersection genes in this study. Considering the genetic diversity, 23 FRGs were finally incorporated into prognostic signatures based on LASSO Cox analysis. Our results indicated that the expression of FRGs was associated with poor clinicopathological features, and the FRG-related risk score had a high predictive value for glioma prognosis, which is consistent with previous literature (Zhuo et al., 2020; Hu et al., 2021; Wan et al., 2021). According to the FRG-related risk score, patients with glioma were successfully classified into high- and low-risk groups, which contributed to prognosis stratification.

To our knowledge, this is the first study to demonstrate the application of multiparametric MRI-derived deep learning network for determining FRG signatures in gliomas. CNNs are the cornerstone of deep learning methods, which remain more efficient in image annotation than classical hand-engineered selections, such as color, geometrical, and texture features (Korfatis and Erickson, 2019). In the present study, we used 3DRESCNN (ResNet50) to predict FRG-related risk signatures and used multiparametric MRI imaging (T1WI, T1CE, T2WI, and FLAIR images) as network inputs. The network (TC or WT mask) achieved highly satisfactory prediction efficiency, with ACCs of 84.2 and 82.5%, respectively. In reviewing these multiparametric MRI images, there were no specific imaging features, indicating that the deep learning network provided additional information that could not be interpreted manually. The TC mask represented an enhancing tumor and non-enhancing portion of the tumor core, and the WT mask represented the whole tumor and peritumoral edema. WT mask and TC mask demonstrated similar performances, indicating that peritumoral edema did not enhance the diagnostic effectiveness for determining the FRG signatures.

Despite the satisfactory results, the present study has several limitations. First, we developed a multiparametric MRI-derived deep learning network, whereas diffusion-weighted MRI images were not available. Second, training deep learning models usually requires large amounts of data (Choy et al., 2018), whereas the cases for training are limited. Despite the application of data augmentation for CNNs, because of their high complexity and the use of 3DCNN in this study, the amount of data is too small, easily leading to poor network training and performance. Third, owing to the relatively large number of low-risk FRG-related signatures, this type of quantitative imbalance has a significant negative impact on the training of the CNN classifier, which affects both the convergence of the training phase and analysis of the test set results, as well as the threefold validation.

5 Conclusion

In conclusion, we developed a multiparametric MRI-derived deep learning network with high accuracy for automatically determining FRG signatures. This study represents an important technological milestone using MR imaging to evaluate genetic diversity, prognosis conditions, and drug-targeted genes for gliomas.

Data availability statement

Publicly available datasets for this study can be found in the Cancer Genome Atlas (TCGA, <https://tcga-data.nci.nih.gov/>), Chinese Glioma Genome Atlas (CGGA, <http://www.cgga.org.cn/>), Genotype-Tissue Expression (GTEx, <http://xenabrowser.net/>), FerrDb database (<http://www.zhounan.org/ferrdb/current/>), and The Cancer Imaging Archive (TCIA, <https://wiki.cancerimagingarchive.net/>).

Ethics statement

Ethical review and approval was not required for the study on human participants in accordance with the local legislation and institutional requirements. Written informed consent for participation was not required for this study in accordance with the national legislation and the institutional requirements.

Background and purpose: Traumatic brain injury (TBI), especially the severe TBI are often followed by persistent cognitive sequelae, including decision-making difficulties, reduced neural processing speed and memory deficits. Diffuse axonal injury (DAI) is classified as one of the severe types of TBI. Part of DAI patients are marginalized from social life due to cognitive impairment, even if they are rated as favorable outcome. The purpose of this study was to elucidate the specific type and severity of cognitive impairment in DAI patients with favorable outcome.

Methods: The neurocognition of 46 DAI patients with favorable outcome was evaluated by the Chinese version of the Montreal Cognitive Assessment Basic (MoCA-BC), and the differences in the domains of cognitive impairment caused by different grades of DAI were analyzed after data conversion of scores of nine cognitive domains of MoCA-BC by Pearson correlation analysis.

Results: Among the 46 DAI patients with favorable outcome, eight had normal cognitive function (MoCA-BC ≥ 26), and 38 had cognitive impairment (MoCA-BC < 26). The MoCA-BC scores were positively correlated with pupillary light reflex ($r = 0.361$, $p = 0.014$), admission Glasgow Coma Scale (GCS) ($r = 0.402$, $p = 0.006$), and years of education ($r = 0.581$, $p < 0.001$). Return of consciousness ($r = -0.753$, $p < 0.001$), Marshall CT ($r = -0.328$, $p = 0.026$), age ($r = -0.654$, $p < 0.001$), and DAI grade ($r = -0.403$, $p = 0.006$) were found to be negatively correlated with the MoCA-BC scores. In patients with DAI grade 1, the actually deducted scores (Ads) of memory ($r = 0.838$, $p < 0.001$), abstraction ($r = 0.843$, $p < 0.001$), and calculation ($r = 0.782$, $p < 0.001$) were most related to the Ads of MoCA-BC. The Ads of nine cognitive domains and MoCA-BC were all proved to be correlated, among patients with DAI grade 2. However, In the DAI grade 3 patients, the highest correlation with the Ads of MoCA-BC were the Ads of memory ($r = 0.904$, $p < 0.001$), calculation ($r = 0.799$, $p = 0.006$), orientation ($r = 0.801$, $p = 0.005$), and executive function ($r = 0.869$, $p = 0.001$).

Conclusion: DAI patients with favorable outcome may still be plagued by cognitive impairment, and different grades of DAI cause different domains of cognitive impairment.

KEYWORDS

diffuse axonal injury, cognitive impairment, outcome, Montreal cognitive assessment, cognitive domain

Introduction

DAI is caused by acceleration-deceleration or rotational forces on brain tissues, resulting in axonal shear injuries and delayed axonal disconnection, categorized as a special type of traumatic brain injury (TBI) (Mu et al., 2021; Zhou et al., 2021; Chen et al., 2022; Kim et al., 2022). A total of 20–38% of TBI patients with DAI were followed up with unfavorable outcome (Extended Glasgow Outcome Scale, GOSE 1–4) (Humble et al., 2018; Lohani et al., 2020), but over 85% suffered from persistent cognitive impairment (Macruz et al., 2022; RaukolaLindblom et al., 2022). Significant differences appeared in the incidence of unfavorable outcome and cognitive impairment, reflecting that part of DAI patients classified as favorable outcome were still plagued by cognitive impairment and could not return to normal social life. However, at present, the prevalence and specificity of cognitive impairment in diffuse axonal injury patients with favorable outcome remain unclear.

“Neurocognition” is defined as a collection of interrelated domains such as executive function (EF), language and perceptual motor function, calculation, complex attention, memory, and visuoperception (George et al., 2018; Holguin et al., 2022; RaukolaLindblom et al., 2022). Found that the Finnish KAT test is a valuable tool to detect cognitive-linguistic deficits by comparing the cognitive function of 48 adults with moderate to severe DAI and 27 healthy controls. The Hopkins Language Learning Test (HVLTL), Trail Making Test (TMT), and Rey–Osterrieth Complex Figure test were used to assess neuropsychological results in 25 DAI patients at 6 and 12 months post-traumatic, revealed that patients’ episodic verbal memory, attention, and executive function were improved at 6 and 12 months after the trauma (Macruz et al., 2022). All of the above test methods could only evaluate certain domains of Neurocognition, and the Montreal Cognitive Assessment (MoCA) (Nasreddine et al., 2005) was considered to be a more appropriate scale to comprehensively assess cognitive function after traumatic brain injury, subarachnoid hemorrhage, stroke and Alzheimer’s disease (Cornea et al., 2022; Holguin et al., 2022; Wang et al., 2022). MoCA and resting-state perfusion magnetic resonance imaging were performed in 40 patients with acute mild TBI and 40 healthy controls within 14 days following injury to elucidate the relationship between cerebral blood flow connectivity differences and cognitive outcomes in the acute phase after mild TBI (Duan et al., 2022). Further more, a study from Shanghai Huashan Hospital confirmed that the Chinese version of the Montreal Cognitive Assessment Basic (MoCA-BC), as a reliable cognitive screening test across all education levels, has the advantages of high acceptance and good reliability, and is more suitable than MoCA for Chinese elderly adults with low years of education (Chen et al., 2016).

The favorable outcome (GOSE 5–8) can not be used as the final prognostic indicator because a large part of DAI patients is still troubled by cognitive impairment at several months after TBI (George et al., 2018). We hypothesized that DAI patients with favorable outcomes still have cognitive impairment in different domains. To test this hypothesis, we analyzed the functional status of nine cognitive domains in patients with DAI at 6 months after injury.

Materials and methods

Participants

Patients with DAI diagnosed by magnetic resonance imaging (MRI) within 30 days after injury were screened in this retrospective observational study between January 2019 and December 2021. Neuropsychological of DAI patients were assessed by MoCA-BC at 6 months after TBI. This data collection site was approved by the local Institutional Review Board, and written informed consent was obtained from all participants or their representatives.

The inclusion criteria were the following: TBI patients’ age between 18 and 70 years, diagnosed as DAI by clinical MRI scan within 30 days after injury, 6-month GOSE score ≥ 5 , years of education ≥ 4 . The exclusion criteria were the following: Progressive brain illness (Dementia, Parkinson disease, multiple sclerosis, seizure disorder, and brain tumor) (2/8), history of brain surgery or stroke without full recovery (1/8), Unable to complete or cooperate with the cognitive function test (speech disorder or mental illness) (5/8).

Parameters

Demographic and clinical characteristics were collected during hospitalization, including age, sex, causes of trauma (road traffic accident, fall, and others), years of education, admission GCS score, pupillary light reflex (none, unilateral or bilateral), Marshall CT classification (evaluated on a scale from 1 to 6) from the first head CT scan, time of the return of consciousness.

Diagnosis and grading of DAI

The clinical MRI was performed with a 1.5T scanner (Siemens Symphony, ATim) within 30 days after injury. DAI were defined as TBI patients with lesions in gray-white matter junction of the cerebrum, corpus callosum, or brain stem with T2-weighted imaging (T2WI), T2-weighted fluid attenuated inversion recovery (T2 FLAIR), and diffusion-weighted imaging (DWI) in magnetic resonance imaging (MRI) (Subash et al., 2020; Yue et al., 2020). These lesions were defined as having hypointense focus presented on T2WI (hemorrhagic DAI), or hyperintense focus presented on DWI, T2 FLAIR, and T2WI (non-hemorrhagic DAI) (Rutman et al., 2017; Benjamini et al., 2021). The MRI and CT images were independently analyzed by two experienced neuroradiologists, who had access to patient clinical information but were blinded to the cognitive function.

The presence of DAI in the hemispheres or cerebellum was recorded as DAI grade 1, in the corpus callosum with or without lesions of grade 1 as DAI grade 2, and in the brainstem with or without lesions of grade 1 and/or 2 as DAI grade 3. Patients without DAI were assigned to grade 0 (Adams et al., 1989; Figure 1).

Extended Glasgow outcome scale

GOSE was used to quantify 6-month outcome as favorable outcome (GOSE 5–8; no or moderate disability) or unfavorable

FIGURE 1

DAI grade 1: Lesions in the hemispheres, DAI grade 2: Lesions in the corpus callosum, DAI grade 3: Lesions in the brainstem (as shown in the red circle). DAI, Diffuse axonal injury.

outcome (GOSE 1–4; severe disability or death). GOSE was divided into eight levels (Wilson et al., 1998; Table 1).

Neuropsychological assessment

The MoCA-BC was translated from the original English version with subtle linguistic and cultural modifications and regarded as an effective cognitive test for Chinese elderly adults with low years of education (Chen et al., 2016; Huang et al., 2018). The MoCA-BC assesses nine cognitive domains including executive function, language, orientation, calculation, abstraction, memory, visuosperception, naming, and attention. It takes about 10 min to complete the test, with a maximum score of 30 points. More than 26 points was regarded as normal and with a lower score indicating greater cognitive impairment (Zhang et al., 2019). Each patient's test was performed by trained staff in a quiet environment at 6 months after injury.

Data conversion

The scores of nine cognitive domains of MoCA-BC were all converted into the actually deducted scores (Ads), because the study focused on analyzing the negative impact of cognitive function (Rainer et al., 2006). The specific conversion method was to subtract the total score of each cognitive domain from the actual score of

this domain, that is, the negative value of the score deducted from each domain, for example, if the patient's orientation score was four, then his a Ads of orientation was four minus six (the total score of orientation), which equals to negative two points.

Statistical analysis

All statistical analyses were performed using GraphPad Prism 8 (GraphPad Software, San Diego, CA, USA). A value of $p < 0.05$ with a two-tailed test was considered statistically significant. Categorical data are presented as frequency or percentage and compared by Fisher exact test. Continuous data are presented as the median and interquartile range (IQR) and were compared by the Mann–Whitney U -test. Pearson correlation analysis was employed to show the association of potential risk factors with neurocognition and the Ads of nine cognitive domains with MoCA-BC after data conversion in different grades of DAI patients, and presented in the form of a forestplot.

Results

Demographic and clinical characteristics of subjects

A total of 79 DAI patients diagnosed by clinical MRI within 30 days after injury were enrolled during the study period. At 6 months after injury, 54 patients met all the criteria for inclusion, eight patients were excluded due to the exclusion criteria, and a total of 46 DAI patients with favorable outcome were analyzed. Among them, eight had normal cognitive function ($\text{MoCA-BC} \geq 26$) and 38 had cognitive impairment ($\text{MoCA-BC} < 26$). Comparing the two groups of DAI patients with 6-month favorable outcome with or without cognitive impairment, it was found that there were significant statistical differences in patients' age, years of education, and time to return of consciousness ($p = 0.003$, $p = 0.009$, and $p < 0.001$). But surprisingly, there were no significant statistical differences in pupillary light reflex, admission GCS, Marshall CT score, and DAI grade (Table 2).

TABLE 1 Extended Glasgow Outcome Scale.

Unfavorable outcome	Favorable outcome
1: Death	5: Moderately disabled, qualified for low-level work
2: Plant state	6: Moderately disabled, resuming the previous job but requiring some adjustments
3: Severely disabled and totally dependent on others for daily activities	7: Good recovery, and accompanied by minor physical and mental deficits
4: Severely disabled and can do some daily activities with the help of others	8: Great recovery

Relationship between risk factors and MoCA-BC scores

Pearson correlation analysis was employed to define the relationship of potential risk factors with the scores of MoCA-BC (Figure 2). The following four factors were found to be negatively correlated with the MoCA-BC scores: Return of consciousness ($r = -0.753$, $p < 0.001$), Marshall CT ($r = -0.328$, $p = 0.026$), age ($r = -0.654$, $p < 0.001$), and DAI grade ($r = -0.403$, $p = 0.006$). The MoCA-BC scores were positively correlated with pupillary light reflex ($r = 0.361$, $p = 0.014$), admission GCS ($r = 0.402$, $p = 0.006$) and years of education ($r = 0.581$, $p < 0.001$). Non-significant correlations were observed between sex, causes of trauma and the MoCA-BC scores.

Cognitive impairment in different grades of DAI patients

Moreover, to identify the association of cognitive impairment and each cognitive domain, Pearson correlation analysis was performed between the Ads of nine cognitive domains and MoCA-BC after data conversion in different grades of DAI patients (Figure 3). In patients with DAI grade 1, the Ads of memory ($r = 0.838$, $p < 0.001$), abstraction ($r = 0.843$, $p < 0.001$), and calculation ($r = 0.782$, $p < 0.001$) were most related to the Ads of MoCA-BC. The Ads of nine cognitive domains and MoCA-BC were all proved to be correlated, among patients with DAI grade 2. However, in the DAI grade 3 patients, the highest correlation with the Ads of MoCA-BC

were the Ads of memory ($r = 0.904$, $p < 0.001$), calculation ($r = 0.799$, $p = 0.006$), orientation ($r = 0.801$, $p = 0.005$), and executive function ($r = 0.869$, $p = 0.001$). The whole correlation analysis results can be found in [Supplementary Table 1](#).

Discussion

This retrospective study indicated that 82.6% (38/46) of DAI patients with 6-month GOSE ≥ 5 were still plagued by cognitive impairment, and the major domains of cognitive impairment caused by different grades of DAI were also distinctive.

More than 50 million people are suffering from TBI each year worldwide, and most TBI patients are diagnosed by clinical MRI with some degree of DAI, especially severe TBI among them (Jiang et al., 2019; Lammy, 2020). DAI manifests in the form of focal axonal shear injuries and axonal breakage, so patients with DAI are more likely to have long-term sequelae or serious neurological deficits, even death (Lang et al., 2021; Palmieri et al., 2021).

GOSE or GOS are usually used by neurosurgeons to evaluate the prognosis of patients with DAI, but these assessment methods are not detailed and comprehensive, because previous studies have found that the rate of cognitive impairment is much higher than that of unfavorable outcome (Humble et al., 2018; Lohani et al., 2020; Macruz et al., 2022; RaukolaLindblom et al., 2022). In our study, MoCA-BC was performed to evaluate the cognitive function of 46 patients with DAI who were classified as favorable outcome, and 38 patients were found to have some degree of cognitive impairment. By comparing the two groups of patients with or without cognitive impairment in the present study, it was concluded that there were significant differences in age, education and return of consciousness, but there were no significant differences in admission GCS, Marshall CT score, pupillary light reflex and DAI grades.

In (Macruz et al., 2022) article, admission GCS and Marshall CT score had significant impact on cognitive function. Outcome was better in patients with DAI grade 1 and DAI grade 2 than in patients with DAI grade 3 (Skandsen et al., 2010; Moe et al., 2020). Have confirmed that age, GCS score, pupillary dilatation, traumatic axonal injury (TAI) grade on clinical MRI were significant predictors for poor outcome. Some of the results in our research were not consistent with the recent literature, which may be due to the deviation caused by the insufficient sample size.

Followed the long-term functional outcome of 134 patients with DAI and found independent prognostic factors were age, return of consciousness ≤ 7 days, pupillary reaction and DAI grade (van Eijck et al., 2018). Education level has been considered to be the strongest non-cognitive factor influencing performance on the MoCA (Chen et al., 2016). Analysis of 228 patients with TBI showed that education status was correlated with MoCA scores: Those patients with higher level of education had significant association with higher MoCA scores ($p = 0.012$) (Panwar et al., 2019). Marshall CT score, pupillary light reflex, duration of coma and admission GCS were predictors of clinical outcome in DAI (Palmieri et al., 2021; Xie et al., 2021; Chen et al., 2022). In the present study we also confirmed that return of consciousness, Marshall CT score, age and DAI grade have a negative correlation with cognitive function in DAI patients with 6-month GOSE 5–8. The more sensitive the pupillary light reflex, the higher the admission GCS and the longer the education, the better the long-term cognitive function of DAI patients. The correlation of these

TABLE 2 Demographic and clinical characteristics of eligible patients with or without cognitive impairment.

risk factors was basically consistent for the cognitive function of TBI patients and DAI patients with favorable outcome.

Severe cognitive impairment and physical disability were caused by lateral hypothalamus and medial hypothalamus damage during DAI (Wang et al., 2021). HVL, TMT, and Rey-Osterrieth Complex Figure test were performed by Macruz et al. (2022) to reveal the impairment and recovery of episodic verbal memory, attention, and executive function of DAI patients. Further, scholars found that cognitive impairment was associated with brain tissue lesions displayed on MRI (Yue et al., 2020). Twenty-four patients with moderate or severe DAI were evaluated at 2, 6, and 12 months post-injury (Stewan et al., 2018) found out that microhaemorrhage load (MHL) was correlated only with white matter volume (WMV) reduction, executive function and episodic verbal memory were not correlated with MHL, but were, in part, correlated with WMV and

total brain volume reduction. Not only severe TBI, but repetitive mild brain injury impair cognitive abilities and increase risk of neurodegenerative disorders in humans (Sai et al., 2020). So far, the persistent cognitive sequelae of patients suffering from DAI have been identified by the current studies, but the specificity of the impairment of nine cognitive domains caused by different grades of DAI have not been noticed by scholars. In our study, according to the diagnostic results of clinical MRI, DAI was divided into three grades for hierarchical interpretation. Finally, it was found that different degrees of DAI lead to significant differences in the domains of cognitive impairment. The decline of cognitive function in patients with DAI grade 1 was mainly caused by dysfunction in the three cognitive domains of memory, abstraction and calculation. But for patients with DAI grade 2, after the damage of the important structure

(corpus callosum) connecting the left and right sides of the brain (Shah et al., 2021; Lewis et al., 2022), the cognitive impairment was most widely distributed, and none of the nine cognitive domains was immune. Patients with DAI grade 3 suffered from brainstem (the bridge of morphological and functional connection between telencephalon, diencephalon, cerebellum, and spinal cord) (Henson et al., 2020; Paton, 2020) injury, showing cognitive impairment dominated by memory, calculation and orientation and executive function dysfunction.

There are several limitations in our present study. First, insufficient sample size may lead to deviation and compromise the statistical power. Second, taking 6-month GOSE score ≥ 5 as the inclusion criteria may exclude some DAI patients who are classified as unfavorable outcome but can cooperate with the cognitive function test, thus affecting the final cognitive domain analysis results. Third, MoCA-BC was translated according to Chinese culture and may not be suitable for people in other countries.

Conclusion

Our current research has revealed that DAI patients with favorable outcome may still be plagued by cognitive impairment. Different grades of DAI cause different domains of cognitive impairment, which requires neurosurgeons to provide patients with targeted cognitive rehabilitation programs.

Data availability statement

The original contributions presented in this study are included in the article/**Supplementary material**, further inquiries can be directed to the corresponding authors.

Ethics statement

The studies involving human participants were reviewed and approved by the Institutional Review Board of Haining People's

Hospital. The patients/participants provided their written informed consent to participate in this study.

Cocaine's addictive properties stem from its capacity to increase tonic extracellular dopamine levels in the nucleus accumbens (NAc). The ventral tegmental area (VTA) is a principal source of NAc dopamine. To investigate how high frequency stimulation (HFS) of the rodent VTA or nucleus accumbens core (NAcc) modulates the acute effects of cocaine administration on NAcc tonic dopamine levels multiple-cyclic square wave voltammetry (M-CSWV) was used. VTA HFS alone decreased NAcc tonic dopamine levels by 42%. NAcc HFS alone resulted in an initial decrease in tonic dopamine levels followed by a return to baseline. VTA or NAcc HFS following cocaine administration prevented the cocaine-induced increase in NAcc tonic dopamine. The present results suggest a possible underlying mechanism of NAC deep brain stimulation (DBS) in the treatment of substance use disorders (SUDs) and the possibility of treating SUD by abolishing dopamine release elicited by cocaine and other drugs of abuse by DBS in VTA, although further studies with chronic addiction models are required to confirm that. Furthermore, we demonstrated the use of M-CSWV can reliably measure tonic dopamine levels *in vivo* with both drug administration and DBS with minimal artifacts.

KEYWORDS

substance use disorder, deep brain stimulation, nucleus accumbens, ventral tegmental area, cocaine, tonic dopamine

1. Introduction

Despite the increasing interest and resources devoted to addiction research, there has been little improvement in the clinical care and prevalence of substance use disorder (SUD) (Substance Abuse and Mental Health Services Administration [SAMHSA], 2020). In the USA alone, management and treatment of SUD costs the healthcare, welfare, and justice systems hundreds of billion dollars annually (United States Department of Health and Human Services [USDHHS], 2016; Peacock et al., 2018). Despite the development of a variety of behavioral and

pharmacological therapeutic options, most SUDs patients do not get treatment, response rates are low, and relapse rates as high as 75–98% have been reported (Brandon et al., 2007; Saloner and Karthikeyan, 2015). To better manage these “treatment-refractory” patients, it is important to further our understanding in the pathophysiology of SUD. One such approach is to study the neurochemical dynamics in the central nervous system associated with drug administration, which has the potential to identify treatment targets.

Dopamine is an important neurotransmitter for neuropsychiatric diseases such as SUD, obsessive compulsive disorder, and Tourette’s syndrome (Denys et al., 2004; Oliva and Wanat, 2016; Maia and Conceicao, 2018). Therefore, controlling the release of dopamine *via* neuromodulation, as has been done for neurological diseases such as Parkinson’s disease, is potentially an effective strategy for the treatment of these pathologies. Indeed, previous attempts have been made to stimulate targets within the mesolimbic dopaminergic pathway as a means to rectify dysfunctional dopamine dynamics (Holtzheimer and Mayberg, 2011).

The ventral tegmental area (VTA) and substantia nigra pars compacta are major producers of dopamine in the mesolimbic dopaminergic pathway (Bjorklund and Dunnett, 2007). A major VTA projection target is the nucleus accumbens (NAc), which has been implicated in mediating important cognitive functions, such as reward and learning (see Figure 1A; Salgado and Kaplitt, 2015). In addition, over- and under-release of dopamine in the NAc are important pathophysiological conditions of neuropsychiatric diseases, such as SUD (Di Chiara, 2002). The NAc is one of the most studied deep brain stimulation (DBS) targets to modulate dopamine release in SUD in both preclinical models and human trials (Liu et al., 2008; Knapp et al., 2009; Henderson et al., 2010; Guo et al., 2013; Vassoler et al., 2013; Hamilton et al., 2015; Müller et al., 2016; Batra et al., 2017; Chen et al., 2019; Sildatke et al., 2020).

Nevertheless, the dimensions and resolution of contemporary *in vivo* measuring methods such as the use of microdialysis have limited the continuous measurement of dopamine as a useful biomarker for interventional therapy, until recently (Watson et al., 2006; Gu et al., 2015). Despite having the ability to unequivocally distinguish between different types of analytes, microdialysis probes have a relatively large dimension (~200 µm in diameter) and the temporal resolution is of the order of ≥ 1 min (Morelli et al., 1992; Di Chiara et al., 1993; Blaha et al., 1996; Chefer et al., 2009; Oh et al., 2018; Rusheen et al., 2020). In addition, microdialysis measurements cannot be made *in situ*, requiring drawing samples from the brain for subsequent laboratory identification. The trauma caused by the probe size and the relatively low temporal resolution means this method is likely to be inadequate to detect the rapid changes in dopamine levels involved in psychopathologies in the neural structures of interest (Blaha et al., 1996; Bungay et al., 2003; Borland et al., 2005). The requirement to extract brain dialysate samples makes microdialysis unsuitable as a technique for human therapy.

We recently reported a new technique known as multiple-cyclic square wave voltammetry (M-CSWV). This method is able to measure tonic extracellular dopamine levels with unprecedented temporal resolution (10 s) and minimal trauma to the neural tissue when used in combination with carbon fiber microelectrodes (CFM) (Oh et al., 2018). This technique uses dynamic background subtraction and capacitive background current modeling to eliminate large capacitive background currents generated by the applied voltammetric waveform. This allows tonic dopamine concentrations

to be measured every 10 s, something not possible with conventional fast-scan cyclic voltammetry (FSCV). Our group has previously demonstrated that M-CSWV is able to record changes in tonic dopamine levels in response to cocaine administration (Yuen et al., 2021a).

NAC DBS has shown promising results for the treatment of SUD (Liu et al., 2008; Knapp et al., 2009; Henderson et al., 2010; Guo et al., 2013; Ma et al., 2013; Batra et al., 2017; Schippers et al., 2017; Yuen et al., 2022b). Here we hypothesized that the therapeutic effects of NAC DBS may be due to its ability to rapidly modulate tonic dopamine concentrations. DBS of the VTA, the main dopaminergic afferent to the NAc, may also achieve a similar effect. In the present study, M-CSWV was utilized to elucidate the effects of high frequency stimulation (HFS) of both the VTA and the NAc on tonic dopamine levels in the nucleus accumbens core (NAcc) with or without acute cocaine administration (Yuen et al., 2021a).

2. Materials and methods

2.1. Animal subjects

Male Sprague-Dawley rats (250–300 g; Envigo, IN, USA) were used for this study. Rats were kept in social housing in an association for assessment and accreditation of laboratory animal care international (AAALAC) accredited vivarium following a standard 12-h light/dark cycle at constant temperature (21°C) and humidity (45%) with *ad libitum* food and water. The present studies were approved by the Institutional Animal Care and Use Committee (IACUC), Mayo Clinic, Rochester. The NIH Guide for the care and use of laboratory animals guidelines (Department of Health and Human Services, NIH publication No. 86-23, revised 1985) were followed for all aspects of animal care.

2.2. Electrode fabrication

Carbon fiber microelectrodes were fabricated using an established standardized CFM design at Mayo Clinic (Chang et al., 2013; Oh et al., 2016). Each microelectrode involved isolating and inserting a single carbon fiber (AS4, diameter = 7 µm; Hexcel, Stamford, CT, USA) into a silica tubing (20 µm ID, 90 µm OD, 10 µm coat with polyimide; Polymicro Technologies, Phoenix, AZ, USA). The connection between the carbon fiber and the silica tubing was covered with epoxy resin. The silica tubing was then attached to a nitinol extension wire (Nitinol #1, an alloy of nickel and titanium; Fort Wayne Metals, IN, USA) by a silver-based conductive paste (Chang et al., 2013). The carbon fiber attached nitinol wire was insulated with polyimide tubing (0.0089" ID, 0.0134" OD, 0.00225" WT; Vention Medical, Salem, NH, USA) up to the carbon fiber sensing segment. The exposed carbon fiber was trimmed under a dissecting microscope to a length of ~50 µm. Teflon-coated silver (Ag) wire (A-M systems, Inc., Sequim, WA, USA) was prepared as an Ag/AgCl counter-reference electrode by chlorinating the exposed tip in saline with a 9 V dry cell battery. CFMs were pretested in a flow cell prior to coating deposition with a PEDOT:Nafion deposition solution (Vreeland et al., 2015), which minimized the effect of biofouling *in vivo*.

2.3. Implantation of recording and stimulating electrodes

Each rat was anesthetized with urethane (1.5 g/kg i.p.; Sigma-Aldrich, St Louis, MO, USA) and administered buprenorphine (0.05–0.1 mg/kg s.c., Par Pharmaceutical, Chestnut Ridge, NY, USA) for analgesia. Following anesthesia, they were placed in a stereotaxic frame (David Kopf Instruments, Tujunga, CA, USA). Respiratory rate (RespiRAT, Intuitive Measurement Systems, AZ, USA) and hind-paw and tail pinch were used to monitor the physiological state and depth of anesthesia, respectively. Using a standard rat brain atlas (Paxinos and Watson, 2007), three trephine holes were drilled, the first for placement of a CFM into the NAcc (all coordinates from bregma: AP 1.2 mm, ML 2.0 mm, DV 6.5–7.5 mm from dura), the second for a stimulating electrode into the VTA (twisted bipolar stimulating electrode–Plastics One, MS 303/2, Roanoke, VA, USA, with the tips separated by ~1 mm; AP –5.3 mm, ML 0.9 mm, DV 7.5–9 mm from dura), and a third for an Ag/AgCl into the contralateral cortex (Figure 1; Clark et al., 2010). For NAcc stimulation experiments, a bipolar concentric stimulating electrode (MicroProbes, Gaithersburg, MD, USA) was implanted immediately posterior and medial to the CFM in the NAcc (~0.3 mm apart).

2.4. Recordings and stimulation parameters

The depths of the stimulating electrode in the VTA and CFM in the NAcc were first adjusted to obtain a robust stimulation-evoked dopamine signal as measured by FSCV (–0.4 to 1.3 V sweep; 10 Hz; see Supplementary Figure A1). Stimulation parameters were biphasic pulses at 60 Hz, 0.2 ms pulse width, 0.2 mA, and 2 s duration. Stimulation and FSCV were both performed using the WINCS Harmoni system (Lee et al., 2017), a wireless stimulation and neurochemical sensing system.

Once the optimal electrode depths were identified, the system was switched to the M-CSWV sensing technique (see Figure 1B). After 60 min of stabilization, either VTA or NAcc biphasic pulse stimulation was applied at 130 Hz (0.2 ms, 0.2 mA) continuously. The delivered stimulation was interleaved with the M-CSWV recording to minimize artifacts. Once the signal was restabilized to a new plateau (≥ 30 min), i.v. saline (1 ml/kg) was administered as a negative control while stimulation and recording continued. After 30 min, i.v. cocaine (2 mg/kg) was administered (infused over 1 min *via* cannula at tail vein; dissolved in 0.5 ml of normal saline). After another 30 min of observation, the stimulation was turned off. Post-stimulation, the animal was observed for another 30 min before being sacrificed using Fatal-Plus injection (pentobarbital 390 mg/ml; 10 ml).

2.5. Pharmacological confirmation

In a separate group of animals ($N = 5$), alpha-methyl-p-tyrosine (AMPT; 250 mg/kg, i.p.), a tyrosine hydroxylase inhibitor, was given to further confirm the recording of dopamine by M-CSWV. Tyrosine hydroxylase is the rate limiting enzyme of catecholamine biosynthesis, converting tyrosine into L-DOPA, the precursor to dopamine. Thus, AMPT administration, acting as a negative control,

was expected to decrease the voltammetric signal if the signal indeed arose from dopamine.

2.6. Calibration of electrodes

After experimentation, changes in dopamine release in individual CFMs were calibrated *in vitro* with dopamine solutions of different known concentrations. This is in a similar fashion to previously described procedures in the literature (Oh et al., 2018).

2.7. Histological analysis

CFM and stimulation electrode trajectories were confirmed by histological analysis. Brains were removed from euthanized animals and immersed in 4% paraformaldehyde overnight for fixation. After fixation, 60 μ m coronal sections were cut on a freezing microtome. The sections were stained with cresyl violet. The location of the stimulating and CFMs were identified under light microscopy (Supplementary Material B) based on (Paxinos and Watson, 2007).

2.8. Statistical analysis

Statistical analysis was performed using repeated measures one-way ANOVA and two-tailed paired *t*-tests in relevant *post hoc* analyses (PRISM 8, GraphPad). For comparison, the levels were all measured by averaging over 10 data points, i.e., 10 s. In cases where i.v. drug was administered, the 10 data points centered at peak within 10 min of injection.

After ANOVA tests were performed among the positive control, negative control, VTA stimulation and NAcc stimulation groups, paired *t*-tests were used to demonstrate sequential changes in the *post hoc* analysis. In the control experiments, pre-injection baseline tonic dopamine concentrations were compared to the post-saline levels, and the post-saline levels were compared with the post-cocaine peak levels. In the NAcc stimulation experiments (see Figure 4), the initial stabilized baseline levels before injection were compared with the trough levels (not seen during VTA experiments) during stimulation. Then, similarly, the new baselines were compared with the post-saline levels, and the post-saline levels were compared with the post-cocaine peak levels. In VTA stimulation experiments (see Figure 5), the initial baselines were compared with the new baselines during stimulation. The new baselines were compared with the post-saline levels, and these post-saline levels were compared with the post-cocaine levels. All error bars and shaded areas are represented as S.E.M. statistical significance was set at $p < 0.05$. Bonferroni correction was applied in cases with multiple comparisons.

3. Results and discussion

3.1. Control experiments

In the positive control experiments, after implanting the CFM at the optimal position within NAcc (see section “Materials and methods”), we elicited cocaine-induced dopamine changes by first administering i.v. saline and then i.v. cocaine, while tonic dopamine

FIGURE 1

(A) Simplified diagram demonstrating some of the major dopaminergic projections from the VTA. (B) The optimal depths of electrodes in the VTA and nucleus accumbens core (NAcc) were first identified using FSCV (maximum dopamine evoked release; 60 Hz, 2 ms, 0.2 mA, 2 s duration; [Supplementary Figure A1](#)). The system was then switched to M-CSWV to record tonic dopamine levels in the NAcc. (C) Experimental set-up of tonic dopamine measurements. With the control and AMPT groups, no stimulation was given. Waiting time for AMPT group (250 mg/kg) was increased compared to the control group due to the different route of administration, with the expectation that i.p. injections would result in a slower onset of action than i.v. injections. The stimulation group consisted of the continuous high-frequency stimulation (130 Hz, 200 micro-sec, 0.2 mA), while saline (1 ml/kg) and cocaine (2 mg/kg) were given intravenously. Partly created with [BioRender.com](#). $N = 5/\text{group}$ (20 in total). AMPT, alpha-methyl-p-tyrosine; CFM, carbon fiber microelectrode; DA, dopamine; FSCV, fast-scan cyclic voltammetry; i.p., intraperitoneal; i.v., intravenous; stim., stimulation; M-CSWV, multiple-cyclic square wave voltammetry; MFB, medial forebrain bundle; NAc, nucleus accumbens; VTA, ventral tegmental area.

levels were recorded using M-CSWV. One-way ANOVA test among the three levels (baseline, saline, cocaine) showed significant differences ($F = 17.95$, $p = 0.0047$). In the *post hoc* analysis, as expected, saline administration did not evoke a statistically significant change in peak tonic dopamine concentration compared to pre-saline levels ($N = 7$ rats; paired t -test, $p = 0.054$; [Figures 2A, B](#), blue). The dopamine levels were then observed to rapidly increase after acute i.v. cocaine administration [$N = 7$ rats; paired t -test, $p = 0.022$; change = $+62.9 \pm 14.9$ nM (59%); time to peak = 6.8 ± 0.8 min; [Figures 2A, B](#), red]. The pseudocolor plots of the peak dopamine concentration after saline administration ([Figure 2C](#)) and after cocaine administration ([Figure 2D](#)) showed clear differences in the magnitude of the dopamine oxidation current, indicating a much higher concentration present.

In the negative control experiments, AMPT, a tyrosine hydroxylase inhibitor, was applied intraperitoneally (i.p.) to reduce dopamine production. This was compared against i.p. saline. One-way ANOVA test among the three levels showed significant differences ($F = 35.45$, $p = 0.0007$). In the *post hoc* analysis, i.p. AMPT administration (250 mg/kg) did acutely reduce tonic NAcc dopamine concentrations over 30 min [$N = 5$; paired t -test, $p = 0.004$; change = -34.5 ± 5.7 nM (-27%); time to stable baseline = 25.3 ± 2.2 min; [Figures 3A, B](#), red] but this was not observed in i.p. saline ($N = 5$; paired t -test, $p = 0.513$; [Figures 3A, B](#), blue). This is further visualized by the pseudocolor plots, demonstrating a sharp decrease in dopamine oxidation current after 30 min of AMPT ([Figure 3D](#)), compared to after 30 min of saline ([Figure 3C](#)).

3.2. NAcc HFS reduces tonic NAcc dopamine levels and attenuates the effects of cocaine

Here, saline and cocaine administration was repeated on the background of NAcc stimulation (starting at least 30 min before saline administration and continued until 30 min after cocaine administration). With one-way ANOVA test, there were significant differences among the six different levels (control, trough during stimulation, new baseline during stimulation, level-post-saline, level-post-cocaine, post-stimulation) ($F = 11.31$, $p = 0.010$). With further *post hoc* analysis, NAcc HFS elicited an initial decrease in tonic dopamine concentration [$N = 5$; paired t -test, $p = 0.011$; change = -28.3 ± 6.3 nM (-20%); [Figures 4A, C](#)], followed by a relatively rapid return to baseline. Pseudocolor plots demonstrate a significant marked decrease in dopamine oxidation current during NAcc HFS ([Figure 4E](#)) compared to pre-stimulation baseline ([Figure 4D](#)).

Next, i.v. saline was administered (1 ml/kg) with continuous HFS, and, as before, did not significantly affect NAcc tonic dopamine concentrations over 30 min ($N = 5$; paired t -test, $p = 0.131$; [Figures 4B, F](#)). Thereafter, surprisingly, with continuous HFS of the NAcc, the cocaine-induced increases in tonic dopamine concentrations seen before were eliminated when i.v. cocaine was given, no longer leading to an increase compared to pre-cocaine levels ($N = 5$; paired t -test, $p = 0.739$; [Figures 4B, F](#)).

Control group – cocaine-associated dopaminergic changes

FIGURE 2

Changes in nucleus accumbens core (NAcc) tonic dopamine concentrations after saline and cocaine. (A) Rapid increase in dopamine was seen after i.v. cocaine administration (2 mg/kg) compared to i.v. saline (1 ml/kg). Arrow denotes time of drug administration. (B) Saline did not significantly alter tonic dopamine levels (-8.0 ± 3.4 nM, $N = 7$ rats, $p = 0.054$), whereas cocaine rapidly increased dopamine levels ($+62.9 \pm 14.9$ nM, $+62\%$, $N = 7$ rats, $p = 0.006$). Two out of seven of the sample had a stimulating electrode (turned off) adjacent to the recording electrode; both showed brisk increase in tonic dopamine levels with cocaine administration. *Denotes $p < 0.025$ (0.05/2, with Bonferroni correction, given there are two t -tests here). (C,D) Representative color plots and voltammograms after saline and cocaine administration, respectively.

3.3. VTA HFS reduces tonic NAcc dopamine levels and attenuates the effects of cocaine

Here, saline and cocaine administration was repeated on the background of VTA stimulation (starting at least 30 min before saline administration and continued until 30 min after cocaine administration). With one-way ANOVA test, there were significant differences among the five different levels (control, new baseline during stimulation, level post-saline, level-post-cocaine, post-stimulation) ($F = 11.28$, $p = 0.011$). With further *post hoc* analysis, VTA HFS elicited a decrease in tonic dopamine concentration which persisted over the 30 min [$N = 5$; paired t -test, $p = 0.002$; change = -47.3 ± 7.0 nM (-42%); Figures 5A, C]. Pseudocolor plots demonstrate a significant decrease in dopamine oxidation current during VTA HFS (Figure 5E) compared to pre-stimulation baseline (Figure 5D).

Next, i.v. saline was administered (1 ml/kg) with continuous HFS, and, as before, did not significantly affect NAcc tonic dopamine concentrations over 30 min ($N = 5$; paired t -test, $p = 0.943$;

Figures 5B, F). Thereafter, with continuous HFS of the VTA, the cocaine-induced increases in tonic dopamine concentrations seen without stimulation were eliminated, no longer leading to a statistically significant increase compared to pre-cocaine ($N = 5$; paired t -test, $p = 0.091$; Figures 5B, F).

3.4. Interpretation

The present study demonstrated that cocaine-induced increases in tonic dopamine levels in the NAcc can be attenuated by HFS of the NAcc or of the VTA. In addition, VTA HFS resulted in a persistent suppression of NAcc tonic dopamine levels.

Interestingly, there was an initial trough in the dopamine levels at the start of NAcc HFS (Figure 4 and Supplementary Figure A3), followed by a return to baseline. Previous *ex vivo* voltammetry studies have shown that both electrical and optogenetic brief stimulation of dopaminergic terminals in the NAc can lead to local phasic release of dopamine (Melchior et al., 2015). Importantly, these studies have also shown that longer duration stimulations lead to lower magnitude stimulation-induced phasic release. Phasic dopamine

FIGURE 3

Changes in nucleus accumbens core (NAcc) tonic dopamine concentrations after saline and alpha-methyl-p-tyrosine (AMPT). (A) Gradual reduction in dopamine tonic levels was seen after i.p. AMPT administration (250 mg/kg) compared to i.v. saline (1 ml/kg). Arrow denotes time of drug administration. (B) Saline did not significantly alter tonic dopamine levels (-2.2 ± 3.1 nM, $N = 5$ rats, $p = 0.513$), whereas AMPT reduced dopamine levels (-34.5 ± 5.7 nM, -27% , $N = 5$ rats; $p = 0.004$). *Denotes $p < 0.025$ ($0.05/2$, with Bonferroni correction, given there are two t -tests here). (C,D) Representative color plots and voltammograms, after saline and AMPT administration, respectively.

release is measured on the order of seconds, whereas in the current study, the time resolution of M-CSWV was every 10 s. Therefore, it is possible that there may have been an initial phasic release of dopamine which was not detected by M-CSWV. This increase in dopamine may have then led to the activation of D2 autoreceptors in the VTA and NAcc, which reduced both the release of dopamine and excitability of dopamine neurons (Wieczorek and Kruk, 1995; Ford, 2014). Together with a depletion of presynaptic dopamine vesicular stores, this may have contributed to a decrease in the tonic levels of dopamine in the NAcc. One possibility is that as the D2 autoreceptor feedback became weaker, the tonic dopamine levels stabilized to an equilibrium. However, previous studies have shown the activation time of D2 autoreceptors is of the order of subseconds to seconds (Kennedy et al., 1992; Benoit-Marand et al., 2001); whereas in the present study, the troughs took ~ 10 min to reach full reduction, implying there are likely other factors at play. Another possibility is back propagation of signals from NAC to VTA but this is yet to be confirmed.

Norepinephrine is a potential electroactive interferent that could affect dopamine measurements given their similarities in reduction-oxidation characteristics. However, previous microdialysis studies show that the NAcc, which we targeted, has a relatively low

concentration of norepinephrine (McKittrick and Abercrombie, 2007).

Inhibition and activation of other local neurons (e.g., glutamatergic and GABAergic) are also possible, but it is difficult to ascertain how this may interact with the dopaminergic neurons in this case. A recent voltammetry study has shown that electrical stimulation leads to multi-synaptic modulation of dopamine release, as a gamma-aminobutyric acid (GABA) antagonist increased electrical stimulation-evoked release of dopamine, compared to optogenetic stimulation, which only targeted dopaminergic terminals (Melchior et al., 2015). In contrast, microdialysis studies have shown conflicting results. In naïve rodents, HFS of the NAC did not affect dopamine and glutamate levels but increased GABA levels (Varatharajan et al., 2015). Another study which specifically stimulated the NAcc also showed no changes in dopamine levels (Van Dijk et al., 2011). However, in rats treated with morphine, NAcc HFS reduced glutamate levels (Yan et al., 2013). In a depressed rat model, there were no changes in GABA or dopamine with NAC shell stimulation (Schumacher et al., 2020). Although microdialysis can measure multiple neurochemicals, most of these studies sampled at 30-min intervals, which would not capture the trough observed here.

NAcc stimulation group

FIGURE 4

Tonic dopamine concentrations during nucleus accumbens core (NAcc) high frequency stimulation (HFS) and after cocaine administration. (A,C) Stimulation suppressed tonic dopamine levels (-28.3 ± 6.3 nM, -20% ; $N = 5$ rats, $p = 0.011$). (B,F) Cocaine-induced increases in tonic dopamine levels were attenuated by stimulation to non-significant levels (new baseline vs. saline, -4.9 ± 2.6 nM, $N = 5$ rats, $p = 0.131$; saline vs. cocaine peak, 1.3 ± 3.5 nM, $p = 0.739$). Black bars represent stimulation period. Arrow denotes drug administration. *Denotes $p < 0.017$ (0.05/3, with Bonferroni correction, given there are three t-tests here); ns, non-statistically significant. (D,E) Representative color plots and voltammograms, corresponding to the time points marked by black and red dotted lines in panel (A), respectively. Further trend in tonic dopamine levels after local HFS was stopped demonstrated no marked changes in levels (Supplementary Figure A2).

Both the NAcc (Liu et al., 2008; Knapp et al., 2009; Guo et al., 2013; Schippers et al., 2017) and shell (Knapp et al., 2009; Henderson et al., 2010; Ma et al., 2013; Batra et al., 2017) have been shown to be promising DBS targets for SUD for substances such as morphine, alcohol, heroin, and methamphetamine. The underlying treatment mechanism has not been fully understood. The present results suggest that one possibility is that accumbal dopamine extracellular levels are modulated by the local HFS, leading to suppression of the reward effect associated with cocaine-induced elevations in tonic dopamine levels (Schultz, 2016). Given its role as a monoamine reuptake inhibitor, cocaine normally increases dopaminergic concentration in the synapses (Sora et al., 2001). It is possible that local DBS may either alter cocaine activity at the local dopamine reuptake transporters and/or dopamine reserve, or it may reduce the ability of cocaine molecules to diffuse to these transporters due to factors such as vasoconstriction or tissue damage. Two out of seven of our control group were performed with a stimulating electrode adjacent to the recording electrode and both showed a brisk increase in tonic dopamine levels after cocaine administration, which makes tissue

damage an unlikely explanation. The possibility that DBS can modify dopamine transporter (DAT) availability has been raised previously in Parkinson's disease patients (Lokkegaard et al., 2007; Loser et al., 2021).

Other possibilities may include down regulation of active dopaminergic transporters. The diminished response is consistent with a preclinical study where DBS of the NAc (shell) increased cocaine self-administration (Kallupi et al., 2021). This may be because the cocaine-associated effect is less marked with DBS and hence the animals would need to self-administer more to attain the same elevations in tonic dopamine levels. However, more experiments are required to confirm this hypothesis.

In contrast to NAc HFS, VTA HFS led to a decrease in NAcc dopamine levels that did not recover over the course of the experiment (Figures 5A, D and Supplementary Figure A4). There are at least two possible explanations for this phenomenon. First, continuous VTA HFS may have depleted presynaptic dopamine vesicular stores in the NAcc, which may have accounted for the initial peak observed immediately upon stimulation. In turn, this would lead

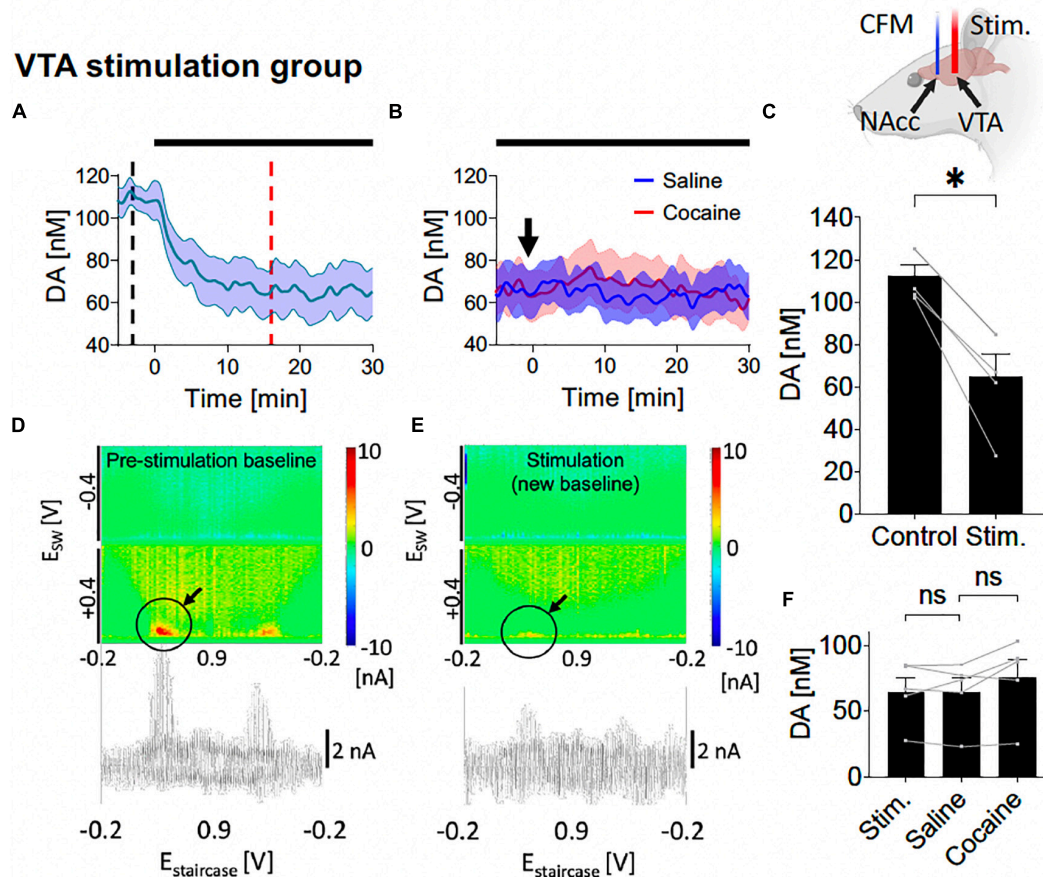

FIGURE 5

Tonic dopamine concentrations during ventral tegmental area (VTA) high frequency stimulation (HFS) and after cocaine administration. **(A,C)** Stimulation suppressed tonic dopamine levels (-47.3 ± 7.0 nM, -42% ; $p = 0.002$). **(B,F)** Cocaine-induced increases in tonic dopamine levels were attenuated by stimulation to non-significant levels compared to the new baseline ($+11.2 \pm 5.0$ nM, $+17\%$; $p = 0.091$). Black bars represent stimulation period. Arrow denotes drug administration. *Denotes $p < 0.017$ (0.05/3, with Bonferroni correction, given there are three t -tests here); ns, non-statistically significant. Further trend in tonic dopamine levels after local HFS was stopped demonstrated no continued suppression in levels (**Supplementary Figure A5**). Representative color plot and voltammogram of new baseline after i.v. cocaine administration (2 mg/kg) during VTA stimulation is shown in **Supplementary Figure A6**.

to a reduced tonic level until vesicular stores could be replenished by dopamine synthesis. This is consistent with a previous study showing medial forebrain bundle (MFB) stimulation could reduce the dopamine level in the NAc to 70–80% of baseline during 2 h of stimulation (Bregman et al., 2015). Amperometry studies also showed that prolonged MFB stimulation can deplete presynaptic dopamine vesicular stores in the NAc (Fielding et al., 2013). As the mesolimbic dopaminergic pathway is contained within the MFB, it is likely that MFB stimulation would involve stimulating the VTA-NAc pathway. Second, dendritic release of dopamine in the VTA has been shown to activate autoinhibitory D2 receptors (De Jong et al., 2015), resulting in reduced terminal release of dopamine in the NAc. However, this effect is expected to be short-lived, as continuous VTA HFS would also be expected to deplete dopamine dendritic stores. One other speculative cause is that VTA HFS induced a depolarization block of dopaminergic axonal firing, which appeared sustained after stimulation was discontinued. Given the tonic dopamine levels did not recover, this suggests dopaminergic dynamics may be different between the VTA and NAc, possibly from different neurochemical and autoreceptor distribution and sensitivity.

Microdialysis studies have shown that extracellular dopamine release in the NAc is regulated by GABA (inhibitory), dopamine (inhibitory), glutamate (excitatory), and acetylcholine (facilitatory) receptors in the VTA (Westerink et al., 1996; Lester et al., 2010). It is possible that the electrical stimulation could lead to overfiring of GABA neurons within the VTA as well as suppression of glutamate neurons. Further pharmacological tests may potentially facilitate confirmation of this hypothesis.

Functional magnetic resonance imaging (fMRI) in rodent and in swine models have shown that electrical stimulation of the VTA not only induced dopamine release in the NAc (phasic release as detected by FSCV) but also led to increased blood-oxygen-level-dependent (BOLD) responses (Helbing et al., 2016; Settell et al., 2017). However, the latter appeared to be glutamate-dependent (Helbing et al., 2016). This suggests that the clinical effects of VTA DBS is likely to be much more complex and involves multiple other neurotransmitter systems besides dopamine.

In addition to SUD, NAc DBS has been of great interest for application to a number of neuropsychiatric diseases, such as depression (Yuen et al., 2021b), Tourette's syndrome

(Baldermann et al., 2016), and obsessive-compulsive disorder (Denys et al., 2010). It is unknown how DBS of the NAc and its surrounding structures, such as the anterior limb of internal capsule, may treat a range of diseases with such different clinical features. Nevertheless, studies have shown that dopamine plays a role in all these diseases. Thus, DBS may possibly modulate or even re-establish the dysregulated dopaminergic signaling, leading to symptomatic improvements and reversing neuroplasticity related changes (Denys et al., 2004; Buse et al., 2013; Tye et al., 2013).

Although the VTA is vital in the expression of a number of drug-related behaviors, such as behavioral sensitization (Oliva and Wanat, 2016), VTA DBS currently has a limited role in clinical practice. However, in a small case series, high-frequency VTA DBS appeared to be an effective treatment for medically refractory cluster headache (Akram et al., 2016). Given there is evidence that dopamine levels are elevated in circulating platelets of cluster headache (and migraine) patients (D'Andrea et al., 2006), it has been suggested that cluster headache may be a consequence of overactivity of the dopaminergic and autonomic systems (D'Andrea et al., 2019). Evidence of dysfunction of dopaminergic systems is further elucidated in a study where apomorphine, a non-selective dopamine D2 receptor agonist, was given to cluster headache patients that resulted in significantly lower evoked growth hormone release compared to healthy volunteers (Lepper et al., 2013).

Optogenetic studies have provided insight into the possible behavioral effects of VTA stimulation. One rodent study demonstrated continuous ("tonic") optogenetic stimulation of VTA dopaminergic neurons can reduce ethanol self-administration (Bass et al., 2013). In addition, other studies showed that optogenetic excitation and inhibition of VTA dopaminergic neurons can both inhibit and induce depression-like behavior, respectively (Tye et al., 2013). Although optogenetic and electrical stimulations have different underlying mechanisms of activation, one mouse study demonstrated they activate similar brain regions under certain conditions (Weidner et al., 2020).

Given the reduction in tonic dopamine levels and attenuation of the cocaine-induced response, VTA DBS may be helpful in not only treating SUD but also pathologies associated with hyperdopaminergic states such as mania, schizophrenia, and dopamine dysregulation syndrome, where excessive dopamine in the system may lead to excessive risk-taking behavior (Berk et al., 2007; Grace, 2016; Ashok et al., 2017). In addition, dopamine-containing cells in the VTA that comprise the mesolimbic dopaminergic projection are highly critical for the regulation of incentive motivation to natural and drug-related rewards (Blaha and Phillips, 1996; Schultz et al., 1997; Horvitz, 2000). In addition, by modifying the tonic level of dopamine here, it may be possible to replicate changes induced by different pharmacological agents and use it as a pathological model for other diseases such as depression. Likewise, given dopamine is also associated with non-drug reward, excessive depression of dopamine levels in a normal dopaminergic state may theoretically lead to anhedonia, anorexia, and/or depression. Therefore, one must be careful with implementing this form of intervention at the level of dopaminergic cells.

It should be noted the current study utilized anesthetized naïve rodent models with acute administration of cocaine. Larger animals and chronic addiction models will be necessary to verify the dopamine-attenuating effect of HFS. It would be useful to know the effects of HFS on models of SUD of other substances, especially those that are not psychostimulants, such as opioids, and alcohol. Also, the effect on behaviors associated with SUD, such as craving

and withdrawal, needs to be explored. Further mechanistic studies such as manipulation of dopamine transporter availability and other biochemical essays are also warranted.

Previous literature also suggested there are persistent exposure of drugs does not necessarily lead to addictive behavior and dopamine is likely to be only one contributing factor to the behavioral changes observed. Therefore, one must consider the impact of other biological processes, such as changes in synaptic plasticity and other neurochemicals (e.g., serotonin) (Pascoli et al., 2011; Li et al., 2021; Yuen et al., 2022a).

4. Conclusion

In summary, this study elucidated the tonic dopaminergic dynamics with NAc and VTA HFS with high spatiotemporal resolution. HFS appeared to have an alleviating effect on the elevations in tonic dopamine levels associated with cocaine administration. This may explain how NAc DBS was found to be therapeutic in both preclinical models and patients suffering from SUD. Dopamine, measured by M-CSWV, may provide a useful closed-loop biomarker for DBS, given the pivotal role of dopamine in many neuropsychiatric pathologies.

Data availability statement

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

Ethics statement

This animal study was reviewed and approved by the Mayo Clinic IACUC.

Author contributions

KL, YO, and JY conceptualized the study. JY conducted experiments, collected the data, and drafted the first manuscript. AR manufactured the 3D-printed electrode holder. JY, YO, and HS designed the analyses. JY and HS conducted the analyses. KL, HS, and YO supervised all aspects of the work. JY and YO drafted the figures. All authors critically reviewed and revised the manuscript and accepted the final version of the manuscript.

Funding

This research was supported by the National Institutes of Health, NIH R01NS112176, R42NS125895, NS129549, and 1F30MH131254 awards. Training grant funding for AR was supported by the NIH F31NS115202-01A1, NIH R25GM055252-23, NIH TL1TR002380-03, and NIH T32GM065841-17. MB was supported by a NHMRC Senior Principal Research Fellowship (1156072).

Conflict of interest

The authors and Mayo Clinic have a Financial Conflict of Interest in technology used in the research and that the authors and Mayo Clinic may stand to gain financially from the successful outcome of the research.

Background: Predicting the consciousness recovery for comatose patients with acute brain injury is an important issue. Although some efforts have been made in the study of prognostic assessment methods, it is still unclear which factors can be used to establish model to directly predict the probability of consciousness recovery.

Objectives: We aimed to establish a model using clinical and neuroelectrophysiological indicators to predict consciousness recovery of comatose patients after acute brain injury.

Methods: The clinical data of patients with acute brain injury admitted to the neurosurgical intensive care unit of Xiangya Hospital of Central South University from May 2019 to May 2022, who underwent electroencephalogram (EEG) and auditory mismatch negativity (MMN) examinations within 28 days after coma onset, were collected. The prognosis was assessed by Glasgow Outcome Scale (GOS) at 3 months after coma onset. The least absolute shrinkage and selection operator (LASSO) regression analysis was applied to select the most relevant predictors. We combined Glasgow coma scale (GCS), EEG, and absolute amplitude of MMN at Fz to develop a predictive model using binary logistic regression and then presented by a nomogram. The predictive efficiency of the model was evaluated with AUC and verified by calibration curve. The decision curve analysis (DCA) was used to evaluate the clinical utility of the prediction model.

Results: A total of 116 patients were enrolled for analysis, of which 60 had favorable prognosis ($GOS \geq 3$). Five predictors, including GCS ($OR = 13.400$, $P < 0.001$), absolute amplitude of MMN at Fz site ($FzMMNA$, $OR = 1.855$, $P = 0.038$), EEG background activity ($OR = 4.309$, $P = 0.023$), EEG reactivity ($OR = 4.154$, $P = 0.030$), and sleep spindles ($OR = 4.316$, $P = 0.031$), were selected in the model by LASSO and binary logistic regression analysis. This model showed favorable predictive power, with an AUC of 0.939 (95% CI: 0.899–0.979), and calibration. The threshold probability of net benefit was between 5% and 92% in the DCA.

Conclusion: This predictive model for consciousness recovery in patients with acute brain injury is based on a nomogram incorporating GCS, EEG background activity, EEG reactivity, sleep spindles, and FzMMNA, which can be conveniently obtained during hospitalization. It provides a basis for care givers to make subsequent medical decisions.

KEYWORDS

acute brain injury, coma, electroencephalogram (EEG), mismatch negativity (MMN), prognosis, prediction model

Introduction

Acute brain injury, such as, severe traumatic brain injury and intracerebral hemorrhage, results in a heavy burden in low- and middle- income countries for its high mortality and disability rates (Injury, 2019; Krishnamurthi et al., 2020). With the advances of medical care, an increasing number of comatose patients survive. The issue of whether these comatose patients can regain consciousness is significant for doctors and families, especially with regard to the follow-up medical decisions. As we all know, the early intervention is critical for the patients with promising prognosis to regain consciousness. Up to now, there are many methods to assess the prognosis of comatose patients after acute brain injury according to the previous studies (Logi et al., 2011; Ballesteros et al., 2018; Claassen et al., 2019; Monteiro et al., 2021; Romagnosi et al., 2022).

The Glasgow Coma Scale (GCS) score, a reflection of the severity of patients' condition is currently the most widely used in clinic for its simplicity (Teasdale and Jennett, 1974). Besides, neuroelectrophysiological examinations, including Electroencephalogram (EEG) and event related potentials (ERPs) get more and more attention in clinical practice (Monteiro et al., 2021; Zhou et al., 2021). Among them, EEG plays an important role for outcome prediction in comatose patients (Synek, 1988; Sandroni et al., 2021). EEG background activity, to a large extent, reflects the functional state of the cerebral cortex and subcortex (Estraneo et al., 2020) and EEG reactivity and sleep spindles can provide the additional information about the sensory conduction pathway and thalamic-cortex circuit (Kang et al., 2015; Wang et al., 2022b).

Auditory mismatch negativity (MMN), one of the event-related potentials (ERPs) components, which can be obtained by subtracting the waveform evoked by standard stimuli from the waveform evoked by deviant stimuli, has been increasingly used in comatose patients or prolonged disorders of consciousness in recent years. The presence of MMN indicates that the patient has the ability to voluntarily distinguish and to induce attention orientation to two stimuli, which called pre-attention processing (Alho, 1995). The appearance of MMN suggests a favorable neurological outcome in patients with low responsiveness (Daltrozzo et al., 2007). In addition, the increase of absolute amplitude of MMN was correlated with recovery of consciousness (Wijnen et al., 2007; Zhou et al., 2021).

However, it is an important but still unclear clinical issue which assessment indicators to choose to achieve the best predictive performance. In this study, we used least absolute shrinkage and selection operator (LASSO) and binary logistic regression analysis methods to establish a prediction model, which made the probability of the consciousness recovery for comatose patients visualized

by nomogram. In this way, it can provide a better basis for clinical practice.

Materials and methods

Patients

We retrospectively reviewed the records of patients with severe brain injury who were admitted to the Neurosurgical Intensive Care Unit of Central South University Xiangya Hospital from May 2019 to May 2022. The inclusion criteria were as follows: (1) craniocerebral injury caused by traumatic brain injury and intracerebral hemorrhage and confirmed by computed tomography or magnetic resonance imaging; (2) $GCS \leq 8$ at the time of electrophysiological assessment; (3) age ≥ 18 years old; and (4) EEG and auditory MMN examinations performed within 28 days from coma onset. The exclusion criteria were: (1) pre-existing neurological diseases; (2) known hearing impairment; (3) received sedatives and/or muscle relaxants, except for dexmedetomidine or low dose of midazolam (≤ 0.02 mg/kg/h) (Riker et al., 2009), during the course of EEG and MMN examinations; and (4) incomplete clinical data. The charts of patients enrollment process of this study was in Figure 1.

MMN paradigm

We used a classical oddball auditory paradigm to elicit auditory MMN. It comprised two types of pure sound with different frequencies: 800 Hz and 1,500 Hz for the standard and deviant stimuli, respectively. In this paradigm, 700 pure sound stimuli (comprising 90% standard stimuli and 10% deviant stimuli, 80 dB sound pressure level, lasting for 75 ms) with a stimulus onset asynchrony of 800 ms were presented to every patient to elicit the MMN response. The sound stimuli were continuously and pseudorandomly presented, although there were at least three standard stimuli between two consecutive deviants. The sound was delivered through headphones. The whole examination lasted about 11 min. Schematic diagram of MMN paradigm was presented in Figure 2.

MMN data acquisition and analysis

Scalp MMN examinations were performed at the patients' besides, while they were free from visible body shaking. Data were

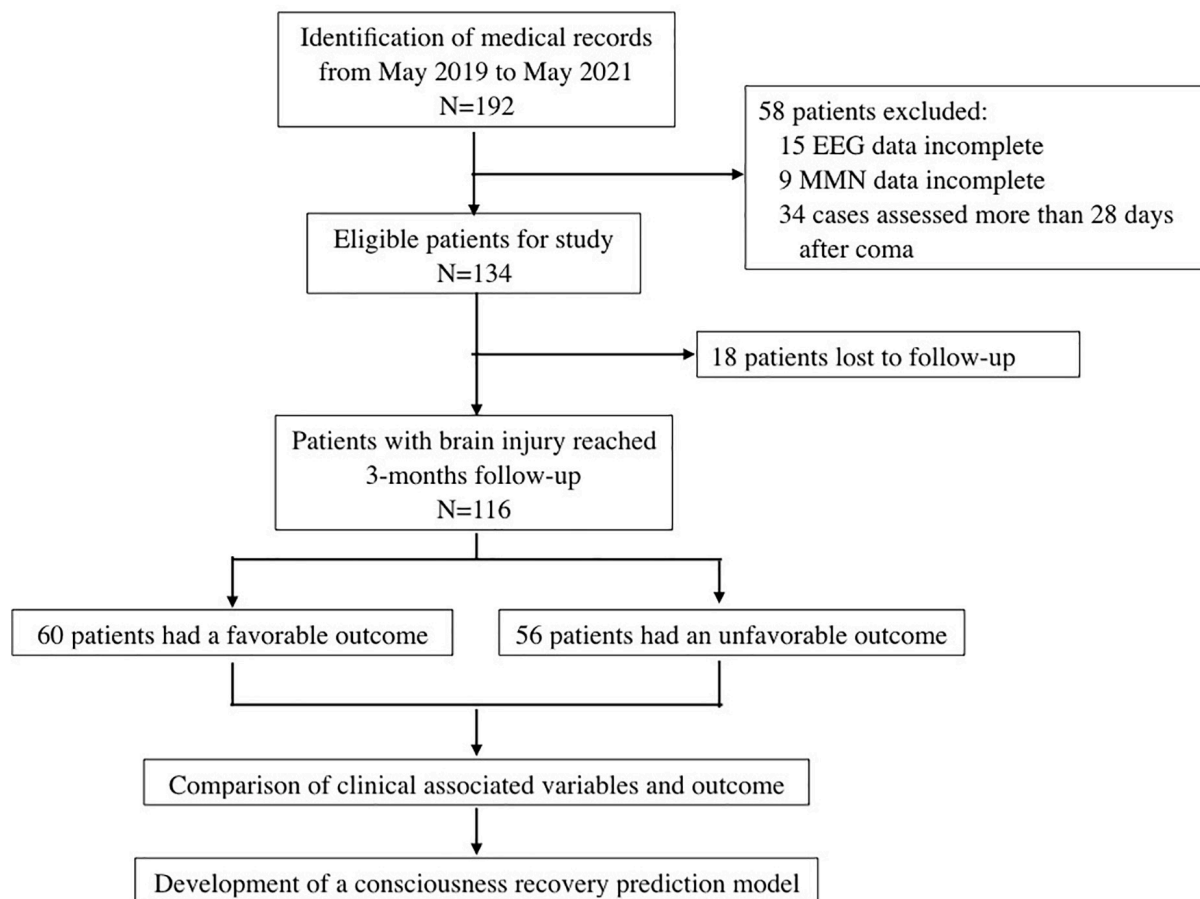

FIGURE 1
Flow chart of this study.

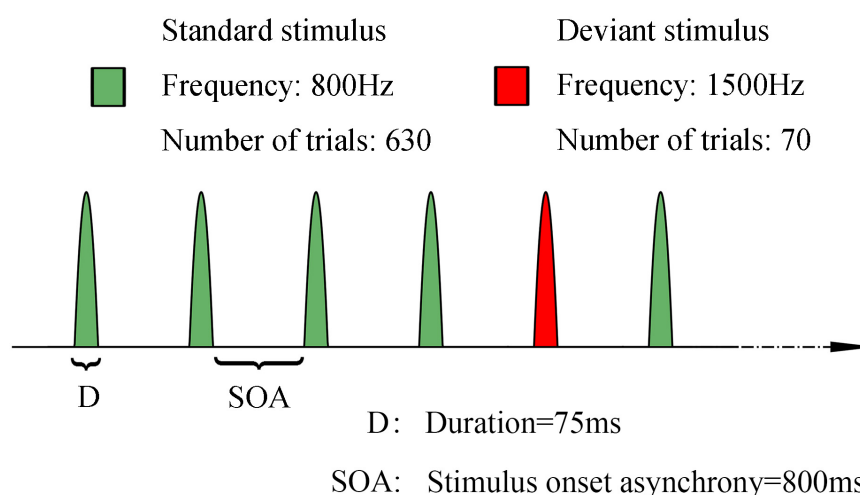

FIGURE 2
Schematic representation of the stimulus paradigm of mismatch negativity. Green: standard stimuli, 800 Hz, 630 trials. Red: deviant stimuli, 1500 Hz, 70 trials. Duration of each sound stimuli is 75 ms. SOA: 800 ms. The sound stimuli were continuously and pseudorandomly presented, although there were at least three standard stimuli between two consecutive deviants.

recorded at four electrodes (F3, F4, Fz, and Cz) according to the 10–20 international system using a Rinjie medical event-related potentiometer (WJ-IA, Guangzhou, China). The impedance of all electrodes was kept below 5 K Ω , and the sampling rate was 1,024 Hz

with an online 1–100 Hz bandpass filter. Data were referenced with the mean potential at electrodes A1 and A2.

Raw ERP data with amplitudes exceeding 100 μ V were automatically rejected, thus eliminating eye movements and other

artifacts. Subsequently, the standard and deviant responses were averaged by extracting the data of 100 ms before each stimulus onset and 500 ms after the stimulus; the former was primarily used for baseline correction. After that, a 3–30 Hz bandpass filter is applied and the MMN can be obtained by subtracting the waveform evoked by standard stimuli from the waveform evoked by deviant stimuli. Finally, ERP components such as N1 and MMN were presented and calculated by an automatic algorithm.

The criteria for identifying MMN components were: (1) Considering that N1 is one of the representative indicators of the auditory gating system and the information stream among the auditory cortex areas is directed from the core area to the band area and then to the sub-band area. Meanwhile, the core area and band area are the main generators of the standard N1 and deviation N1 components, respectively (Jones, 2002). We considered that MMN was not present only if the standard and deviation N1 were both evoked (Rosburg, 2019); (2) The largest negative waves of averaged difference waveforms in the latency interval between 100 and 300 ms were considered to represent the presence of MMN components (Grimm et al., 2011; Wang et al., 2018); (3) Considering that some of the patients underwent unilateral or bilateral decompressive craniectomy and MMN had maximal amplitude at Fz (Wang et al., 2018), we mainly investigated the absolute amplitude of MMN at the Fz site in this study.

EEG data acquisition and analysis

Continuous digital EEG monitoring (SOLAR electroencephalogram acquisition system, Beijing, China) was routinely performed and lasted for over 24 h in the study, with 16 electrodes (FP1, FP2, F3, F4, C3, C4, P3, P4, O1, O2, F7, F8, T3, T4, T5, and T6) placed according to the 10–20 international system. Video was simultaneously recorded to identify clinical events and artifacts. All EEG data were analyzed by two certified neurophysiologists.

Electroencephalogram background activity was classified into spindle coma, alpha coma, and five other categories as follows (Synek, 1988; Estraneo et al., 2020): (1) normal EEG activity, with a predominant posterior alpha rhythm and anterior-posterior gradient (APG), without focal or hemispheric slowing or epileptiform abnormalities; (2) mildly abnormal (MiA) EEG, characterized by predominant posterior theta activity ($> 20 \mu\text{V}$), symmetric or not, with frequent (10–49% of recording) posterior alpha rhythms; (3) moderately abnormal (MoA) EEG, characterized by predominant posterior theta activity ($> 20 \mu\text{V}$), symmetric or not, poorly organized APG, with rare ($< 1\%$ of recording) or occasional (1–9% of recording) posterior alpha rhythms; (4) diffuse slowing (DS), defined as EEG background activity with predominant diffuse theta or theta/delta rhythms with an amplitude $> 20 \mu\text{V}$, without APG; (5) low voltage (LV) EEG, defined as predominant EEG activity (theta or delta) $< 20 \mu\text{V}$ over most brain regions.

Sleep spindles were defined as 10–15 Hz bursts, lasting 0.5–2 s, that were best seen in the central channel (Rasch and Born, 2013). Sleep spindles that were not clearly detectable were considered as absent.

EEG-R was performed as follows (Admiraal et al., 2018): (1) pain stimulus: the patient's nail bed was pressed using a pen for at least 5 s. There were three repeats at each side with each pressing separated by a 5-min interval. (2) Sound stimulus: loud claps were performed for at least 5 s near the patient's ear on one side. There were three

repeats at each side with each clapping separated by a 5-min interval. The presence of EEG-R was defined as stable and repeatable (at least twice) changes in amplitude or frequency in the EEG, which were visible with the naked eye, except for muscle and eye blink artifacts within at least one stimulus type.

The percent of alpha variability (PAV) was determined by visual inspection of three points on the PA histogram: the PA baseline, the PA peak value, and the PA trough value that most directly follows the peak. The PA baseline was deemed to be the mean PA occurring during the 4 h prior to a peak in PA. The PAV was calculated using the following formula: $(\text{Peak PA} - \text{Trough PA}) / (\text{Peak PA} + \text{Trough PA})$. Then, the PAV were divided into four levels, which were poor (level 1, $< 2\%$), fair (level 2, 2–10%), good (level 3, 10–15%), and excellent (level 4, $> 15\%$), respectively (Vespa et al., 1997). PAV of two bipolar channels of each patients were calculated using bilateral frontoparietal, which were (F3–P3) and (F4–P4) (Friberg et al., 2013). Besides, the global PAV scores were evaluated as the mean of the two hemispheric PAV values (Hebb et al., 2007).

Prognosis assessment

The prognosis of patients was determined by telephone follow-up 3 months after coma onset. The Glasgow Outcome Scale (GOS) ranging from 1 to 5 (1, dead; 2, vegetative state or minimally conscious state; 3, able to follow commands but unable to live independently; 4, able to live independently but unable to return to work or school; or 5, able to return to work or school) (Jennett et al., 1981), was used to evaluate prognosis. GOS scores 1–2 were defined as unfavorable prognosis (no recovery of consciousness), and GOS scores 3–5 were defined as favorable prognosis (recovery of consciousness).

Predictive variables

The variables including sex, age, etiology, pupillary light reflex, GCS, absolute amplitude of N1 at electrode Fz (FzN1A), absolute amplitude of MMN at electrode Fz (FzMMNA), EEG background activity, sleep spindles, EEG-R, and PAV, which were generally considered to be associated with the prognosis of comatose patients. These 11 factors were preliminary screened, using the least absolute shrinkage and selection operator (LASSO) analysis. LASSO analysis was conducted with R software (version 4.2.1).

Statistical analysis

In this study, continuous and categorical variables were expressed by the mean value \pm standard deviation or median (interquartile range, IQR) and the frequency (percentage), respectively.

The binary logistic regression model was used for multivariate analysis of wakefulness in comatose patients. A nomogram for the predictive model was developed based on the results of the binary logistic analysis. The calibration of the nomogram was used for internal validation by the 100 bootstrap resampling procedure. In addition, the predictive efficiency of the nomogram was quantified with area under the curve (AUC) of receiver operating characteristic curve (ROC). Furthermore, the clinical utility of the nomogram was

assessed by the decision curve analysis (DCA). Statistical analysis was conducted with R software (version 4.2.1). For all tests, statistical significance was set at $P < 0.05$.

Results

Patients

A total of 116 patients, including 29 females and 87 males, were enrolled in our study. There were 73 cases of traumatic brain injury and 43 cases of intracerebral hemorrhage. The mean age was 51.8 ± 16.4 years old, and the EEG and MMN recordings took place on average 14 (10.0, 21.3) days after coma onset. The most frequent pattern of predominant EEG activity was diffuse slowing (DS), followed by moderately abnormal (MoA); 4 patients showed a spindle coma pattern and 2 showed an alpha coma pattern. Of 116 patients, 60 had favorable outcomes and 56 had unfavorable outcomes. Additionally, components N1 and MMN were absent in 19 patients. And in our study, there were no patients with normal or alpha coma EEG background activity. Compared with the unfavorable prognosis group, the percentage of the GCS 6–8 scores, presence of EEG-R and sleep spindles, and better EEG background activity in favorable prognosis group were significantly higher. Furthermore, the mean amplitude of FzMMNA in favorable prognosis group was higher than the other group. These baseline characteristics were shown in [Table 1](#).

Predictors selection

Eleven factors, sex, age, etiology, pupillary light reflex, GCS, FzN1A, FzMMNA, EEG background activity, EEG-R, sleep spindles, and PAV, were extracted from demographic characteristics, clinical features, and EEG and MMN examination related indicators. Of these, 5 factors, GCS, FzMMNA, EEG background activity, EEG-R, and sleep spindles, were selected as potential predictors by LASSO analysis ([Figure 3](#)). It should be mentioned that Lasso analysis did not provide p -value in R language. Furthermore, these 5 predictors have been shown to be significantly associated with wakefulness of comatose patients after acute brain injury by binary logistic regression analysis ($P < 0.05$). Additionally, the results were expressed as odd ratio (95% confidence interval) for GCS [13.400 (3.976, 54.478)], FzMMNA (μV) [1.855 (1.085, 3.510)], EEG background activity [4.309 (1.262, 16.251)], EEG-R [4.154 (1.177, 15.965)], and sleep spindles [4.316 (1.169, 17.253)]. The Positive Predictive Value (PPV) and Negative Predictive Value (NPV) of EEG-R were 78.0 and 62.7%, respectively. The results of binary logistic regression was shown in [Table 2](#).

Development of a prediction nomogram

After the binary logistic regression analysis, the independent predictors including GCS, FzMMNA, EEG background activity, EEG-R, and sleep spindles were used for developing a prediction nomogram. Nomogram, like a scoring system, was established based on the odd ratio values. The score of each predictor can be clearly seen in this system. In addition, the sum of scores and corresponding

probabilities for the consciousness recovery of each comatose patient after acute brain injury can be effectively estimated and visualized in the nomogram ([Figure 4](#)).

Validation of the nomogram

The performance of nomogram was internally validated by using the 100 bootstrap resampling method, in which the model development cohort (original sample) served as the validation set, and each resampled sample cohort served as the training set. The calibration curve ([Figure 5](#)) showed a high consistency between the observed and predicted values in the probability of the consciousness recovery of comatose patients after acute brain injury. Besides, the

FIGURE 3

Predictors selection by using the least absolute shrinkage and selection operator (LASSO) model. **(A)** LASSO coefficient profiles of 11 alternative factors. Each curve represents a factor. Since PAV is a triadic variable, it was divided into three variables when analyzed in R language software. As a result, there are thirteen curves shown in the figure. **(B)** Tuning parameter (λ) selection in the LASSO model using 10-fold cross-validation via minimum criteria. The red dots in the figure indicate the binomial deviance corresponding to each lambda. The two dashed lines represent two special lambda values, min and 1 s, respectively. The 1 s corresponds to the optimal lambda value of a model with excellent performance and the smallest number of independent variables. Finally, combined with figure **(A)**, five factors (GCS, FzMMNA, EEG background activity, EEG-R, and sleep spindles) were selected into the following binary logistic regression analysis.

TABLE 2 Binary logistic regression analysis of the predictors of consciousness recovery in comatose patients.

Predictors	OR (95% CI)	P-values
GCS	13.400 (3.976, 54.478)	<0.001
FzMMNA	1.855 (1.085, 3.510)	0.038
EEG background activity	4.309 (1.262, 16.251)	0.023
EEG-R	5.154 (1.177, 15.965)	0.030
Sleep spindles	4.316 (1.169, 17.253)	0.031

OR, odd ratio; CI, confidence interval; FzMMNA, the absolute amplitude of MMN at electrode Fz; EEG-R, electroencephalogram activity.

AUC [0.939 (95% CI: 0.899–0.979)] was obtained for evaluating the accuracy of this predictive model by ROC (Figure 6).

Clinical utility of the nomogram

In the DCA shown in Figure 7, the threshold probability of the nomogram ranged from 5 to 92%, which indicated a wide range of clinical utility. In other words, the nomogram will achieve the net benefit in varying degrees when the threshold probability value of the predictive model is between 0.05 and 0.92. Moreover, the reason for the fluctuation at the end of the prediction model curve is mainly considered as the sample size is not large enough.

Discussion

Multimodal monitoring can be applied in the assessment of consciousness recovery of comatose patients after acute brain injury.

Although some efforts have been made in resolving this issue, it is still unclear which factors can be used to establish model to directly predict the probability of patients' consciousness recovery. In fact, the results of the comprehensive assessment will affect doctors' medical decisions determining final outcome of patients to a great extent. In this study, clinical characteristics and parameters derived from electrophysiological examinations, including GCS, FzMMNA and EEG background activity, EEG-R, and sleep spindles have been selected in the predictive model by LASSO and binary logistic regression analysis. By intuitively predicting the consciousness recovery of comatose patients after acute brain injury, this predictive model can identify patients with relatively favorable prognosis at early stages and allows active clinical intervention.

Glasgow coma scale, a clinical behavioral scale, is easy to perform and widely used in the intensive care unit and often included in prognostic models. Our study found that GCS correlated with the outcomes of comatose patients ($P < 0.001$); the findings are in accordance with those in previous studies (Emami et al., 2016; Nik et al., 2018).

Electroencephalogram is the result of recording the spontaneous electrophysiological activity emitted by cortical vertebral cells of the human brain. Three EEG related indicators in the predictive model can be applied to assess the brain injury condition of comatose patients from different layers. The EEG background activity reflects the electrical activity of the patient's brain and it's a clue to how active the brain is. EEG background activity was classified into two categories based on predominant frequency and amplitude (Wang et al., 2022a), and proved to be associated with the prognosis of comatose patients. At baseline, the two prognostic groups differed significantly for predominant EEG background activity, since poor EEG patterns was more frequently observed in patients in unfavorable group, whereas mildly and moderate

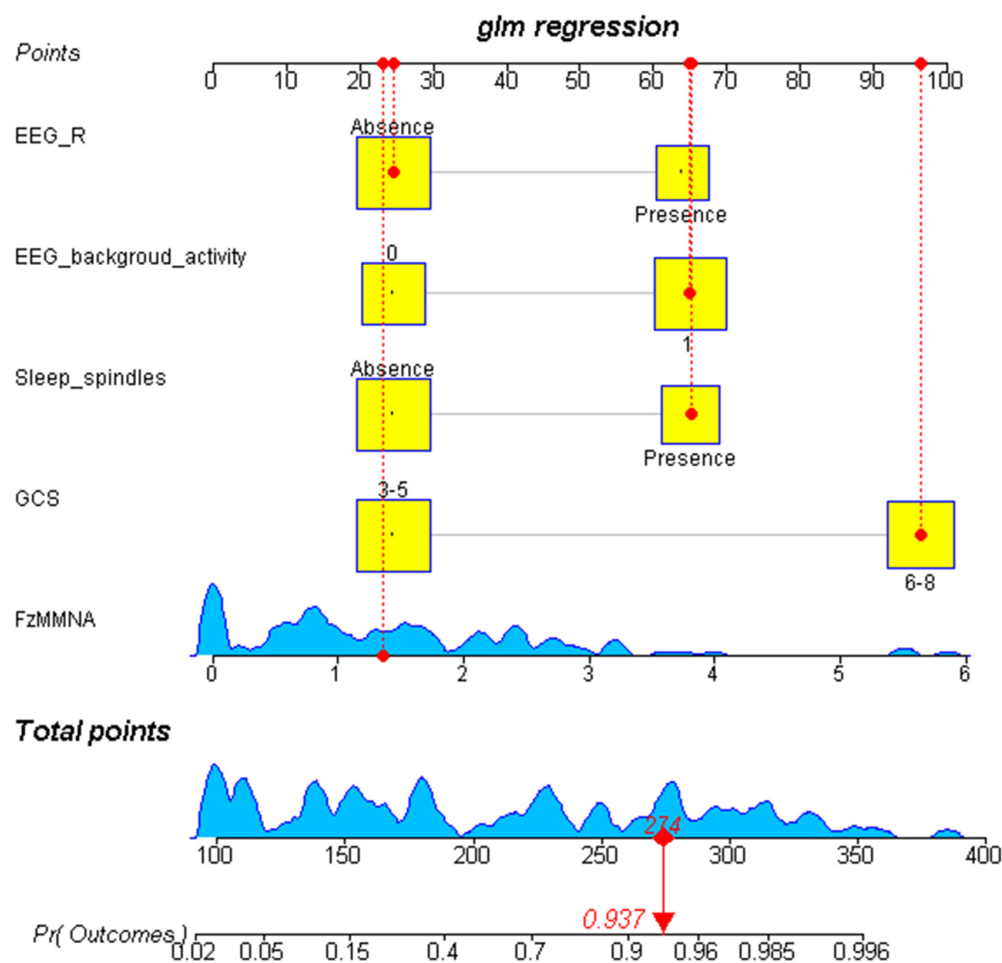

FIGURE 4

Visualization nomogram to predict the consciousness recovery of comatose patients after acute brain injury. The total score of each variable and the corresponding probability of consciousness recovery of comatose patients can be visualized in the nomogram. For example, a case is shown in the nomogram (red). This case represents a comatose patient with GCS scores of 8, the EEG-R is absent, the sleep spindles is present, the EEG background activity at level 3, and the FzMMNA is 1.42 μ V. In consideration of these five variables, the total score for this patient was 274, corresponding to a probability of regaining consciousness of 0.937. Number 0 in EEG background activity refers to diffuse slowing (DS), low voltage (LV), and Alpha coma. Number 1 in EEG background activity refers to normal, mildly abnormal (MiA), moderately abnormal (MoA), and spindle coma.

abnormal EEG activities in another group. Besides, two special EEG coma patterns, alpha and spindle coma were also included. When a prominent generalized, often frontally predominant, non-reactive alpha frequency activity constitute the principal EEG features in comatose patients, the patterns are referred to as alpha coma (Nuwer, 2021). And this kind of pattern often imply a poor prognosis, because its appearance suggests either the inputs from the thalamus or the neural filtering networks of the cortex are disturbed, or both are damaged. Spindle coma is an electroclinical entity that has been used to describe an EEG pattern of “sleep-like” activity in comatose patients (Emidio et al., 2019). Although, the spindle coma is usually resulted from a pontomesencephalic junction lesion (Husain, 2006), it is associated with favorable outcome in most situations, according to previous studies (Cologan et al., 2013; Rasch and Born, 2013). For the reason that existence of spindles often indicates the residual function of thalamus and thalamic-cortex circuit. On the contrary, the absence of spindles in comatose patients with acute brain injury results from the interruption of either the ascending reticular thalamocortical pathway or of the thalamocortical loops, which may result in difficulty in regaining consciousness.

EEG-R is defined as the diffuse, transient, and repeatable changes in electroencephalogram activity (amplitude and/or frequency) following environmental stimuli, such as pain or sound (Azabou et al., 2018a). The presence of EEG-R suggests the integrity of the peripheral sensory pathways, brainstem, subcortical structure, and cerebral cortex, and lack of EEG-R may indicate severe dysfunction in any of the aforementioned structures, tampering the cortical activity secondary to external stimuli (Altwegg-Boussac et al., 2017). Our study found that EEG-R was an independent predictive factor for outcome in comatose patients with acute brain injury. In addition, we noticed that EEG-R had a PPV of 78.0% and a relatively low NPV of 62.7%. We propose that this finding might be attributed to the fact that the results were evaluated with the naked eye because the stimulation protocol in EEG-R has not been uniformly standardized. Accordingly, subjectivity cannot be ruled out when assessing the presence of EEG-R. In other words, the absence of EEG-R, as judged by the examiner, does not necessarily reflect the real brain functional status of the patients. Thus, further studies are warranted to better standardize and clarify the EEG-R protocol.

FIGURE 5

Calibration curve of the nomogram. Internal validation was performed using the 100 bootstrap resampling method. The predicted probability and the actual probability are presented by the X and Y axes, respectively.

FIGURE 6

Receiver operating characteristic curve (ROC) of the nomogram. The AUC of the nomogram was 0.939 (95% CI: 0.899–0.979). AUC, area under the curve.

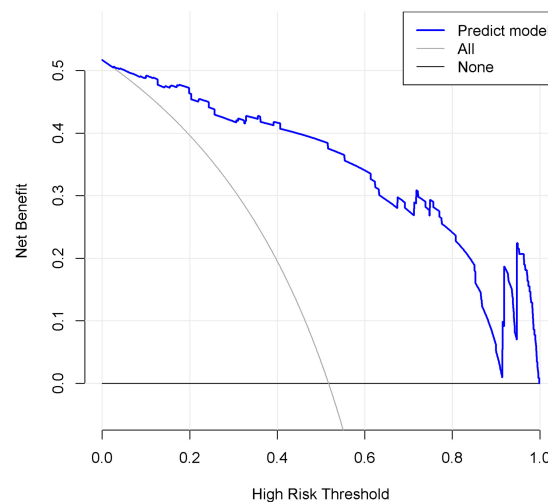

FIGURE 7

Decision curve analysis (DCA) of the nomogram. X-axis and y-axis represent threshold probability and net benefit, respectively. When the threshold probability value of the predictive model is between 0.05 and 0.92, the patients will obtain the corresponding net benefit.

Mismatch negativity is the maximal negative wave presented after standard and deviant stimuli during the latency of 100–250 ms. In patients with disorders of consciousness, the latency can be

up to 300 ms (Wang et al., 2018). MMN indicates the cortical function of differentiation and orientation to different sound stimuli, or so-called pre-attention processing. MMN originates from the auditory cortex in the Heschl's gyri and fronto-central area, and

generally has a maximal amplitude at the Fz site (Pakarinen et al., 2007; Wang et al., 2020). Besides, MMN can also be evoked in patients under sedation (Azabou et al., 2018b), anesthesia (Kenemans and Kahkonen, 2011), sleep (Chennu and Bekinschtein, 2012), and disorders of consciousness (Morlet and Fischer, 2014; Wang et al., 2020). Previous studies have demonstrated a correlation between MMN and favorable outcomes, yet few studies have incorporated the MMN amplitude into quantitative analysis. Subjective factors can easily be mixed into the interpretation of MMN, and it is difficult to apply in clinical practice (Morlet and Fischer, 2014; Schall, 2016). Therefore, we investigated the relationship between FzMMNA and patient's outcomes and found that FzMMNA could be a valuable indicator to predict consciousness recovery of comatose patients. It is worth mentioning that patients who regained consciousness had higher MMN amplitudes than patients who did not. A higher MMN amplitude suggests an increase in alertness levels, which is crucial for detecting changes in the environment and adapting behavior. Indeed, the MMN amplitude is also possibly associated with the binding of the glutamic acid and the N-methyl-D-aspartate receptors, which play an important role in modulating MMN-indexed auditory discrimination (Impey et al., 2016); this may be the reason why MMN amplitude increased in DoC patients who regained consciousness after tDCS treatment (Wang et al., 2020).

In this study, age, coma etiology, pupillary light reflex as well as PAV were not associated significantly with prognosis in our study. This result may be attributed to the selection bias and limited sample size. Certainly, further studies with a larger sample size are needed for verification.

In deed, 5 indicators in our predictive model evaluated the brain function of the comatose patients after acute brain injury from different dimensions and achieved a high accuracy (AUC = 0.939). As long as conditions permit, we should use as many tools as possible to predict the prognosis of patients synthetically in clinical practice.

Limitations

There are three major limitations in our study. Firstly, the sample size of this study was not large enough to support the selection of more factors into the model. As we all know, the prognosis assessment of comatose patients after brain injury requires as many monitoring methods as possible to achieve a more accurate and stable prediction. Secondly, taking into account the medical safety and clinical needs of patients, it was impossible to eliminate prognosis in clinical work without using any sedative drugs when EEG and MMN examinations were performed; thus, we included patients treated with dexmedetomidine, which is commonly used in our ward for sedation. Thirdly, most of the patients in our study underwent neurosurgery, while a small number did not. This difference may affect the outcome of patients. These three limitations may affect the results of this study.

Conclusion

In summary, our study develops a promising prediction model with a wide range of clinical utility for the consciousness recovery of comatose patients after acute brain injury. Besides, considering the spread of clinical practice, it is critical that, as a clinical

tool, the predictors in the model can be conveniently obtained at the patients' bedsides, which will provide important reference value for clinicians. Certainly, further prospective multimodal monitoring to predict the consciousness recovery of comatose patients after brain injury study is needed for the establishment of prediction model.

Data availability statement

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

Ethics statement

The studies involving human participants were reviewed and approved by the Medical Ethics Committee of Xiangya Hospital of Central South University ethical approval number (202210230). Written informed consent for participation was not required for this study in accordance with the national legislation and the institutional requirements.

Author contributions

LZ, JW, YC, and XC contributed to the consult literature materials and design the study. LZ and JW acquired the data. LZ, YY, and XC analyze the data. LZ, SC, and GL prepared the tables and figures. LZ, JW, and ZL were major contributors in writing the manuscript. JY, YC, and XC revised the manuscript and made the final version of the manuscript. All authors read and approved the final manuscript.

Funding

This work was supported by grants from the Research and Development Plan of Key Areas of Hunan Province, China (2020SK2070) and the China Foundation for International Medical Exchange for Young and Middle-aged Medical Research Special Fund (Z-2018-35-2004).

Objective: To investigate the value of the MRI arterial spin labeling (ASL) in evaluating the blood-brain barrier permeability of anterior circulation ischemic lesions in subacute ischemic stroke (SIS) and the risk of hemorrhage transformation (HT) after endovascular recanalization.

Materials and methods: Patients with anterior circulation SIS treated with endovascular recanalization were prospectively enrolled. The imaging presentations in the MRI ASL sequences, dynamic contrast-enhanced (DCE) sequence, and Xper CT were studied. The relative cerebral blood flow (rCBF), volume transfer constant (Ktrans), and the weighted Kappa coefficient (rKtrans) were analyzed.

Results: Among 27 eligible patients, HT occurred in 7 patients (25.92%). Patients with HT had significantly higher rCBF value (1.56 ± 0.16 vs. 1.16 ± 0.16), Ktrans, (0.08 ± 0.03 min vs. 0.03 ± 0.01 min) and rKtrans (3.02 ± 0.89 vs. 1.89 ± 0.56). The ASL imaging sequence had a high consistency with the DCE sequence and Xper CT with a high weighted Kappa coefficient of 0.91 for the DCE sequence and 0.70 for the Xper CT imaging. The DCE sequence was also highly consistent with the Xper CT in imaging classification with a high weighted Kappa coefficient of 0.78. The rCBF value in the 21 patients with the subcortical and basal ganglia infarction was significantly lower than that in the other 6 patients with the cortical infarction (1.222 ± 0.221 vs. 1.413 ± 0.259 , $t = 1.795$, $P = 0.004$).

Conclusion: The MRI ASL sequence has an important role in evaluating the blood-brain barrier permeability and the risk of hemorrhagic transformation of anterior circulation SIS following endovascular recanalization.

ischemic stroke, arterial spin labeling, blood-brain barrier permeability, hemorrhagic transformation, arterial recanalization

Introduction

For patients with subacute ischemic stroke caused by symptomatic intracranial atherosclerotic stenosis or occlusion, endovascular recanalization can be safely performed with good effects after strict selection of appropriate indications, especially within two weeks after symptom onset (Topakian et al., 2007). Nonetheless, some patients may still have hemorrhagic transformation after endovascular recanalization (Arba et al., 2021). Hemorrhagic transformation is one of the main complications after endovascular treatment of ischemic stroke and may seriously affect the prognosis of these patients. How to effectively predict the hemorrhagic transformation is of great significance for guiding the endovascular treatment of ischemic stroke.

Destruction of the blood-brain barrier is one of the major pathological mechanisms of hemorrhagic transformation after ischemic stroke. To some extent, detection of the blood-brain barrier permeability can predict occurrence of hemorrhage transformation after endovascular recanalization of occluded arteries. However, because the damage and dynamic repair of the blood-brain barrier are highly individualized, how to accurately detect the permeability of the blood-brain barrier becomes the key. It has been reported that dynamic contrast-enhanced (DCE) sequence magnetic resonance imaging (MRI) can be applied to quantitatively assess the permeability of the blood-brain barrier according to its sequence parameter, the volume transfer constant (K_{trans}) across the blood-brain barrier [3–4]. The K_{trans} is proportional to the barrier permeability, but evaluation of the blood-brain barrier with the K_{trans} requires injection of contrast agents, which may lead to some adverse reactions (Raja et al., 2018; Varatharaj et al., 2019). Arterial spin labeling (ASL) MRI examination only marks the patient's own water proton imaging without contrast agent injection. In the study of acute ischemic stroke, it was found that local measurement of the ASL's sequence parameters relative to the cerebral blood flow (rCBF) could also be used to evaluate the permeability of the blood-brain barrier, and the rCBF value > 1.3 could effectively predict the presence of hemorrhagic transformation after endovascular treatment (Nogueira et al., 2015; Niibo et al., 2017). It was hypothesized that ASL could be used to efficiently evaluate the permeability of blood-brain barrier in patients with cerebral infarction and predict hemorrhagic transformation after endovascular recanalization of stenotic or occluded arteries. This study was thus performed to investigate the value of ASL in assessing the permeability of blood-brain barrier and predicting hemorrhagic transformation after the endovascular treatment in patients with subacute anterior circulation ischemic stroke caused by severe intracranial atherosclerotic stenosis or occlusion. This may provide more technical support for evaluation of the brain tissue status during the perioperative period, facilitate targeted classification and staging treatment of patients, and prevent hemorrhagic transformation.

Materials and methods

Subjects

This prospective one-center study was carried out after approval by the ethics committee of our hospital (2020108), and all patients or their family members had signed the informed consent to participate. Between January 2021 and September 2021, consecutive patients with subacute ischemic stroke of the anterior circulation who received endovascular recanalization were prospectively enrolled. The inclusion criteria were age ≥ 18 years, the modified Rankin scale (mRS) score before stroke onset < 3, anterior circulation ischemic stroke confirmed by clinical and imaging examinations and managed with medication for 2–3 weeks after stroke onset, responsible arteries being the middle cerebral artery and the intra- or extracranial segments of the internal carotid artery with the stenosis $\geq 70\%$ or complete occlusion, examination of the MRI ASL sequence and DCE sequence 24 h before and immediately after endovascular balloon angioplasty alone or stent angioplasty, and Xper CT being performed immediately after the endovascular treatment. The exclusion criteria were non-intracranial atherosclerotic stenosis caused by Moyamoya disease, Moyamoya syndrome or vasculitis, a previous ischemic lesion ≥ 1.5 cm in diameter in the responsible vascular basin of this ischemic stroke lesion, presence of hemorrhagic transformation before endovascular treatment confirmed by imaging examination, suffering from malignant tumors, and complicated with renal insufficiency or allergy to gadolinium contrast agent.

Imaging examination

All the MRI ASL sequence, DCE sequence and Xper CT examinations were completed on the "one-stop multimodal image fusion stroke treatment platform." The platform was composed of a 3.0T MR scanner (MAGNETOM Skyra), a 64 row multi-slice CT scanner (SOMATOM Definition AS), and a dual C-arm DSA system (Artis Q biplane) (Siemens, Germany). In MRI, images were collected with a 8-channel head coil. The repetition time of axial T1WI fast echo sequence was 4.1 ms, an echo time 120 ms, and a visual field 24 cm \times 24 cm. The DWI sequence had a repetition time 4200 ms, an echo time 100 ms, a b value 1000 s/mm², and a field of view 24 cm \times 24 cm. The repeat time of 3D-ASL sequence was 4564 ms, an echo time 10.5 ms, a matrix 128 \times 128, a field of view 24 cm \times 24 cm, layer thickness 3 mm, excitation times 2 times, delay time after labeling 1550 ms, 2550 ms (multi-delay technique), and scanning time 447 s. The repetition time of DCE sequence was 5.3 ms, an echo time 1.9 ms, layer thickness 5 mm, no spacing, a matrix 256 \times 256, a field of view 24 cm \times 24 cm, a reverse angle 15°, time resolution 380/35 s, tracer kinetic model of the Tofts model, and same scanning and positioning parameters as the above sequence. The number of layers was 40, including 35 times of acquisition. After the third image acquisition, the contrast agent (Gd³⁺ injection, 20 mL/tube, Guangzhou Kangchen Pharmaceutical Co., Ltd.) was injected through the elbow vein at a rate 4 mL/s and a dose 0.1 mmol/kg, and the scanning time was 380 s with a temporal resolution of 380/35 s.

Imaging post-processing

The imSTROKE software (Nanjing Yuexi Medical Technology Co., Ltd., Nanjing, China) was used for the ASL image *post*-processing. Firstly, ASL, DWI and apparent dispersion coefficient (ADC) data were input before rigid registration of the ASL data with the DWI and ADC data. After the DWI and ADC sequences were classified with the artificial intelligence, the infarct core region was automatically calculated, and the final region of interest (ROI) was obtained through morphological processing. The contralateral healthy region corresponding to the infarcted ROI was selected to obtain the median value of the pixel in the region as the reference value before calculating the rCBF and converting it into pseudo-color display in the ROI. The Siemens Syngo workstation software was used to select the corresponding ROI on the DCE sequence according to the ROI on the ASL sequence before automatically measuring and recording the Ktrans value and rKtrans value (the ratio of the ROI Ktrans value on the infarcted side to that on the healthy side). The rCBF parameters in the MRI ASL sequence and the Ktrans parameters in the DCE sequence were used, respectively, to reflect the permeability of blood-brain barrier and local hyperperfusion state. The Ktrans is a parameter of the MRI DCE sequence and calculated as the mean value in a certain ROI region, and it is a volume transfer constant across the blood-brain barrier (Raja et al., 2018; Varatharaj et al., 2019) and can be applied to quantitatively assess the permeability of the blood-brain barrier because it is proportional to the barrier permeability (Raja et al., 2018; Varatharaj et al., 2019).

Imaging classification of hemorrhagic transformation

On the ASL and DCE sequences, hemorrhagic transformation was presented as areas of high signals (high signals on the ASL sequence represented an increase of local rCBF, and high signals on the DCE sequence represented an increase of contrast agent exudation, which reflected the increase of blood-brain barrier permeability) (Nogueira et al., 2015; Niibo et al., 2017; Raja et al., 2018; Varatharaj et al., 2019). According to the high-signal distribution range of hemorrhagic transformation, the imaging presentations of hemorrhagic transformation were classified as follows: Type I: the high signal areas were distributed in dots or stripes around the edge of the cerebral infarction focus; Type II: The high signal areas in the cerebral infarction focus were distributed in patches, with the volume less than 30% of the cerebral infarction focus; Type III: The high signal areas in the cerebral infarction focus were distributed in sheets, with the volume $\geq 30\%$ of the cerebral infarction focus (Figure 1). On Xper CT imaging, high-density lesions in low-density background infarction area immediately after endovascular treatment were hemorrhagic transformation. According to the range of high-density lesions shown on the Xper CT imaging immediately after endovascular treatment (Sandoval and Witt, 2008), the imaging classification was as follows: Type I: the contrast agent exuded around the edge of the cerebral infarction, and high-density lesions were distributed in spots or strips; Type II: the contrast agent exuded in the cerebral infarction focus, and high-density lesions were distributed in patches, with the

FIGURE 1
Classification of hemorrhagic transformation on arterial spin labeling imaging (ASL), dynamic contrast-enhanced (DCE) sequence of magnetic resonance imaging, and Xper CT. volume less than 30% of the cerebral infarction focus; Type III: the contrast agent exuded in the cerebral infarction focus, and high-density lesions were distributed in sheets, with the volume $\geq 30\%$ of the cerebral infarction focus (Figure 1). The ASL, DCE and Xper CT imaging classifications were independently assessed by two imaging experts with senior professional titles who were not aware of the diagnosis, treatment and prognosis of the disease. If disagreements arose, consultation to a third senior physician was performed to reach a consensus.

In addition, all patients were reexamined with plain CT scan 24–48 h after endovascular treatment. Presence of high-density lesions on the low-density background layer of cerebral infarction was defined as the occurrence of hemorrhagic transformation, and the Heidelberg classification standard was used for the classification of three entities (von Kummer et al., 2015): HI type 1 (scattered small petechiae with no mass effect), HI type 2 (confluent petechiae with no mass effect), and PH 1 Hematoma within the infarcted tissue occupying $< 30\%$ with no substantive mass effect.

Treatment plan

Before endovascular recanalization, all patients were treated with dual antiplatelet therapy. After successful arterial puncture during the endovascular procedure, intravenous bolus loading of unfractionated heparin (70 IU/kg) was administered. During the procedure, 1000 IU of unfractionated heparin was added every hour. Glycoprotein II b/III α receptor antagonists such as tirofiban were not used during the perioperative period.

HT, hemorrhagic transformation; MCA, middle cerebral artery; ICA, internal carotid artery; ASL, arterial spin labeling; DCE, dynamic contrast-enhanced magnetic resonance sequence; rCBF, relative cerebral blood flow; Ktrans, volume transfer constant; rKtrans, relative volume transfer constant.

Statistical analysis

The SPSS 25.0 software (IBM, Chicago, IL, USA) was used for data analysis. Measurement data were expressed as the mean \pm standard deviation if in the normal distribution and tested with the *t*-test but as the median (interquartile range) if in the skew distribution and tested with the Mann–Whitney U test. Categorical variables were presented in frequency and percentages and tested with the Chi square test or Fisher's exact probability test. The weighted Kappa coefficients were used to check the consistency among ASL, DCE and Xper CT imaging classifications. The difference was statistically significant if $P < 0.05$.

Results

General information

Twenty-seven patients were enrolled, including 17 males and 10 females, with a mean age of 62.37 ± 7.76 (61–76) years (Table 1). Hypertension was present in 19 cases, diabetes mellitus in 9,

hyperlipidemia in 21, and stroke history in 14. The responsible vessels were the middle cerebral artery in 13 cases, the internal carotid artery intracranial segment in 7 cases, and the extracranial segment of the internal carotid artery in 7 cases. The cerebral infarction site was in the cortex in 6 cases and in the subcortical and basal ganglia in 21 cases (Figures 2, 3). Severe arterial stenosis was presented in 14 cases, and occlusion in 13 cases. In endovascular treatment, balloon angioplasty alone was performed in 4 cases, and stent angioplasty in 23 cases.

The time from onset to imaging examination was 18.96 ± 1.81 (14–21) days. On the ASL imaging, type I was in 8 cases, type II in 11, and type III in 8, with an average rCBF of 1.32 (1.120, 1.510). On the DCE imaging, type I was in 9 cases, type II in 11, and type III in 7. The Ktrans was 0.04 ± 0.02 (0.01–0.16), and the rKtrans was 2.18 ± 0.82 (1–4.3). On the Xper CT imaging, type I was in 12 cases, type II in 11, and type III in 4.

Clinical and imaging presentations

Among 27 patients, 7 (25.92%) patients had hemorrhagic transformation after endovascular recanalization, all of whom were

FIGURE 2

Imaging data of a patient with subacute ischemic stroke with hemorrhagic transformation after endovascular therapy. (A) Seven days after stroke onset, diffusion weighted imaging sequence of MRI shows subacute cerebral infarction in left frontal temporal lobe. (B–D) Cerebral angiography revealed long-segment occlusion of the left internal carotid artery, but the left middle cerebral artery and its branches remain patent. (E) The pseudo color image (left) and post-processing image (right) of the ASL (arterial spin labeling) sequence are shown with the cerebral blood flow of 1.9. (F) The original image (left) and the post-processing image (right) of the DCE (dynamic contrast enhanced) MRI sequence are shown with the Ktrans of 0.16/min).

of Heidelberg type II (Figures 2, 3 and Table 1). There were no significant ($P > 0.05$) differences in the gender, age, high risk factors, location of cerebral infarction, distribution of responsible vessels, extent of disease, modes of endovascular treatment, time from onset to imaging examination, and imaging types on ASL sequence, XperCT and DCE MRI between patients with and those without hemorrhagic transformation. However, the rCBF value (1.56 ± 0.16 vs. 1.16 ± 0.16), Ktrans, (0.08 ± 0.03 vs. 0.03 ± 0.01) and rKtrans (3.02 ± 0.89 vs. 1.89 ± 0.56) were all significantly ($P < 0.05$) higher in patients with than those without hemorrhagic transformation.

Consistency between the ASL, DCE, and Xper CT imaging classifications

The imaging classification was consistent on the ASL sequence with that on the DCE sequence in 25 patients, but inconsistent in only 2 patients, with a weighted Kappa coefficient of 0.91 (95% CI: 0.79–1.03, $P < 0.001$), indicating strong consistency (Table 2). The imaging classification was consistent on the ASL sequence with that on the Xper CT imaging in 19 patients, but not in the other 8 patients, resulting in a weighted Kappa coefficient of 0.70 (95% CI: 0.50–0.89, $P < 0.001$), with strong consistency (Table 2). The imaging classification was consistent on the DCE sequence with that on the Xper CT imaging in 19 patients, but not in the other 8 patients, leading to a weighted Kappa coefficient of 0.78 (95% CI: 0.60–0.96, $P < 0.001$), with strong consistency (Table 3).

rCBF and Ktrans values in different cerebral infarction sites

The rCBF value in the 21 patients with the subcortical and basal ganglia infarction was significantly lower than that in the other 6 patients with the cortical infarction (1.222 ± 0.221 vs. 1.413 ± 0.259 , $t = 1.795$, $P = 0.004$), however, no significant difference was found in the Ktrans (0.04 ± 0.02 vs. 0.06 ± 0.03 , $P = 0.13$) or rKtrans (2.08 ± 0.79 vs. 2.54 ± 0.89 , $P = 0.23$) between the two groups.

Discussion

In this study investigating the value of the ASL imaging sequence in evaluating the blood-brain barrier permeability of anterior circulation ischemic lesions in subacute ischemic stroke and in assessing the risk of hemorrhage transformation after endovascular recanalization, it was found that the ASL sequence had a strong role in evaluating the blood-brain barrier permeability in patients with anterior circulation subacute ischemic stroke and that Type III ASL imaging presentation may have a high prediction effect on the risk of hemorrhagic transformation.

For patients with subacute ischemic stroke caused by severe stenosis or occlusion of large intracranial vessels, endovascular recanalization at an appropriate time can benefit most patients and effectively reduce the poor prognosis. However, some complications after endovascular arterial recanalization cannot be ignored. Among them, hemorrhage transformation is one

FIGURE 3

Imaging data of the same patient as in [Figure 2](#). (A,B) On the 20th day after symptom onset, endovascular recanalization was performed to recanalize the long-segment occlusion of the left internal carotid artery, and two resolute stents (4.0 mm × 33 mm and 4.0 mm × 36 mm) were deployed in sequence. After recanalization, the occluded internal carotid artery was successfully recanalized. (C) Xper CT immediately after the surgery showed that the imaging classification of hemorrhagic transformation was type III. (D) Hemorrhage transformation was detected by CT plain scan on the next day after surgery.

of the serious and even fatal complications after endovascular treatment of ischemic stroke, and its occurrence is closely related to the increase of blood-brain barrier permeability ([Sandoval and Witt, 2008](#)). Damage of the blood-brain barrier will cause large-molecular neurotoxic proteins in the blood to leak out into the brain tissue gap, mediating inflammatory reaction to cause perivascular interstitial edema, neuronal and nerve fiber damage and subsequent blood leakage out of the cerebral arteries (or bleeding), which is the hemorrhagic transformation from ischemic stroke after endovascular treatment. This hemorrhagic transformation cannot be directly measured, but can be indirectly reflected by measurement of the blood-brain barrier permeability. In addition, increased permeability in the blood-brain barrier caused by cerebral ischemic injury appears not only in the acute phase, but also in the subacute phase and the early stage of

angiogenesis associated with the recovery of ischemic stroke ([Jiang et al., 2012](#)). Therefore, quantitative analysis of the blood-brain barrier permeability is a promising approach to predict the risk of hemorrhagic transformation in patients with subacute ischemic stroke.

The blood-brain barrier is crucial for maintaining a stable cellular environment in the central nervous system for regulation of cellular and solute traffic between the blood and the brain. Permeability of the blood-brain barrier is a physiological phenomenon in the healthy state but increases with aging and in the disease status ([Elwood et al., 2017](#)). The first blood-brain interface is formed by the endothelial cells that have tight junction proteins, and the next layer is formed by the basal lamina which is composed of extracellular matrix proteins and surrounded by the astrocytic foot processes with embedded pericytes. Under normal conditions, the interface between brain tissues and blood is a relatively limited “barrier” to non-lipid molecules and has low permeability. Besides the tight junction proteins, there are also transport or carrying molecules to facilitate transport into the brain, and enzymes may exist to degrade substances and prevent transport into the brain ([Raja et al., 2018](#)). When the blood-brain barrier is damaged in brain tumors, stroke or multiple sclerosis, large proteins may leak into the brain tissue and cerebrospinal fluid, which can be detected with CT or MRI. Disruption of the blood-brain barrier in chronic vascular disease is associated with hypoxia-induced inflammation ([Raja et al., 2018](#)). One potential condition to involve chronic vascular changes is secondary to long-standing elevated blood pressure, which may lead to stenosis of the vascular lumen, limiting blood flow and producing hypoxia. This finding has been proved by animal studies of hypertensive rats ([Weaver et al., 2014](#)) and human studies ([Fernando et al., 2006](#)) with hypoxia-induced factors being found in the brains of patients with vascular dementia. Nonetheless, measurement of the blood-brain barrier permeability is not straightforward. The ratio between the cerebrospinal fluid and the serum albumin is a well-established approach to evaluate the barrier permeability, but is invasive and may not reliably reflect the real permeability, with a great influence from the cerebrospinal fluid flow ([Varatharaj et al., 2019](#)). Neuro-imaging with use of an intravenous injection of tracer is an approach to measure the blood-brain barrier permeability, and positron emission tomography has also been used in this aspect ([Varatharaj et al., 2019](#)). Nonetheless, some disadvantages in these approaches have precluded the widespread application, including the suboptimal resolution and radioactivity.

Currently, a variety of neuroimaging techniques can be used to obtain the volume of cerebral infarction, the perfusion status of infarction focus, the degree of vascular disease, and the permeability

of diseased vascular wall to predict the risk of hemorrhagic transformation in patients with ischemic stroke. The use of DCE sequence MRI is a commonly used imaging method to detect the permeability of the blood-brain barrier before endovascular treatment. Its parameter Ktrans represents the speed of contrast agent penetrating from the cerebral vessels into the interstitium and is calculated by measuring the mean Ktrans in a certain ROI region. It can reflect the concentration and flow of contrast agent in the blood of cerebral tissue. Thus, it can be used as an indicator of the blood-brain barrier permeability, and has been shown to be able to sensitively detect the changes of the blood-brain barrier permeability at the early stage of cerebral ischemia (2 to 3 h) (Jiang et al., 2005). However, it is undeniable that the sensitivity of MRI based on the gadolinium chelate contrast agent for ischemic stroke is relatively low, and adverse reactions such as nephrogenic systemic fibrosis and intracranial gadolinium deposition may occur. Immediate plain CT scanning after endovascular treatment can also detect contrast agent extravasation in the local cerebral infarction, so as to judge the permeability of the diseased vascular wall, extent of blood-brain barrier damage and risk of hemorrhagic transformation. Nonetheless, these findings are after rather than before endovascular recanalization, which is not conducive to early intervention. In addition, although the exudation of contrast agent on Xper CT after surgery had been demonstrated to be associated with the risk of hemorrhagic transformation (Seevinck et al., 2010; Chen et al., 2020), only qualitative analysis had been performed without classifying the exudation characteristics or quantity.

ASL is the only non-invasive technique using endogenous tracers in perfusion imaging. In a study investigating the MRI ASL sequence imaging in 27 patients with acute ischemic stroke after endovascular treatment (Shimonaga et al., 2019), it was found that among 13 patients with local hyperperfusion areas, 8 patients had hemorrhagic transformation after endovascular recanalization, and the prognosis of these patients was poor, suggesting that the increase of local cerebral blood flow in cerebral infarction can be used to predict the occurrence of hemorrhagic transformation. In our study, the image scanning of the ASL sequence, DCE sequence and Xper CT was completed on the "one-stop multimodal image fusion and stroke treatment platform" dedicated to stroke diagnosis and treatment, which not only helped to achieve unification of relevant parameters, but also reduced the time interval of image inspection, ensuring the accuracy and repeatability of image data to the maximal extent. In our study, the DCE sequence and Xper CT were used to cross verify the evaluation effect of the ASL sequence on the blood-brain barrier permeability of cerebral infarction focus in patients with subacute ischemic stroke and the

predictive value of hemorrhage transformation. The results showed that in the same ROI, the rCBF and Ktrans values in patients with hemorrhagic transformation were significantly higher than those without hemorrhagic transformation.

After further classification of the high signal distribution on the ASL and DCE sequence and the high-density image characteristics on the Xper CT, it was found that the ASL imaging sequence had a high consistency with the DCE imaging sequence and the Xper CT with a Kappa coefficient of 0.91 and 0.70, respectively. Consequently, the ASL sequence may be just like the DCE sequence and the Xper CT, playing a strong role in assessing the blood-brain barrier permeability in the cerebral infarction area of subacute ischemic stroke. The risk of hemorrhagic transformation in patients with ASL type III was relatively high. The synergy of the three imaging tools may be able to make a more accurate prediction of postoperative hemorrhagic transformation, thus providing more objective evidence for guiding the classification, staging and individualized treatment of stroke patients.

The location of contrast agent extravasation is more valuable than the extravasation itself in predicting the hemorrhagic transformation. Because contrast agent is mostly injected near the opening of the lenticular artery in the middle cerebral artery trunk, contrast agent extravasation limited to the basal ganglia is common, but its value in predicting the hemorrhagic transformation is low. Extravasation of contrast agent in the cortex may indicate extensive damage of the blood-brain barrier, serious reperfusion injury, and increased risk of symptomatic hemorrhagic transformation (Kim et al., 2015). However, further analysis in our study found no significant difference in the Ktrans value between patients with subcortical and basal ganglia infarction and those with cortical infarction ($P > 0.05$), even though the rCBF value of the former was significantly lower than that of the latter. This may indicate differences in the blood-brain barrier permeability between infarcted tissues in different parts of subacute ischemic stroke, which may be associated with different ischemic tolerance of the blood-brain barrier in different parts of brain tissue with subacute ischemic stroke as well as different repair efficiency of the blood-brain barrier permeability. It has been found that the ischemic focus of subacute ischemic stroke will have functional neurovascular remodeling, which is accompanied by neovascularization, and establishment of collateral circulation will accordingly increase blood perfusion in the area with neovascularization (Bokkers et al., 2009; Yang and Torbey, 2020). In patients with subacute ischemic stroke, the leptomeningeal collateral branch is easier to be established in patients with cortical infarction than in patients with subcortical and basal ganglia infarction, which may lead to the earlier and more perfect repair of the blood-brain barrier in patients with cortical infarction.

Our study also suggested that the ASL and DCE sequences have different abilities in detecting the blood-brain barrier permeability in different parts of subacute ischemic stroke, which may be related to the difference in imaging characteristics between the two sequences. The ASL sequence is marked by water protons which are more sensitive to changes in the blood-brain barrier permeability than gadolinium ions (Lin et al., 2018; Mahroo et al., 2021). Therefore, the ASL sequence is more sensitive to changes in the blood-brain barrier permeability than the DCE sequence. Moreover, in our study, the ASL sequence imaging used the "multiple delay labeling" technology, which is easy to capture long

delayed signals in different parts of tissues (Mato Abad et al., 2016), resulting in more sensitivity of the ASL sequence to changes in the blood-brain barrier permeability in different parts than that of the DCE sequence. Based on the results of our study and the above analysis, the ASL sequence imaging using the "multiple delay labeling" technology in clinical work may be more suitable to detecting the nervous system diseases with slight changes in the blood-brain barrier permeability.

Some limitations existed in our study, including enrollment of Chinese patients only, one-center study design and a small cohort of patients due to the strict inclusion and exclusion criteria, which may all affect the bias of the outcome. Further prospective, randomized, controlled clinical trials with multicenters involved and a large sample size are needed to verify the outcomes of this study.

To sum up, application of the ASL sequence and its advanced post-processing technology can effectively assess the blood-brain barrier permeability in patients with subacute ischemic stroke in the anterior circulation and predict the risk of hemorrhagic transformation following endovascular recanalization, thus conducive to selection of surgical timing for different patients, reduction of perioperative complications, and achievement of real staging and individualized treatment for the patients.

Rumination is closely related to mental disorders and can thus be used as a marker of their presence or a predictor of their development. The presence of masking and fabrication in psychological selection can lead to inaccurate detection of psychological disorders. Human language is considered crucial in eliciting specific conscious activities, and the use of natural language processing (NLP) in the development of questionnaires for psychological tests has the potential to elicit immersive ruminative thinking, leading to changes in neural activity. Electroencephalography (EEG) is commonly used to detect and record neural activity in the human brain and is sensitive to changes in brain activity. In this study, we used NLP to develop a questionnaire to induce ruminative thinking and then recorded the EEG signals in response to the questionnaire. The behavioral results revealed that ruminators exhibited higher arousal rates and longer reaction times, specifically in response to the ruminative items of the questionnaire. The EEG results showed no significant difference between the ruminators and the control group during the resting state; however, a significant alteration in the coherence of the entire brain of the ruminators existed while they were answering the ruminative items. No differences were found in the control participants while answering the two items. These behavioral and EEG results indicate that the questionnaire elicited immersive ruminative thinking, specifically in the ruminators. Therefore, the questionnaire designed using NLP is capable of eliciting ruminative thinking in ruminators, offering a promising approach for the early detection of mental disorders in psychological selection.

natural language analysis, immersive questionnaire, EEG coherence, psychological selection, rumination

Introduction

Rumination is defined as continuous attention to negative stimuli, including the causes and consequences of negative events and the resulting negative emotions, which may lead to depression, anxiety, and other mental disorders. This phenomenon is considered a non-adaptive way of regulating emotions (Nolen-Hoeksema, 1991; Nolen-Hoeksema and Morrow, 1991; Nolen-Hoeksema et al., 1995). In the Self-Regulatory Executive Function (S-REF) model of emotional disorders, Wells and Matthews identified a persistent thinking mode that included worry and rumination and further defined it as an ineffective coping strategy. Rumination involves persistently focusing on negative thinking and feelings rather than problem solving, which is counterproductive by way of amplifying and prolonging the experience of suffering (Wells and Matthews, 1996). The relationship between rumination and depression has been widely studied (Castanheira et al., 2019; Li et al., 2020; Van Doorn et al., 2021). According to response styles theory, rumination can prolong and intensify the pain of negative or stressful events, increase despair, and aggravate depressive symptoms (Nolen-Hoeksema et al., 2008). Rumination is also associated with alcohol abuse, anxiety symptoms, generalized anxiety disorder, social anxiety disorder, obsessive-compulsive disorder, PTSD, schizophrenia, borderline personality disorder, and bulimia nervosa, among others, and other mental disorders (Watkins and Roberts, 2020).

Although there are numerous scales available for assessing rumination, the most widely used remains the Ruminative Response Scale (RRS), developed by Nolen-Hoeksema in 1991 (Nolen-Hoeksema and Morrow, 1991) and compiled by Nolen-Hoeksema in 1991. While RRS has been widely employed in ruminative research, the limitations of this scale are also significant, especially regarding the presence of psychological selection (Wang et al., 2020; Miao et al., 2021). Camouflage, falsification, social approval, and other issues (Dunning et al., 2005; Schwarz, 2012; Wang et al., 2020, 2021) have greatly affected the acceptance and validity of rumination-related psychological testing. Therefore, further advancements are necessary in inducing ruminative conscious activity accurately, measuring the associated brain activity objectively, and exploring the neural biomarkers of rumination to identify ruminators and predict future rumination for precise psychological selection.

Previous studies have found that rumination arises as a result of negative situational memories (Sutherland and Bryant, 2007). Hence, the resurfacing of specific situational memories is considered one of the most effective and rapid means to induce rumination. In episodic memory-related studies, Wilson-Mendenhall proposed “scenario immersion” and defined it as precise language that could facilitate immersive psychological imagination and enable subjects to place themselves into various imagined situations and memories (Wilson-Mendenhall et al., 2019). After experiencing different emotions, subjects form an episodic memory in their long-term memory, thus affecting the emotions they will experience in similar situations in the future. For example, when someone perceives that a car is approaching them quickly in a given scenario, their episodic memory from a previous similar scenario is activated in response. This implicitly, rapidly, and synergistically generates fearful cognitive, interoceptive, and behavioral processes in relation to the current situation (Lebois

et al., 2020). Research has shown that rumination can be activated quickly when encountering situations that are similar to a past fearful event or when encountering only a small component of the original event (Wilson-Mendenhall et al., 2015). In 2022, Priyamvada Rajasethupathy confirmed the core idea of the “scenario immersion” theory with the finding that a holistic episodic memory composed of multiple sensory experiences can indeed be evoked by a single sensory cue (Yadav et al., 2022). Therefore, eliciting a specific episodic memory can be the most effective and efficient means to initiate ruminative thinking (Sutherland and Bryant, 2007).

Natural language (i.e., the language used in daily life) is an important means of human communication and an essential feature that distinguishes human beings from other animals (Assale et al., 2019). A specific questionnaire based on natural language can be used to comprehensively induce the recall of the complete episodic memory (Wilson-Mendenhall et al., 2019; Ancin-Murguzur and Hausner, 2021). At present, natural language processing (NLP) technology has accomplished a series of complex functions, such as machine translation, automatic summarization, emotion analysis, and text classification (Castanheira et al., 2019). Compiling questionnaires based on natural language corpuses and NLP of rumination are the two methods that are considered effective in inducing and analyzing rumination accurately (Ferrario et al., 2020). The theory of “scenario immersion” is a useful tool for inducing rumination; therefore, we drew upon this theory and further incorporated NLP to develop a questionnaire that could elicit ruminative thinking both efficiently and effectively.

Compared to cognitive neural technologies, such as functional magnetic resonance imaging (fMRI), magnetoencephalography (MEG), and functional near-infrared spectroscopy (fNIRS), wireless EEG technology is cheap, easy to transport, convenient for recording brain activity during experiments, sensitive to the alternation of brain activity, flexible across various experimental paradigms, and provides high temporal resolution signals, thereby rendering it suitable for language evaluation and the detection of brain activity during psychological selection (Deshpande et al., 2017).

EEG coherence, first proposed by Robinson (Robinson, 2003), is an index of brain connectivity that is calculated by the covariance of the power spectral density at two electrodes. Coherence shows the synchronicity of neural activity and reflects brain dynamics (Markovska-Simoska et al., 2018). Neuroimaging studies have provided a great deal of data on the dysfunction and dysregulation that occurs in the brains of clinically and nonclinically depressed ruminators, including hypofunctional and hyperfunctional connectivity (Ferdek et al., 2016; Li et al., 2018; Benschop et al., 2020). Such studies were designed to examine network characteristics while ruminators were at rest or engaged in a task, thereby exposing the synchronicity of neural activity either between the brain areas (Ferdek et al., 2016) or between the brain networks (Zhang et al., 2020). Both EEG and fMRI studies have shown that altered functional connectivity in the brain networks of subjects with depression was positively related to ruminative thoughts (Benschop et al., 2020). These results indicated that the altered synchronicity within the brain might be an indicator of altered brain activity. EEG coherence may be a suitable indicator to depict the change of the brain activities in subjects with mental disorders.

TABLE 1 Demographic information of 4,591 participants ($n = 4,591$).

Ethnicity (n, %)		
Han	4,109	89.50
Others	482	10.50

In this study, we developed a situational ruminative questionnaire using the natural language characteristics of ruminators to demonstrate the ability of the questionnaire to elicit immersive ruminative thinking in ruminators, as determined by their behavioral responses and characteristics of EEG signals.

Methods

The ruminative response scale

The Ruminative Response Scale (RRS) is a questionnaire composed of 22 items that is used to measure the ruminative tendency of an individual. Each item uses a 4-point Likert scale (1 = rarely, 2 = sometimes, 3 = often, 4 = almost always). The Chinese version used in this study was translated by Han Xiu and has been verified to have good reliability and validity among Chinese senior high school and college students (Han and Yang, 2009). The higher the total score, the higher the rumination level, and the highest score is 88. The demographic information of the participants is shown in Table 1.

Natural language processing and questionnaire development

We selected 607 subjects with a high tendency for rumination (577 men and 30 women) for semi-structured interviews that were conducted on an individual basis. The interviews were recorded and saved, and an intelligent conference system (version 5.0) was used to transcript the interview information for each interviewee. The demographic information of the participants is shown in Table 2. The obtained transcripts were analyzed, and the elicited material was compiled using the following six steps. (1) Proofreading and denoising: The text was thoroughly analyzed to check for errors and delete any extraneous characters, spaces, and so on. (2) Chinese participle: Chinese word segmentation was performed using Chinese LIWC software. (3) Stop word filtering: More uniform word segmentation text was created using the HIT edition of the “Stop Word Dictionary” to filter stop words.

TABLE 2 Demographic information of individuals who participated in the semi-structured interviews ($n = 607$).

	Frequency/mean	Percentage/standard deviation
Gender (n, %)		
Women	30	4.94
Men	577	95.06
Age (mean \pm SD)	21.80	3.03
Home location (n, %)		
Urban	196	32.29
Village	411	67.71
Ethnicity (n, %)		
Han	525	86.49
Others	82	13.51

(4) Feature word extraction and coding: The TF-IDF approach was used to determine the frequency of feature words in the text (Reviewer-Lee, 2000; Jurafsky, 2009). The feature words were specifically selected by using the TF-IDF algorithm to calculate the frequency of all the words in the interview transcript of the extreme ruminators to obtain the high-frequency feature words first and then by referring to the 66 “scenario materials” words in Mendenhall’s article (Wilson-Mendenhall et al., 2019). Only the content words (to construct the scenario) and the depictive words (to express the emotional experience) of the feature words were retained, and function words with no real meaning were removed. The bag-of-words model used a real-valued vector to label each transcribed word and encoded it using feature words (Ferrario et al., 2020). (5) Based on the semantic characteristics of the feature words, the LDA (latent Dirichlet allocation) topic model was used to extract text topics (Ghosh and Guha, 2013; Min et al., 2019, 2020), which were then used to group words under the topics. The detailed analysis pipeline of the LDA model and the document generation process are shown in Supplementary Figure 1 (Blei et al., 2003; Hao et al., 2017). Quantitative analysis was then used to identify the overarching topic of the interview material, while artificial naming was used to identify the situational topics. An example of extracting text topics is shown in Supplementary Table 1. (6) Creation of situational inducing materials: We recreated real-life scenarios that the interviewees had described, merged them with the six syntaxes of Mendenhall’s “scenario immersion” theory, and then generated materials that elicited rumination. The neutral items were derived from paragraphs that were cut from the third edition of the Encyclopedia of China, whereby the number of words was kept similar to that of the rumination items and the chosen content was relatively boring and meaningless.

Questionnaire evaluation

The ruminative questionnaire was revised by three linguistics professors. The revisions made included connotation logic,

TABLE 3 Demographic information of the 1,685 participants (*n* = 1,685).

	Frequency/mean	Percentage/standard deviation
Gender (<i>n</i> , %)		
Women	0	0
Men	1,685	100
Age (mean ± SD)	21.19	1.60
Home location (<i>n</i> , %)		
Urban	308	18.28
Village	1,377	81.72
Ethnicity (<i>n</i> , %)		
Han	1,489	88.37
Others	196	11.63

grammar application, and character norms, among others. To verify the validity of the questionnaire regarding its ability to induce rumination, it was evaluated again by high- and low-degree ruminators. We then recruited another 1,685 subjects (all males) to complete the RRS. Of these, 78 participants were randomly selected for the final evaluation of the developed questionnaire. These participants comprised 40 high-degree ruminators (ruminators, mean age = 23.30 years, SD = 3.40 years; RRS score: 53.65 ± 8.89) and 38 low-degree ruminators (controls, mean age = 20.84 years, SD = 1.55 years; RRS score: 22.13 ± 0.34). We based the degree of rumination on the cutoff values specified in the [Rosenbaum et al. \(2018b\)](#) article: high-degree ruminators were defined as having a mean RRS score higher than 2.36 ($PR > 65$), while low-degree ruminators were defined as having an RRS score lower than 1.9 ($PR < 27$) ([Rosenbaum et al., 2018b](#)). Neutral items were also evaluated in comparison with the rumination items. The evaluation included seven dimensions: (1) repetition; (2) persistence; (3) associativity; (4) vividness; (5) uncontrolled nature; (6) assumption; (7) representativeness. The first six dimensions represent ruminative characteristics summarized from both our literature review and from interviews conducted with a large number of highly ruminative individuals. The last dimension, representativeness, reflects the extent to which an entry matched the subject's recall. These seven dimensions combine to represent the level of "scenario immersion" experienced by subjects while they were filling out the questionnaire. The demographic information of the 1,685 and 78 participants is shown in [Tables 3, 4](#), respectively.

EEG experimental procedures

EEG experiment participants

We recruited subjects from the 1,685 freshmen enrolled in the 2022 cohort of Shaanxi Police College to participate in the EEG experiment. Finally, 56 voluntary participants (mean age = 22.48 years, SD = 7.73 years) selected from the high-degree ruminators ($PR > 65$, RRS score: 63.79 ± 6.38) were recruited as

TABLE 4 Demographic information of the 78 participants who participated in the evaluation of the questionnaire (*n* = 78).

	Frequency/mean	Percentage/standard deviation
Gender (<i>n</i> , %)		
Women	0	0
Men	78	100
Age (mean ± SD)	22.10	2.92
Home location (<i>n</i> , %)		
Urban	33	42.31
Village	45	57.69
Ethnicity (<i>n</i> , %)		
Han	71	91.03
Others	7	8.97

the rumination group, while 29 voluntary participants (mean age = 20.59 years, SD = 1.64 years) ($PR < 27$, RRS score: 22.14 ± 0.44) were recruited as the control group. The exclusion criteria were as follows: (1) patients with a history of psychiatry; (2) patients who had been hospitalized in the psychiatric department; (3) patients with current or past use of antipsychotic drugs; (4) patients with a history of neurological disorders; (5) patients who were left-handed. The study was approved by the Ethics Committee of the Air Force Medical University and was conducted in accordance with the approved guidelines (Ethics Approval Number KY20193304-1). All participants provided their informed consent prior to undergoing the formal experiment and received a small amount of compensation.

Resting-state EEG data acquisition

Resting-state EEG data were collected for all subjects before the test. First, the subjects were instructed to sit down in front of a screen in a comfortable position, with their eyes distanced ~70 cm from the stimulating screen. When the subjects were ready, the experimenter instructed them to close their eyes for more than 1 min and then to open them for more than 1 min.

Task EEG data acquisition under material stimulation

After recording resting-state EEG data, the subjects were instructed to complete the exam using the 53-item questionnaire (containing 37 rumination items and 16 neutral items). Items were displayed on the screen randomly, with a fixed 500-ms plus sign separating each stimulus from the next. All items presented the same following question: "Does the above description induce you to have repeated/continuous recall?". The subjects selected "yes" or "no" as their response to this question using the mouse or keyboard. There were no time constraint for how long subjects were allowed to respond to each question. The item inquiry was completed as soon as the subject clicked the mouse to answer the questions.

EEG recording and data preprocessing

A 32-channel semi-dry electrode cap was used to record EEG data using a wireless multi-channel EEG acquisition device (ZhenTec NT1, ZhenTec Intelligence, China) (Yuan et al., 2021; Han et al., 2022). The sampling rate was 500 Hz. Data were referenced to CPz with a ground at FPz, and electrode placement followed the International 10-10 system. Impedance levels were set at <20 k Ω . The common mode rejection ratio was 120 dB, the input impedance was 1 G, and the input noise was <0.4 μ Vrms for all EEG channels.

For each subject, more than 2 min of resting-state EEG signals were recorded under two conditions: with eyes closed and with eyes open, with each condition lasting more than 1 min. Additionally, while participants completed the test items, EEG signals were acquired. All of the EEGs were pre-processed prior to the commencement of further research using the FildTrip (Version 20221122) (Oostenveld et al., 2011) toolbox implemented in MATLAB 2018b. We first checked the quality of the data and processed the band channel using the interpolation method. Both the resting state and task signals were notched by 50 Hz to remove power-line interference. Then, the EEGs were band filtered with a 1–100 Hz zero-phase band filter. Subsequently, the signals were divided into two 1-min epochs for the eyes-closed and eyes-open conditions for resting-state EEGs. We segmented the task EEGs into each item-related signal epoch based on the time markers of eye movements where signals were acquired simultaneously (53 items and 53 task signals for each participant in each channel). We manually checked and removed any data with large interference. The data were considered invalid if the faulty segments totaled more than five. The task EEG analysis was performed on 75 subjects—the average EEG length of the ruminator.

The remaining EEG data were then subjected to independent component analysis (ICA) to determine brain signals. Based on the spatial distribution and spectral power, FildTrip was used to find the independent components (ICs), including motor activity, eyeblinks, and ECG, which were then eliminated prior to further analysis.

EEG power analysis

After preprocessing, both the eyes-closed and eyes-open resting state signals were filtered into theta, delta, alpha, and beta bands. Then, we employed the “pwelch” function in MATLAB to calculate the spectral power during the resting state for all 30 channels in each of the four frequency bands: delta (0.5–4 Hz), theta (4–8 Hz), alpha (8–13 Hz), and beta (13–30 Hz).

Coherence analysis

Referring to the analysis method of a previous study by Bakker, we also adopted the coherence method to reflect the alternation in brain activity (den Bakker et al., 2018). The task EEG signals were then filtered into theta and gamma frequency bands (4–80 Hz). The bands were theta (4–8 Hz), alpha (8–13 Hz), beta (13–30 Hz), gamma1 (30–60 Hz), and gamma2 (60–80 Hz).

Subsequently, we employed the “mscohere” function in MATLAB to calculate magnitude-squared coherence, which reflects how well signal x corresponds to signal y at each frequency band. The “mscohere” function estimates the magnitude-squared coherence function using Welch’s overlapped averaged periodogram method (we used 512 points per window with 90% overlap). The coherence value of signals x and y $C_{xy}(f)$ was calculated as a function of the following: the spectral densities of signal x , which was denoted as $P_{xx}(f)$; the spectral densities of y , which was denoted as $P_{yy}(f)$; and the cross spectral density of x and y , which was denoted as $P_{xy}(f)$:

$$C_{xy}(f) = \frac{|P_{xy}(f)|^2}{P_{xx}(f)P_{yy}(f)}$$

Then, the coherence values were averaged across all pairs of electrodes over the brain for further analysis. We also calculated the average coherence in each band. To minimize the effects of volume conduction, we set the coherence of neighboring electrodes to zero before calculating the average coherence in each band (Peters et al., 2013; den Bakker et al., 2018).

Correlation between the coherence of EEGs and the arousal rate

The arousal rate of each participant induced by the rumination items was calculated as the proportion of “yes” responses given to the total number of rumination items. Finally, we adopted the Pearson correlation method to investigate the relationship between brain EEG coherence in different frequency bands and the arousal rate induced by the rumination items.

Statistical analysis

Both the behavior results and EEG characteristics were analyzed statistically using SPSS 26 (IBM). To examine the behavioral difference between the two groups across the two item types in each of the seven dimensions, a two-sample t -test was utilized. To determine the power differential of the resting-state EEGs in each frequency band, we utilized a two-way repeated ANOVA using the group and channel as factors. Mauchly’s test was applied to test for sphericity, while the Greenhouse–Geisser correction was used to correct the sphericity. The coherence in the five bands was then compared, both in-group and item-wise. The statistical method was also referred to in the previous study (den Bakker et al., 2018). For group-wise comparison, we first employed a two-way repeated ANOVA with the item type and band as factors to compare the averaged coherence across the brain. The difference between the rumination items and the neutral items was determined using the two-sample t -test, and Bonferroni’s correction was used for multiple comparisons ($p < 0.01$). We then adopted a two-way ANOVA using item type and frequency as factors to assess their differences in each frequency band (theta, alpha, beta, gamma1, and gamma2). For item-wise comparison, we set the group and band as factors and performed the same statistical procedure.

Results

Demographic information of the participants

Table 1 shows the demographic information of the 4,591 subjects who used the RRS. In this study, the total average score of the RRS was 31.57 ± 8.33 ($n = 4,591$), and Cronbach's α coefficient for this scale was 0.925 ($n = 4,591$).

Table 2 shows the demographic information of the 607 high-degree ruminators (577 men and 30 women) who participated in the semi-structured interviews.

Table 3 shows the demographic information of the 1,685 subjects. In this part, the total average score of the RRS was 28.64 ± 6.97 ($n = 1,685$), and Cronbach's α coefficient for this scale was 0.925 ($n = 1,685$).

Table 4 shows the demographic information of the 78 chosen subjects from the 1,685 pool of subjects who completed the questionnaire.

Table 5 shows the demographic information of the 75 participants who were recruited for the following EEG experiment.

Natural language feature adaptation paradigm

Using NLP techniques, we identified 17 ruminative scenario themes and constructed 37 ruminative arousal-inducing items (including 28 social dilemmas and 9 personal injuries). The validation results for the rumination questionnaire showed that the main effects of the item types were significant in all dimensions ($p < 0.001$). Further simple effect analysis showed that the ruminators' scores on rumination items were higher than those of the control group ($p < 0.05$), while the rumination group scores of the neutral items were no different from those of the control group (Figure 1). This result confirmed the effectiveness and reliability of the rumination items.

TABLE 5 Demographic information of the 75 participants who participated in the EEG study ($n = 75$).

	Frequency/mean	Percentage/standard deviation
Gender (n, %)		
Women	0	0
Men	75	100
Age (mean \pm SD)	21.75	6.18
Home location (n, %)		
Urban	23	30.67
Village	52	69.33
Ethnicity (n, %)		
Han	66	88.00
Others	9	12.00

The reaction time was longer in ruminators for rumination items

The ANOVA of the two groups and item type revealed that the main effect of the two groups was not significant [$F_{(1,73)} = 0.792$, $p = 0.377$, $\eta^2 = 0.11$], while the main effect of the item type was significant [$F_{(1,73)} = 107.968$, $p < 0.001$, $\eta^2 = 0.597$], reflecting that the reaction time of rumination items was longer than that of the neutral items. Additionally, a significant interaction between item type and person category was found [$F_{(1,73)} = 31.901$, $p < 0.001$, $\eta^2 = 0.304$]. Therefore, further simple effects analysis was conducted, and the results are as follows (Table 6).

The results of the simple effects analysis showed that the response time of the ruminators while engaging with rumination items was longer than that of the control group ($df = 73$, $p < 0.01$), while the response time of the ruminators while engaging with neutral items did not differ from that of the control group. This result further verified the effectiveness of the ruminative questionnaire in inducing the ruminators to immerse themselves in and resonate with the different scenarios established by the questionnaires.

The arousal rate was significantly higher in ruminators for rumination items

In the questionnaire response task, whether for the rumination items or the neutral items, we set the same following question: "Does the above description induce you to have repeated/continuous recall?". This question reflects the core definition of the concept of rumination. Therefore, we interpreted the choice of "yes" to mean that the participants were aroused by the scenario. Conversely, participants who chose "no" were not considered to be aroused.

Arousal rate: the arousal rates elicited by the two item types were calculated as the proportion of the given response "yes" to the total for each kind of item (i.e., the number of "yes" responses given in rumination items/the total number of rumination items).

The main effect of the two groups was found to be significant, $F_{(1,73)} = 32.554$, $p < 0.001$, $\eta^2 = 0.308$, and the arousal rate of the ruminators was higher than that of the control group. The main

effect of the item type was also significant, $F_{(1,73)} = 82.300$, $p < 0.001$, $\eta^2 = 0.530$, and the arousal rate for the rumination items was higher than that for the neutral items. The main effect of the item type and group was found to be significant, $F_{(1,73)} = 82.300$, $p < 0.001$, $\eta^2 = 0.530$, and was higher than that of the neutral items. A significant interaction of the item type with the two groups was found [$F_{(1,73)} = 46.382$, $p < 0.001$, $\eta^2 = 0.389$]. Therefore, further simple effects analysis was conducted, and the results are as follows (Table 7).

The results of the simple effects analysis showed that, for the rumination items, the arousal of the ruminators was significantly higher than that of the control group ($df = 73$, $p < 0.001$), while for the neutral items, the arousal of the ruminators did not differ from that of the control group. This finding indicates that the rumination items constructed in this study targeted the recall of the rumination group and thus triggered continuous and repeated recall.

TABLE 8 Average EEG length (time points) of the two types of items in different groups ($\bar{x} \pm SD$).

Type of item	Ruminators ($n = 46$)	Controls ($n = 29$)
Rumination	6,750 \pm 1,993	7,124 \pm 2,146
Neutral	6,695 \pm 2,274	6,709 \pm 1,963

The brain power of normal subjects and high-degree rumination subjects were highly similar

The topography of the two groups in terms of the absolute power of each frequency band is depicted in Figure 2. In both the eyes-closed and eyes-open conditions, the two-way ANOVA did not reveal any group differences.

The coherence of the whole brain was decreased while engaging with the rumination items

Table 8 shows the average EEG length of each group in different kinds of items. No significant differences were found in the length of EEG data either in groups or items.

As shown in Figure 3, the coherence of the whole brain was decreased in both groups while engaging with the rumination items compared to the neutral items in the test. In the rumination group, the two-way repeated ANOVA revealed a significant main effect on the item type [$F_{(1,90)} = 9.445$, $p = 0.003$]. Additionally, a no item \times frequency band interaction effect was found [Greenhouse-Geisser corrected, $F_{(1.452,130.724)} = 0.271$, $p = 0.691$]. All the two-sample t -tests for *post hoc* analysis satisfied the test of homogeneity of variance ($p > 0.05$) and revealed that the coherence decreased significantly in the theta (two-tail, $t = -3.373$, $df = 90$, $p = 0.001$), alpha ($t = -2.827$, $df = 90$, $p = 0.006$), beta ($t = -3.287$, $df = 90$, $p = 0.001$), and gamma1 ($t = -2.649$, $df = 90$, $p = 0.01$) bands. In the subjects from the control group, there was no significant effect of the item type [$F_{(1,56)} = 1.724$, $p = 0.195$] and no item type \times frequency band interaction effect [Greenhouse-Geisser correction, $F_{(1.583,88.654)} = 0.015$, $p = 0.967$]. The two-sample t -test showed no significant change in the coherence in the five bands while engaging with the two kinds of items in the normal subject group.

The coherence of the whole brain increased in the rumination group

Next, we assessed the difference in coherence between the subjects from both groups while they were engaged with the two kinds of items. As shown in Figure 4, the coherence of all frequency bands increased [main effect of group $F_{(1,73)} = 4.916$, $p = 0.030$, no group \times frequency band interaction effect, $F_{(1.496,109.172)} = 0.834$, $p = 0.407$, Greenhouse-Geisser corrected], especially for the

beta (two-tail, $t = 2.301$, $df = 71.088$, $p = 0.017$) and gamma2 (two-tail, $t = 2.411$, $df = 72.953$, $p = 0.018$) bands while the subjects were engaged with the rumination test. It is worth noting that the two groups showed a significant difference while interacting with the neutral items [main effect of group $F_{(1,73)} = 16.844$, $p < 0.000$, no group \times frequency band interaction effect, $F_{(1.538,112.238)} = 1.467$, $p = 0.235$, Greenhouse-Geisser corrected]. As Figure 4D shows, significantly increased coherence emerged in all frequency bands (two-tail: theta, $t = 4.698$, $df = 72.949$, $p < 0.000$; alpha, $t = 4.160$, $df = 72.224$, $p < 0.000$; beta, $t = 4.684$, $df = 72.210$, $p < 0.000$; gamma1, $t = 3.446$, $df = 71.754$, $p = 0.001$, and gamma2, $t = 4.057$, $df = 72.662$, $p < 0.000$) in ruminators engaging with the neutral items compared to the normal subjects. This phenomenon may have been due to the decreasing speed of the ruminative mood. This will be discussed later.

The arousal rate was only significantly correlated with the coherence of the gamma2 frequency band

We conducted a Pearson correlation analysis to identify the relationship between the arousal rate induced by the rumination items and the EEG coherence of different frequency bands. We only found a significant correlation for the gamma2 band ($r = 0.231$, $p = 0.046$).

Discussion

In this study, we first developed an immersive rumination-inducing questionnaire that could elicit situational recall in ruminators using NLP combined with scales, interviews, and “scenario immersion” theory. The results of behavioral indicators revealed that, for the rumination items of the questionnaire, the average reaction time was longer for the ruminators, and their arousal rate was significantly higher than that of the subjects in the control group. Then, we used EEG techniques to investigate whether the immersive ruminative questionnaire could induce certain neural activities, specifically in the ruminators. The resting-state EEG results showed that there was no difference in the power of the brain between the ruminators and the control group. However, the EEG coherence analysis showed that the brain activity of the ruminators was significantly higher than that of the control group for the rumination items. Combined with the behavior result and EEG evidence, the immersive ruminative questionnaire developed with natural language features and the scenario immersion theory was successful in eliciting more immersive ruminative thinking, specifically in the ruminators. In conclusion, the questionnaire based on NLP appears to be suitable as a novel paradigm for psychological selection in the early detection of mental disorders.

The immersive ruminative questionnaire elicited immersive ruminative thinking, specifically in the ruminators

Previous studies have used various methods to induce rumination, including short statement prompts (Cooney et al., 2010; Berman et al., 2014; Milazzo et al., 2016), texts extracted from Wikipedia (Curci et al., 2015), characteristic words (Yoshimura et al., 2009; Moran et al., 2014; Apazoglou et al., 2019), music clips (Figuerola et al., 2017), self-reports (Rosenbaum et al., 2018a), emotive facial expressions (Aker et al., 2014), goal prompting tasks (Zhan et al., 2017; Mollaahmetoglu et al., 2021), videos (Bostanov et al., 2018), and other materials. However, it remains unclear whether these methods successfully induce subjects' rumination. Natural language is the first means by which humans express their thoughts and rapidly communicate accurately (Sun et al., 2013; Lee et al., 2014). Written materials pertaining to specific episodic memories represent one of the most effective forms of content to induce rumination (Haque

et al., 2014; Wilson-Mendenhall et al., 2019). Rapidly developing NLP technology and "scenario immersion" theory provide us with technical support and a theoretical basis for constructing state-inducing questionnaires.

In this study, we used the natural language corpus of 607 ruminators and NLP to develop a mental state-eliciting questionnaire that could elicit situational memories according to "scenario immersion" theory to activate the unique ruminative state of rumination-prone individuals both effectively and accurately. The evaluation results showed that the scores of ruminators were significantly higher than those of the control group only on the rumination items in all dimensions. On the contrary, there was no significant difference between the neutral items. Therefore, the results indicate that the ruminators agreed with the scenario description constructed by the rumination items, which could not only trigger repeated, vivid, and continuous negative immersive memories but was also highly representative of ruminative elicitation. In other words, the questionnaire we developed could elicit immersive ruminative thinking in ruminators.

The rumination items were capable of inducing brain activity in ruminators

The analysis of EEG power in the four frequency bands revealed no significant difference between the ruminators and the control group while they were at rest, indicating that there was no difference in brain activity between the ruminators and the control group in this state, which might be a contributing factor to the difficulty of diagnosing depression during its nonclinical state.

EEG coherence is a measure of synchronization of the two recorded EEG signals and has been widely used to indict the dysregulation of the human brain (den Bakker et al., 2018; Minami et al., 2022; Wang et al., 2022). We examined the task EEG data from both the item type aspect and group aspect to study if the different items could elicit different brain activities in the two groups. First, we discovered that EEG coherence decreased in both groups while subjects engaged with the rumination items. The ruminators presented a significantly greater decrease

in the theta, alpha, beta, and gamma frequency bands. Although a slight decrease was also observed in the control group, no statistically significant differences were identified for any of the frequency bands. EEG coherence reflects the synchronization between brain cortical regions (Markovska-Simoska et al., 2018), whereby the observed significant decrease in the coherence of the whole brain indicates that the rumination items caused more dyssynchronization of the whole brain in the ruminators, thereby demonstrating that the questionnaire was capable of inducing ruminative thinking in these subjects. We also discovered that the EEG coherence of the ruminators dramatically increased both in the beta and gamma2 bands compared to the control group while engaging with the rumination items. In the ruminators, this aberrantly elevated coherence may indicate a decreased inhibitory ability of the brain, which might be caused by a depressed state of mind (Cheng et al., 2016), excessive self-focus, and the recall of unpleasant memories that the rumination items elicited (Berman et al., 2011; Zamoscik et al., 2014). The hyper-synchronization in the beta band combined with the longer reaction time suggests

that the attention ability was damaged in the ruminators (Li et al., 2017). As the EEG gamma band has been shown to be related to emotions (Li et al., 2015), the increased coherence observed in the gamma2 band provides evidence that the rumination items induced an unpleasant mood in the ruminators. Finally, we found that the coherence of the whole brain in the five frequency bands increased significantly, which can be explained by the phenomenon where the influence of the rumination items did not subside immediately in the ruminators but instead was prolonged to influence the brain activity of these subjects while they were engaged with the neutral items. This also indicates a decline in their ability to control the brain after engaging with the rumination items.

The above findings showed that ruminators are more susceptible to negative scenarios, such as poor memories, bad moods, and inaccurate self-referential thinking. Over the past several years, studies have been conducted to identify the neurological bases of rumination in both clinical and nonclinical psychological diseases with the goal of developing potential biomarkers for the diagnosis and therapy of rumination-related mood disorders such as depression (Zhang et al., 2020), euthymic bipolar disease (Apazoglou et al., 2019), posttraumatic stress disorder (Philippi et al., 2020), and so on. Prior fMRI and EEG studies revealed that rumination is associated with altered brain functional connectivity, both increased (Benschop et al., 2020) and decreased (Tozzi et al., 2021). According to some studies, ruminators process self-related information excessively when exposed to external, which may be related to the overactive core subsystem in the default mode network (Lin et al., 2022), particularly the functional connectivity to the prefrontal cortex, which can be a useful neural marker to identify an individual at risk for depression (Benschop et al., 2020). Consistent with the findings of previous studies, we found that the EEG coherence of the whole brain increased significantly in the ruminators, suggesting that, through situational immersion, the questionnaire we developed can elicit excessive processing of self-related information in the high ruminators. This result indicates the validity of the questionnaire we developed. However, more research is required to determine the neurological mechanisms underlying the brain alteration that the questionnaire elicited, i.e., the prefrontal cortex activity and the relationship between different brain networks, which might be used as a neural marker of ruminative thinking.

Limitations

There are some limitations to this study. First, all the participants were men due to the nature of the police academy. Although it is widely acknowledged that women tend to ruminate more than men do, one review reported that both men and women showed strong and significant statistical correlations between depressive symptoms and ruminative thoughts ($\rho > 0.50$; $p < 0.05$), suggesting that the relationship between depressive symptoms and rumination does not necessarily explain the sex differences observed in depression (Shors et al., 2017). Hence, further study is required to explore the responses of women. Moreover, since all the subjects were enrolled in the Shaanxi Police College, more subjects will be needed from the general

population in the following experiment. Second, the EEG evidence of ruminative thoughts from the perspective of the entire brain was the focus of this study, while specific brain regions or brain networks should be considered to identify the neuromechanism underlying rumination. Finally, neural biomarkers of rumination may be used to predict ruminators, which would be of great significance in psychological selection. In the future, we will explore the predictive power of the rumination items and EEG data.

Data availability statement

The original contributions presented in the study are included in the article/Supplementary material, further inquiries can be directed to the corresponding authors.

Ethics statement

The studies involving human participants were reviewed and approved by Ethics Committee of the Air Force Medical University. The patients/participants provided their written informed consent to participate in this study.

Author contributions

YuL contributed to the development of the questionnaire and completed the whole experiment. CL analysis the EEG data and wrote the manuscript. TZ and LWu contributed to revision of the manuscript. XL, YiL, and LWa helped to analyze the questionnaire behavior data. DL and HY contribute big work to the experiment. DM and PF organized and managed the whole experiment and manuscript. All authors contributed to the article and approved the submitted version.

Spinal cord injury is a serious traumatic disease. As Ferroptosis has been increasingly studied in recent years, it has been found to be closely related to the pathophysiological processes of spinal cord injury. Iron overload, reactive oxygen species accumulation, lipid peroxidation and glutamate accumulation associated with Ferroptosis are all present in spinal cord injury, and thus Ferroptosis is thought to be involved in the pathological processes secondary to spinal cord injury. This article highlights the relationship between Ferroptosis and spinal cord injury, lists substances that improve spinal cord injury by inhibiting Ferroptosis, and concludes with a discussion of the problems that may be encountered in the clinical translation of Ferroptosis inhibitors as a means of enabling their faster use in clinical treatment.

KEYWORDS

spinal cord injury, Ferroptosis, Ferroptosis inhibitors, clinical translation, animal models

1. Introduction

Spinal cord injury (SCI) is a serious traumatic condition (Quadri et al., 2020) that is most commonly caused by car accidents and falls (Zipser et al., 2022). The global incidence rate is 10.4–83 cases per million per year (Karsy and Hawryluk, 2019), and SCI is associated with a high rate of disability and mortality (Chen C. et al., 2022), placing a severe physical burden on the patient. In addition, SCI is associated with a higher incidence of psychological disorders such as depression and anxiety than the general population (Hearn and Cross, 2020). The annual cost of treatment and care for each SCI patient has been reported to be as high as US\$77,334 (Lo et al., 2021). However, in current clinical management, the treatment of SCI mainly includes surgery and related anti-inflammatory and anti-swelling medication (Liu X. et al., 2021). However, due to the complex pathophysiological process of SCI, the current treatment outcome is not satisfactory. Therefore, it is particularly important to explore the pathological process of SCI and new treatment methods.

Ferroptosis is a type of programmed cell death (PCD) (Shi et al., 2021). Its main mechanism is to catalyze the lipid peroxidation of polyunsaturated fatty acids (PUFA) highly expressed on cell membranes in the presence of divalent iron (Fe^{2+}) or lipoxygenase (LOX), thereby inducing cell death (Ursini and Maiorino, 2020). It is mainly characterized by a decrease in the core enzyme glutathione peroxidase 4 (GPX4), the regulatory core of the antioxidant system glutathione (GSH) system (Wu et al., 2021). In recent years, Ferroptosis has been extensively studied in a number of conditions including cardiovascular disease (Wu et al., 2021), renal disease (Ni et al., 2022), and neurological disorders (Song and Long, 2020).

The pathological process of SCI is divided into primary and secondary injury (Shen and Cai, 2023), with primary injury being irreversible and secondary injury being reversible (Liu X. et al., 2021). Secondary injury is a cascade amplification response triggered by primary injury, which is divided into three stages: acute, subacute, and chronic injury, manifested as post-traumatic inflammatory response, free radical formation, and PCD of cells (Alcántar-Garibay et al., 2022). While PCD includes autophagy, necroptosis, cell scorching, and Ferroptosis, among others (Li et al., 2022), and it has been recently demonstrated that iron overload (Gong et al., 2022), ROS accumulation (Feng et al., 2021), lipid peroxidation (Baazm et al., 2021), and glutamate accumulation (Zhao et al., 2022) associated with Ferroptosis are all present in SCI, it is therefore suggested that Ferroptosis may be involved in the pathological process of secondary injury associated with SCI.

There is a large body of literature that demonstrates the close association of Ferroptosis with SCI, but very little literature that specifies the involvement of Ferroptosis in the pathological process of SCI. There is also little literature summarizing the substances that repair SCI by inhibiting Ferroptosis. And there is no literature that identifies the problems that may arise in the clinical translation of Ferroptosis inhibitors associated with SCI. This review therefore first describes the basic process of Ferroptosis and its close relationship with SCI, then briefly outlines the substances currently available to ameliorate SCI by inhibiting Ferroptosis, thus demonstrating that Ferroptosis is involved in the pathophysiology of SCI and that we can repair SCI by inhibiting Ferroptosis. Finally, this review discusses the problems that may be encountered in the clinical translation of Ferroptosis inhibitors associated with SCI and looks at the future direction of Ferroptosis research in SCI. It opens up a new way of thinking for the treatment of SCI.

2. The basic process of Ferroptosis and its relation to SCI

2.1. Iron metabolism

Iron is one of the important trace elements essential to the human body (Das et al., 2020). Abnormal iron metabolism is an important cause of Ferroptosis. When intracellular iron is overloaded, on the one hand, large amounts of Fe^{2+} undergo Fenton reaction with hydrogen peroxide (H_2O_2), generating hydroxyl radicals with stronger oxidative capacity, thus increasing intracellular levels of reactive oxygen species (ROS) and promoting lipid peroxidation and ultimately Ferroptosis (Liu J. et al., 2022). On the other hand, Fe is a cofactor that enhances the activity of various metabolic enzymes such as LOX, which directly catalyze lipid peroxidation and induce Ferroptosis (Tang D. et al., 2021; Figure 1).

Basic experiments have found that in animal models of SCI, there is massive erythrocyte rupture at the site of injury, which can be observed as early as 1 h after injury and more commonly at 24 h (Wang Z. et al., 2022). In contrast, massive bleeding leads to increased iron concentrations at the site of injury (Gong et al., 2022), followed by Ferroptosis from ROS accumulation (Feng et al., 2021). Other researchers conducted *in vivo* and *in vitro* experiments with SCI rats and primary cortical neurons and found that there

was significant microglia activation in the motor cortex after SCI resulting in the release of excess nitric oxide (NO), and that the large amount of NO interfered with the expression of proteins related to iron metabolism, ultimately leading to iron overload in the motor cortex of SCI rats at 4 weeks, resulting in ROS accumulation leading to neuronal Ferroptosis (Feng et al., 2021). Furthermore, the researchers found that iron deposition in the motor cortex was significantly increased in SCI patients compared to healthy controls. This triggered the accumulation of ROS, lipid peroxidation, mitochondrial atrophy and dysregulation of genes related to Ferroptosis, which ultimately led to Ferroptosis in motor neurons (Feng et al., 2021). And there are also many neurological disorders such as stroke (Cao et al., 2018), traumatic brain injury and neurodegenerative diseases (Daglas and Adlard, 2018) whose pathogenesis is linked to iron overload in the brain.

2.2. Lipid metabolism

Studies have shown that the polyunsaturated fatty acid (PUFA) family of arachidonic acid (AA)/adrenaline (AdA) undergoes acylation and lipidation to phosphatidylethanolamine-polyunsaturated fatty acids [Phosphatidyl Ethanolamine (PE-PUFA)] (Kagan et al., 2017). Ultimately PE-PUFA is involved in the downstream process of Ferroptosis, which can be divided into two pathways: (i) non-enzymatic oxidation (Conrad and Pratt, 2019) and (ii) enzymatic oxidation. Non-enzymatic reactions involve the Fenton reaction involving Fe^{2+} to produce hydroxyl radicals ($\text{HO}\cdot$) that deprive lipids of H- to form lipid radicals, which then form lipid peroxides, leading to lipid peroxidation leading to Ferroptosis (Conrad and Pratt, 2019). In contrast, two pathways have been identified for enzymatic oxidation reactions. One is the formation of oxides PE-PUFA-OOH and related derivatives such as malondialdehyde (MDA) and 4-hydroxynonenal (4-HNE), which in turn react with DNA bases, proteins and other nucleophilic molecules, catalyzed by LOX leading to severe cytotoxicity (Kagan et al., 2020). Another pathway is the promotion of lipid peroxidation by cytochrome P450 oxidoreductase (POR), which leads to Ferroptosis (Zou et al., 2020; Figure 1).

It has been shown that the spinal cord contains high levels of polyunsaturated fatty acids, which have been shown to be involved in the oxidative stress response following SCI (Baazm et al., 2021). Studies on the regulation of SCI by unsaturated fatty acids such as short-chain fatty acids (SCFA) have been widely reported in recent years (Filippone et al., 2020). Thus suggesting that lipid metabolism in Ferroptosis may be involved in the pathological process of SCI. And SCFAs are also major metabolites produced by fermentation of dietary fiber bacteria in the gastrointestinal tract. It has been shown that SCFAs can directly or indirectly affect the brain-gut axis and have a mediating role in the microbiota-gut-brain axis (Dalile et al., 2019). Moreover, SCFAs is also a metabolite of intestinal bacteria and its concentration depends on the composition of the intestinal microbial population (Markowiak-Kopeć and Śliżewska, 2020). In contrast, Ferroptosis is an emerging mode of cell death in which lipid metabolism plays a crucial role (Conrad and Pratt, 2019). We therefore speculate that Ferroptosis, intestinal flora and the brain-gut axis may be linked around lipid metabolism as a regulatory factor, which may also provide some ideas and directions for future studies.

FIGURE 1

Mechanism of Ferroptosis. Fe³⁺ binds to TF on the cell membrane and is transported via TFR1 on the cell membrane surface, and the TFR1-TF-Fe³⁺ complex enters the cell by endocytosis. Under acidic conditions, Fe³⁺ is released from the binding and reduced by STEAP3 to Fe²⁺, which then enters the cytoplasm via DMT1 from the endosome. In the cytoplasm Fe²⁺ is partly transported outside the cell and converted to Fe³⁺ by FPN1, partly bound to ferritin to form LIP, and NCOA4 can recognize and rely on the autophagic pathway to degrade ferritin in the iron pool, releasing large amounts of Fe²⁺. TF, transferrin; TFR1, transferrin receptor1; STEAP3, six-transmembrane epithelial antigen of prostate 3; DMT1, divalent metal transporter 1; FPN1, membrane iron transporter 1; FPN1, ferroportin1; FTL, ferritin light chain; FTH, ferritin heavy chain; LIP, labile iron pool; NCOA4, nuclear receptor coactivator 4; H₂O₂, hydrogen peroxide; ACSL4, acyl-CoA synthetase long-chain family member 4; LPCAT3, lyso-phosphatidylcholine acyltransferase-3; LOX, lipoxygenase; MDA, malondialdehyde; 4-HNE, 4-hydroxynonenal; POR, cytochrome P450 oxidoreductase; IREB2, iron-responsive element-binding protein 2; HSPB1, heat shock protein beta-1; IRP, iron-regulatory protein; HIF-1, hypoxia-inducible factor-1; HO-1, heme oxygenase-1.

2.3. System Xc-GSH-GPX4 axis

The cystine/glutamate antiporter (System Xc-) transports glutamate out of the cell and transports cystine into the cell, where the transported cystine is reduced to cysteine (Parker et al., 2021) and then combined with glutamate and glycine in the presence of glutathione synthetase (Wu et al., 2022) (GPX4 is a selenocysteine-containing and GSH-dependent enzyme that is a key regulator of Ferroptosis (Seibt et al., 2019). It converts GSH to oxidized glutathione (GSSG) and reduces lipid peroxidation, thereby reducing lipid peroxide formation and oxidative stress damage and ultimately inhibiting Ferroptosis (Forcina and Dixon, 2019; Figure 2). Currently modulating cystine uptake, interfering

with GSH and the expression of GPX4 remain the most common means of Ferroptosis in basic research.

One study found that GPX4 knockout-induced degeneration of spinal motor neurons exhibits Ferroptosis, and when supplemented with the Ferroptosis inhibitor vitamin E delayed the onset of paralysis and death in GPX4 knockout-induced mice (Chen et al., 2015). And some researchers have observed downregulation of GPX4 and upregulation of acyl-CoA synthetase long-chain family member 4 (ACSL4) in the acute phase of an animal model of SCI (Zhou et al., 2020). It can therefore be hypothesized that the pathological process of SCI is closely related to the Xc-GAH-GPX4 axis, a protective mechanism system for Ferroptosis.

FIGURE 2

Protection mechanism for Ferroptosis. SLC7A11, recombinant solute carrier family 7, member 11; SLC3A2, recombinant solute carrier family 3, member 2; GSS, glutathione oxidized; GCL, glutamate cysteine ligase; GSH, glutathione; GPX4, glutathione peroxidase 4; GR, glutathione reductase; GSSG, glutathione oxidized; NADPH: nicotinamide adenine dinucleotide phosphate; NADP, nicotinamide adenine dinucleotide phosphate; FSP1, Ferroptosis inhibitory protein 1; CoQ10, Coenzyme Q10; DHODH, dihydroorotate dehydrogenase; CoQ Coenzyme Q; GCH1, GTP cyclohydrolase-1; BH4, tetrahydrobiopterin; IPP, isopentenyl pyrophosphate; MVA, mevalonate; Nrf2, nuclear factor erythroid 2-related factor 2.

2.4. NADPH-FSP1-CoQ10 pathway

CoQ10 is a lipophilic free radical trapping antioxidant that blocks the delivery of lipid peroxides and thus inhibits Ferroptosis (Liu J. et al., 2021). The glutathione non-dependent Ferroptosis inhibitory protein (Ferroptosis inhibitory protein 1, FSP1) is one of the redox enzymes of coenzyme Q10 (CoQ10), and FSP1 can, in the presence of reduced coenzyme II (nicotinamide adenine dinucleotide phosphate, NADPH) to reduce CoQ10 to reduced coenzyme Q10 (CoQ10H2) and also catalyze the regeneration of CoQ10 via NAD(P)H (Santoro, 2020; Figure 2).

It has been found that in animal models of SCI, the IncGm36569/miRNA-5627-5p/FSP1 axis was inhibited by molecular sponge action and thus targeting of the IncGm36569/

miRNA-5627-5p/FSP1 axis to inhibit neuronal Ferroptosis (Shao et al., 2022). In the NADPH-FSP1-CoQ10 pathway, FSP1 has already been reported in basic studies at the molecular level as another target protein for Ferroptosis. Future studies on FSP1 may not only target the molecular level, but also natural and synthetic drugs that interfere with FSP1 expression may be one of the hot spots for future Ferroptosis studies.

2.5. DHODH-CoQH2 pathway

The dihydroorotate dehydrogenase-dihydroubiquione (DHODH-CoQH2) pathway is the third major Ferroptosis protection system on mitochondria in addition to the GPX4

pathway on the cytoplasm and mitochondria and the FSP1 pathway on the plasma membrane (Mao et al., 2021). CoQH2 acts as an antioxidant to eliminate lipid peroxyl radicals and thus inhibit Ferroptosis (Mao et al., 2021; Figure 2). Little linkage of SCI to this pathway has been reported and future studies could focus on this pathway.

2.6. GCH1-BH4 pathway

The GTP cyclohydrolase-1-tetrahydrobiopterin (GCH1-BH4) pathway is a lipid antioxidant pathway independent of the Xc-GSH-GPX4 axis and the NADPH-FSP1-CoQ10 pathway (Liu M. et al., 2022). GTP cyclohydrolase-1 (GTP Cyclohydrolase-1, GCH1) is a rate-limiting enzyme of BH4 (Larbalestier et al., 2022). overexpression of GCH1 enhances the production of BH4 (Kraft et al., 2020), a potent free radical-trapping antioxidant that protects cells from Ferroptosis by reducing lipid peroxidation (Vasquez-Vivar et al., 2022; Figure 2).

It has been shown that the GCH1-BH4 metabolic pathway is a protective mechanism for cellular Ferroptosis and that GCH1 inhibitors are a novel therapeutic measure for the treatment of colorectal cancer (Hu et al., 2022). However, this pathway has been largely unreported in SCI, and the development of related studies will certainly enhance the emerging field of Ferroptosis.

2.7. The MVA pathway

The mevalonate (MVA) pathway plays a key role in the regulation of Ferroptosis (Yao et al., 2021). the MVA pathway can influence GPX4 synthesis by regulating the maturation of selenocysteine tRNA (Warner et al., 2000), while CoQ10 can be synthesized using acetyl-coenzyme A (Acetyl-CoA) via the MVA pathway (Ball et al., 2021). The MVA pathway therefore links the Xc-GSH-GPX4 axis and the NADPH-FSP1-CoQ10 pathway (Figure 2). However, little research has been reported on the inhibition of Ferroptosis and thus repair of SCI through modulation of the MVA pathway. In contrast, MVA, as a synthetic precursor of cholesterol (Guerra et al., 2021), also has a considerable role in lipid metabolism. The MVA pathway therefore re-emphasizes the role of lipid metabolism in Ferroptosis. Aerobic oxidation, glucose metabolism and lipid metabolism play a crucial role in life activities, all three being interconnected and independent of each other. The role of lipid metabolism in Ferroptosis has been widely reported (Baazm et al., 2021). In contrast, the role of aerobic oxidation and sugar metabolism in Ferroptosis has hardly been reported. Some researchers have found that the role of both the mitochondrial tricarboxylic acid cycle (TCA cycle) and the electron transport chain (ETC) is required for Ferroptosis, and that the mitochondrial ETC can regulate Ferroptosis induced by cysteine deprivation. In contrast, the mitochondrial TCA cycle can be involved in cysteine deprivation-induced Ferroptosis (Gao et al., 2019). In turn, the tricarboxylic acid cycle is the ultimate metabolic pathway for the three major nutrients (sugars, lipids, and amino acids) and is the hub for the metabolic linkage of sugars, lipids, and amino acids (Martinez-Reyes and Chandel, 2020). We therefore hypothesize that aerobic

oxidation as well as sugar metabolism may also have an integral role in Ferroptosis. Future studies that focus on this will be of great significance for Ferroptosis and related areas of research.

2.8. Nrf2

Nuclear factor erythroid 2-related factor 2 (Nrf2) is an important anti-oxidative stress transcription factor that improves cellular tolerance to oxidative stress (He et al., 2020). It has been shown that its downstream target proteins and enzymes include (i) proteins related to iron metabolism: ferritin light chain (FTL), ferritin heavy chain (FTH), and ferroportin1 (FPN1), which is responsible for iron transport (Chen et al., 2021). (ii) Enzymes related to NADPH regeneration: glucose-6-phosphate dehydrogenase (G-6-PD), phosphogluconate dehydrogenase (PGD), and malic enzyme (ME) (Zhang H. S. et al., 2019). ME (Zhang H. S. et al., 2019), and NADPH regeneration is essential for GPX4 activity. (iii) Proteins and enzymes related to GSH metabolism: Solute Carrier Family 7 Member 11 (SLC7A11), a subunit of the cystine/glutamate transporter protein xCT (Dong et al., 2020) and GSS (Zheng et al., 2014). All these proteins and enzymes are involved in the regulation of Ferroptosis and therefore Nrf2 is considered a key regulator of Ferroptosis (Dodson et al., 2019) and has been a star target in Ferroptosis studies in recent years (Figure 2).

In summary, the two most critical targets for the inhibition of Ferroptosis initiation, xCT and GPX4, have been modulated by NRF2. It has also been shown that Nrf2 can be used to regulate Ferroptosis to treat neurodegenerative diseases (Song and Long, 2020), delay the progression of diabetic nephropathy (DN) (Li S. et al., 2021) and prevent acute lung injury due to intestinal ischemia/reperfusion (Dong et al., 2020), and it has been found that proanthocyanidins (Zhou et al., 2020), alginose (Gong et al., 2022), metformin (Wang H. et al., 2020), and growth differentiation factor-15 (Xia et al., 2022) are all inhibited by NRF2. These materials have been found to inhibit Ferroptosis through the Nrf2 pathway to treat SCI, but the specific downstream target proteins and enzymes that these substances affect through the Nrf2 pathway to inhibit Ferroptosis to treat SCI have not been clearly investigated. The above-mentioned roles of Nrf2 in various diseases demonstrate the importance of the Nrf2 pathway in Ferroptosis, which suggests that we need to focus more on the star targets such as Nrf2 in future Ferroptosis research, especially in the study of novel drugs, which may play an indispensable role in the application of Ferroptosis-related drugs and the treatment of related diseases.

3. Related substances that improve SCI by inhibiting Ferroptosis

3.1. Natural materials

3.1.1. Proanthocyanidins

Proanthocyanidins (PACs), often extracted from grape seeds, are potent free radical scavengers (Wang C. et al., 2022). PACs have been shown to promote recovery of motor function in rats with SCI (Liu W. Z. et al., 2022). And in 2020 an investigator

found that proanthocyanidins promote recovery of motor function in SCI mice by inhibiting Ferroptosis (Zhou et al., 2020). PACs inhibit the recovery of motor function in SCI mice by upregulating the expression of GSH, GPX4, Nrf2, and HO-1 and downregulating the expression of iron, ACSL4 and thiobarbituric acid reactive substances (TBARS). TBARS expression to suppress Ferroptosis in the microenvironment at the site of injury (Zhou et al., 2020). However, PACs treatment had no significant effect on the expression of Recombinant Lysophosphatidylcholine Acyltransferase 3 (LPCAT3) levels in SCI, so it is uncertain whether PACs inhibit Ferroptosis by affecting AA/AdA levels and further studies are needed. further study.

3.1.2. Epigallocatechin gallate

Epigallocatechin gallate (EGCG) is a catechin isolated from green tea. It has very strong antioxidant activity, at least 100 times more active than vitamin C (Tang G. et al., 2020). EGCG has been shown to have neuroprotective effects in SCI (Wang F. et al., 2022). Zhang H. S. et al. (2019) researchers found that EGCG can upregulate the expression of GPX4 and FTH1 and downregulate the expression of ACSL4, thereby inhibiting Ferroptosis to promote recovery of motor function in rats after spinal cord transection (ST). Thus, EGCG may have a very good future as a promising novel natural substance in the clinical treatment of SCI.

3.1.3. Carnosic

Carnosic acid is a natural phenolic diterpene that can be extracted from rosemary (Satoh et al., 2022). Cheng et al. (2021) showed that Carnosic acid could down-regulate the expression of iron, ROS and MDA and up-regulate the expression of GSH in Erastin-treated PC12 cells. It was further demonstrated that syringic acid inhibited Erastin-induced Ferroptosis in PC12 cells by activating the Nrf2 pathway (Cheng et al., 2021), further demonstrating that the Nrf2 pathway is closely related to Ferroptosis.

3.1.4. Trehalose

Trehalose, a non-reducing disaccharide composed of two glucose molecules, is a typical stress metabolite (Zhang and DeBosch, 2019). Gong et al. (2022) first demonstrated that trehalose inhibited Ferroptosis of neurons after SCI in mice by activating the Nrf2/HO-1 pathway, thereby promoting neuronal survival and improving recovery of motor function. In addition, alginate also inhibited the expansion of neural tissue cavities and suppressed neuronal loss and inflammatory responses in SCI mice (Gong et al., 2022).

3.2. Metabolites

3.2.1. Lipoxin A4

Lipoxin A4 (LXA4) is a metabolite of arachidonate lipoxygenase (ALOXE). LXA4 has been previously shown to repair SCI by activating the Nrf2/HO-1 signaling pathway (Lu et al., 2018). Wei et al. (2021) used Erastin to induce Ferroptosis in neuronal cells, and LXA4 effectively alleviated the downregulation of GPX4, GSH, and cysteine, and prevented the downregulation of Prostaglandin Endoperoxide Synthase 2 (PTGS2), ACSL4, and ROS upregulation. This study provides strong evidence that LXA4 improves SCI even more.

3.2.2. Colony-stimulating factor

Erythropoietin (EPO), also known as erythropoietin-stimulating factor, is a human endogenous protein hormone that stimulates erythropoiesis. EPO has been reported to improve recovery of motor function in rats with SCI (Zhong et al., 2020). However, whether its mechanism is related to Ferroptosis has not been clarified. Recently, some investigators found that EPO has similar effects to Ferrostatin-1, an Ferroptosis inhibitor, on inhibiting the expression of Ferroptosis-related proteins and restoring mitochondrial morphology. EPO was also found to increase the expression of xCT and GPX4. Thus suggesting a potential anti-Ferroptosis effect of EPO (Kang et al., 2023), further improving the rationale for the use of EPO in the clinic.

3.3. Drug

3.3.1. Edaravone

Edaravone is a free radical scavenger (Dang et al., 2022). Pang et al. (2022) found that edaravone upregulated GPX4/xCT and downregulated ACSL4/5-LOX to inhibit Ferroptosis during the acute phase of SCI in rats, thereby improving recovery of motor function in SCI.

3.3.2. Metformin

Metformin (Met) is an organic compound that is a first-line drug for the treatment of type 2 diabetes (Flory and Lipska, 2019). One study found that Met promotes axonal regeneration after SCI via the Nrf2 pathway (Wang H. et al., 2020). And Met has also been found to upregulate GPX4 expression (Ma et al., 2021) and reduce MDA levels (Zeng et al., 2019), thereby improving recovery of motor function in rats with SCI (Wang Z. et al., 2022).

Taken together, these substances can improve motor recovery after SCI by inhibiting Ferroptosis, providing further evidence for their clinical application and also suggesting that SCI is closely related to Ferroptosis and that Ferroptosis will be a new target for the treatment of SCI in the future.

3.4. Trace elements

3.4.1. Zinc

Zinc is an essential trace element in the human body (Kim and Lee, 2021). Researchers found that zinc increased the expression of Nrf2/HO-1 and thus upregulated GPX4 and GSH in a mouse model of SCI, and that zinc also effectively prevented oxidative stress in mitochondria and effectively reduced inflammation (Ge et al., 2021).

3.4.2. Selenium

Selenium can replace sulfur in cysteine and is incorporated into selenoproteins as a selenosubstituted cysteine. GPX4 is the most important of the selenoproteins in human 25 (Zhang and Song, 2021). Therefore selenium is essential for GPX4. One researcher injected sodium selenite in a rat model of SCI and found that sodium selenite treatment downregulated iron levels and the expression of lipid peroxidation products MDA and 4-HNE, in addition to finding that sodium selenite inhibited Ferroptosis via

the FSP1/GPX4 pathway thereby improving recovery of motor function in SCI rats (Chen Y. X. et al., 2022).

The role played by zinc and selenium in SCI provides a solid theoretical basis and dosing recommendations for the clinical use of micronutrients that can protect against neurological injury.

3.5. miRNAs

miRNA is a non-coding RNA of 21–25 amino acids in length, which can inhibit translation or induce target mRNA degradation at the post-transcriptional level by binding to the 3'-untranslated region (UTR) in messenger RNA (mRNA) (Saliminejad et al., 2019). One study found that miRNA-672-3p could inhibit Ferroptosis via the FSP1 pathway, thereby improving motor function in rats (Wang F. et al., 2022). Since miRNA is an RNA that does not encode a protein, one target protein may be regulated by multiple miRNAs, and one miRNA may also regulate multiple target proteins, so it may also be involved in the regulatory mechanisms related to Ferroptosis. However, little research has been reported on Ferroptosis and miRNAs. More importantly, miRNAs are only one type of non-coding RNAs, and studies on non-coding RNAs such as lncRNAs, circRNAs, and co-regulatory networks between non-coding RNAs and Ferroptosis have also been rarely reported. Therefore, future studies on Ferroptosis could focus more on the molecular level, especially in non-coding RNAs, to provide more targets for Ferroptosis studies at the molecular level.

3.6. Mesenchymal stem cell transplantation

Mesenchymal stem cells (MSCs) and long non-coding RNA (lncRNA) are an important class of exosome contents. It has been found that exosomes from MSCs are dependent on a novel lncRNA, Gm36569, which inhibits Ferroptosis in neuronal cells by competing for the expression of miR-5627-5p and thereby enhancing the expression of FSP1 (Shao et al., 2022). This study links MSC transplantation, exosomes, Ferroptosis and SCI closely together, further promoting the development of MSC transplantation in SCI and providing theoretical support for the clinical application of MSC transplantation.

3.7. Cytokines

Growth-differentiation-factor-15 (GDF-15) is a cytokine that is a member of the transforming growth factor β (TGF- β) superfamily, which is a stress response protein (Wang D. et al., 2021). One researcher examined the level of GDF-15 in SCI and found that the expression level of GDF-15 was significantly elevated in SCI and in neuronal Ferroptosis *in vitro*. And the knockdown of GDF-15 significantly exacerbated Ferroptosis. Subsequent researchers have found that GDF-15 inhibits Ferroptosis by activating the p62-Keap1-Nrf2 signaling pathway, thereby improving motor recovery in SCI (Xia et al., 2022). However, other modulatory effects of GDF-15 on Ferroptosis and neuroinflammation in the neurocloud after SCI remain uncertain, and therefore further studies on the modulatory effects of GDF-15 are needed in the future.

3.8. Newly synthesized substances

3.8.1. SRS16-86

SRS16-86 is a newly synthesized small molecule inhibitor of Ferroptosis (Linkermann et al., 2014). One study found that SRS16-86 upregulated the levels of XCT, GSH and GPX4 in rat SCI and downregulated the lipid peroxidation product 4-hydroxynonenal (4-HNE) thereby inhibiting Ferroptosis. In addition, SRS16-85 inhibited the inflammatory response and astrocyte proliferation after SCI. SRS16-85 increased neuronal survival and improved motor recovery from SCI in rats by inhibiting Ferroptosis (Zhang Y. et al., 2019).

3.8.2. DFO

Deferoxamine (DFO) is an effective iron chelator that has been approved by the Food and Drug Administration (FDA) for the treatment of iron overload disorders (Li et al., 2019). It has been found that DFO promotes the repair of rat SCI by upregulating the levels of XCT, GSH, and GPX4 and inhibiting lipid reactive oxygen species in rat SCI, which in turn upregulates Ferroptosis related genes Acyl-CoA synthase family member 2 (ACSF2) and iron response element binding protein 2 (IREB2) ultimately inhibiting the Ferroptosis pathway (Yao et al., 2019). The application of DFO directly indicates its great promise in Ferroptosis. This may accelerate the clinical application of DFO in SCI.

3.8.3. Liproxstatin-1

In 2021 a study found that Liproxstatin-1 was more effective than edaravone and DFO in rescuing oligodendrocytes. And Liproxstatin-1 was found to not only inhibit mitochondrial lipid peroxidation but also restore the expression of GSH, GPX4, and FSP1 (Fan et al., 2021).

3.8.4. Ferrostatin-1

Ferrostatin-1 was shown to inhibit Ferroptosis in neurons, thereby improving functional recovery after TBI and SCI (Xie et al., 2019). Ge et al. (2022) found that Ferrostatin-1 could inhibit Ferroptosis in oligodendrocytes by reducing the accumulation of iron and ROS and downregulating the Ferroptosis-related genes IREB2 and PTGS2 (Ge et al., 2022).

The above studies provide a theoretical basis for the clinical use of these substances in the treatment of SCI. In particular, studies of natural compounds and related molecules have confirmed the potential of these substances in Ferroptosis and clinical treatment. It is also clear from the above table that both natural and newly synthesized substances inhibit Ferroptosis and thus repair SCI mainly by affecting xCT, GSH, GPX4, FSP1, and Nrf2 factors (Table 1). However, this does not mean that substances that inhibit Ferroptosis and thus repair SCI only do so by affecting the above pathways, but may also inhibit Ferroptosis and thus repair SCI by affecting the DHODH-CoQH2 pathway, the GCH1-BH4 pathway and the MVA pathway, etc. However, there is little research on these pathways, so the targets of future Ferroptosis inhibitors for repairing SCI and Therefore, future studies on the targets of Ferroptosis inhibitors for SCI repair and the mechanisms of action of natural products that can inhibit Ferroptosis and thereby repair SCI could focus on these pathways.

TABLE 1 Improvement of SCI-related substances through Ferroptosis.

Classification	Substance	Type	Mechanism
Natural products	PACs	Free radical scavengers Antioxidants	Upregulation of GSH, GPX4, Nrf2 (Zhou et al., 2020) Downregulation of ACSL4, Fe, TBARS (Zhou et al., 2020)
	EGCG	Antioxidants	Upgraded GPX4, FTH (Wang J. et al., 2020) Downward revision of ACSL4 (Wang J. et al., 2020)
	Carnosic	Anti-inflammatory Neuroprotective	Upregulation of GSH, Nrf2 (Cheng et al., 2021) Downregulation of iron content, ROS, MDA (Cheng et al., 2021)
	Trehalose	Prevents lipid peroxidation Inhibits inflammation	Upregulates Nrf2 (Gong et al., 2022)
Metabolic products	LXA4	Anti-inflammatory	Upregulation of GSH, GPX4, Nrf2 (Wei et al., 2021) Downregulation of ACSL4, PTGS2, ROS (Wei et al., 2021)
	EPO	Colony-stimulating factor	Up-regulation of xCT GPX4 (Kang et al., 2023)
Drugs	Edaravone	Free radical scavenger	Upregulated xCT GPX4 (Pang et al., 2022) Downregulation of ACSL4, 5-LOX (Pang et al., 2022)
	Met	Glucose-lowering drugs	Upregulated GPX4, Nrf2 (Ma et al., 2021) Downregulation of MDA (Zeng et al., 2019)
Trace elements	Zinc	Trace elements	Upregulation of GSH, GPX4, Nrf2 (Ge et al., 2021) Downregulation of ROS (Ge et al., 2021)
	Selenium	Trace elements	Upregulation of GPX4 FSP1 (Chen Y. X. et al., 2022) Downregulation of MDA 4-HNE (Ge et al., 2021)
miRNA	miRNA-672-3p	RNA	Upregulates FSP1 (Wang F. et al., 2022)
Stem cell transplantation	lncRNA-Gm36569	RNA	Upregulates FSP1 (Shao et al., 2022)
Cytokines	GDF-15	Neuroprotective factor	Upregulated Nrf2 (Xia et al., 2022)
New synthetic substances	SRS16-86	Small molecule Ferroptosis inhibitors	Upregulates xCT, GSH, GPX4 (Zhang Y. et al., 2019)
	DFO	Iron chelator	Upregulates xCT, GSH, GPX4 (Yao et al., 2019)
	Liproxstatin-1	Ferroptosis Inhibitors	Upregulates xCT, GPX4, FSP1 (Fan et al., 2021)
	Ferrostatin-1	Ferroptosis Inhibitors	Downregulation of Iron, ROS, IPEB2, PTGS2 (Ge et al., 2022)

4. Possible problems in the clinical translation of Ferroptosis inhibitors for the treatment of spinal cord injury

Recently, DFO has been approved by the US Food and Drug Administration (FDA) for the treatment of iron overload disorders (Li et al., 2019), for example to reduce systemic iron load in patients with thalassemia major and sickle cell (Farr and Xiong, 2021). However, DFO currently has some limitations for clinical translation in other diseases. For example, in Intracerebral Hemorrhage (ICH), studies have shown that high doses of DFO are dangerous in treating patients with ICH (Farr and Xiong, 2021). In SCI, it has been shown that DFO can improve SCI by promoting neovascularization in rats, but there are limitations to this study such as the uncertainty of the therapeutic effect of DFO in the chronic phase of SCI and the need to verify the therapeutic effect of DFO in SCI in high quality clinical studies, of which there are few (Tang G. et al., 2020). Most other Ferroptosis inhibitors have not yet been translated for clinical use and face many challenges.

4.1. Mode of administration

4.1.1. Injection localized at the traumatized spinal cord

In basic research, some investigators microinjected Ferrostatin-1, an Ferroptosis inhibitor, into the dorsal 2 mm cephalad and 2 mm caudal aspects of the spinal cord in a rat model of SCI and inhibited the accumulation of iron and ROS, resulting in improved functional recovery after SCI (Ge et al., 2022). Other studies have injected sodium selenite spinal cord into a rat model of SCI and found downregulation of iron levels, MDA and 4-HNE expression levels and functional recovery after SCI (Chen Y. X. et al., 2022). Although this method is accurate in its localization (Falsafi et al., 2021), this localization of drug delivery at the traumatized spinal cord may be difficult to manipulate when applied clinically and may predispose patients to secondary injury (Table 2).

4.1.2. Intraperitoneal injection

Some researchers injected DFO (Yao et al., 2019) and SRS16-86 (Zhang Y. et al., 2019) intraperitoneally into a rat model of SCI and found that the Xc-GSH-GPX4 axis was upregulated to inhibit Ferroptosis, thereby improving the functional recovery of SCI in rats. However, whether the drug crosses the blood-brain barrier

(BBB) or blood–spinal cord barrier (BSCB) during intraperitoneal injection for clinical application still deserves further study (Table 2).

4.1.3. Intranasal administration

Intranasal administration has been shown to bypass the BBB or BSCB and allow access to the central nervous system in animal models (Long et al., 2020), and it has been shown that intranasal administration of Liproxstatin-1 and Ferrostatin-1 treatment significantly improved infarct size in a mouse stroke model (MCAO ischemic stroke model) (Tuo et al., 2017), so the mode of administration may be clinically applicable in the treatment of spinal cord injury (Table 2).

4.1.4. Intravenous injection

Intravenous injection is probably the most suitable mode of administration for emergency treatment in clinical practice because of its ease of handling, high volume of administration and low risk. However, the ability of this mode of administration to cross the blood–brain barrier during clinical application is still debatable (Table 2). One investigator injected the third generation Ferroptosis inhibitor SRS16-86 (Zhang Y. et al., 2019) intravenously into mice and collected cerebrospinal fluid, brain tissue fluid and serum samples. Both cerebrospinal fluid and brain tissue fluid were found to be below detection levels, indicating that intravenous SRS16-86 did not cross the BBB.

In the treatment of central nervous system diseases, the BBB limits the ability of 98% of small molecules and almost all large molecules to reach the lesion effectively. Therefore, it is extremely important that the mode of administration of Ferroptosis inhibitors crosses the BBB when used in clinical practice. There are several ways to increase the BBB, for example (i) carotid artery injection of high concentrations of mannitol can deliver drugs to the brain that are not permeable to the BBB. However, this method is not clinically applicable as it is complex and has a high risk of causing seizures, cerebral artery embolism, cerebral hemorrhage and cerebral edema (Wang W. et al., 2021). (ii) Use of vasoactive agents to increase BBB permeability throughout the brain (Gao et al., 2014). (iii) Use of cell-penetrating peptides, adenovirus-associated virus (AAV) that penetrates the BBB (Yao et al., 2022) and receptor-mediated transcytosis to increase brain transport (Terstappen et al., 2021). (iv) Localized increase in brain penetration by ultrasound stimulation of microvesicles (Rezai et al., 2020). (v) Molecularly targeted nanoparticles irradiated by picosecond pulsed laser to reversibly open the BBB and deliver drugs to brain tissue, specifically by synthesizing a gold nanoparticles (AuNPs) that are specifically targeted intravenously to tight junctions (TJs) on the BBB, followed by cranial picosecond laser stimulation to increase BBB permeability, a strategy that allows immunoglobulin and viral gene therapy vectors and drug-laden liposomes to enter the brain, and a process that is reversible and does not result in spontaneous vascular diastole or significant disruption of the structure of the neurovascular unit (Li X. et al., 2021). Although the above possible solutions for BBB have not been studied in BMSC, they may also provide relevant ideas and inspiration for the clinical use of Ferroptosis inhibitors in SCI.

TABLE 2 Advantages and disadvantages of drug delivery methods.

Method of administration	Advantages	Disadvantages
SCI site injection	Accurate positioning (Falsafi et al., 2021)	May be difficult to use in clinical practice and may cause secondary harm to patients
Intraperitoneal injection	Easy to absorb (Dou et al., 2013)	Improper handling can easily cause damage to organs
Intranasal drug delivery	Easy to pass BBB or BSCB (Long et al., 2020)	Improper handling can easily lead to upper respiratory tract infections
Intravenous injection	Easy handling, high dosing and, low risk	Difficult to pass BBB or BSCB (Zhang Y. et al., 2019)

4.2. Dosing

4.2.1. Selection based on preliminary experiments

For example, when the researchers selected the dose to be administered for SRS16-86, five groups were modeled as sham group, SCI group, SCI + 5 mg/kg SRS16-86 group, SCI + 10 mg/kg SRS16-86 group and SCI + 15 mg/kg SRS16-86 group, and then tested motor recovery 2 weeks after SCI to select a dose of 15 mg/kg SRS16-86 (Zhang Y. et al., 2019).

4.2.2. Selection based on experience

For example the dose of 100 mg/kg administered for DFO was selected by the investigators with slight modifications based on previous studies.

The dose administered in the basic study was determined in both of these ways, but in the clinical setting the dose needs to be studied further, taking into account the patient's age, weight and dosing pattern. If too small a dose is administered, it may not be effective, and if too large a dose is administered, adverse effects and side effects may occur.

4.3. Time window for dosing

Some of the Ferroptosis inhibitors in basic studies were administered before SCI, for example DFO was administered to rats 30 min before injury and then injected once a day for 7 days after injury. However, this dosing time window is not achievable in clinical applications and therefore needs to be further explored.

5. Conclusion and outlook

In summary: (1) The existing studies suggest that Ferroptosis is closely related to SCI and that Ferroptosis may be a new target for SCI treatment. (2) Most of the current studies on Ferroptosis in SCI are at the animal stage, and future studies could be conducted on human cell lines or non-human primates to lay the foundation for

clinical development of Ferroptosis inhibitors. (3) Although there is increasing evidence that Ferroptosis inhibitors can be used as a new generation of targets for the treatment of SCI, future clinical translation may face a number of problems such as poor *in vivo* solubility, short half-life, dose and mode of administration. (4) In addition to Ferroptosis, studies on the characteristics of different death modes, such as cuproptosis (Tsvetkov et al., 2022) and parthanatos (Wang and Ge, 2020), as well as studies on the linkage between these death modes, are still a hot topic for future research.

Author contributions

X-YB, X-LL, and Z-ZD were responsible for writing and revising the text. X-YB played a major role in writing this article. X-LL was responsible for the preparation of figures and revisions of this article. Z-ZD was responsible for the post-writing and revisions of this article. D-MW and DZ were responsible for data collection. H-LX, Q-YW, and M-ZH were responsible for revising the article. Y-LY was responsible for conceptualizing, funding, and guiding the article. All authors contributed to the article and approved the submitted version.

Background: Frontal lobe epilepsy (FLE) is the second most common type of focal epilepsy, however, imaging studies of FLE have been far less than Temporal lobe epilepsy (TLE) and the structural findings were not consistent in previous literature.

Object: Investigate the changes in cortical thickness in patients with FLE and the alteration of the structural covariance networks (SCNs) of cortical thickness with graph-theory.

Method: Thirty patients with FLE (18 males/12 females; 28.33 ± 11.81 years) and 27 demographically matched controls (15 males/12 females; 29.22 ± 9.73 years) were included in this study with high-resolution structural brain MRI scans. The cortical thickness was calculated, and structural covariance network (SCN) of cortical thickness were reconstructed using 68×68 matrix and analyzed with graph-theory approach.

Result: Cortical thickness was not significantly different between two groups, but path length and node betweenness were significantly increased in patients with FLE, and the regional network alterations were significantly changed in right precentral gyrus and right temporal pole (FDR corrected, $p < 0.05$). Comparing to HC group, network hubs were decreased and shifted away from frontal lobe.

Conclusion: The topological properties of cortical thickness covariance network were significantly altered in patients with FLE, even without obvious surface-based morphological damage. Graph-theory based SCN analysis may provide sensitive neuroanatomical biomarkers for FLE.

graph theory, structural covariance network, cortical thickness, frontal lobe epilepsy, default mode network (DMN)

1. Introduction

Frontal lobe epilepsy (FLE) is the second common type of focal epilepsy behind temporal lobe epilepsy, accounting for ~20%–30% of sufferers (Manford et al., 1996). As the largest lobe of neocortex, the highly interconnected nature of the frontal lobe allows for a quick and widespread propagation of epileptic activity to the other brain regions, which may give rise to

the perplexing clinical and electrophysiological finding of FLE. A variety of semiologies are common for FLE patients, such as unilateral clonic seizures, tonic asymmetric seizures with preserved consciousness, hypermotor seizures, and secondary generalized seizures. The ambiguity in localization and lateralization of deficits of EEG is well known, even false negative EEG is not uncommon (Beleza and Pinho, 2011). Seizures in FLE are mostly likely to be associated with multi-cognitive defects and motor-related abnormality networks (Kellinghaus and Lüders, 2004; Beleza and Pinho, 2011), and the treatment outcome is disappointing, as only 20%–30% of patients achieve seizure freedom with medication (Regesta and Tanganelli, 1999). Of all patients with refractory focal epilepsies referred to epilepsy surgery, 25% have FLE, and only 30%–50% achieve seizure freedom with surgery (Bagla and Skidmore, 2011). As epileptogenic zone may be subtle and not obvious in routine MRI examination (Bonini et al., 2014), it presents challenges in FLE patients with ambiguous EEG pattern, and calls for better clarification of the underlying neuroanatomic characteristic of FLE, especially for patients with normal routine MRI examination.

As a brain network disorder, epilepsy has been widely studied using quantitative neuroimaging data, which supported that epileptogenic network are involved in the generation and expression of seizures, and to the maintenance of the disorder (Spencer, 2002). In contrast to make low-level regional and connective alterations with conventional approach, graph-theory analysis provides a correlational framework to reveal the persistent functional-trophic cross-talk, maturational inter-change, as well as common developmental and pathological influences (Bullmore and Sporns, 2012; Alexander-Bloch et al., 2013; Bernhardt et al., 2013), and can be used for various modalities of neuroimaging data. Normal topological network is characterized by high clustering coefficients and short average path lengths. According to previous graph-theory based fMRI and diffusional MRI (dMRI) studies (Vaessen et al., 2013, 2014; Gleichgerrcht et al., 2015; Zhou et al., 2019; Lin et al., 2020; Togo et al., 2022), rearrangement of global and local topological parameters has been found in patients of focal epilepsy (including FLE and TLE), such as diminished network strength, clustering coefficient, path length, and global efficiency, both within and beyond the epileptogenic zone.

Unlike fMRI and dMRI, structural T1-weighted images is a standard component of every clinical imaging protocol with short acquisition time. These images are generally unaffected by distortion and signal drop out artifacts in orbitofrontal and temporo-basal regions which often occur in echo-planar functional and diffusion MRI sequences (Bernhardt et al., 2013; Gleichgerrcht et al., 2015). Graph theory based structural covariance network (SCN) of cortical thickness directly seeds from cortical gray matter regions in a high-resolution space, which is not limited by the imaging voxels but by the sampling density of the points on the cortical mesh (Hosseini et al., 2012; Alexander-Bloch et al., 2013). SCN analysis has been applied to investigate in various central nervous system disorders (Hosseini et al., 2012; Singh et al., 2013), and considered a promising tool in investigating the brain network alterations in epilepsy (Li et al., 2020), but it was rarely used in FLE patients. In order to investigate the topological property alteration of cortical thickness in FLE, SCN analysis was performed between a group of clinically diagnosed FLE patients with negative MRI and a age-, gender-, education-matched healthy control (HC) group in the present study.

2. Patients and methods

2.1. Patients

Thirty FLE patients (18 males, age range = 16–62 years; average age \pm standard deviation = 28.33 years; standard deviation = 11.81 years) were recruited from Department of Neurology, the Third Xiangya Hospital, Central South University. All patients were diagnosed by senior neurologists based on comprehensive evaluation of clinical history, 24-h video-EEG recording, ictal semiology, routine MRI examination according to the International League Against Epilepsy (ILAE) guidelines (Engel, 2001). No structural abnormalities can be identified responsible for these FLE patients through the routine MRI examination, such as malformation, tumor, reactive gliosis, and other epileptogenic lesions. All patients underwent 24-h (overnight including the sleep period) scalp video-EEG recordings (EEG-1200C, Nihon Kohden, Tokyo, Japan). For EEG, 16 electrodes were distributed according to 10–20 international standard system, and the sampling rate was set at 256 Hz. All patients received antiepileptic drug (AED) treatments with regular out-patient follow-up. The detailed demographic information and the clinical characteristics of FLE patients can be seen in Table 1. A total of 27 age-, gender- and education-matched healthy volunteers were also recruited as controls (15 males, age range = 18–60 years, average age \pm standard deviation = 29.22 years; standard deviation = 9.73 years). Written consent forms of all FLE patients and controls were obtained. The study protocol was approved by the Ethics Committee of the Third Xiangya Hospital, Central South University.

Duration of illness, epileptic seizure types, initial and follow-up EEGs, medication protocol, the follow-up seizure attacks after treatment were also collected for all patients. The National Hospital Seizure Severity Scale (NHS3) which contains seven seizure-related factors on a score of 1 to 27 was used to assess the severity of epilepsy (O'Donoghue et al., 1996). The seizure attack frequency after treatment for each patient was evaluated according to International League Against Epilepsy (ILAE) scale (Wieser et al., 2001).

TABLE 1 Demographic, clinical, and neuropsychological test difference between FLE and HC group.

Clinical characteristic	FLE patients (n=30)	HC (n=27)	p value
Age at examination/year ^a	28.33 (11.81)	29.22 (9.73)	0.76
Gender/male ^b	18 (60%)	15 (56%)	0.73
Education/year ^a	12.47 (2.73)	13.04 (3.31)	0.48
Disease duration/year ^a	8.50 (9.64)		
Localization (left/right/bilateral/unknown)	3/5/21/1		
Seizure frequency (grade 0/1/2/3)	9/13/1/7		
Medication (mono/multi medication)	24/6		

^aData in average (standard deviation).

^bData in number (percent).

2.2. Image acquisition

MRI data were acquired using a 3.0T MRI scanner (Ingenia, Philips Medical Systems, Netherlands) with a 15-channel receiver array head coil at the Department of Radiology, Third Xiangya Hospital, Central South University. The participants were instructed to lie quietly with their eyes closed but remain awake, and to avoid specific thoughts during scanning. To improve image quality, earplugs were used to attenuate scanner noise, and foam pads were applied to minimize head movements.

Structural images were acquired with a three-dimensional turbo fast echo (3D-TFE) T1WI sequence with high resolution as follows: repetition time (TR)/echo time (TE)=9.1/4.5 ms; slices=170; thickness=1 mm; gap=0 mm; flip angle (FA)=8°; acquisition matrix=256×256; field of view (FOV)=240 mm×240 mm.

2.3. Data preprocessing

The cortical thickness (CT) was determined using CAT12¹ and SPM12² based on the MATLAB 2014a operating environment (MathWorks, Natick, MA, USA). Briefly, the T1-weighted images underwent tissue segmentation to estimate white matter distance. Local maxima were then projected to other grey matter voxels by using a neighbor relationship described by the white matter distance. These values equal cortical thickness. Topological correction was performed through an approach based on spherical harmonics (Fischl and Dale, 2000). After preprocessing and visual checks for artefacts, all scans passed through the automated quality check promoted in the manual of CAT12. No participant was excluded by the automated quality check protocol. The brain was parcellated into 68 cortical regions using the Desikan-Killiany atlas (Desikan et al., 2006) and the mean cortical thickness was calculated for each region. The individual map of CT was smoothed with a Gaussian filter with a full-width at half-maximum of 15 mm to statistical analysis.

2.4. Cortical thickness structural covariance networks construction

Graph Analysis Toolbox (GAT) was used to construct the SCNs based on CT (Hosseini et al., 2012). A linear regression analysis was conducted for each cortical region to adjust the effect of age and gender, so that the corrected cortical thickness was obtained to construct SCN. According to the Desikan-Killiany Atlas (Desikan et al., 2006), a 68×68 correlation matrix was established for each group by calculating Pearson correlation coefficients between interregional corrected CT values. Thereafter, the correlation matrix was converted into a binary adjacency matrix by thresholding correlation coefficients into values of 1 or 0 (Figure 1). Here, these thresholds were defined as a range of network densities varying from 0.38 to 0.5 (increments

of 0.02), which ensured that FLE and HC SCNs had the same number of nodes and edges at each density. The minimum density (0.38) was determined to ensure that the networks were not fragmented for both groups. For density above 0.5 the networks approached random configuration (Humphries et al., 2006; Singh et al., 2013). Inter-group differences of network topologies were compared across the range.

2.5. Global and regional network analyses

According to the definitions of these parameters in previous studies (He et al., 2008; Rubinov and Sporns, 2010), a series of global and regional network parameters was calculated to characterize the topological properties of the SCNs. Global network parameters included normalized clustering coefficient, normalized path length, and small-world index. Briefly, the human brain can be regarded as a small-world network that has the highest clustering coefficient (Cp) and shortest path length (Lp). Cp of a node pertains the number of existing connections linking the adjacent nodes divided by all their possible connections. The Cp of a network is the average of clustering coefficients across all nodes in a network, which represents network segregation. The shortest path length (Lp) is equal to the minimum number of edges that connect two nodes. The Lp of a network pertains to the average shortest path length involving all node pairs in the network, which represents network integration. The normalized clustering coefficient (gamma) and normalized path length (lamda) were calculated, respectively, by comparing the Cp and Lp to the mean Cp and mean Lp of 1,000 random network (Maslov and Sneppen, 2002).

The nodal characteristics of the CT structural covariance network were examined and the alteration of regional network between groups were analyzed. Which included that the nodal local efficiency, nodal clustering coefficient and nodal betweenness centrality. The node local efficiency reflects the connection degree between a node and other nodes, representing the communication efficiency of the node. Nodal betweenness centrality is an important index which is defined as the number of shortest paths between any two nodes in the network that pass through a given node (Rubinov and Sporns, 2010). The graph index is used to detect important functional or anatomical connections. The quantified nodal local efficiency, clustering coefficient, and betweenness centrality were, respectively, normalized by the average network local efficiency, clustering coefficient, and betweenness centrality. Inter-group differences of these normalized region network parameters were compared.

2.6. Network hubs

Hubs are the most globally connected regions in the brain and are essential for coordinating brain function through the connectivity with numerous brain regions. Hubs play a central role in integrating diverse information sources and supporting fast information communication with minimal energy cost. In our study, the criteria for defining hub is that the node's betweenness was at least 2 standard deviation higher than the mean network betweenness centrality (Hosseini et al., 2012).

FIGURE 1

Correlation matrices and adjacency matrices with 68×68 for healthy controls (Ctrl) and frontal lobe epilepsy (FLE) patients. Correlation matrices for HC (A) and FLE patients (B) and binary adjacency matrices at the minimum density (0.38) for HC (C) and FLE patients (D). Correlation matrices show the Pearson correlation coefficient between any two regions of the network and the color bar denotes the absolute value of the Pearson correlation coefficient and represents the strength of the connections.

2.7. Statistical analysis

Clinical data analysis was completed using IBM SPSS 26.0. Chi-square tests were used to compare categorical variables. Student's *t*-test or the Mann–Whitney U-test were used to compare continuous variables between two groups.

For the CT maps, general linear modeling, installed in the CAT toolbox, was used to perform vertex-wise group inference on the smoothed cortical surfaces. To calculate significance of the differences in SCN parameters between groups, we analyzed the network parameters both at Dmin and across the density range (0.38–0.5 with an interval of 0.02) using area under the curve (AUC). A non-parametric permutation test (1,000 repetitions) was used to investigate the statistical significance of the difference in global and regional network parameters. The comparison of the global and regional parameters between groups was completed with the GAT toolbox with the result corrected by $p < 0.05$ with false discovery rate (FDR) considered to be statistically significant.

3. Results

3.1. Demographic and clinical characteristics

The demographic and clinical information of FLE and HC groups were listed in Table 1. All the patients were complex-partial seizure

with secondary generalized tonic–clonic attack, with typical frontal lobe epilepsy characteristic such as hypermotion, dominance of attack during sleep. The average duration of disease was 8.50 (SD = 9.64). The NHS3 score for the patients ranged from 2 to 18, with the average \pm SD of 9.67 ± 4.14 .

3.2. Between-group comparison of CT

Comparing to HC group, only the cortical thickness of left postcentral gyrus was decreased in FLE group ($p < 0.001$, uncorrected), but the difference was not significant after FDR correction.

3.3. Inter-group differences in global network metrics

Changes and between-group differences in global network parameters were significant between two groups at densities ranging from 0.38 to 0.50, as shown in Figure 2. Compared to HC group, both the characteristic and normalized path length of FLE group were significantly longer, and the mean node betweenness was also significantly higher in FLE group. The global and local efficiency, clustering coefficient (Gamma), and small-world index (Sigma) were lower in FLE, but they did not reach statistical significance (data not shown).

3.4. Inter-group differences in regional network metrics

Inter-group differences in regional network metrics of normalized clustering and local efficiency were shown in Figure 3. Compared to HC group, both the normalized clustering and local efficiency of right precentral gyrus were significantly higher, and that of right temporal pole were significantly lower in FLE ($p < 0.05$ with FDR correction).

3.5. Network hubs

Figure 4 displayed group-specific hubs for HC and FLE groups. Hubs determined for HC group network included left inferior temporal gyrus, left medial orbito-frontal gyrus, bilateral precuneus gyri, and superior frontal gyrus. Hub number for FLE group was reduced, which included left inferior parietal gyrus, right inferior parietal gyrus, and left supramarginal gyrus.

4. Discussions

This study investigated the topological property alteration of cortical thickness based SCN in FLE patients without structural abnormality on conventional MR. Both the global and regional network parameters were significantly different between FLE and HC groups. The results revealed that the structural network properties were significantly changed in MRI-negative FLE patients, suggesting higher sensitivity of graph-theory based analysis in detecting the neurobiological injury in FLE patients. To the best of our knowledge, the present study reported for the first time the cortical-thickness related topological property alteration in MRI-negative FLE patients and it may be a valuable tool in future clinical practice.

The structural alterations of FLE were not consistent in previous studies. In the study of Widjaja et al. (2011), widespread cortical thinning was found, while in other studies, there was no significant difference in cortical /GM volume between FLE and HC (Lu et al., 2022). In the present study, cortical thickness was not significantly different between the two groups. However, our study demonstrated that FLE patients had significantly different topological change for both global and regional network parameters, though both groups showed a small-world topology. Consistent with previous functional graph-theory based neuroimaging studies of epilepsy (Vaessen et al., 2013), the path length and node betweenness were significantly increased in FLE, indicating the global network topology was altered toward a regularized pattern. However, variations in structural network were also found. In the study of Vaessen et al. (2013), the structural path length and clustering remained normal in children with FLE, structural modularity was different between two groups and it was increased with stronger cognitive impairment. Thus modularity may be associated with cognitive status, which was not included in present study and warrants further investigation. In addition to methodological approach difference (e.g., different atlases and morphometric features), patient selection variation may also contribute to the discrepancy. For the study of Vaessen et al. (2013, 2014) and Widjaja et al. (2011), the patients recruited were children, but the patients in the present study were adults older than 14 years old. As cortical structure should be closely associate with age, and the variation during development and maturation of frontal lobe may be huge even in normal population (Silver et al., 2021; Herring et al., 2022), future studies with larger sample size is warranted to clarify the influence of age.

In FLE, the clinical symptoms of these seizures are variable and dependent on the brain regions, which may include peri-rolandic, supplementary sensorimotor area, dorsolateral frontal, orbitofrontal, anterior frontopolar, opercular, and cingulate types (Bagla and

FIGURE 2

Changes and between-group differences of normalized path length (A,B; Lambda), characteristic path length (C,D), and mean node betweenness (E,F) as a function of network density in healthy control (Ctrl) and frontal lobe epilepsy (FLE) groups. For between-group differences (B,D,E), Except for a few densities, there are significant difference between two groups, as indicated by dots lying outside the 95% confidence intervals (dashed lines) ($p < 0.05$ after FDR correction).

prominent seizure characteristics of hypermotor attacks and secondary generalized clonic-tonic seizure. This is in agreement with previous report on FLE (Bagla and Skidmore, 2011; Bonini et al., 2014) and we speculated that motor-related network abnormality

should be found. In agreement with this speculation, both normalized clustering and local efficiency of right precentral gyrus were significantly increased, indicating an abnormal increase in network segregation in sensorimotor network. Similar findings were reported in previous study of FLE (Woodward et al., 2014).

Connections between temporal lobe and sensorimotor cortex have been repeatedly reported in previous neuroimaging studies of MRI-negative TLE patients, especially for right MTS to influence ipsilateral thalamus and temporal pole (Coan et al., 2014; Roggenhofer et al., 2020). In addition to TLE, temporal pole and precentral gyrus involvement is also reported for patients with GTCS (Liu et al., 2017; Li et al., 2020). Thus, it is not surprising that regional topological parameters were also compromised for right temporal pole in the study. As a seizure is typically the result of the networks that are recruited or traveled by the epileptiform discharges, therefore seizure-onset localization can be misled by clinical manifestations that may arise from recruited networks that are remotely located from the ictal source. The decreased clustering and local efficiency of right temporal pole may reflect the intrinsic network pattern of fronto-limbic system.

Similarly, network hub analysis showed that there were significant difference between FLE and HC groups. In HC group, the hubs were evenly distributed around the neocortex, including bilateral precuneus, left inferior temporal gyrus and left medial orbitofrontal gyrus, which was consistent with DMN network hubs (Zhou et al., 2019). However, for FLE patients, the hubs were reduced and shifted posterior and none was found in frontal lobes. The hubs identified in FLE group, the inferior parietal lobule which is usually closely connected with precuneus (Togo et al., 2022). Together with supramarginal gyrus, IPL is a region implicated in a diverse range of higher cognitive functions and may be associated with multiple brain networks, including DMN, Frontoparietal control network, and cingulo-opercular network (Igelström and Graziano, 2017). This hub alteration pattern may reflect the DMN abnormality in FLE, which was also reported in previous fMRI studies of epilepsy (Lin et al., 2020; Togo et al., 2022). The mechanism was unknown, but it may result from the interrupted small-world properties within frontal lobe in FLE, as noted by the disappearance of network hub in frontal lobe in FLE.

In addition, the hubs found in FLE, were among regions of reduced cortical thickness reported by Widjaja et al. (2011), in a study of FLE children. Similarly, in the functional connectivity study of FLE patients by Wu et al. (2019), increased ALFF in the precuneus of FLE patient, despite their response to antiepileptic medication, and these were the hubs for HC group in the present study. Inferior parietal lobules were also found to be affected in patients with hyperkinetic seizures (Sasagawa et al., 2021). The clinical significance of the network hub alteration remains unknown and warrants further investigation.

The present study has several limitations. Firstly, the FLE patients were clinically diagnosed, which was based on seizure semiology and EEG; while magneto encephalography, FDG-PET, and invasive intracranial monitoring were unavailable for the patients. Thus the possibility of multiple origin other than frontal lobe could not be completely excluded. In addition, most of the patients could not be lateralized, thus it is not clear whether the laterality affected the cortical thickness and brain volume distribution. Also, the sample size was relatively small with various illness duration, and the medicine used was not the same among subjects. These would have potential effects on the topological results, and future studies with larger sample size and better homogeneity of FLE patients may provide further

insights. Secondly, cross-sectional design was used in the present study which brings difficulty to get a causal conclusion. Longitudinal design may be needed in the future to further confirm our finding and assess whether the changes of network graph properties is the consequence of seizures.

In summary, the present study investigated topological properties of cortical thickness covariance network alteration in patients with FLE using the graph theory method. Both global and regional network parameters were significantly different between patients with FLE and normal controls, despite the surface-based cortical thickness was not significantly different between two groups. These results indicated that graph-theory based structural covariance network analysis may provide clues to reveal the structural alterations in MRI-negative FLE.

Data availability statement

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

Ethics statement

The studies involving human participants were reviewed and approved by the Ethics Committee of the Third Xiangya Hospital, Central South University. The patients/participants provided their written informed consent to participate in this study.

Author contributions

YiL, WW, DL, and ZS designed the study. QL, DY, QZ, JD, YH, and HH collected the clinical and imaging data. DY, QL, and LD analyzed the data. YiL, QL, DY, DL, LD, and WW co-wrote the manuscript. All authors contributed to the article and approved the submitted version.

Funding

This study was supported by Hunan Provincial Natural Science Foundation (2022JJ30890) and Natural Science Foundation of Changsha City (No. kq2208363).

Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

Currently, neurointervention, surgery, medication, and central nervous system (CNS) stimulation are the main treatments used in CNS diseases. These approaches are used to overcome the blood brain barrier (BBB), but they have limitations that necessitate the development of targeted delivery methods. Thus, recent research has focused on spatiotemporally direct and indirect targeted delivery methods because they decrease the effect on nontarget cells, thus minimizing side effects and increasing the patient's quality of life. Methods that enable therapeutics to be directly passed through the BBB to facilitate delivery to target cells include the use of nanomedicine (nanoparticles and extracellular vesicles), and magnetic field-mediated delivery. Nanoparticles are divided into organic, inorganic types depending on their outer shell composition. Extracellular vesicles consist of apoptotic bodies, microvesicles, and exosomes. Magnetic field-mediated delivery methods include magnetic field-mediated passive/actively-assisted navigation, magnetotactic bacteria, magnetic resonance navigation, and magnetic nanobots—in developmental chronological order of when they were developed. Indirect methods increase the BBB permeability, allowing therapeutics to reach the CNS, and include chemical delivery and mechanical delivery (focused ultrasound and LASER therapy). Chemical methods (chemical permeation enhancers) include mannitol, a prevalent BBB permeabilizer, and other chemicals—bradykinin and 1-O-pentylglycerol—to resolve the limitations of mannitol. Focused ultrasound is in either high intensity or low intensity. LASER therapies includes three types: laser interstitial therapy, photodynamic therapy, and photobiomodulation therapy. The combination of direct and indirect methods is not as common as their individual use but represents an area for further research in the field. This review aims to analyze the advantages and disadvantages of these methods, describe the combined use of direct and indirect deliveries, and provide the future prospects of each targeted delivery method. We conclude that the most promising method is the nose-to-CNS delivery of hybrid nanomedicine, multiple combination of organic, inorganic nanoparticles and exosomes, via magnetic resonance navigation following preconditioning treatment with photobiomodulation therapy or focused ultrasound in low intensity as a strategy for differentiating this review from others on targeted CNS delivery; however, additional studies are needed to demonstrate the application of this approach in more complex *in vivo* pathways.

KEYWORDS

therapeutics, central nervous system, wounds and injuries, targeted delivery, nanoparticles, exosomes, magnetics

1. Introduction

The main central nervous system (CNS) treatments used today, including neurointervention, surgery, medication, and CNS stimulation (Daroff et al., 2016), are often invasive, extending the patient's recovery and rehabilitation time. While the injection of neurotropic drugs such as chondroitinase (Kasinathan et al., 2016), anti-nogo (Zörner and Schwab, 2010), and Rho antagonists (Bertrand et al., 2005) has been considered a replacement for these other treatments in *in vitro/in vivo* CNS injury models, this method affects not only diseased tissues but also nonrelated healthy tissues (Perez-Herrero and Fernandez-Medarde, 2015). Therefore, CNS therapeutics have recently focused on targeted spatiotemporal therapy to rapidly induce the accumulation of high-concentration therapeutics in damaged areas, thereby making the treatment more intelligent, safer, more effective, and more efficient than the aforementioned methods.

To achieve targeted delivery into the CNS, it is essential for therapeutic agents to pass directly through the blood brain barrier (BBB; Chacko et al., 2013). The BBB is a semipermeable layer of endothelial cells between the circulatory system and the CNS. While the BBB functions to protect the CNS from toxic substances and regulate ions, molecules, and cells for proper neuronal function (Daneman and Prat, 2015), its high selectivity, in which enzymatic and physical barriers are involved, also prevents therapeutics from reaching the CNS (Tewabe et al., 2021). Therefore, direct delivery methods such as nanoparticles (NPs; Dong, 2018; Tewabe et al., 2021), extracellular vesicles (EVs), and magnetic-field mediated delivery (Yu et al., 2018), and indirect delivery methods such as chemical and physical delivery methods are being developed to pass through the BBB and directly affect the CNS: direct delivery methods that allow therapeutics to pass through the BBB as a vehicle or a navigator versus indirect delivery methods that increase the permeability of the BBB as a permeabilizer (Figure 1).

While the direct and indirect methods have been mainly used separately, the authors of this review seek to shed light upon cases

where the two methods are used together to create a synergistic effect and introduce the limitations and/or remaining unknowns in the field in regard to their combination. The direct and indirect CNS-targeted delivery strategies introduced in this article have demonstrated promise in *in vitro* and in animal studies as the next-generation platform for the treatment of CNS diseases ranging from Alzheimer's disease to brain tumors. Therefore, this review aims to describe various direct and indirect CNS-targeted delivery methods and how they relate to one another to stimulate more interest and research in CNS-targeted delivery by defining the mechanism of each delivery method, discussing their advantages and disadvantages, and analyzing future perspectives for neuroscientists who may aim to understand or even use some of the ideas discussed here in the context of their own work. In addition, although numerous types of therapeutic agent administration, such as subcutaneous, intramuscular, intravascular, transintestinal, transperitoneal, and intrathecal ones, have been tried, all of these routes are currently being evaluated in pioneering studies and thus demand further investigation prior to discussion about whether these approaches have any validity on the CNS-targeted delivery of therapeutics. Just one type of administration, nose-to-CNS route, has been discovered as a promising tool in animal and human models, especially for neurological disease treatment (Mittal et al., 2014). Hence, it should be in mind that the current review is full of examples depicting nose-to-CNS delivery, using viral vectors for delivery, etc.

2. Direct targeted delivery

In direct CNS-targeted delivery, therapeutics may be preserved by methods such as encapsulation to permeabilize through the BBB safely, arrive in the CNS, and take effect. Among variety of direct methods in progress, nanomedicine and magnetic field-mediated deliveries are the most commonly used methods in a field of CNS disease treatment. Nanomedicine allows sustainable selective delivery

to the target tissue (Dong, 2018; Tewabe et al., 2021), and magnetic field-mediated deliveries incorporate an external or internal magnetic field to directly navigate and accumulate magnetic therapeutics to the targeted area, resulting in a higher controllability than nanomedicine (Yu et al., 2018). Both nanomedicine and magnetic field-mediated deliveries could be seen as effective, promising delivery platforms for CNS diseases ranging from acute stroke to neurodegenerative disease to brain tumors, which have been most affected by the advancements made in direct delivery methods (Tiebosch et al., 2012; Tietze et al., 2013; Tentillier et al., 2016).

2.1. Nanomedicine

There are three types of nanomedicine: NPs, EVs, and hybrid. NP structures, including 1D nanowires, 2D nanosheets, and 3D structures (Huang et al., 2020), such as carbon nanotubes (CNTs), liposomes, micelles, dendrimers, nanocapsules/nanospheres, and polymeric NPs (Perez-Herrero and Fernandez-Medarde, 2015). This review focuses on 3D structures since they allow for easier encapsulation and additional protection of therapeutics. The current review divides NPs into organic and inorganic type. Such classification of NPs focuses on their biocompatibility and stability depending on the consistency of the drug-containing shell. Also, this review introduces EVs, especially exosomes, which are the most up-to-date nanomedicine. Recent studies have focused on hybrids, as they minimize the disadvantages and maximize the advantages of organic, inorganic NPs, and EVs by combining the two or more (Ferreira Soares et al., 2020). Additionally, nanomedicine may be magnetized and incorporated in magnetic field-mediated delivery.

2.2. Organic nanoparticles

Organic NPs consist of organic materials, including lipids and aqueous molecules (Xie et al., 2019), allowing for high biocompatibility. Usually, NPs (liposomes, dendrimers, etc.), are prepared with functional moieties such as polyethylene glycol (PEG). For example, organic NPs made of lipids break down into lactic and glycolic acids after the loaded therapeutics are released into the target area, which can then be used up in the metabolic cycle (Vanden-Hehir et al., 2019). Additionally, organic NPs such as dendrimers, which are polymeric molecules with numerous branch structures enabling their surface to be easily modified, exhibit high bioavailability (Palmerston Mendes et al., 2017). When combined with organic NPs, the unstable hydrophobic drugs showed improved dissolution and stability (Pentek et al., 2017). For instance, the 100% dissolution time of resveratrol, a compound often known as an antioxidant, was found to be approximately 4.5 h when tested alone, while it took approximately 0.5 h in dendrimer-drug complexes (Chauhan, 2018). Additionally, 90% of resveratrol remained in dendrimer-resveratrol complexes compared to 10% for pure resveratrol, which indicates that dendrimers can mitigate stability issues (Pentek et al., 2017). Furthermore, organic NPs have been designed to mitigate the issue of crossing the BBB so that such liposomes and micelles have been reported to protect their vehicles from degradation and transport their loaded therapeutics across the BBB (Spuch and Navarro, 2011; Zou et al., 2017). For another example, the CD163 receptor-targeted liposomes

incorporating dexamethasone showed a 3-fold higher delivery rate in the brain than sham group in 6-hydroxydopamine Parkinson's disease rat models (Tentillier et al., 2016). The solid lipid NPs encapsulating acetylcholinesterase reactivators with the help of multiple emulsion technique presented a 9-fold higher delivery rate than acetylcholinesterase reactivator only group 45 min after injection in organophosphate-induced brain injury rat models (Pashirova et al., 2017).

Another notable advantage of organic NPs is their allowance for active cellular targeting; ligand tagging techniques allow the attachment of ligands, such as antibodies, peptides, aptamers, and folate molecules to the NP surface. The ligands make the organic NPs bind to target cell receptors, leading to efficiently selective delivery with high therapeutic efficacy (Mullen and Banaszak Holl, 2011); the L-carnitine-conjugated poly lactic-co-glycolic acid NPs containing paclitaxel showed a 10-fold higher accumulation in the brain than paclitaxel only injection 2 h after administration in brain tumor mouse models (Kou et al., 2018). In a review article in 2021, apolipoprotein E-conjugated polymeric NPs were emphasized regarding their merits such as the improved transport across the BBB, accumulation in the brain, and inhibition of the accumulation of neurodegenerative disease-related factors (Hartl et al., 2021). Similar to the protein derivative conjugation, glucose-coated micelles piled up in the mouse brains 56-fold higher than micelles without glucose conjugation (Anraku et al., 2017).

Despite exhibiting high biocompatibility, high bioavailability, high penetrability of the BBB, and high targetability, the use of organic NPs still faces several obstacles. One major problem is the difficulty of large-scale production. For example, liposome production currently involves numerous steps, increasing the complexity of the entire manufacturing process and making commercialization difficult (Roces et al., 2020). Moreover, light, temperature, and metal ions may trigger chemical changes in the NPs such as lipid oxidation, leading to permeability changes when these NPs could be exposed to such changes (e.g., during transportation, in storage, in the body after administration; Guimarães et al., 2021). Although promising results—the variety of polymer coatings has been developed to prevent the removal of NPs by mononuclear phagocyte systems, which almost recognize the administered NPs as a foreign body and make those defending systems activated, before they would arrive in the targeted CNS (Owens and Peppas, 2006) and coating NPs with PEG is the most effective manner to prohibit nonspecific protein adherence and subsequent phagocytosis—have been reported (Vonarbourg et al., 2006), potential problem with organic NPs such as liposomes is that they can still accumulate in the liver and spleen; this accumulation triggers phagocyte uptake by mononuclear phagocyte systems, dominantly by Kupffer cells in the liver, and 99% of the administered NPs can be eliminated (Campbell et al., 2018). Additionally, it is another issue that microglia facilitate NP clearance in the CNS, capturing even PEGylated NPs (Gu et al., 2020).

Many promising studies are in progress to overcome these limitations (Guimarães et al., 2021). For example, microfluidics used in liposome manufacturing can simplify and scale up production while enhancing drug encapsulation using “bottom-up” approaches, which have no needs of additional size reduction process (Forbes et al., 2019). Moreover, controlling cholesterol, phosphatidic acid, and PEG content in liposomes has been shown to improve stability (Szabová et al., 2021). However, studies on these areas are limited,

these may be described as possible future directions for the development of organic NPs. Despite the efforts to mitigate the limitations of organic NPs, recent studies have focused on hybrid NPs and indirect methods (Shah et al., 2020). But still, the biocompatible, bioavailable, BBB-penetrable characteristics of organic NPs are noteworthy (Table 1).

2.3. Inorganic nanoparticles

Inorganic NPs made of materials such as gold, iron oxide, and carbon have a high surface area to volume ratio (Yao et al., 2020), which enables a high drug-carrying capacity. For example, CNTs have a diameter of 0.4–3.0 nm and a length of 20.0–1000.0 nm, resulting in a high carrying capacity; when the antitumor agent 10-hydroxycamptothecin, which has been investigated for the treatment of brain glioma, was covalently attached to the surface of a multiwalled CNT, it showed a sufficient loading efficiency of approximately 16% (Kostarelos et al., 2005; Wu et al., 2009; Perez-Herrero and Fernandez-Medarde, 2015). Additionally, mesoporous silica NPs have a large inner pore amount, making them advantageous drug-carrying agents (Yao et al., 2020) with a carrying capacity of 100 wt% for anticancer drugs in mouse models (Cheng et al., 2019). The surface modifiability of inorganic NPs enables effective targeting; for example, attaching a folate-containing compound to CNTs enabled specific delivery of therapeutics to folate-receptor + cancer cells (Dhar et al., 2008; Perez-Herrero and Fernandez-Medarde, 2015). Gold NPs, Au-SMCC linker-doxorubicin nanoconjugates, also displayed surface modifiability made by connecting doxorubicin to the surface of gold NPs and showed effective drug accumulation in HepG2-R cancer cells (Cheng et al., 2013). Like aforementioned findings, modified gold NPs on strategies for CNS-targeted delivery have gained considerable attention as the relevance to the context of CNS disease treatment including brain tumors. In addition to the high drug-carrying capability, inorganic NPs such as silver, gold, or quantum dots can cross the BBB with their own mechanisms; gold NPs increased the BBB permeability by disrupting the endothelial tight junctions, in which Na, K, and/or Ca ion channels are involved, and reached their peak concentration in the cerebrospinal fluid (CSF) 3-fold higher than that in the blood 6 h after transperitoneal injection in rats, and quantum dots conjugated with fluorescein hydrochloride, which uses glucose transporters to penetrate the BBB, accumulated in the central canal and in the cervical spinal cord, especially in the gray matter, following transcatheter and intravenous injection in zebrafishes and rats, respectively (Sela et al., 2015; Seven et al., 2021). Also, multiwalled CNTs, which use energy-dependent transcytosis, completely crossed the BBB and remained persistently in the brain even 24 h following intravascular injection in rats while notable decrement occurred in the peripheral capillaries (Kafa et al., 2015).

Despite the advantages of inorganic NPs, they exhibit immunotoxicity, genotoxicity, or specific tissue toxicities such as neurotoxicity, leading to inflammation, carcinogenesis, fibrosis, cardiovascular diseases, etc. (Mohammadpour et al., 2019). For example, after a month of accumulation in the spleen, gold NPs have been shown to downregulate the expression of genes relevant to wound healing, responses to external stimuli, and defense responses (Balasubramanian et al., 2010). In the liver, genes relevant to lipid metabolism or the cell cycle process were upregulated (e.g., squalene

epoxidase expression showed a fold change of 2.9; Balasubramanian et al., 2010). Additionally, cells incubated with polymer-coated multiwalled nanotube F127 for 24 and 48 h showed 60 and 40% cell viability, respectively, indicating cytotoxicity (Ali-Boucetta et al., 2011).

However, inorganic NPs can be controlled by regulating size, morphology, dosage, and chemical factors to regulate their toxicity (Madani et al., 2011). During the generation of NPs, doping, a technique in which impurities are added to the NPs for chemical/physical improvements, may be used to reduce cytotoxicity (George et al., 2010). In doping methods, three types are commonly used; first, elemental doping is conducted at atomic level, and divided into metal doping using such as cerium, cobalt, copper, iron, lanthanum, manganese, potassium, silver, and zinc as dopants, among which manganese is widely used, and nonmetal doping using such as boron, carbon, fluorine, nitrogen, phosphorus and sulfur, among which nitrogen is the mostly applied dopant. Second, it can be performed at molecular level (molecular doping), in which active molecules are encapsulated into vehicles such as metal–organic frameworks, polymers, quantum dots, and silica, among which silica is the mostly used matrix. Third, codoping combines the benefits of codoped elements, through which metal combination, such as iron and sulfur, nitrogen and sulfur, copper and manganese, as well as combination of metal and nonmetal dopants have been achieved (Wang et al., 2022). However, such relationship between the matched dopants and NP matrix is not clearly known so that further studies will be required to establish a guideline for reliable manufacture of doped NPs.

Additionally, iron oxide NPs can be degraded into Fe ions in lysosomes of cells or under other acidic conditions, reducing the potential long-term toxicity (Yu et al., 2012; Mitchell et al., 2021). In a long-term (approximately 13 months) study regarding the safety of ferumoxytol, an FDA-approved iron oxide NP, in the treatment of iron-deficient anemia patients with chronic kidney disease on hemodialysis, no patients experienced intravenous ferumoxytol replacement treatment-related serious adverse events (Macdougall et al., 2019), indicating the relevance of the safety of iron NPs in the context of long-term administration. If toxicity issues can be resolved, inorganic NPs could have a high potential for use in effective direct delivery methods in the treatment of CNS disease due to their ability to easily cross the BBB and their efficient drug loading capacity (Table 1).

2.4. Extracellular vesicles/exosomes

While NPs are in common synthetic drug delivery vehicles (Sun et al., 2022), EVs are innate, nano-sized, phospholipid bilayer-enclosed vesicles (Elsharkasy et al., 2020) that can be, in theory, released by all kinds of cells (Rufino-Ramos et al., 2017) through exocytosis for intercellular communication. Recently, EVs have gained attention as a delivery tool of therapeutics owing to their groundbreaking preclinical success in brain-targeted delivery. Though the degree may vary depending on the type, EVs hold notable advantages for CNS-targeted delivery of therapeutics because of their noninvasiveness, high biocompatibility, permeability across the BBB, and high stability *in vivo* (Elsharkasy et al., 2020). Moreover, the surface of EVs can be engineered to increase brain targetability (Marie et al., 2021). Three main types of EVs include apoptotic bodies

TABLE 1 Types of nanoparticles.

Type	Advantage/Disadvantage		Authors	Subject	Result
Organic	Advantage	High biocompatibility/low immunogenicity	Vanden-Hehir et al. (2019)	Organic NPs made of lipids	Break down after delivering the drug to the target area, and are used up in the metabolism cycle
		Dissolution and stability improvements	Chauhan (2018)	Dendrimers combined with organic NPs	100% dissolution time took about 0.5 h but 4.5 h when tested alone
			Pentek et al. (2017)	Resveratrol in dendrimer-drug complexes	90% remained compared to 10% in pure resveratrol
	Disadvantage	Difficulty of large-scale production	Roces et al. (2020)	Producing organic NPs involves numerous steps	Increases the complexity of the entire manufacturing process and serves as an obstacle to commercialization
		Instability (chemical degradations by metal ions)	Guimarães et al. (2021)	Lipid oxidation	Lead to permeability changes
		Early elimination	Campbell et al. (2018)	Organic liposomes	The phagocyte system in the liver can take up to 99% of the administrated NPs
Inorganic	Advantages	High drug-carrying capacity	Kostarelos et al. (2005); Perez-Herrero and Fernandez-Medarde (2015); Wu et al. (2009)	HCPT covalently attached to the surface of a multi-walled carbon nanotube	Showed a sufficient loading efficiency of approximately 16%
			Cheng et al. (2019)	MSNs with a large internal pore volume	Resulting in a vast carrying capacity of 100 wt% for anticancer drugs
		Surface Modifiability/Effective Targeting	Dhar et al. (2008)	CNTs with the folate compound	Allowed for specific delivery of the therapeutics to FR(+) cancer cells
			Cheng et al. (2013)	Au-SMCC-DOX nanoconjugates	Showed effective drug accumulation in hepG2-R cancer cells
	Disadvantages	Toxicity problem	Ali-Boucetta et al. (2011)	AuNPs accumulated for over 1 month in the spleen and liver of rats	Changed the expression of genes, squalene epoxidase showed fold change of 2.9 ± 0.7 , $p < 0.05$
			Ali-Boucetta et al. (2011)	Cells incubated with polymer-coated multi-walled nanotube: F127	F127 (concentration of 125 µg/ml) for 24 h and 48 h showed 60 and 40% of cell viability
Hybrid	Advantages	Tunable size	Bose et al. (2020)	Antibiotic-loaded LPHNPs engineered with CA and ZA lipids	NA was shown to have a diameter of 226 ± 9.6 nm, CA LPHNPs were 203 ± 6.6 nm and ZA LPHNPs were 191 ± 5.4 nm in diameter, size of hybrid NPs are tunable
		Surface charge		CA or ZA LPHNPs introduced into the LPHNP formulation in the same study	Charge reduction of -29 ± 2.1 mV occurred
		High drug loading yield	Bose et al. (2020)	Comparing the %EE and vancomycin %EE of BNPs and CA or ZA lipid layered LPHNPs	The %EE of both CA and ZA LPHNPs is greater than that of bare organic NPs
		Sustained drug release	Bose et al. (2020)	Cumulative antibiotic release from doxycycline-encapsulated BNPs and vancomycin-encapsulated BNPs	The antibiotic release rates of doxycycline BNPs at 12, 24, and 48 h were each 65, 69, and 75%
		High stability	Yang J. et al. (2021)	<i>In vivo</i> gene delivery study; bare pCas9/MGMT degraded within 3 min of incubation with DNase I, and the pCas9/MGMT plasmids in LPHNs-cRGD	Remained intact throughout varying incubation durations with DNase I

(Continued)

TABLE 1 (Continued)

Type	Advantage/Disadvantage		Authors	Subject	Result
		Biocompatibility	Khan et al. (2020)	CCK-9 assay results of LPHN-cRGD	Demonstrated cell viability of >80% after exposure to varying concentrations of NPs
		Efficient selective delivery and higher therapeutic efficacy by tagging ligands	Anraku et al. (2017)	Glucose-administered micelles for the treatment of Alzheimer's	Shown a 56-times higher accumulation rate in the CNS than micelles without ligands
			Hartl et al. (2021)	Conjugation of apolipoprotein E(Apo E) with NPs	Improved transport across the BBB, accumulation in the brain, and inhibition of the accumulation of neurodegenerative disease-related factors
	Disadvantages	Unbalanced ratio of the components, less controlled antigen release, lipid layer not fully stabled, and unprotected hybrid structure integrity during long-term storage	Hu et al. (2010)		
		Harmful tissue deposition in the kidneys, reticuloendothelial system, and microvasculature, unintended activation of host immune response, and damage to target cells	Howard et al. (2014)	ALAs	

NPs, nanoparticles; HCPT, hydroxycamptothecin; MSNs, mesoporous silica nanoparticles; CNTs, carbon nanotubes; FR, folate-receptor; AuNPs, gold nanoparticles; LPHNPs, lipid-polymer hybrid nanoparticles; CA, cationic; ZA, zwitterionic; %EE, encapsulation efficiencies; BNPs, bare nanoparticles; CNS, central nerve system; and BBB, blood-brain barrier.

(ApoBDs), microvesicles (MVs), and exosomes. Major difference among the three types include their formation process, size, and origin ([Shao et al., 2018](#); [Nederveen et al., 2021](#)). ApoBDs and most MVs have a large particle size ([Elmore, 2007](#); [Shao et al., 2018](#)), making them not ideal candidates for targeted delivery to the CNS. Therefore, authors briefly introduce ApoBDs and MVs, and then concentrate on describing exosomes—the smallest EV type, which may easily pass through the BBB so that it holds a superior potential for CNS-targeted delivery than other EVs ([Shao et al., 2018](#)).

Apoptotic bodies are the largest of EVs (500–4,000 nm; [Elmore, 2007](#)) that are formed during apoptotic cell disassembly where fragmented cell contents such as organelles and nuclear content are enclosed in membrane-bound vesicles ([Santavanond et al., 2021](#)). ApoBDs successfully trigger clearance of damaged cells in tissue development and regeneration of the kidney and bone ([Li et al., 2020](#)). MVs are EV subtypes that are released directly from the cell surface of platelets, red blood cells, and endothelial cells ([Yang J. et al., 2021](#)) and range in size from 200 to 2,000 nm ([Shao et al., 2018](#)). MVs may transport proteins and miRNA between cells and have been used for the diagnosis of autoimmune diseases, treatment of acute kidney injury, etc. ([Liu et al., 2016](#)). While ApoBDs and MVs may be tried for CNS-targeted therapy with the help of indirect, BBB penetration-assisting methods, there is limited evidences on the two methods.

Exosomes are the smallest EVs (40–200 nm) that are formed in all types of cells when vesicles bud into endosomes inside cells ([Shao et al., 2018](#)). Exosomes may directly penetrate the BBB, are highly stable in peripheral circulation, and thus may protect disease-specific therapeutic molecules, unlike ApoBDs and MVs. At the beginning of

researches, exosomes were studied as a biomarker to monitor disease development, allowing early diagnosis and treatment optimization in such stroke, glioma, Parkinson's diseases, Alzheimer's diseases, Huntington's diseases, and amyotrophic sclerosis ([Liu et al., 2019](#); [Fan et al., 2022](#)). After that period, exosome trials have been extended to therapeutic role for CNS disease as well ([Fan et al., 2022](#)). In a Martins et al.'s research, the ability of two A β -binding proteins—alpha-1-antichymotrypsin and C4b-binding protein alpha chains—was analyzed to validate exosome levels in patients by using antibody-based methods, indicating significant correlations between alpha-1-antichymotrypsin exosomal concentrations and mini-mental state examination scores and clinical dementia rating scores, indicators of cognitive alterations. Moreover, C4b-binding protein alpha chains was reported to limit the complement activation by A β and dead cells in Alzheimer's disease brains, potentially protecting the neurons from immune responses ([Soares Martins et al., 2022](#)). Recently, another notable advantage of exosomes was discovered; their inherited membrane proteins—such as CD9, CD63, prostaglandin F2 receptor negative regulator, and Lamp2b—can be genetically and/or chemically engineered to increase tissue-targetability, showing promising results in preclinical studies for CNS targeting ([Sun et al., 2022](#)). In a study by Alvarez-Erviti et al., Lamp2b-RVG plasmids were created to transfect autologous-derived dendritic cells, stimulating the secretion of engineered exosomes. Following that engineering, the exosomes were intravenously injected to mice, resulting in specific delivery of siRNA to neurons, oligodendrocytes, and microglia in the brain, ultimately leading to specific gene (BACE1) knockdown for Alzheimer's diseases ([Alvarez-Erviti et al., 2011](#)). As such, exosomes

may be used for targeted delivery of various therapeutics, such as proteins, siRNAs, miRNAs and even drug ingredients of low molecular weight, to injured CNS neurons with the help of genetically and/or chemically engineered surface modification (Sun et al., 2022; Zhou et al., 2022).

Despite such advantages, however, clinically approved CNS-targeted exosomes would require further investigation regarding detailed methods in pointed view of penetration efficiency of the BBB as well as the development of quantitative and qualitative monitoring and imaging tracking methods about targeted delivery to the CNS neurons (Hojun Choi et al., 2022). Moreover, in a research on wound healing promotion using adipose cell-derived exosomes, it was found that the metabolic condition of exosome donors affects the biogenesis, biological activity, and composition of the adipose stem cells (Cianfarani et al., 2013), thus affecting the adipose stem cell exosomes. Technically, isolation and purification methods should also be validated for reliable production in large scale (Rufino-Ramos et al., 2017).

2.5. Hybrid nanomedicine

Hybrid NPs are a combination of organic and inorganic NPs, which enable the combined advantages of both types of NPs to be leveraged for the treatment of CNS disease, and these NPs exhibit tunable size and surface charge based on the components included. The size and surface chemistry of NPs are critical since they affect the efficacy of NP delivery to diseased tissues, redistribution of NPs within the body, and potential toxicity (Walkey et al., 2012). One example of the tunability of the size of hybrid NPs is the use of different lipids; in a study comparing antibiotic-loaded lipid-polymer hybrid NPs (LPHNPs) engineered with cationic and zwitterionic lipids, the diameter of cationic LPHNPs was 203 ± 6.6 nm and that of zwitterionic LPHNPs was 191 ± 5.4 nm (Bose et al., 2020). Moreover, when cationic or zwitterionic LPHNPs were introduced into the LPHNP formulation, the charge was reduced by -29 ± 2.1 mV, indicating that LPHNPs are more advantageous in terms of their ability to interact with surrounding cells, their penetration of the BBB, and their colloidal stability (Bose et al., 2020).

High drug-loading yield and sustained drug release are other advantages of hybrid NPs; when the encapsulation efficiencies (%EE) of doxycycline-bare NPs and cationic or zwitterionic lipid layered LPHNPs loaded with doxycycline were compared, the results corresponded to a %EE of 63, 71, and 79%, respectively. Moreover, the antibiotic release rates of cationic LPHNPs at 12, 24, and 48 h were 38, 54, and 66% when zwitterionic LPHNPs were 32, 47, and 61% and doxycycline-bare NPs were 65, 69, and 75%, respectively (Bose et al., 2020).

Hybrid NPs also exhibit high stability and biocompatibility because their outer shells are combinations of the organic and inorganic shells. In an *in vivo* gene delivery study, bare pCas9/methylguanine methyltransferase degraded within 3 min of incubation with DNase I, and pCas9/MGMT plasmids loaded in LPHNPs remained intact throughout varying durations of incubation with DNase I (Yang Q. et al., 2021). This result indicates that LPHNPs successfully protected pCas9/methylguanine methyltransferase from enzyme degradation and can be used as a stable delivery vehicle (Yang Q. et al., 2021). In addition, the application of LPHNPs after exposure

to varying concentrations of cisplatin and curcumin demonstrated a cell viability of >80% based on CCK-9 assay results in A2780 tumor cells (Khan et al., 2020). Nevertheless, for the hybrid NPs, there were only *in vitro* performed studies that depicted *in vitro* or plainly brain cell uptake; for instance, Fe₃O₄ LPHNPs manufactured by self-assembly technique penetrated a BBB model composed of human brain microvascular endothelial cells (BMVECs) under magnetic field guidance (Qiao et al., 2020), and mesoporous silica liposome of poly(acrylic acid)-hybrid NPs conjugated with angiopep-2 showed the enhanced penetration rate of the BBB model of BMVECs (Tao et al., 2019). Yet, without *in vivo* studies, it becomes difficult to explain the validity of the targeting experiment.

Despite such advantages, further studies are needed to determine the proper balance of the ratio of the components of the outer shell (i.e., cholesterol). This ratio is important in CNS targeting, as it affects the stability of antigen release, lipid layer stability, and the protection of the integrity of the hybrid structure during long-term storage (Hu et al., 2010). Therefore, recent studies have focused on manufacturing hybrid NPs in an appropriate ligand/receptor density ratio, as this ratio substantially affects their targeting abilities (Alkilany et al., 2019). For example, there was a study in which equimolar amounts of five different lipids—ethyl arachidate, myristic acid, stearic acid, ethyl myristate, and glycerol monostearate—were tested in the form of BBB-crossing terpolymer lipid-hybrid NP, in which polysorbate 80 was covalently attached to poly(methacrylic acid)-grafted-starch, for colloidal stability and *in vitro* application when delivering doxorubicin to glioblastoma multiform (GBM) brain tumor cells. Of the different lipids tested, the ethyl arachidate doxorubicin-hybrid NP showed the most ideal colloidal properties, stability, and highest cytotoxicity against GBM cells (Ahmed et al., 2021). To address the remaining challenges in identifying the ideal out shell composition of hybrid NPs for different CNS therapies, additional studies should focus on determining the proper ratio of the outer shell components in correspondence with degree of *in vivo* stability, targetability, and bioavailability, respectively, in individual types of CNS disease and therapeutics (Table 1).

Similar to the hybrid NPs, hybrid nanomedicine, a combination of NPs and exosomes, has been recently tried, especially in cancer researches; for example, a CD47-expressing exosome cRGD-modified liposome-hybrid nanomedicine inhibited activation of mTOR pathway in ovarian cancer cells indicating targeted codelivery of triptolide and miR₄₉₇ (Li et al., 2022), and another hybrid nanomedicine combining granulocyte-macrophage colony-stimulating factor-overexpressing exosomes and docetaxel-loaded liposomes showed enhanced codelivery of granulocyte-macrophage colony-stimulating factor and docetaxel in metastatic peritoneal cancer rats (Lv et al., 2020). Meanwhile, reported are just few studies showing a potential of hybrid nanomedicine application to CNS-targeted delivery (Rufino-Ramos et al., 2017); for instance, enveloped protein nanocages precisely matching the targeted scaffold via viral glycoprotein were inserted into the EV (Votteler et al., 2016), and exosome-mimetic nanovesicle, in which therapeutic drugs were contained through repetitive macrophage and monocyte breakdown using sequential filtering of extrusion (Jang et al., 2013). However, application of hybrid nanomedicine to CNS-targeted delivery is at its initial stage of development so that it would require further approval in feasibility and validity as the limitations of hybrid NPs do.

In addition to researches on improving the hybrid nanomedicine themselves, it is expected that future studies on hybrid nanomedicine will be focused on their combination with other indirect methods, such as focused ultrasound (FUS; [Ahmed et al., 2021](#)) and photodynamic therapy (PDT; [Zhang et al., 2020](#)), approaches of which will hold promise despite the need for additional studies.

3. Magnetic field-mediated delivery

This review introduces magnetic delivery in chronological order of their development: magnetic field-mediated passive navigation, magnetotactic bacteria (MTB), magnetic resonance navigation (MRN), and magnetic nanobots. It is important to note that due to preexisting categorical limitations of targeted delivery, this review classifies magnetic field-mediated delivery as a direct method, although it actually has indirect characteristics in nature.

Magnetic navigation is a delivery method that accumulates magnetic micro/nanodrug carriers in the targeted area by controlling the direction and propulsion of the carriers with externally provided permanent magnets or electromagnets; this technique has the advantages of navigational delivery to an injury site and exclusive localization within the injury site, allowing therapeutics to escape from emulous binding with non-*in situ* receptors, specifically in the context of CNS-targeted delivery ([Chorny et al., 2011](#)). *In vitro* and *in vivo* studies involving centralizing scattered ferromagnetic rods/microcapsules have shown that magnetic forces may be used to successfully manipulate magnetic materials for directional navigation ([Nacev et al., 2015](#); [Voronin et al., 2017](#)). Furthermore, magneto-nanobots can be utilized as magnetic field-mediated, actively assisted navigational vehicles that enable cell-specific targeting; in a study where an external magnetic field and magnetic nanobots consisting of magnetic NPs (Fe_3O_4 NPs) were used to deliver anticancer drugs, the nanobots were shown to gain thrust from O_2 emissions produced from the decomposition of H_2O_2 released from tumor cells ([Andhari et al., 2020](#)). Attaching Fe_3O_4 to the NPs provides autonomous propulsion and superparamagnetic properties to the nanobot system ([Andhari et al., 2020](#)), suggesting a potential of the targeted delivery to deeply located lesions within the CNS. However, using an external magnetic field is difficult in tissues greater than 2 cm deep within the body, as the aforementioned advantages of magnetic field-mediated directional navigation sharply decrease with increasing distance between the magnets and the carriers ([Hwang, 2020](#)). Although internal methods such as the implantation of magnets within the body have been devised as an alternative (e.g., intrathecal implant; [Lueshen et al., 2015](#)), implants can trigger side effects such as infection and intolerance to them ([Ganz, 2017](#)). Thus, these disadvantages of external and internal methods should be augmented to promise better magnetic field-mediated delivery.

Magnetotactic bacteria are groups of bacteria that contain magnetosomes, which are intracellular structures that consist of biological materials such as magnetite (Fe_3O_4) and greigite (Fe_3S_4); MTB-derived magnetosomes thus have higher biocompatibility than artificial NPs due to their biological properties ([Alphandery et al., 2017](#)). Magnetosomes can be isolated from MTB and used as drug delivery carriers, and, as an alternative to paramagnetic/superparamagnetic NPs, MTB themselves can be loaded with

drug-carrying vehicles for magnetic field-mediated navigation into target tissues. In one recent study, when magnetosome toxicity was evaluated in mice, complete blood counts and the results of a basic metabolic panel were within the normal range, and no change in the composition of urine or weight was found ([Nan et al., 2021](#)). Additionally, drug-carrying MTB with long actin-like filaments encoded by the *mamK* gene exhibit magneto-aerotaxis, which enables them to align with the direction of an applied magnetic field, move toward the hypoxic regions of targeted cells, and directly navigate the MTB-loaded vehicles to the CNS ([Marcuello et al., 2018](#)). In addition, magnetosomes have been shown to promote the axonal outgrowth of neurons through stretch growing when magnetic fields are applied ([De Vincentiis et al., 2021](#)). In one study, a total of 500–700 μg of magnetosomes coated with poly-L-lysine and magnetic fields of 202 kHz and 27 mT were used to treat GBM brain tumor cell models, and living GBM cells in all mice completely disappeared after 68 days ([Alphandery et al., 2017](#)). Although MTB have many advantages, they may adversely affect the human immune system by decreasing the level of lymphocyte proliferation ([Nan et al., 2021](#)). The composition of magnetosomes produced in MTB is often difficult to reproduce, leading to their low production yield ([Alphandery et al., 2017](#)). To overcome these limitations, MRN was developed.

Magnetic resonance navigation is a delivery method that uses a magnetic resonance imaging (MRI) scanner to provide propulsion to microcarriers (up to 400 mT/m) and to make them follow a preprogrammed route to the targeted area ([Martel, 2010](#)). Administering MRN consists of three steps—steering, creating a magnetic gradient, and real-time tracking imaging—that are repeated until the carrier reaches the target ([Pouponneau et al., 2014](#); [Li et al., 2019](#)). In a study testing MRN targeting in a two-level bifurcation, magnetic drug-eluting beads aggregated with targeting success rates of 84, 100, 84, and 92% for the four different ends of the branch routes ([Li et al., 2019](#)). In another study on rabbit hepatic arteries, the MRN successfully steered therapeutic magnetic microcarriers to the left lobes ([Pouponneau et al., 2014](#)). In these studies, MRN showed targeting effectivity both in the one-level bifurcation in an animal model and in the higher level of bifurcation of artificial pathways; these findings demonstrate its potential use in targeting more complex pathways in the human body ([Pouponneau et al., 2014](#); [Li et al., 2019](#)). However, the references currently cited are based on the treatment of hepatocellular carcinoma by liver chemoembolization. Hence, it is unsure how well it will perform for the brain, which should be evaluated in future studies.

Furthermore, factors such as pulsatile flow can currently limit the use of MRN in *in vivo* studies to even simple pathways, such as one or two Y-bifurcations and 2D vascular phantoms ([Folio and Ferreira, 2017](#)). Moreover, some nonspherical microparticles navigated using MRN occasionally attach to the surface of nontarget tissues ([Ghosh et al., 2021](#)). However, this problem may be solved by increasing the magnetic gradient to overcome friction and by administering orthogonal pulses ([Ghosh et al., 2021](#)). While limitations exist, these studies demonstrate the targeting effectivity and potential of MRN for use in more complex pathways, making it one of the most promising tools for CNS-targeted therapy ([Table 2](#)). However, it should be in mind that it comes from the authors' personal extrapolation from the current information and their use in clinical paradigms cannot be justified yet due to such major limitations.

4. Indirect targeted delivery

The most considerable barrier to the use of direct targeted delivery has been their inability to allow therapeutics that exceed 400 Da to pass through the BBB (Pardridge, 2012; Cui and Cho, 2022). To overcome this disadvantage of the direct targeted delivery, development of indirect targeted methods has been demanded. In this section, the authors aim to introduce indirect chemical and physical methods that open the BBB, the mechanisms of each method, their advantages and disadvantages, and discussion of the recent findings with important implications. Chemical and physical methods can increase the permeability of the BBB using chemicals and physical energy, respectively. Mannitol has been widely used to decrease intracranial pressure (Chengyan Chu et al., 2018), but shown side effects such as edema and renal failure (Visweswaran et al., 1997) and a short efficacy time (Cosolo et al., 1989). Therefore, other chemicals, such as bradykinin and 1-O-pentylglycerol, have been studied. After briefly introducing chemical methods, this section mainly focuses on describing two main physical methods that are being developed: FUS and LASER therapy.

4.1. Chemical delivery

Indirect chemical targeted delivery is a method that chemically increases the permeability of the BBB, thereby allowing therapeutics to pass the BBB and take effect in the CNS (Pardridge, 2012; Dong, 2018; Cui and Cho, 2022). Hyperosmotic mannitol is the most widely used BBB permeabilizer (Chengyan Chu et al., 2018). It triggers dehydration of BBB endothelial tissues and deflates cell bodies, causing loosening of tight junctions, which enhances the permeability of drugs, stem cells, liposomal vehicles, and antibodies (Hendricks et al., 2015). However, when mannitol was injected into adult Sprague–Dawley rats at the optimum rate of 0.25 ml.s⁻¹.kg⁻¹ for 20 s, BBB disruption has been shown to last for approximately 5 min at maximum and then rapidly reverse (Cosolo et al., 1989), and administering 1,171 ± 376 g mannitol to a patient with normal baseline renal function resulted in acute renal failure (Dorman et al., 1990). Moreover, intracarotid arterial hyperosmolar mannitol increased the production of cytokines, chemokines, and trophic factors, leading to a neuroinflammatory response (Burks et al., 2021). Therefore, as mannitol has a short efficacy time and potential provocation of renal failure and systemic toxicity, and causes a neuroinflammatory response, other chemical methods are being developed to overcome such limitations.

Bradykinin is another agent used to permeabilize the BBB. Bradykinin is a vasoactive compound that selectively increases the permeability of abnormal brain capillaries (Black, 1995). A study using an RG2 rat glioma model demonstrated that stimulating the B2 bradykinin receptor rapidly increases the permeability of the BBB, especially in brain-tumor-associated tissue (Bartus et al., 1996). Moreover, treating female Wistar rats with bradykinin caused a 3.3-fold increase in the number of small arterioles, a 2.1-fold increase in the number of medium arterioles and a 1.5-fold increase in the number of large arterioles, alluding to an increase in pinocytotic vesicle density and BBB permeability (Raymond et al., 1986). However, it has a short half-life (27 ± 10 s; Cyr et al., 2001), may decrease the blood flow to the cerebrum, and causes

extravasation, necrosis, edema, and BBB breakdown at high dosages or pathological conditions, since it is a potent vasoactive compound for arterial dilation (Wahl et al., 1999). To overcome such limitations, bradykinin receptor agonist NG291 is being developed to induce a rapid onset of transient BBB disruption without early brain injury. In a Sprague Dawley rat and CD-1 mouse model study, notable NG291-induced increase in BBB permeability was revealed in a localized, reversible, dose-dependent and P-gp efflux transport-mediated manner. Moreover, NG291 did not evoke short-term neurotoxicity, nor the increase of brain water content, the number of Fluoro-Jade C positive cells, and astrocyte activation (Rodríguez-Massó et al., 2021), indicating that biased agonism may play a role in enabling therapeutics to specifically target BBB opening without causing brain injury.

1-O-pentylglycerol is an alkylglycerol that has also been investigated for its ability to permeabilize the BBB. 1-O-pentylglycerol affects the endothelial cell morphology of the barrier and disrupts the BBB structure (Hülper et al., 2013). For example, an *in vivo* tumor-free and C6 glioma-bearing rat experiment indicated that intracarotid injection of 1-O-pentylglycerol caused a transfer of fluorescein and lissamine-rhodamine B200 across the BBB, as the mean ratio of ipsilateral to contralateral fluorescence intensity in the coronal sections for fluorescein was 6.45 ± 1.4, and the mean ratio of lissamine-rhodamine B200–albumin was 2.66 ± 1.0 (Erdlenbruch et al., 2003), which indicates applicability as one of brain tumor therapeutics. Additionally, no 1-O-pentylglycerol accumulation was found in the brain, and more than 70% of the administered dose was excreted within 270 min after administration, which suggests rapid renal elimination and the nontoxicity of 1-O-pentylglycerol (Erdlenbruch et al., 2005). While 1-O-pentylglycerol raised concerns regarding immunogenicity and thus adverse effects in nontarget cells, incubating bEnd3 mouse brain cells with poly(alkyl cyanoacrylate)-alkylglyceryl dextran did not show significant toxicity at concentrations <25 µg/mL (Ibegbu et al., 2017).

Although various indirect chemical targeted delivery methods exist and are under development, it is not easy to reach a consensus regarding a specific chemical to recommend. The most researched and used chemicals—mannitol, bradykinin, and 1-O-pentylglycerol—each has unignorable shortcomings, such as short efficacy time (Erdlenbruch et al., 2005), drug leakage (Rodríguez-Massó et al., 2021), and systemic toxicity (Dorman et al., 1990). Due to the aforementioned significant side effects, their use in clinical paradigms cannot be justified yet because of such major limitations. Therefore, indirect physical targeted delivery methods are being developed to remedy such limitations.

4.2. Physical delivery

4.2.1. Focused ultrasound

Focused ultrasound is a noninvasive augmentation method that opens the BBB through the application of high-intensity focused ultrasound (HIFU), which helps deliver therapeutics to the targeted brain region. When the FUS wave is applied in a pulsed manner, tissues experience a cycle of high and low pressure (Timbie et al., 2015). FUS is used to generate microbubbles, which act as contrast media, and these bubbles function as echo-enhancers that pass through the ultrasound field, resulting in stable cavitation (Lee et al.,

TABLE 2 Magnetic field-mediated delivery.

Type	Advantage/Disadvantage		Authors	Subject	Result
Magnetic field-mediated passive navigation using external magnetic field	Advantages	Magneto-nanobots allows cell-specific targeting	Andhari et al. (2020)	External magnetic field and magnetic nanobots consisting of Fe ₃ O ₄ NPs	Provides autonomous propulsion ability and superparamagnetic property to the nanobot system
	Disadvantages	Sharply reduced effective delivery as the distance between the magnets and the carriers increases	Hwang (2020)		Unable to target tissues greater than 2 cm deep within the body
		Internal methods caused unexpected side effects to the body	Ganz (2017)	Magnetic implants around the gastroesophageal junction	Caused dysphagia, persistent nausea, and postoperative nausea
MTBs	Advantages	Higher biocompatibility than artificially synthesized NPs	Alphandery et al. (2017)	Magnetosomes consist of biological materials such as magnetite (Fe ₃ O ₄) and greigite (Fe ₃ S ₄) crystals	
		Less toxicity	Nan et al. (2021)	Tested its toxicity with mice	Complete blood count and basic metabolic panel showed normal range, and no change in the composition of urine and weight was found
		Exhibit magneto-aerotaxis which allows the drug to be directly navigated to the brain across the BBB when conjugated with NPs	Alphandery et al. (2017)	Magnetosome coated with poly-L-lysine (M-PLL) that contains 500–700 µg of iron was administered in a magnetic field of 202 kHz and 27 mT to treat GBM	Living GBM cells completely disappeared after 68 days for all treated mice
	Disadvantages	May adversely affect the human immune system	Nan et al. (2021)	Regarding the decreased level of lymphocyte proliferation	
		Difficulty in reproducing the composition of magnetosome and its low production yield	Alphandery et al. (2017)		
MRN	Advantages	Targeting effectivity both in the one-level bifurcation of an animal model and in the higher level of bifurcation of artificial pathways	Li et al. (2019)	Testing the MRN in a two-level bifurcation phantom with magnetic drug-eluting beads aggregates	Showed targeting success rates of 84, 100, 84, and 92%
			Pouponneau et al. (2014)	Rabbit's hepatic artery to the left/right liver lobes	Successfully steered therapeutic magnetic microcarriers to the left lobes
	Disadvantages	As pulsatile flow currently limits MRN to simple pathways <i>in vivo</i> studies	Folio and Ferreira (2017)	Applied to one or two simple Y-bifurcations or only 2D vascular phantoms	
		Some non-spherical microparticles occasionally attach to the surface of tissues and cannot travel to the target	Ghosh et al. (2021)		

CNS, central nerve system; BBB, blood–brain barrier; MTBs, magnetotactic bacteria; GBM, glioblastoma; and MRN, magnetic resonance navigation.

2017). Then, the blood vessels are mechanically stimulated by the microbubbles, which leads to opening of the BBB. Since the microbubbles can concentrate the ultrasonic energy, the initial

ultrasound pressure needed for opening the BBB is considerably reduced, leading to the BBB opening with lesser risks of skull bone heating ([Burgess et al., 2015](#)).

Focused ultrasound increases the bioavailability of therapeutics in the target area and helps them maintain their bioactivity throughout the delivery processes (Huttunen and Saarma, 2019). In a recent mouse study of Parkinson's disease, FUS was used with two sonication locations in regions that showed severe damage in Parkinson's disease: the caudate-putamen and substantia nigra (Dauer and Przedborski, 2003), and varied pulse lengths of 5,500 cycles (3.3 ms) to 10,000 cycles (6.6 ms) were used. When neurturin, a type of neurotrophic factors, was directly injected, its bioavailability area was limited to an average of $0.20 \pm 0.05 \text{ mm}^2$. However, with FUS, the bioavailability of neurturin was $5.07 \pm 0.64 \text{ mm}^2$ in the caudate-putamen and $2.25 \pm 1.14 \text{ mm}^2$ in the substantia nigra, showing a maximum 25-fold increase due to BBB opening, allowing neurotrophic factors to pass through (Samiotaki et al., 2015). Additionally, FUS causes minimal damage to the nervous system while increasing the delivery rate of therapeutics passing through the BBB. In a study of nonhuman primates in which the short-term (2 days) and long-term (18 days) effects on FUS-mediated BBB opening and the secondary effect on visual-motor cognitive task-related touch accuracy or reaction time were assessed, response accuracy did not decrease in the short term (from 0.76 ± 0.08 to 0.80 ± 0.03) and nor in the long term (from 0.62 ± 0.08 to 0.68 ± 0.05), which suggests that cognitive performance does not worsen following the FUS-induced BBB opening in nonhuman primates. In addition, no observable damage, microhemorrhage, or necrosis was observed in the histological test after the nonhuman primates were euthanized (Pouliopoulos et al., 2021). The aforementioned results suggest that FUS should be evaluated in healthy human populations to check whether it causes deterioration of cognitive functions or additional damage to the nervous system.

Although FUS has advantages, there are also limitations in applying FUS in clinical practices, especially regarding intensity. HIFU treatment with a frequency of 20 MHz generating a focal intensity ranging of 1,000–10,000 W/cm² may induce skin burns and neuronal damage due to thermal injuries caused by the inverse piezoelectric effect, leading to irreversible coagulative necrosis (Fan et al., 2012). In contrast to HIFU, low-intensity focused ultrasound (LIFU) with a peak intensity ranging of 10–500 W/cm² can increase the penetration of the therapeutics but may not cause side effects such as microhemorrhage and ischemia (Meng et al., 2018). Regarding the safety margin of FUS, LIFU treatment with a frequency ranging of 220–650 KHz producing a focal intensity of 80 W/cm² through an intact cranium induced no significant hemorrhage or necrosis in the necropsic cortex of eight 3–4-month-old swine (Zibly et al., 2014). Therefore, controlling the intensity and establishing clinical evidence is necessary for FUS to be an effective treatment. In authors' personal opinion, the focal peak intensity ranging of 10–80 W/cm² is ideal for FUS-based indirect delivery of therapeutics into the CNS in term of safety and efficiency: the stronger intensity, the better permeability but more adverse effects. Nevertheless, if more animal studies can be performed and the results applied to humans, FUS may be an effective way to help deliver therapeutics in a minimally invasive manner.

4.2.2. Light amplification by the stimulated emission of radiation therapy

Light amplification by the stimulated emission of radiation (LASER) therapy has been used in neurosurgery to destroy unhealthy brain tissue by creating heat. However, excess heat can induce damage

to neighboring nontarget tissues. Therefore, various studies have been conducted to increase the spatial precision of LASER therapy, leading to the development of CNS-targeted therapy that includes using LASER to change cells into a specific state in which LASER increases the permeability of the BBB and subsequently deliver therapeutics. Currently, LASER interstitial therapy (LITT), PDT, and photobiomodulation therapy (PBM) are three approaches to LASER therapy that are studied for CNS-targeted delivery. LITT is a technique used to increase local BBB permeability by directing a LASER to the target area, transmitting light energy through a thin fiber, which is then converted into thermal energy, and creating a local disruption of the BBB (Melnick et al., 2021). LITT has been applied to the treatment of CNS diseases such as GBM (Patel et al., 2020). LITT-induced hyperthermia disrupts the BBB, with peak permeability for anti-neoplastic drugs happening by 1–2 weeks following ablation and disappearing by 4–6 weeks (Leuthardt et al., 2016). However, there are difficulties in controlling temperature to prevent thermal damage to nearby organs or structures (Salem et al., 2019); specifically, high temperature—close to or above 100°C—at the tissue can cause water to boil, and undesirable air bubbles can be produced (Zhu et al., 2017). To overcome this problem, thermal MRI has been introduced to monitor the heating process in real time and deactivate the system when the temperature reaches a critical level (Salem et al., 2019; Chen et al., 2021). However, well-designed prospective clinical trials and appropriate follow-up time are required to check patient outcomes with using LITT.

Another type of LASER therapy is PDT, which consists of three major elements: photosensitizers, light energy, and tissue oxygen. When a specific wavelength of light activates the photosensitive agent, the photosensitizer generates cytotoxic reactive oxygen species (ROS) such as hydroxyl radicals and singlet oxygen. With the help of photosensitizers such as 5-aminolevulinic acid and phthalocyanines, PDT can site-selectively open the BBB by destroying tight junction proteins and increasing the tight junction gap (Semyachkina-Glushkovskaya et al., 2020). However, although PDT can increase BBB permeability, it cannot utilize near-infrared light, making it difficult to allow deep penetration and low phototoxicity to normal tissues (Lan et al., 2019). Therefore, two-photon excitation and upconversion NPs, such as angiopep-2 conjugated NPs, are being studied to minimize invasiveness (Tsai et al., 2018).

The mechanism of PBM action in cells is the same as that observed in the use of PDT, but the two have apparent differences. PDT requires exogenous photosensitizers, and its high level of ROS generation causes cellular damage, while PBM utilizes endogenous cellular photosensitizers, resulting in low ROS levels that may not deteriorate cellular functions (Lubart and Friedmann, 2011). Furthermore, the combination of PDT and PBM can act as a synergistic therapeutic tool with the help of increased efficacy of anti-neoplastic treatment by increasing ATP production in mitochondria and increasing the production and homogeneity of protoporphyrin X, which is an endogenous photosensitizer required in PDT (Joniová et al., 2021). Additionally, in a study, PDT (660 nm) combined with PBM (850 nm) in which the Ru complex was used as a photosensitizer, increased photocytotoxicity was observed in A375 tumor cells (Negri et al., 2019). However, in the transcranial PBM approach, light cannot penetrate the brain more than 20 mm from the cortex, making it difficult to use in delivering sufficient doses to the targeted region (Moro et al., 2014). Further study and clinical tests are required to

fully understand the mechanism of PBM, solve these limitations, and improve the efficacy of PBM.

5. Limitations/challenges

Direct and indirect targeted deliveries have many advantages and a great potential for use in CNS disease treatments, but have some limitations to be overwhelmed. Organic NPs require complicated process in production, and accumulate in the liver and spleen, and have a short half-life, and inorganic NPs have systemic toxicity involving multiple organs to be solved. Exosomes need further studies to figure the dependency of their characteristics on progenitor cells and nonstandardization of isolation and purification out. Hybrid nanomedicine demands the appropriately balanced ratio of the outer shell components, such as ligand/receptor density ratio, for the stability. Also, magnetic field-mediated delivery has difficulty in maintaining magnetic field greater than 2 cm deep within the body and navigational ability properly with increasing distance, MTB may trigger activation of the human immune system, and MRN has the obligation to use pulsatile flow, which disturbs its constant magnetic guidance even in simple pathways, and the tendency of nonspherical microparticles to attach to nontarget tissues surfaces. Regarding challenges of indirect methods, chemical deliveries, such as bradykinin and 1-O pentyglyceol, have numerous disadvantages; a short half-life, extravasation, adverse effects in nontarget organs. FUS has safety issues, intensity-related thermal injury by the inverse piezoelectric effect, and LASER therapy has problems of phototoxicity and generation of local hyperthermia and ROS to be solved.

Meanwhile, many of the delivery methods, especially NPs, described in the current manuscript have been known to reduce libido; for example, silver NPs compromised reproductive activity such as sperm motility 7 days after intravascular injection in rabbits (Castellini et al., 2014). Similarly, treatment of unconjugated titanium, gold, and silver NPs reduced the motility and viability of cryopreserved bovine spermatozoa from post-equilibration to post-thaw period following ejaculation (Pande et al., 2022). Furthermore, gender difference was reported in hepatic toxicity, especially dominant in female sex, after oral exposure of titanium NPs over 90 days in rats (Chen et al., 2019). Also, male sex-dominant differences in histopathology and mortality were noticed after single oral administration of copper NPs at higher dose in rats (Lee et al., 2016). To the contrary, no gender difference was revealed in bone marrow toxicity after oral exposure of silver NPs for 28 days in rats (Kim et al., 2008). Now, there are few clinical studies investigating gender difference of NPs; interestingly, in a randomized controlled clinical trial in which 19 patients with carious teeth were recruited, subgroup analysis showed no gender difference in marginal integrity restoration of resin composites following pretreatment with silver and gold NPs (Nemt-Allah et al., 2021). Hence, it requires further studies prior to discussion about their gender based effect.

6. Future directions and conclusion

In direct CNS-targeted delivery, organic NPs show high biocompatibility and low immunogenicity but are difficult to

produce at a large scale, lack stability, and are eliminated too early. Inorganic NPs show a high drug-carrying capacity, surface modifiability, and magnetic field-mediated navigability, but have toxic side effects. To overcome these limitations, efforts have been made to control the components of outer shells for better stability and reduce factors that cause toxicity. Although hybrid NPs, a combination of organic and inorganic NPs, have many advantages, such as tunable size, high stability, and high drug-loading yield, they have side effects, including harmful tissue deposition patterns, unintended activation of the host immune response, and damage to nontarget cells. Among EVs, exosomes show a notable potential for CNS-targeted delivery of therapeutics because of genetically and/or chemically engineered targetability of inherited surface proteins as well as biocompatibility and permeability across the BBB. Therefore, studies are in progress to manufacture NPs, exosomes, and ligands in an appropriate ratio, and contingencies such as PEG stealth technology have evolved, making hybrid nanomedicine, a combination of NPs and EVs, an effective direct delivery method. Another advantageous direct delivery method is magnetic field-mediated delivery, which utilizes magneto-nanobots, MTB, and MRN. However, methods using an external magnetic field have difficulty reaching deep targeted regions, and MTB negatively affect immune system of the human body and have a low production yield. Therefore, MRN was developed to overcome these issues, showing successful targeting efficacy in simple pathways in *in vivo* studies. While further studies are needed to apply MRN in more complex pathways, due to its pulsatile flow-induced navigability weakening in real time, it is one of the most promising direct CNS-targeted delivery methods.

As there are obstacles to overcome in the use of direct CNS-targeted delivery methods, indirect delivery methods have been developed and are used together with direct methods to create a synergistic effect. Chemicals such as mannitol and bradykinin effectively increase the BBB permeability but have a short half-life and show toxicity when injected. Although short-chain alkylglycerols do not have the same drawbacks as mannitol and bradykinin, they lead to complications related to immunogenicity problems and can invade nontarget cells. While FUS, one of the physical targeted delivery methods, increases and maintains the bioavailability of therapeutics and causes minimal damage to the CNS, it has problems related to delivery intensity that need to be solved to make this method more advantageous. LASER therapies, such as LITT, PDT, and PBM, have recently gained prominence and have been increasingly used for disrupting the BBB. However, they still have limitations—thermal damage, shallow penetration, and phototoxicity—to overcome, so thermal MRI is being introduced in LASER therapies, and two-photon excitation and upconversion NPs are being studied. Based on the outcomes, such as anti-neoplastic activity and validity of endogenous photosensitizers, LASER therapy may be one of the most promising indirect CNS-targeted therapy methods. While this article has recommended the most promising direct and indirect targeted therapies, it is important to note that combining the direct and indirect methods, such as hybrid nanomedicine of organic, inorganic NPs, and exosomes via MRN following preconditioning treatment with either PBM or LIFS, will be more effective and focused in the future (Figure 2).

Frontiers in Neuroscience

Provides a holistic understanding of brain
function from genes to behavior

Part of the most cited neuroscience journal series
which explores the brain - from the new eras
of causation and anatomical neurosciences to
neuroeconomics and neuroenergetics.
