A mixture of tin powder, red phosphorus powder, and I_2, with stoichiometric ratio, was sealed in an evacuated silica ampoule. Subsequently, the sealed ampoule was heated to 400°C within 40 min, kept for 10 h, and slowly cooled down to room temperature in 75 h. The ternary compounds were then collected from the silica ampoule.

Synthesis of Black Phosphorus (BP)

In a typical experiment, a mixture of red phosphorus (300 mg) and mineralizers (SnI_4: 6 mg, Sn: 12 mg) was sealed in an evacuated silica ampoule (∼10 cm in length and ∼10 mm in inner diameter). The ampoule was placed horizontally in the center zone of a muffle box furnace with a viewing window. It

should be noted that the temperature at the center of the furnace is slightly different from that near the wall. The temperature of the furnace was increased from room temperature to 650°C in 1 h, and then decreased to 550°C within 1 h. Afterwards, the temperature was further decreased to 500°C in 8 h, and then to 200°C in 4 h. Finally, the furnace was turned off for natural cooling to room temperature. After the reaction, BP crystals were collected from the ampoule, washed with hot toluene (∼60°C) for three times until the toluene was colorless, dried at N_2 atmosphere and stored at ambient environment.

BP crystals were also prepared in the presence of different mineralizers, such as $Sn_{24}P_{19.3}I_8$ (21.6 mg), SnIP (10.6 mg), a mixture of Sn and I_2 (Sn: 4.5–14 mg, I_2: 4.8 mg) and a mixture of SnI_2 and Sn (SnI_2: 7.1 mg, Sn: 11.2 mg), by keeping other conditions identical. Notably, despite the differences among varied mineralizers, the molar amount of I element was kept the same (0.038 mmol) when different mineralizers were used. All synthesis reactions, including the control experiments, were carried out under the same temperature program unless otherwise noted. To record the reaction processes, photographs were taken from the viewing window of the furnace at different stages during the reaction.

CHARACTERIZATION

Powder X-ray diffraction (XRD) patterns were recorded using a Rigaku Smartlab (9 kW) X-ray diffractometer with Cu Kα radiation (λ = 1.5406 Å). Raman spectra were acquired on a HR Evaluation spectrometer (Horiba, Confocal Raman Microscope) with a 532 nm laser. Thermogravimetric (TG) analysis was performed on a METTLER TGA2 under the N_2 atmosphere at a heating rate of 10°C/min. Scanning electron microscopy (SEM) image and corresponding energy dispersive X-Ray spectroscopy (EDX) analysis were carried out in a JSM-7800F (JEOL) scanning electron microscope. Low resolution transmission electron microscopy (TEM) measurements were carried out on a JEM-1400 transmission electron microscope at an acceleration voltage of 120 kV. High resolution TEM, dark-field scanning transmission electron microscopy (STEM), and corresponding EDX measurements were conducted on a 2100F transmission electron microscope at an acceleration voltage of 200 kV. Photographs were taken by a digital camera.

RESULTS AND DISCUSSION

Characterization of BP Crystals

Prior to studying the growth process of BP crystals, we first confirmed that high quality BP crystals can be obtained under our synthetic conditions. On a separate note, considering that the mixture of SnI_4 and Sn is one of the most commonly used mineralizers, we here chose the SnI_4/Sn mixture as a representative mineralizer in the following sets of experiments. As shown in **Figure 1A**, the obtained bulk BP crystals present a flower-like (radial) shape, with many sheetlike branches, on a centimeter scale and black color with metallic luster. Meanwhile, as revealed by the scanning electron microscopy (SEM) image, the BP crystal has a layered structure (**Figure 1B**), exhibiting the essential feature as a layered material (**Figure 1C**, upper panel). Further powder X-ray diffraction (XRD) analysis shows that the as-synthesized BP crystals give three main diffraction peaks at ∼16, 34, and 52° (**Figure 1D**). The XRD pattern reveals that the BP crystals are in orthorhombic phase with excellent crystallinity, while the three diffraction peaks indicate that the crystals grow in a highly oriented manner. Consistently, in the Raman spectrum, three characteristic peaks, at ∼361, 438, and 466 cm^{-1}, were observed (**Figure 1E**), which can be attributed to the characteristic A_g^1, B_{2g}, and A_g^2 modes in the orthorhombic BP lattice (**Figure 1C**, lower panel) (Guo et al., 2015; Ribeiro et al., 2018; Wang et al., 2018). In addition, high resolution transmission electron microscopy analysis of the exfoliated BP sheets, together with the energy dispersive X-Ray spectroscopy (EDX) analysis, shows the good crystallinity and purity of the as-synthesized BP crystals (**Figure S1**). Collectively, orthorhombic BP crystals, with excellent quality, can be successfully synthesized in the presence of the SnI_4/Sn mineralizer under our reaction conditions.

Influence of Mineralizer Composition on the Synthesis of BP Crystals

In order to understand the functions of the Sn-I containing mineralizers in the reactions, we first systematically tuned the molar ratio of Sn and I elements in the mineralizer by changing the amount of Sn. We found that the molar ratio of Sn:I had a threshold at ∼0.9:1, below which almost no BP crystals can be synthesized (**Figure 2A** and **Figure S2**). It should be mentioned that a similar threshold of the Sn:I molar ratio (2:1) was also observed by a previous report (Li et al., 2017), although the reported ratio is slightly different from that we found here. The difference may be due to variations in reaction conditions, including heating process, silica tube, and furnace. In particular, BP crystals with high quality can be obtained in high yield (∼90%) when the molar ratio of Sn:I is in the range from ∼0.9:1 to 3:1 (**Figures 2A,B**). Further increase of the Sn:I ratio can also produce BP crystals, but the yield of BP crystals declines in most cases. For example, when the Sn:I ratio was set at ∼10:1, small-sized BP crystals, scattered on the inner wall of the ampoule, were observed with a large number of side products (**Figure 2B**). These results indicate that the optimal molar element ratio of Sn and I, for preparing high quality BP crystals in high yield under our conditions, is in the range from ∼0.9:1 to 3:1, when the SnI_4/Sn mineralizer is used.

To check whether the Sn:I ratio for BP synthesis is dependent on the types of the Sn-I containing mineralizers, we then employed other commonly used Sn-I containing mineralizers, such as Sn/I_2 and SnI_2/Sn (**Figure S3**), to synthesize BP crystals under the same reaction conditions. As expected, high quality BP crystals can be successfully prepared in the presence of Sn/I_2 or SnI_2/Sn mineralizer if the Sn:I ratio was kept in the range from ∼0.9:1 to 3:1 (**Figure 2B** and **Figure S4**). If the Sn:I ratio was set smaller than ∼0.9:1, the reproducibility of the reaction became poor and few BP crystals were obtained in most cases (**Figure S5**). To further verify the Sn:I ratio, two ternary Sn-P-I compounds, SnIP (**Figure S6**) and $Sn_{24}P_{19.3}I_8$ (**Figure S7**), were

applied as mineralizers (Shatruk et al., 1999; Pfister et al., 2016). It should be mentioned that the Sn:I ratio of each Sn-P-I compound is near either the upper or lower limit of the determined range. Similar to other mineralizers, both SnIP and $Sn_{24}P_{19.3}I_8$ can yield centimeter-sized high quality BP crystals (**Figure 2B**) under the same reaction conditions, validating the determined optimum range of Sn:I ratio.

Collectively, these results reveal that the mineralizers, despite the different chemical compositions such as SnI_4/Sn, Sn/I_2, SnI_2/Sn, SnIP, and $Sn_{24}P_{19.3}I_8$, can facilitate the growth of BP crystals if a proper molar ratio of Sn and I elements is applied. Furthermore, according to these results, we can suppose that all Sn-I containing mineralizers should facilitate the formation of BP crystals through the same way.

Growth of BP Crystals and Transformation of Mineralizer

Next, we monitored the synthesis of BP crystals (**Figure 3** and **Figure S8**), by taking *in situ* photos at different stages during the reaction as marked in **Figure 3A**, to reveal the functions of the mineralizer. For comparison, pure red phosphorus and the SnI_4/Sn mineralizer were also sealed solely in ampoules and monitored under the same conditions. As shown in **Figure 3B1**, the solid reactants initially were placed at the right side of

the sealed ampoules. With the increase of the temperature, the SnI_4/Sn mineralizer began to react with red phosphorus, exhibiting some mineralization effects at ∼350°C (**Figure 3B2**, dotted box). When the temperature reached 650°C, almost all reactants including the mineralizer became vapor, leaving small amount of reactants at the original zone, and the whole ampoule exhibited orange color (**Figure 3B3**). Notably, the same orange color was also observed in the ampoule containing only the SnI_4/Sn mineralizer, indicating the orange color comes from the vapor of mineralizer. Finally, the BP crystals appeared at the other side of the ampoule during the decrease of temperature, while some solid remained at the zone where the initial reactants were placed (**Figures 3B5,B6**). Interestingly, in the ampoules containing only the SnI_4/Sn mineralizer, some orange-red colored solid appeared at almost the same position where BP crystals grew (**Figure 3B6**, dotted boxes). In stark contrast, in the absence of the mineralizer, the red phosphorus finally deposited randomly in the ampoules. Furthermore, we observed similar growth processes, with slight differences, when different types of mineralizers, such as Sn/I_2, SnIP, and $Sn_{24}P_{19.3}I_8$, were used (**Figures S9–S11**). These results show that the Sn-I containing mineralizer may first undergo transformation to form certain compounds and then react with phosphorus vapor to help the formation of BP crystals during the reaction.

To gain more insights into the growth process of BP crystals, we then tried to identify the transformation of mineralizer during the reaction. According to the thermogravimetric (TG) analysis (**Figure 3C**) and *in situ* photos (**Figure 3B**), all reactants, except Sn, should become vapor or decompose at 650°C. Comparing the status of pure I_2, SnI_4, and SnI_2 at 650°C (**Figure S12**) with the observation shown in **Figure 3B**, we can deduce that the mineralizer should decompose to form gaseous SnI_2 that exhibits orange color during the reaction. This deduction is also consistent with the previous report in which SnI_2 is believed to be the most thermodynamically stable species in the reaction system at 650°C (Li et al., 2017). Regarding the material remaining at the zone where the initial reactants are placed at 650°C, we believe that it is liquid Sn because the boiling point of Sn is ∼2,600°C (Dean, 1999). In addition, other compounds, including the common Sn-P and Sn-P-I compounds, cannot remain intact at such high temperature (∼650°C) according to the TG analysis (**Figure 3C** and **Figure S13**). Accordingly, in the Sn-I assisted synthesis of BP crystals, we suggest that the Sn-I containing mineralizer should form SnI_2 and Sn during the reaction.

To further verify the transformation of the mineralizer, we heated the SnIP and $Sn_{24}P_{19.3}I_8$ compounds under the same reaction conditions and then analyzed the final compounds (**Figure S14**). As expected, SnI_2 was observed at the place away from the zone where initial compounds were placed. Meanwhile, Sn_4P_3, formed by the reaction of Sn and P during the cooling process, appeared at the zone which originally contains the Sn-I-P compounds. In addition, we also found the presence of SnI_2 on the as-prepared BP crystals. In this set of experiments, the BP crystals, prepared with the assistance of various mineralizers, were collected from the ampoule and then immersed into hot toluene. The toluene, with light yellow color (**Figure S15**), was then distilled, producing a few powders. As characterized by Raman spectroscopy, the powders can be identified as SnI_2 (**Figure S15**).

Taken together, in the Sn-I assisted synthesis of BP crystals, the Sn-I containing mineralizer should first form sufficient SnI_2. Subsequently, the gaseous SnI_2 can react with gaseous phosphorus, forming a certain active Sn-P-I intermediate, and assist the formation of BP crystals.

Active Site Identification and Characterization

In the following set of experiments, we intended to figure out the gaseous Sn-P-I intermediate and growth details of BP crystals by both monitoring the reaction and characterizing the as-synthesized BP crystals. Actually, we observed that BP crystals grew from the bottom of the ampoule at the cooling stage (mainly from 550 to 500°C) in reactions (**Figure 3** and **Figures S8–S11**), and the growth of the crystals apparently exhibited an epitaxial manner. After the reaction, we collected the BP crystals from the ampoule tube and checked their back side which formerly attached on the wall of the ampoule. As shown in **Figures 4A,B**, a distinct intersection point with clear trails can be typically observed, indicating that the point is the starting point for growing BP crystals. Thus, we here suggest that the intersection point should be the active site for the growth of BP crystals. It should be mentioned that similar intersection points were also observed and considered as the nucleation sites for BP growth in previous studies (Zhao et al., 2016b).

Consequently, we analyzed the composition of the intersection point by energy dispersive X-Ray spectroscopy (EDX). At the intersection point of the as-prepared BP crystal, the molar ratio of Sn:I was determined as ∼0.6:1 by EDX (**Figure S16**). After thoroughly washed by hot toluene, as exampled in **Figures 4C–F**, the Sn:I ratio at the intersection point was found as ∼3.1:1 (**Figure S17**). Similarly, for the BP crystals obtained in the presence of $Sn_{24}P_{19.3}I_8$ as a mineralizer, the Sn:I ratio at the intersection point was found as ∼2.9:1 after toluene washing (**Figure S18**). Taking previous studies into account (Zhang et al., 2016; Li et al., 2017), we believe that the $Sn_{24}P_{19.3}I_8$ compound should serve as the active site for the growth of BP crystals.

Besides, in order to find out if there were any other components at the active site, we studied the intersection point of BP by Raman spectroscopy. By comparing the obtained Raman spectra at the intersection point, the presence of Hittorf's phosphorus can be deduced (**Figure S19**). It should be pointed out that we also checked the products just near the intersection point by Raman spectroscopy. Only characteristic Raman peaks of BP crystals were observed (**Figure S19**). These results show that Hittorf's phosphorus may also play a certain role during the growth of BP crystals.

Growth Mechanism of BP Crystals

As discussed in the former parts, in the Sn-I assisted synthesis of BP crystals, SnI_2 should be a critical gaseous compound that may form gaseous intermediate to facilitate the growth of BP. Meanwhile, $Sn_{24}P_{19.3}I_8$ should be the active site on

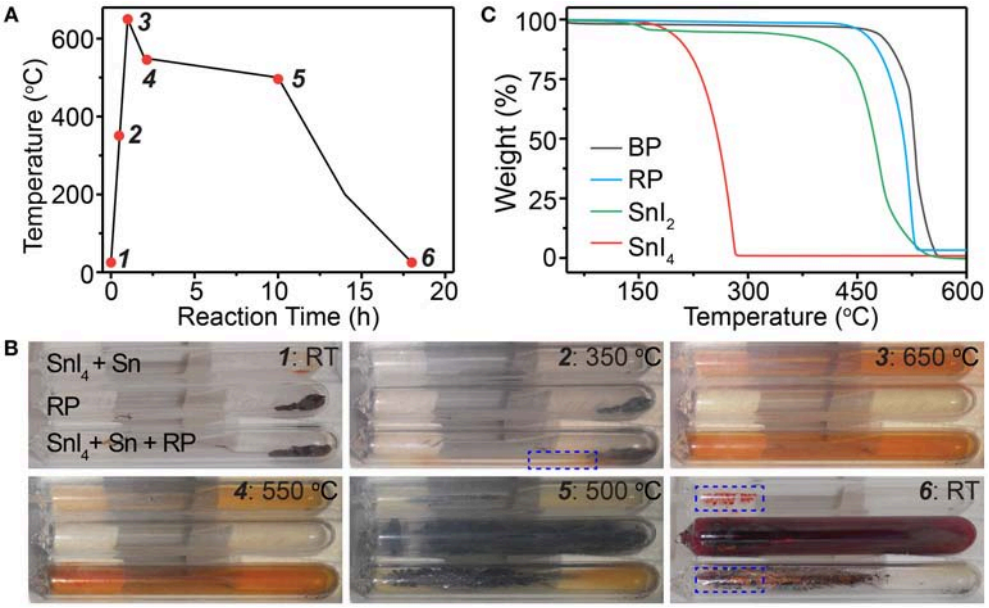

FIGURE 3 | (A) Typical time dependent temperature profile for synthesizing BP crystals and **(B)** corresponding *in situ* photos taken during the synthesis. which the BP crystals start to grow. Combining our results, the fundamentals of chemical vapor transport reactions (Binnewies et al., 2012), and previous proposed growth mechanisms of BP crystals together (Zhao et al., 2016a,b; Li et al., 2017; Zhang Z. et al., 2017; Shriber et al., 2018), we here propose the following formation mechanism of BP crystals in the Sn-I assisted reaction (**Figure 5A**).

At the beginning of the Sn-I assisted reaction, temperature increases for reactant sublimation. At this stage, despite different mineralizers, all reactants, placed at the right side of the ampoule in our studies (**Figure 3**), sublime or decompose gradually to generate gaseous SnI_2, gaseous P_4, and liquid Sn. The resulting gaseous SnI_2, gaseous P_4, and liquid Sn can further react to form $Sn_{24}P_{19.3}I_8$ (Equation 1) and also probably some other Sn-P-I compounds at high temperature (e.g., ∼650°C in this study).

$$4SnI_2 + 20Sn + 4.825P_4 \leftrightarrow Sn_{24}P_{19.3}I_8 \quad (1)$$

Notably, in a sealed ampoule, the reaction (Equation 1), at high temperature, can be at equilibrium that is neither reactant-favored nor product-favored. Moreover, synthesis of $Sn_{24}P_{19.3}I_8$

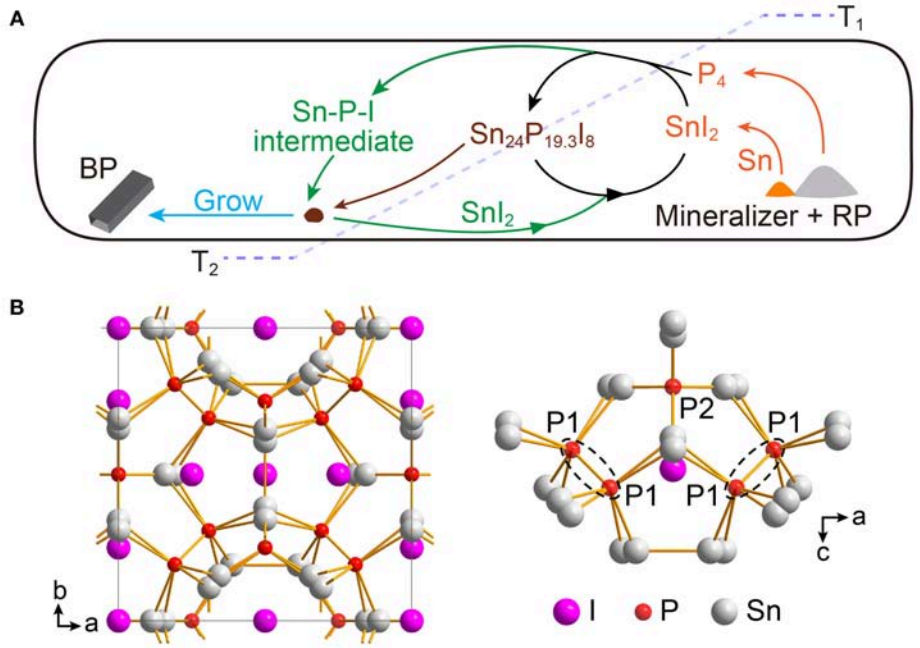

FIGURE 5 | (A) Schematic illustration of the proposed mechanism of BP growth in the Sn-I assisted reaction. The mineralizer and red phosphorus (RP) first form SnI_2, P_4, and Sn at high temperature (T_1) (orange colored arrows). The resulting SnI_2, P_4, and Sn then react to yield $Sn_{24}P_{19.3}I_8$ which can deposit at the place with relatively low temperature (T_2) (brown colored arrow). Subsequently, the BP crystals can grow with the assistance of SnI_2 (green colored arrows). **(B)** Crystal structure of $Sn_{24}P_{19.3}I_8$ where Sn and P atoms form a three dimensional framework with I atoms as guests.

typically needs much longer time than that for preparing BP crystals (Shatruk et al., 1999). Therefore, we suggest that there are still some gaseous SnI_2 in the reaction system. Regarding the liquid Sn presented at this stage, we believe that the slightly excess Sn can ensure the formation of $Sn_{24}P_{19.3}I_8$ and gaseous SnI_2.

After the temperature of the reaction system reaches 650°C, the reaction temperature starts to cool to 500°C with a low cooling rate. At this cooling stage, some $Sn_{24}P_{19.3}I_8$ molecules deposit first at the place with a bit lower temperature because of vapor oversaturation. Remarkably, we here propose that $Sn_{24}P_{19.3}I_8$, at the temperature of ∼550–500°C, should be highly active as growth sites, due to its unique structure. Structurally, $Sn_{24}P_{19.3}I_8$, with a clathrate type-I structure, is a three dimensional framework of tin and phosphorus atoms (**Figure 5B**, left panel), where I atoms are guests in the framework (Shatruk et al., 1999). There are two types of P atoms in the structure, and one type of P atoms appears in pairs with a P-P separation of 2.20 Å, similar to typical P-P bond (**Figure 5B**, right panel) (Shatruk et al., 1999). Furthermore, $Sn_{24}P_{19.3}I_8$ crystals typically can have phosphorus vacancies in their structure (Li et al., 2017). Taking the TG analysis into account (**Figure S13**), we thus reason that the positions for P atoms in the $Sn_{24}P_{19.3}I_8$ crystals, either P atoms or vacancies, can be the starting points for BP growth at the temperature of ∼550–500°C.

After the formation of growth sites, BP crystals then can continuously grow with the assistance of SnI_2, following a typical chemical vapor transportation process. More specifically, gaseous SnI_2 molecules first react with gaseous P_4 molecules at the high temperature zone, forming a Sn-P-I intermediate. The intermediate compounds then migrate to the zone with slightly lower temperature, where the growth sites are formerly formed. Subsequently, the intermediate compounds react with the active $Sn_{24}P_{19.3}I_8$, yielding BP and releasing SnI_2 for further reaction. The reaction would continue like polymerization until most of the P_4 molecules are consumed. Finally, the gaseous SnI_2 molecules are deposited randomly, mainly in the zone with lower temperature, when the temperature further decreases.

On a separate note, at the intersection points (growth sites) of the obtained BP crystals, we found Hittorf's phosphorus (**Figure S19**) which was also observed in some former studies (Chen et al., 2017; Zhang Z. et al., 2017). According to the experimental observations, Hittorf's phosphorus may function as the active sites or intermediate state for BP growth (Chen et al., 2017; Zhang Z. et al., 2017). However, considering that Hittorf's phosphorus can be directly obtained by heating red phosphorus in a vacuum container (Chen et al., 2017), we here believe that Hittorf's phosphorus should be the by-product formed at the beginning of BP growth.

CONCLUSION

In conclusion, we have successfully synthesized BP crystals with various mineralizers, including SnI_4/Sn, SnI_2/Sn, Sn/I_2, SnIP, and $Sn_{24}P_{19.3}I_8$. By monitoring the Sn-I assisted reactions and characterizing the products, together with a series of control experiments, we here propose that BP crystals grow

through a SnI_2 mineralized reaction, and the $Sn_{24}P_{19.3}I_8$ compound serves as an active site for BP growth. Although more detailed *in situ* studies are still needed, we believe that our studies shown here should provide insights into the growth mechanism of BP crystals, facilitating further manipulation of BP synthesis.

Upconversion is a non-linear optical phenomenon by which low energy photons stimulate the emission of higher energy ones. Applications of upconversion materials are wide and cover diverse areas such as bio-imaging, solar cells, optical thermometry, displays, and anti-counterfeiting technologies, among others. When these materials are synthesized in the form of nanoparticles, the effect of temperature on the optical emissions depends critically on their size, creating new opportunities for innovation. However, it remains a challenge to achieve upconversion materials that can be easily processed for their direct application or for the manufacture of optoelectronic devices. In this work, we developed nanocomposite materials based on upconversion nanoparticles (UCNPs) dispersed in a polymer matrix of either polylactic acid or poly(methyl methacrylate). These materials can be processed from solution to form thin film multilayers, which can be patterned by applying soft-lithography techniques to produce the desired features in the micro-scale, and luminescent tracks when used as nanocomposite inks. The high homogeneity of the films, the uniform distribution of the UCNPs and the easygoing deposition process are the distinctive features of such an approach. Furthermore, the size-dependent thermal properties of UCNPs can be exploited by a proper formulation of the nanocomposites in order to develop materials with high thermal sensitivity and a thermochromic response. Here, we thus present different strategies for designing optical devices through patterning techniques, ink dispensing and multilayer stacking. By applying upconverting nanocomposites with unique thermal responses, local heating effects in designed nanostructures were observed.

Keywords: upconversion nanoparticles, polymer nanocomposites, luminescent coatings, optical thermometry, electrochromic devices, thermochromism, optoelectronic devices, thermoplasmonics

INTRODUCTION

Upconversion materials are the subject of intense study both from the fundamental physics point of view and because of their potential applications in various fields of technology (Nadort et al., 2016; Zhou et al., 2018a). They can be synthesized in the form of nanoparticles with controlled composition, morphology, size, crystalline structure and surface chemistry (Wang and Liu, 2008; Bettinelli et al., 2015). The size-dependent thermal properties of upconversion nanoparticles

(UCNPs) have recently received much attention. It was shown that below a critical size of about 30 nm, the emission intensity is enhanced as the temperature increases, while thermal quenching occurs for bigger particles (Li et al., 2014). This opens up new opportunities for applications where the size-dependent thermal properties of UCNPs can act as an extra degree of freedom for controlling the optical emissions (Shao et al., 2017). However, in the attempt to apply these materials in the manufacture of optoelectronic devices, the main challenge lies in the method by which UCNPs are to be deposited and integrated into fabrication processes, ensuring a uniform distribution with controlled spatial location. Methods need to be simple, yet sufficiently versatile to be adapted to serial production or to achieve specific architectures. A common strategy to achieve this goal is the formulation of nanocomposite materials.

The topic of hybrid materials formed by inorganic nanoparticles in polymer matrices has been addressed in several review papers (Binnemans, 2009; Kango et al., 2013; Bai et al., 2016; Pastoriza-Santos et al., 2018). Luminescent NPs have already been included in polymers by polymerization of different monomers, which may or may not be attached to the NPs by covalent bonds. A common strategy for this is the polymerization of methacrylate monomers catalyzed by 2,2′-azo-bisisobutyronitrile (AIBN). This approach has successfully been applied to include QDs (Lee et al., 2000; Sun et al., 2008; Guan et al., 2009), plasmonic nanoparticles (Pastoriza-Santos et al., 2018) and upconverting crystals (Wang et al., 2007; Tabanli et al., 2017; Zhang et al., 2018). Although this strategy is well-suited for obtaining monoliths and molded pieces with excellent optical properties, it is not appropriate for direct application of the nanocomposites in forming coatings or microstructures. On the other hand, luminescent inks composed by inorganic nanoparticles dispersed in solutions with different additives (including polymers) were developed in the past by the groups of May (Blumenthal et al., 2012; Meruga et al., 2012, 2014), Xu (You et al., 2015) and others (Tan et al., 2010; Furasova et al., 2017; Ma et al., 2017).

Here, we advance the development of simple, yet reliable polymer-based nanocomposite materials as a convenient and versatile way to deposit temperature sensitive UCNPs on rigid and flexible substrates. This allows the formation of homogeneous coatings, multilayer structures and the application of soft-lithography techniques, to form luminescent patterns. We explored two different polymers to act as a matrix material: polylactic acid (PLA) and poly(methyl methacrylate) (PMMA). The former constitutes a biodegradable polymer, which is increasingly used as a feeding material for additive manufacturing (3D printing) becoming affordable and accessible; the latter, on the other hand, presents a higher thermal and mechanical stability. In addition, PMMA can be used as a positive tone resist for electron beam lithography (EBL) for fabrication of patterns in the nanoscale. Both polymers are soluble in chloroform, a fast evaporating solvent that can also act as a dispersion medium for UCNPs; therefore, the integration of both materials is straightforward. As a distinctive feature, we take advantage of the size-dependent thermal properties of UCNPs by combining particles with different sizes and compositions. The thermo-sensitive nanocomposites were tested as probes for heat dissipation in two kinds of nanostructures: first, dry deposits of gold nanostars (AuNSs) where the thermoplasmonic effect takes place. Second, by assembling an electrothermal device using percolating networks of silver nanowires (AgNWs) (Martínez et al., 2016, 2018a, 2019). In the former nanostructure, when the local surface plasmon resonance (LSPR) of AuNSs is excited, energy is dissipated via electron-phonon scattering generating heat (Baffou et al., 2010; Rodríguez-Oliveros and Sánchez-Gil, 2012). Therefore, a local increase in temperature can be triggered externally by light. In fact, the spectral position of the LSPR in AuNSs can be tuned during the synthesis to match the wavelength of the light used to excite the upconversion luminescence in UCNPs. In the case of AgNWs networks, this is a system of increasing technological interest. Among other applications, they are used in transparent electrodes (Anh Dinh et al., 2013; Ye et al., 2014), solar-cells (Langley et al., 2014), flexible and wearable electronics (Myers et al., 2015; Lee et al., 2017). Moreover, upon electrical currents flows, heat is dissipated due to the Joule effect. Therefore, AgNWs networks are also used as nanoheater films (Kim et al., 2013; Huang et al., 2015) being an ideal system for testing the thermometric nanocomposites developed here.

In this work, we show some of the potential uses of the polymer-UCNPs composite materials by performing neat examples of microfabrication, multichromatic inks and multilayers, and thermally sensitive optical coatings. We are certain that this can provide new routes for the integration of nanoparticles in the development of optoelectronic devices and luminescence-based technologies.

EXPERIMENTAL SECTION

Materials

Sodium trifluoroacetate 98% (CAS 2923-18-4), yttrium(III) trifluoroacetate >99.99% (CAS 304851-95-4), erbium(III) oxide (CAS 12061-16-4), ytterbium(III) oxide (CAS 1314-37-0), thulium(III) oxide (CAS 12036-44-1), trifluoroacetic acid 99% (CAS 76-05-1), gold(III) chloride trihydrate >99.9% (CAS 16961-25-4), $AgNO_3$ 99.9999% (CAS 7761-88-8), L-ascorbic acid, reagent grade (CAS 50-81-7), trisodium citrate dihydrate (CAS 6132-04-3), mercaptosuccinic acid 97% (CAS 70-49-5), poly(sodium 4-styrenesulfonate) MW ∼70 000 g mol^{-1} (PSS, CAS 25704-18-1), ethylene glycol (EtGOH) anhydrous (99.8%), polyvinylpyrrolidone (PVP) 360,000 mol. wt., iron(III) chloride 97% (CAS 7705-08-0), oleic acid (OA, technical grade, 90%) and 1-octadecene (ODE, technical grade, 90%) were purchased from Sigma-Aldrich Co. Gadolinium(III) acetate hydrate 99.9% (CAS 100587-93-7) and Cerium(III) chloride heptahydrate 99% (CAS 18618-55-8) were purchased from Alfa Aesar. PMMA 7% wt. in chlorobenzene resist (PMMA C7) was purchased from MicroChem Corp, USA. All commercial reagents were used without further purification. Rare-earth acetates and trifluoroacetates not listed above were prepared in our laboratory using the corresponding rare-earth oxides (X_2O_3, X = Yb, Tm, Er). In a 500 mL round bottom flask containing 30–50 mL of a 50% (v/v) aqueous solution of either acetic acid or trifluoroacetic

acid, 1–2 g of the respective oxide was added. The mixture was refluxed for 1–2 h until the complete dissolution of the oxides resulted in a clear solution. The solution was then transferred to a Pyrex open vessel and maintained at 60°C to evaporate the liquid. The dried precipitates of acetate/trifluoroacetate salts were extracted.

Synthesis of UCNPs

Large (300 nm) pure hexagonal phase $NaYF_4$ nanoparticles co-doped with ytterbium (20 mol%) and erbium (2 mol%) were synthesized by the well-established thermal decomposition method of fluoroacetates, adapting protocols described by Ye and co-workers (Ye et al., 2010). In a three neck 200 mL round bottom flask containing 15 mL of ODE and 15 mL of OA, a total of 6.2 mmol of $NaCOOCF_3$, 2.6 mmol of $Y(COOCF_3)_3$, 0.68 mmol of $Yb(COOCF_3)_3$ and 0.068 mmol of $Er(COOCF_3)_3$ were added. The flask was sealed and heated under vacuum at 125°C in order to dissolve the precursors and degas the solution. After 1 h, a condenser was mounted, and the temperature was rapidly increased (10–20°C·min^{-1}) up to 330°C under an argon flux. After 30–35 min from the beginning of the heating stage, the reaction flask was retired from the mantle and 15 mL of ODE were added to quench the reaction. Extraction of the UCNPs was performed by adding an ethanol: hexane 4:1 v/v mixture and centrifugation for 5 min at 2,400 rpm, corresponding to a relative centrifugal force (RCF) of 1,004 RCF. The washing procedure was repeated four times and the UCNPs were finally dispersed in hexane with a final concentration of about 2 g·cm^{-3}. Same method was applied for the synthesis of additional large-sized UCNPs with compositions detailed in **Table 1**.

Small size hexagonal core-UCNPs (<12 nm) were synthesized by the co-precipitation route adapting the protocols reported by Wang and co-workers (Wang et al., 2014) using rare-earth acetates as the main precursors. A total of 1 mmol of $X(COOCH_3)_3$ (X = Gd, Yb, Tm, Er) was added in a 200 mL round bottom flask containing 15 mL of ODE and 9 mL of OA. The nominal molar ratio of each system was 1:0.78:0.2:0.02 Na:Gd:Yb:Er and 1:0.695:0.3:0.005 Na:Gd:Yb:Tm. The mixture was heated up to 160°C for 1 h to dissolve the precursors and then cooled down to room temperature. At this point, a freshly prepared mixture containing 2.5 mL of a 1 M NaOH methanol solution and 10.1 mL of 0.4 M NH_4F solution in methanol was rapidly injected. The flask was heated to 50°C for 30 min and then sealed. The temperature was raised to 100°C and the vacuum pump was connected. After 15 min, the vacuum pump was shut down, a condenser was mounted, and the temperature was increased to 280°C under argon flux. The flask was retired from the mantle after 1 h and allowed to cool down to room temperature. Extraction of the UCNPs was performed by adding excess anhydrous ethanol and centrifugation using 15 mL Falcon tubes. Centrifugation was performed at 1,004 RCF (2,400 rpm) for 7 min. The precipitated UCNPs were redispersed in 4 mL of cyclohexane and ethanol was added to complete the volume. The centrifugation and washing procedure was repeated twice. Finally, the UCNPs were dispersed in 8 mL of cyclohexane. As the quantum yield of the UC process is lower for smaller particles due to surface-related quenching processes, a core–shell structure was formed by growing a thin inert layer on the surface of the pre-synthesized core UCNPs. For this, 1 mmol of $Gd(COOCH_3)_3$ was added to 8 mL of OA and 12 mL of ODE in a 200 ml three-neck round bottom flask. The mixture was heated up to 160°C for 1 h and then cooled down to room temperature. Then, 6 mL of the core UCNPs colloid in cyclohexane were added. The subsequent addition of a methanol solution of NaOH and NH_4F and the following procedures were identical to those previously described for the synthesis of core nanoparticles. The same protocol was used for the synthesis of small-sized UCNPs doped with Ce^{3+}/Ho^{3+} as detailed in **Table 1**.

TABLE 1 | Nomenclature, nominal composition and particle size ± std (determined using the TEM images) of the UCNPs employed in the formulation of the nanocomposites.

Sample	Composition	Size (nm)	Obs.
1S	$NaGd_{0.695}Yb_{0.300}Tm_{0.005}F_4$@$NaGdF_4$	8.8 ± 0.8	Small

3L	$NaY_{0.63}Yb_{0.20}Ce_{0.15}Ho_{0.02}F_4$	(85 ± 5) × (40 ± 3)	

Synthesis of AuNSs

Gold nanostars (AuNSs) were synthesized following a seed mediated protocol at room temperature. Gold nanoparticles (AuNPs) were first synthesized to be used as seeds by adding 15 mL of a 1 wt.% trisodium citrate aqueous solution into 100 mL of a boiling solution of gold(III) chloride 1 mM and maintained at boiling temperature for 15 min. When cooled down to room temperature, the resulting colloid was filtered through a 0.22 μm PES syringe filter. For the synthesis of AuNSs, 20 μL of a 1 M HCl solution were added to 20 mL of 0.25 mM gold(III) chloride solution in Milli-Q ultrapure water. 200 μL of the seed AuNPs were added and stirred at 800 rpm for 3 min in a 100 mL round bottom flask. Immediately afterwards, 200 μL of 3.3 mM $AgNO_3$ and 100 μL of 0.1 M L-ascorbic acid solutions were added quickly and simultaneously to the reactor vessel. After 1 min, 50 μL of a 1 mM mercaptosuccinic acid solution was added followed by 1 mL of a 1 wt.% PSS solution. All steps described before were performed at ambient temperature. It is worth mentioning that by varying the ratio between the ascorbic acid, the $AgNO_3$ added and the acid concentration in the reactor, it is possible to tune the branching growth of the resulting AuNSs and therefore the spectral position of the surface plasmon resonance. Here, concentration values were tuned to produce AuNSs with a plasmon resonance in the 900–1,000 window, matching the wavelength of the excitation light used for upconversion experiments. Further details of the procedure and the influence of the synthesis parameters in the resulting AuNSs can be found in Yuan and co-workers (Yuan et al., 2012).

Synthesis of AgNWs

Silver nanowires (AgNWs) were synthesized by adapting the method described by Jiu and co-workers (Jiu et al., 2014). Briefly, 0.2 g of PVP (360,000 g·mol^{-1}) were dissolved in 15 mL of anhydrous EtGOH and a solution containing 0.25 g of $AgNO_3$ in 10 mL of EtGOH was added at room temperature simultaneously with 3.25 mg of a 0.6 mM $FeCl_3$ solution in EtGOH. The final mixture was poured into a 100 mL round flask and sealed. The flask was then placed into an oven at 130°C for 5 h without agitation. After cooling down to room temperature, extraction of the AgNWs was performed by adding excess volume of acetone. The mixture was centrifuged at 1,000 rpm and the precipitates were dispersed in isopropanol. This procedure was repeated three times until a final dispersion of AgNWs in isopropanol was prepared in a 2.5 g·L^{-1} mass concentration.

Materials Characterization

UCNPs, AuNSs and AgNWs were characterized using optical and electron microscopy. Electron microscopy was performed at LNNano, CNPEM, Campinas, Brazil. SEM images were acquired in a FEI Quanta 650 FEG microscope operated at 20 kV. Transmission electron microscopy (TEM) images were obtained with a JEM 2,100 (JEOL) equipped with a LaB_6 filament and operated at 200 kV. X-ray diffraction (XRD) was performed in a Phaser D2 diffractometer (Bruker) while dynamical light scattering (DLS) was performed in a Nanopartica SZ-100 DLS (Horiba). UV-Visible spectrophotometry was performed in a Cary 8454 Agilent Technologies. Profilometry measurements were performed at LAMULT-IFGW using a Dektak 150, Veeco stylus profilometer. Upconversion was recorded using as excitation a collimated BL976-PAG900 FBG stabilized laser (ThorLabs). All measurements were performed at a nominal power of 500 mW, except otherwise indicated. The emission was analyzed with a QEPro spectrometer (Ocean Optics) coupled to a 600 μm diameter optical fiber. A short-pass optical filter was used to avoid the spectrometer saturation by the 976 nm laser. The thermal response of UCNPs was studied by depositing the upconverting material on silicon substrates. This was carried out in two ways: the formulated nanocomposites were spin-coated at 3,000 rpm, while dry deposits of UCNPs were formed by drop-casting the colloids and evaporating the solvent (hexane or cyclohexane) at 130°C. The samples were placed in thermal contact on a Peltier plate controlled by an Arduino board. The emission spectra were acquired at varying temperatures of the plate. Spin-coating was also used to deposit nanocomposite films on glass substrates for transmittance and profilometry characterization.

RESULTS AND DISCUSSION

Two sets of UCNPs were synthesized consisting of small-sized (<20 nm) and large-sized (>50 nm) UCNPs and containing one of the following emitting ions (activators): Tm^{3+}, Er^{3+} or Ho^{3+}, with main emission lines in the blue, green or red part of the spectrum, respectively. All particles were co-doped with a certain amount of Yb^{3+} ions acting as sensitizer. The composition of each system and the nomenclature adopted here is detailed in **Table 1**. TEM images of each UCNPs system are shown in **Figure 1** and the particle size distributions resulting from the analysis of the images are presented in **Supplementary Figure 2**. In **Supplementary Figure 3**, TEM images and partcticle size analysis are shown for UCNPs of the set 2S before and after the formation of the shell layer. X-ray diffraction shows that all particles present a hexagonal (β-) crystal structure (**Supplementary Figure 1**). UCNPs containing Er^{3+} either large- and small-size (from now on 2L and 2S, respectively) are shown in **Figures 1B,F**, whereas the emission spectra obtained at calibrated temperatures using a Peltier plate are displayed in **Figures 1D,H** for each nanoparticle system. The characteristic parameters resulting from the thermal calibration are summarized in **Supplementary Table 1**. The thermal dependence of the emission spectra for additional UCNPs

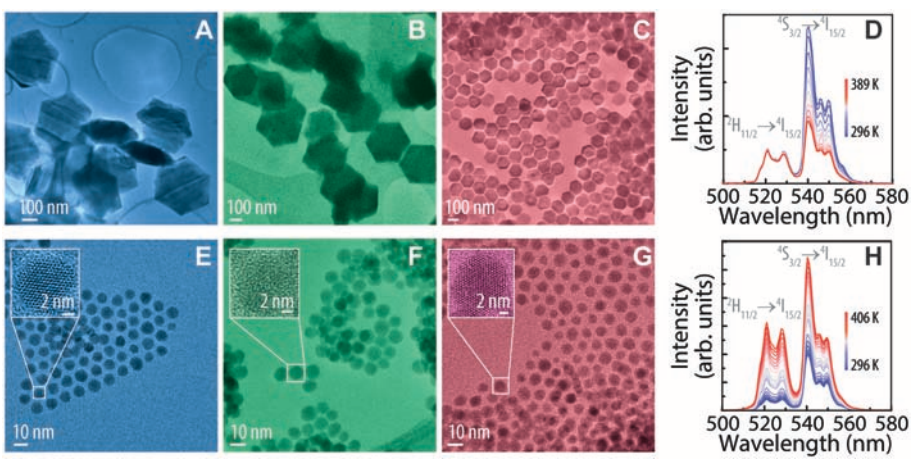

FIGURE 1 | TEM images of **(A–C)** large-size and **(E–G)** small-size UCNPs doped with **(A,E)** Tm^{3+}, **(B,F)** Er^{3+} and **(C,G)** Ce^{3+}-Ho^{3+}. Temperature dependent emission in the green spectral range of **(D)** 2L and **(H)** 2S UCNPs under 976 nm excitation.

studied in this work is presented in the **Supplementary Figure 5**. In all cases, the emission intensity is thermally quenched for large-sized UCNPs and thermally enhanced for small-sized UCNPs. This is in agreement with the size-dependent thermal response of UCNPs as already reported by Li and collaborators (Li et al., 2014). On one side, the thermal quenching effect for large-sized UCNPs is well-known and typically associated with non-radiative multiphonon relaxation (Shen et al., 2010; Yu et al., 2016). However, the thermal enhancement effect that takes place in small-size UCNPs was reported only recently and a conclusive explanation is still lacking. So far, quantum size effects affecting the phonon density of states (Li et al., 2014), thermal desorption of water molecules (Shao et al., 2017), and energy transfer between Yb^{3+} ions and anchoring groups of the capping molecules (Zhou et al., 2018b), have been proposed as an explanation for this anomalous effect. Although at this time we can not add new information to solve this issue, we can take advantage of the thermal responses by formulating nanocomposites combining both kinds of UCNPs.

UCNPs-Polymer Nanocomposites

For preparation of the nanocomposites, a certain amount of the colloids formed by UCNPs in cyclohexane was placed in a glass vial under a gentle flux of N_2 until complete evaporation of the solvent. The dried UCNPs were dispersed either in pure chloroform or in a 2 %wt. PLA solution in chloroform by means of vortex agitation and ultrasonic bath. For PMMA nanocomposites, equal amounts of the PMMA resist and the chloroform-UCNPs colloid were mixed. The approximate concentration of particles in the polymer solutions were ∼0.04 $g{\cdot}mL^{-1}$ for small-size UCNPs and ∼0.0015 $g{\cdot}mL^{-1}$ for large-size UCNPs. The prepared nanocomposite solutions were spin-coated at 3,000 rpm on glass substrates,

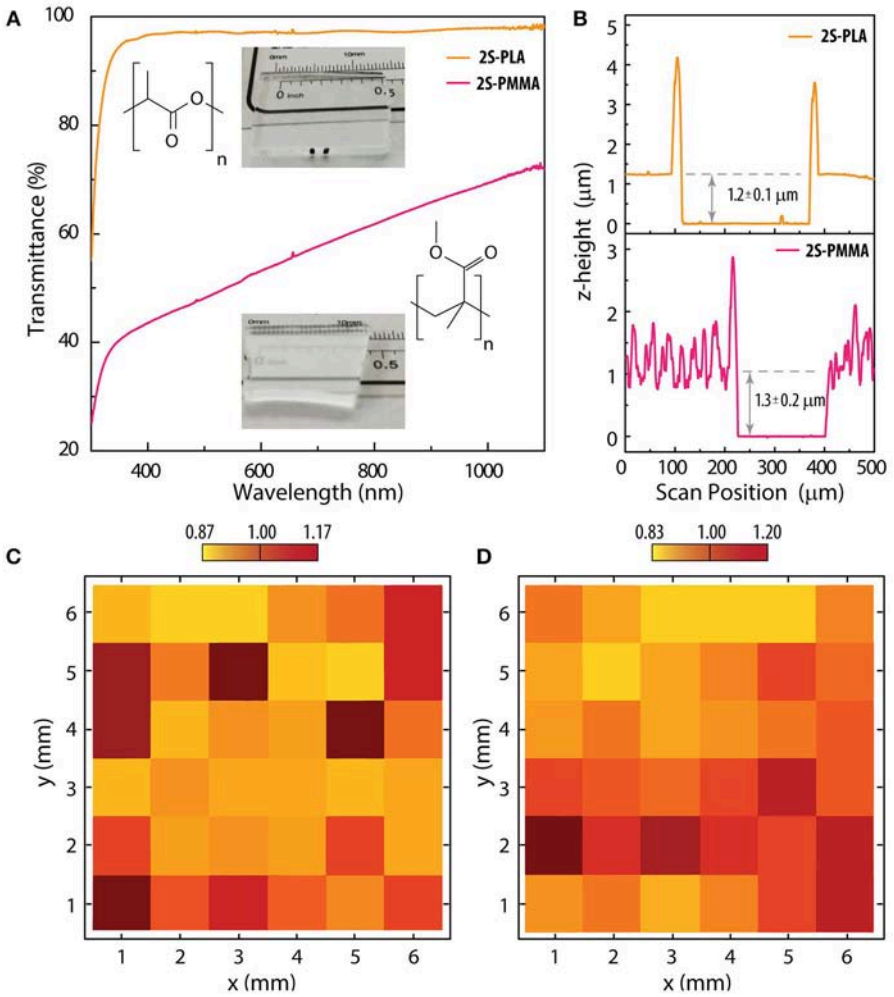

FIGURE 2 | Nanocomposites containing small-size UCNPs doped with Yb^{3+}-Er^{3+} deposited on glass substrates by spin-coating at 3,000 rpm. **(A)** Optical transmittance and pictures of 2S-PMMA and 2S-PLA samples. **(B)** Stylus profilometry performed on a scratch made on the films. forming a thin uniform layer. In order to compare the PMMA and PLA based films, the optical transmittance, the integrated intensity of the upconversion emissions and the thickness of the films were measured in samples containing 2S UCNPs. The optical transmittance was measured using a UV-visible spectrophotometer in the transmission mode (**Figure 2A**) showing a much higher transparency for the case of PLA films, while PMMA films present an opaque aspect. This could be due to the content of chlorobenzene in the PMMA resist used, which has a slower evaporation rate (1.07 compared to butyl acetate) than that of chloroform (11.6 compared to butyl acetate). The evaporation of chloroform could induce a coarse-grained deposition of the polymer. It is worth mentioning that the surface topography is not due to a clustering of the UCNPs as similar optical haze is observed for films without UCNPs. Also, it was observed that reducing the fraction of chloroform in the UCNPs-PMMA solution improves the transparency, although the viscosity is increased and therefore, the film thickness after coating is higher. The thickness of the films were characterized by stylus profilometry on a scratch made *ad-hoc* (**Figure 2B**), showing similar values for each film (∼1.2 μm for PLA and ∼1.3 μm for PMMA). The roughness was also analyzed finding values of root mean square roughness (R_q) of 0.005 μm and 0.37 μm for PLA and PMMA films, respectively. The higher R_q observed for the case of PMMA films is consistent with the lower transmittance discussed previously. The material removed from the scratches accumulated on the edges causing the peaks observed in the profilometry scans. In order to analyze the homogeneity of the coverage with UCNPs, the samples were mounted on a *x-y* micro-positioner stage. The emission spectra under excitation with a 976 nm collimated laser beam (ca. 1 mm spot size) was registered at different positions scanning a square region of 6 × 6 mm^2. A 2D map was constructed (**Figures 2C,D**) by integrating the emission spectrum at each point. Normalizing by the mean value, the emission intensity remains under a 15–20% deviation for the PLA and PMMA films, respectively.

The development of polymer-based nanocomposites is driven by the necessity of controlling the integration of nanoparticles into functional surfaces and structures. With that purpose, we tested the direct application of the formulated nanocomposites in different ways. On one side, the PLA based nanocomposite solutions containing large-size UCNPs emitting in the blue (1L, Tm^{3+} doped), green (2L, Er^{3+} doped) or red (3L, Ce^{3+}/Ho^{3+} co-doped) were used as inks to directly deposit drops and tracks with characteristic luminescent properties. Optical images of the handmade deposits are shown in **Figure 3** under white light (bright field, **Figure 3A**), dark field (**Figure 3B**) and near infrared (NIR, 976 nm) excitation (**Figures 3C,D**). Similar results (not shown) were obtained by using the UCNPs-PMMA nanocomposites. **Figure 3D** shows the use of a PLA-based nanocomposite for drawing luminescent tracks. As PLA is one of the mainstream polymer used in conventional 3D printing, this particular nanocomposite constitutes a step forward. Although

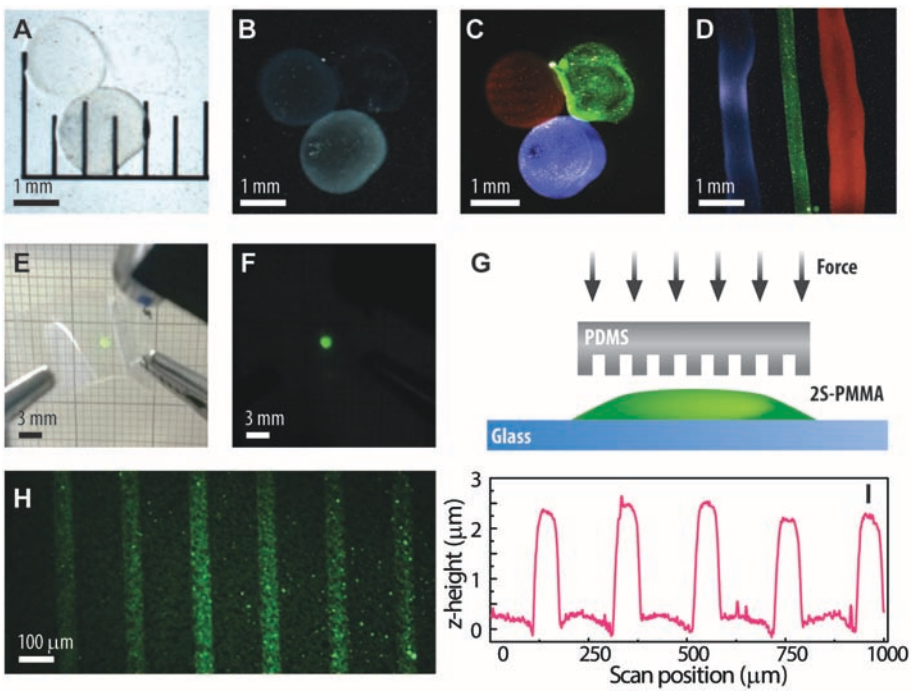

FIGURE 3 | Strategies to apply the PLA based nanocomposites as ink to directly write multicolor luminescent features. Optical images under **(A)** bright field, **(B)** dark field and **(C,D)** NIR light illumination. **(E,F)** 2L-PLA nanocomposite deposited on a flexible substrate. Scheme **(G)** of the soft lithography process to transfer micro-patterns. Luminescent tracks produced by soft lithography on 2L-UCNPs in PMMA under **(H)** NIR illumination and **(I)** height profile revealed by stylus profilometry.

we show here a proof of concept by applying the nanocomposite ink manually with a syringe, the deposition may be further improved by adopting controlled injection methods well-established in the additive manufacturing technology (Ligon et al., 2017). Additionally, the rheology of the composite inks can be optimized for a better control of the dispensing mechanism by varying the mass fraction of the polymers, while the surface tension can be adjusted by adding proper surfactants (Kumar et al., 2016).

The excellent properties of the PLA based nanocomposite can be clearly exposed by spin-coating the 2L-PLA solution into flexible substrates, in this case, a cellulose acetate sheet. The resulting film shows a high transparency and luminescence under NIR excitation as shown in **Figures 3E,F**.

By using the UCNPs-PMMA nanocomposite, we applied soft lithography methods to produce line patterns in the microscale. For that, a polydimethylsiloxane (PDMS) stamp was first prepared from a Sylgard 184 kit (Dow Chemicals®) following standard protocols (Qin et al., 2010). On a glass slide, 5 μL of the 2L-PMMA nanocomposite was poured; immediately afterwards the PDMS stamp was pressed and held in that position for 5 min, and then placed in a hot plate at 180°C for another 5 min. Once the sample was cooled down to room temperature, the stamp was carefully retired. A scheme of the method is depicted in **Figure 3G**. The resulting film presents a structure composed of the inverse pattern of the stamp, in this case, with parallel lines, ∼60 μm wide, showing a clear contrast in the luminescence under NIR excitation (**Figure 3H**). The luminescence contrast arises from the topography of the sample as revealed by the profilometry scan shown in **Figure 3I**. Each line track has a step height of 2.0–2.5 μm. It is worth mentioning that a background luminescence is detected as residual material containing UCNPs remains in the regions of contact between the PDMS and the base glass substrate.

Thermal Properties of UCNPs-Polymer Nanocomposites

The distinctive thermal properties of small- and large-sized UCNPs can be exploited to produce polymer nanocomposites with unique thermal response. We explored two approaches for the application of the polymer based UCNPs nanocomposites as thermally sensitive materials. For the first approach, depicted in **Figure 4A**, part of a glass substrate was first covered with AuNSs (**Figures 4B,C**) by drop-casting. Then, a PLA based nanocomposite containing UCNPs of the set 1L and 2S was

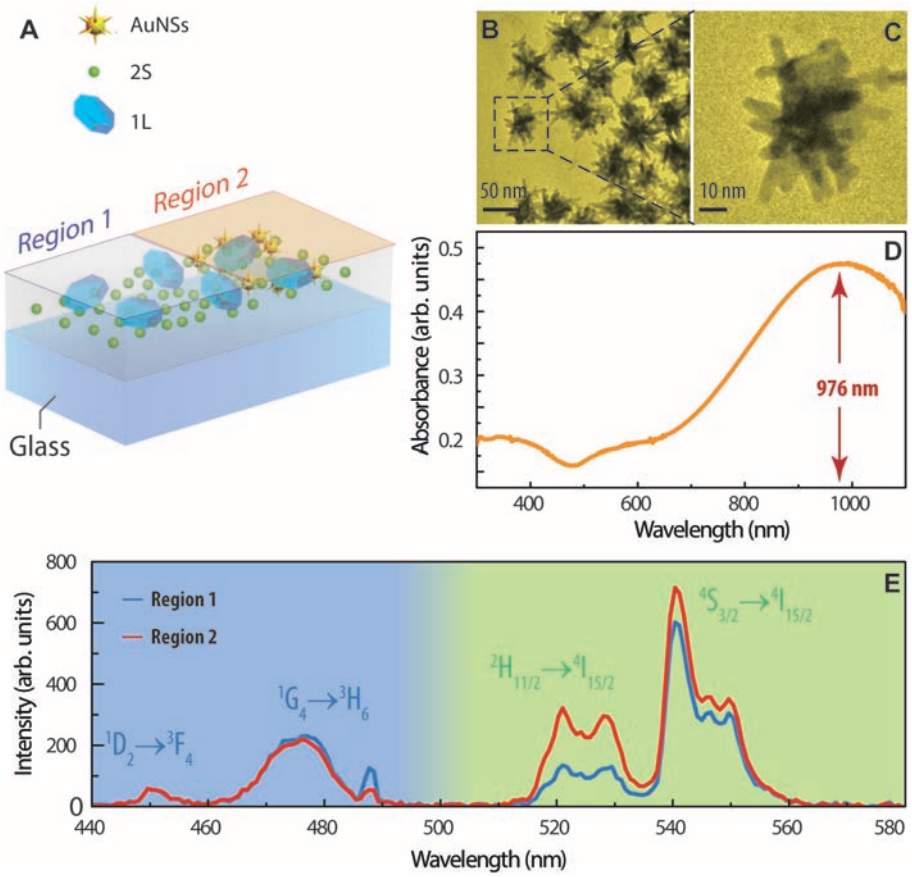

FIGURE 4 | Thermal effects on the emissions of polymer-UCNPs nanocomposites. **(A)** Scheme of samples for the study of the thermoplasmonic effect in AuNSs. **(B,C)** TEM images of AuNSs and **(D)** absorption spectra of AuNSs colloids. **(E)** Emission spectra obtained on regions without (region 1) and with (region 2) AuNSs.

spin-coated on top of it; therefore, two regions of the sample can be distinguished and compared: region 1 containing only the UCNPs and region 2 where UCNPs are deposited above AuNSs. The plasmon resonance of AuNSs (**Figure 4D**), which can be tuned by synthesis, is spectrally located at the NIR region, matching the wavelength of the light used to excite the UCNPs. The absorbed electromagnetic energy dissipates in the form of heat, which is transferred to the UCNPs located above. In the region containing AuNSs (region 2) the intensity of emissions of particles 2S (Er^{3+} doped) is enhanced compared to that measured in region 1 (**Figure 4E**). However, the emissions of UCNPs 1L is slightly reduced; therefore, the overall color of the total emission is different in both regions due to the presence of AuNSs. For UCNPs containing Er^{3+}, the local temperature can be directly calculated from the emission spectra, following the procedures described in the **Supplementary Material**. By using Equation S1 (**Supplementary Material**), the temperature in region 2 was determined to be $T = (92 \pm 4)°C$ while in region 1, $T = (25 \pm 3)°C$. It is worth noticing that by using the PLA-based nanocomposites, the homogeneous covering with UCNPs after spin-coating allows a precise comparison between both regions, being an improvement of previous methodologies in which the UCNPs were deposited by drop-casting the colloids and evaporating the solvent (Martínez et al., 2018b). This demonstrates the clear benefits of the nanocomposites formulated in this work.

In the second approach, we applied the PMMA-based nanocomposite to characterize the heat dissipation in AgNW conductive networks. A transparent thin film formed by a percolating network of AgNWs in PMMA was used as nanoheater film (**Figures 5A–C**) following previous protocols (Martínez et al., 2016, 2018a). On top of it, a PMMA based nanocomposite containing UCNPs of the set 2L and 1S was deposited by spin-coating. Again, the use of the nanocomposite presented here represents a clear improvement of our previous work (Martínez et al., 2019) by ensuring a homogeneous

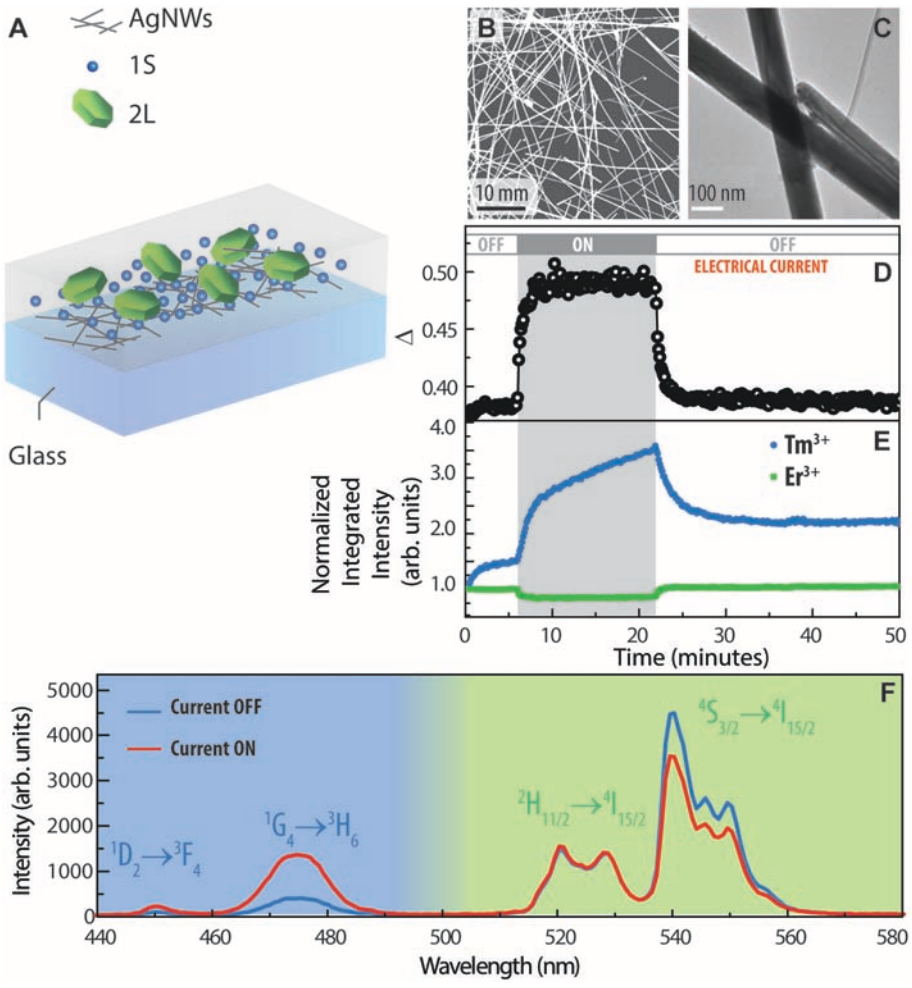

FIGURE 5 | (A) Scheme of the electrothermal devices formed by AgNWs and UCNPs nanocomposites. **(B)** SEM and **(C)** TEM images of AgNWs. **(D)** Evolution of the thermometric parameter and **(E)** integrated emissions of blue and green part of the spectrum during an electrothermal action off-on-off with an applied electrical power of 1.3 W. **(F)** Emission spectra of the electrothermal device under states on and off.

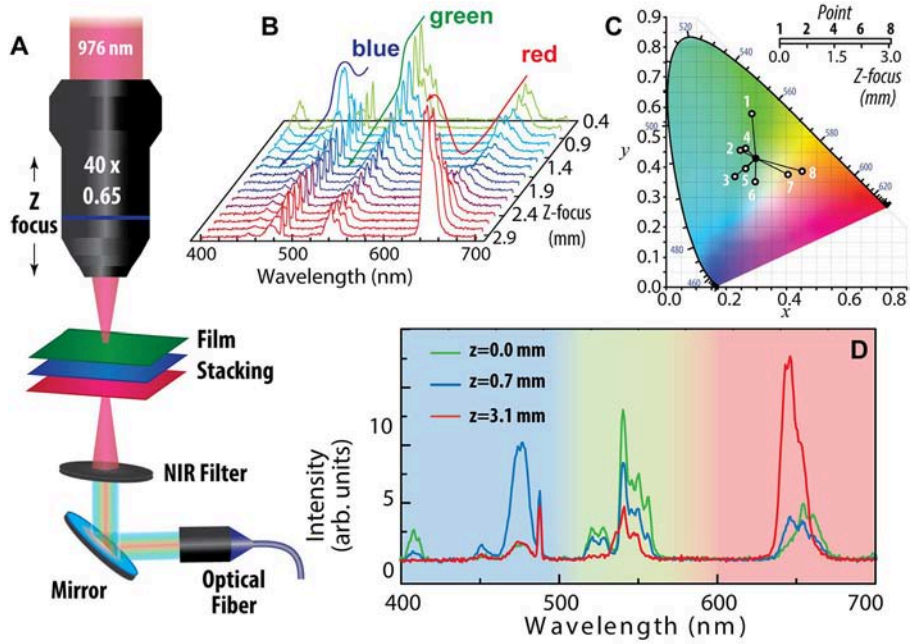

FIGURE 6 | Multicolor structure based on film stacking of UCNPs-PLA layers and z-focusing. **(A)** Scheme of the experimental set-up. **(B)** Emission spectra as a function of the z-focus position. **(C)** CIE 1931 chromaticity diagram showing the emission color obtained at selected z-focus positions. Calculations were made using ColorCalculator v7.15 OSRAM SYLVANIA, Inc. **(D)** Spectra at z-focus positions of maximum green ($z = 0$ mm), blue ($z = 0.7$ mm) and red ($z = 3.1$ mm) emission color.

covering. The resulting device, depicted in **Figure 5A**, allows for the external electrical control of the temperature of UCNPs by supplying a DC current throughout the AgNWs network, dissipating heat because of the Joule effect. When the power supply (1.3 W) was turned on, a noticeable change in the emission spectra was observed (**Figure 5F**). While the main emission line coming from the 2L UCNPs is thermally quenched, the emissions arising from UCNPs 1S are thermally enhanced. The integration of the spectra considering the blue band (440–500 nm) and the green band (500–580 nm) shows clearly that the effect of the current flow through the AgNWs film produces an augmented blue emission and a diminished green emission; furthermore, the spectral changes are reversible (**Figure 5E**). Interestingly, when considering the emissions from Er^{3+}, as discussed previously, it is possible to register the thermometric parameter (**Figure 5D**) throughout the experiment and use it to calculate the effective temperature at the emitter position. The temperature reached during the electrothermal action was $(87 \pm 3)^{\circ}$C.

Multilayer Stacking

Finally, to take advantage of the homogeneous coatings formed by spin-coating PLA-UCNPs, we built a multilayer structure formed by stacking PLA films deposited on thin glass coverslips (130–160 μm thick) containing UCNPs emitting in the green (2S), blue (1L) or red (3L) part of the spectrum. When mounting the multilayer stack under an objective lens (40x, NA 0.65), the NIR excitation laser can be focused in a spot of small volume whose position can be adjusted by micrometer screws. By using the set-up shown in **Figure 6A** we were able to register the overall emission spectra by varying the position of the z-focus (**Figure 6B**) and observing a clear shift in the emission color from green to blue, and then to red, as the characteristic emission lines of Er^{3+}, Tm^{3+}, and Ho^{3+} are successively excited. The change in the emission spectra in the blue (400–500 nm), green (500–600 nm) and red (600–700 nm) bands at each z-focus position (**Figure 6D**) modified the overall color of the emitted spectra, as shown in a chromaticity diagram Commission Internationale de l'Éclairage (CIE) 1931 on **Figure 6C**.

Notice that the multilayer stacking concept displayed in this section can be improved and adapted for other systems. For example, by forming stacking of UCNPs-nanocomposites on thin or flexible substrates, membranes can be produced whose deformation could be followed optically.

CONCLUSION

Polymer based nanocomposites containing UCNPs with different sizes and compositions were developed. Two polymers were used as matrix materials: PMMA and PLA, both of which are soluble in chloroform, forming stable suspensions upon the addition of UCNPs with oleic acid capping. The nanocomposite solutions can be deposited by spin-coating on several substrate materials, including flexible polymer sheets, producing homogeneous films (∼1 μm thick) with uniform upconversion luminescence. The nanocomposite solutions can also be applied directly, resembling an ink, providing a simple way to draw tracks and features with a precision mainly limited by the dispensing method. By using the nanocomposite inks in combination with PDMS stamps and soft lithography techniques it is possible to transfer microscale patterns forming luminescent structures.

Furthermore, we take advantage of the size-dependent thermal properties of UCNPs by formulating nanocomposites containing different combinations of small- and large-size UCNPs. We have successfully tested the thermally sensitive materials developed here by applying the nanocomposites of thermally active nanostructures. Two approaches were adopted, first, by using AuNSs with remarkable photothermal conversion efficiencies due to the thermoplasmonic effect; and second, by using conductive networks of AgNWs that can act as nanoheater films when DC currents are supplied. We successfully probed the external control of the intensity of emission lines due to the local change in the temperature, which could be directly measured by following the emissions of Er^{3+} in the green part of the spectrum or directly detected as a change in the emission color. The versatility of the nanocomposites was explored by constructing a multilayer stacking in combination with focusing optics, a simple set-up that showed to be highly sensitive to vertical displacements resulting in clear changes in the emission color. With these advances, we demonstrate that nanocomposites colloids presented in this work are extremely useful materials for direct application of UCNPs, and possibly other nanomaterials, in the assembling of novel photonic and optoelectronic devices.

DATA AVAILABILITY

The raw data supporting the conclusions of this manuscript will be made available by the authors, without undue reservation, to any qualified researcher.

AUTHOR CONTRIBUTIONS

EM conceived the project, synthesized the particles and performed all measurements. CB and LC discussed the project, analyzed the data, performed the calculations of thermometry and prepared all figures. RU and CR contributed to the experimental set-up and discussion of the project. The manuscript was written with contributions from all authors.

FUNDING

This study was financed in part by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior—Brasil (CAPES)—Finance Code 001, and by Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP) through Grants #2011/19924-2, #2012/04870-7, #2012/05903-6, #2015/21290-2, and #2015/21289-4. Work was partially developed in the scope of the project CICECO—Aveiro Institute of Materials (Ref. FCT UID/CTM/50011/2013), financed by Portuguese funds through the Fundação para a Ciência e a Tecnologia/Ministério da Educação e Ciência (FCT/MEC) and when applicable co-financed by FEDER under the PT2020 Partnership Agreement. The financial support of FCT (PTDC/CTM-NAN/4647/2014 and POCI-01-0145-FEDER-016687) is also acknowledged. EM acknowledges, respectively, the post-doctoral FAPESP fellowship #2015/23882-4 and BEPE #2018/12489-8. CB acknowledges the grant financed by the SusPhotoSolutions project CENTRO-01-0145-FEDER-000005.

ACKNOWLEDGMENTS

We acknowledge the funding institutions and the facilities and institutions where the work was performed: Department of Quantum Electronics—Gleb Wataghin Institute of Physics (DEQ-IFGW), UNICAMP; physics department and CICECO, University of Aveiro. Electron microscopy (SEM and TEM) was performed at LNNano, Centro Nacional de Pesquisa em Energia e Materiais (CNPEM) in Campinas, SP, Brazil. Stylus profilometry was realized at LAMULT, IFGW-UNICAMP.

Luminescent Schiff-Base Lanthanide Single-Molecule Magnets: The Association Between Optical and Magnetic Properties

*Jérôme Long**

Institut Charles Gerhardt, Equipe Ingénierie Moléculaire et Nano-Objets, Université de Montpellier, ENSCM, CNRS, Montpellier, France

Luminescent Single-Molecule Magnets (SMM) belong to a new class of multifunctional molecule-materials that associate luminescence and slow relaxation of their magnetization within a single crystalline phase. We present in this mini-review the major advances that have been achieved in this new field over the last few years. More particularly, we will focus on the use of Schiff-base complexes in order to correlate magnetism and luminescence, as well as discussing the future outlooks of the field.

Keywords: lanthanides, single-molecule magnet, multifunctional molecular materials, luminescence, anisotropy, crystal-field splitting

Long J (2019) Luminescent Schiff-Base Lanthanide Single-Molecule Magnets: The Association Between Optical and Magnetic Properties. Front. Chem. 7:63. doi: 10.3389/fchem.2019.00063

INTRODUCTION

Nowadays, developing optimized molecule-based materials for future applications such as biomedicine (Horcajada et al., 2012; Long et al., 2016a), gas separation (Dechambenoit and Long, 2011), catalysis (Li et al., 2016), and quantum computing (Bogani and Wernsdorfer, 2008) frequently requires the association of different properties within a single-crystalline structure. Molecule-based materials benefit from specific assets related to their molecular nature, with respect to usual solid-state materials such as an unlimited structural diversity, weak density, optical transparency and the possibility to finely adjust and control their properties. Remarkably, coordination chemists have been at the front lines of science since the turn of the century, taking advantage of the respective intrinsic properties of metal ions and organic/inorganic ligands, to design original architectures with targeted functionalities. From a fundamental point of view, these unique molecular materials may display these properties independently, but the design of systems in which these functionalities strongly interact, constitutes the central objective for one property to control another.

Since the pioneering work of (Ishikawa et al., 2003), lanthanide-based Single-Molecule Magnets (SMM) have been investigated thoroughly because of their tremendous technological potential in high-density storage and quantum computing (Leuenberger and Loss, 2001; Woodruff et al., 2013; Liddle and van Slageren, 2015; Tang and Zhang, 2015; Ungur and Chibotaru, 2016). In such coordination complexes, an anisotropic barrier, Δ, originating from the interplay between the magnetic anisotropy and crystal-field splitting, opposes the reversal of the magnetization and leads to superparamagnetic-like behavior, comparable to that observed in magnetic nanoparticles. This feature may eventually give rise to a magnetic bistability that is strictly intrinsic to the molecular entity. Obviously, utilizing lanthanide ions constitutes a straightforward approach to implement simultaneous magnetic and luminescent properties because of their strong magnetic anisotropy and exceptional luminescence properties, dominated by f-f electronic

transitions, which results in long-lived emission, narrow bandwidth, important Stokes shifts and high quantum yields (Bunzli and Piguet, 2005). While the collection of lanthanide SMM is growing exponentially, only a small percentage of those systems exhibit lanthanide luminescence and can therefore be viewed as multifunctional. In this mini-review, we discuss the use of Schiff-base ligands and associated complexes for the design of luminescent SMM, as well as providing future outlooks and directions in the field.

CRITERIA TO DESIGN LANTHANIDE LUMINESCENT SMM

Slow relaxation of the magnetization and lanthanide luminescence, arises in both cases from the subtle association between a defined lanthanide ion and appropriate ligand(s). Therefore, the SMM behavior depends on the nature of the lanthanide ion, such as its angular momentum value, *J*, its Kramers/non-Kramers character as well as the angular dependence of the 4*f* electronic density which can be oblate (flattened spheroid) or prolate (elongated spheroid) (Rinehart and Long, 2011; Ungur and Chibotaru, 2016). On the other hand, and considering simple electrostatic considerations, the crystal-field generated by the surrounding ligands could result in the formation of m_J states largely separated in energy. Since it is mostly the single-ion anisotropy that dominates the slow relaxation, Δ is therefore directly related to crystal-field splitting, through relaxation involving the first or higher excited states. Other mechanisms involved in spin-phonon coupling (Raman and direct processes) or Quantum tunneling of Magnetization (QTM) complicate this scenario however, by creating underbarrier relaxation paths. In this sense, significant advances have been achieved in recent years, with either coordination (Chen et al., 2016; Liu et al., 2016; Meng et al., 2018) or organometallic complexes (Chen et al., 2016; Ding et al., 2016; Gregson et al., 2016; Gupta et al., 2016; Goodwin et al., 2017; Guo et al., 2017) showing for instance magnetic hysteresis higher than liquid nitrogen boiling's temperature (Guo et al., 2018). Remarkably, while the QTM affects the magnetic relaxation at a low temperature, recent studies have highlighted the decisive role of molecular vibrations (spin-phonon coupling) at a higher temperature (Goodwin et al., 2017; Escalera-Moreno et al., 2018).

With regards to lanthanide luminescence, the parity and spin forbidden character of the *f-f* transitions usually require an indirect excitation through the use of sensitizer ligands that transfers the absorbed energy to the excited state of the lanthanide ion. Consequently, the ligand is of utmost importance since it directly dictates the coordination environment suitable for the slow relaxation of the magnetization, while ensuring an efficient luminescence sensitizing toward a specific lanthanide ion. Among the lanthanide series, Dy^{3+} ion represents one of the most promising candidates to design luminescent SMM, because of its large $J = 15/2$ value, its Kramers character leading to a doubly degenerated ground state and its oblate electronic density which could be easily stabilized by usual coordination chemistry ligands. Dy^{3+} luminescence could be observed both in the visible and Near-Infra Red (NIR) (Long et al., 2018b). To a lesser extent, the NIR emissive Yb^{3+} has also been widely employed to design luminescent SMM (Pointillart et al., 2015), but optimizing the slow relaxation remains more difficult to realize with respect to Dy^{3+}. Tb^{3+} and Er^{3+} could also be employed to design luminescent SMM. Nevertheless, in practice they exhibit some drawbacks associated either to the Tb^{3+} non-Kramers nature (Ehama et al., 2013; Yamashita et al., 2013) or to the difficulty to observe Er^{3+}-based luminescence (Ren et al., 2014). Historically, the first example of SMM simultaneously exhibiting a slow relaxation of the magnetization and a weak lanthanide luminescence was reported by Bi et al. in a tetranuclear calixarene dysprosium complex in 2009 (Bi et al., 2009). Following this, various ligand families (beta-diketonates, carboxylates, aromatic amines) have been successfully explored (Long et al., 2018b; Jia et al., 2019). We will however, next focus on another class belonging to Schiff bases and describe examples that go further than the simple observation of both properties.

LUMINESCENT SCHIFF-BASE SMM: MAGNETO-LUMINESCENCE CORRELATION

Schiff-base ligands are known as simple efficient sensitizers of Ln^{3+} (Yang et al., 2014; Andruh, 2015) while benefiting from a large tunability including the denticity, rigidity/flexibility, and selective coordination sites (**Figure 1**). Several 4*f* or 3*d*/4*f* luminescent complexes based on a myriad of Schiff-base ligands and incorporating various lanthanide ions such as Eu^{3+}, Nd^{3+}, Tb^{3+}, Yb^{3+}, have been reported since the beginning of the century (Wong et al., 2002, 2006; Yang and Jones, 2005; Burrow et al., 2009; Wang et al., 2009). Nevertheless, the occurrence of slow relaxation of magnetization in these complexes was either not achieved, due to the lack of magnetic anisotropy, or was not investigated. Thus, the first example of a bifunctional Schiff-base SMM was reported by our group in 2012 in a $[Zn(NO_3)L^1Dy(NO_3)_2(H_2O)]$ complex [H_2L^1: N,N'-bis(3-methoxysalicylidene)-1,2-diaminoethane)] and based on a simple compartmentalized ligand obtained from the condensation of *o*-vanillin and ethylenediamine (Long et al., 2012). The complex could be described as a dinuclear entity in which the connections between Zn^{2+} and Dy^{3+} ions are provided by phenolate bridges (**Figure 2**). Introduction of the diamagnetic Zn^{2+} ion clearly has two benefits: it increases the negative charge (basicity) of the phenolate moieties and in turn the crystal-field splitting of the lanthanide ion (Upadhyay et al., 2014) while it does not quench the rare-earth emission in the visible spectral window. At room temperature, both a broad emission band, ascribed to the zinc complex and the typical Dy^{3+} emission lines were observed, indicating a partial energy transfer toward the lanthanide ion. Lowering the temperature (14 K) results in the exclusive observation of well-resolved Dy^{3+} emission bands. Such feature is of prime interest since the emission lines involving the electronic transitions also involve the magnetic ground state $^6H_{15/2}$ and

as a consequence directly reflects its crystal-field splitting. Remarkably, such an approach was previously utilized in the 60's, using absorption spectroscopy for ytterbium (Buchanan et al., 1967) or dysprosium garnets (Grünberg et al., 1969) and this methodology was later extended by Cucinotta et al. (2012) to correlate luminescence and magnetic properties in the archetypical SMM $Na[Dy(DOTA)(H_2O)]\cdot 4H_2O$ complex (Cucinotta et al., 2012). The emission spectrum for the complex $[Zn(NO_3)L^1Dy(NO_3)_2(H_2O)]$ shows more than eight expected transitions, resulting from the splitting of $^6H_{15/2}$ ground state into eight Kramers doublets ($J + 1/2$). This indicates the presence of "hot bands" arising from the first excited state of the emitting level $^7F_{9/2}$ (**Figure 2**). Deconvolution of the emission bands, using Gaussian functions, allows one to experimentally obtain the crystal-field splitting of the Kramers doublets. Hence, the gap between the ground and first excited doublets is estimated at 48 cm^{-1}, in line with the value of $\Delta = 35$ cm^{-1} obtained by alternate currents (ac) magnetic measurements. This suggests that the relaxation occurs *via* the first excited Kramers doublet corresponding to an Orbach process. Nevertheless, the slight discrepancy between luminescence and magnetism indicates that additional magnetic relaxation mechanisms are involved. This is further corroborated through the study of both the magnetic and luminescence properties of the aforementioned complex, diluted in a diamagnetic yttrium matrix (Long et al., 2016b). Photoluminescence confirms that: (i) the Dy^{3+} ion remains in a similar environment upon chemical dilution; (ii) as expected, the energy gap between the ground and first excited doublets is identical. The magnetic measurements for the diluted sample reveal an increased anisotropic barrier of $\Delta = 45$ cm^{-1} due to the removal of the dipolar interactions, known to enhance the QTM, that decrease the effective barrier. The value of Δ is in remarkable accordance with that obtained by luminescence, which confirms that such an approach can be used to compare the results from these two experimental techniques and further shed light on the mechanisms that govern the slow relaxation of magnetization.

Such simple methodology has been widely extended, by other groups and including our own, to numerous SMM or coordination networks that exhibit a single-ion based magnetic relaxation in order to obtain a detailed picture of the lanthanide crystal-field and therefore improves comprehension of the relaxation dynamics (Long et al., 2018b; Jia et al., 2019). We would also like to emphasize that such outcomes could also be further confirmed by the decisive input from *ab initio* calculations, especially with systems that exhibit multiple crystallographically independent sites (Long et al., 2015).

Pure 4*f* Schiff base complexes also represent another class of promising systems. However, it remains difficult to simultaneously increase the magnetic anisotropy to generate a genuine slow relaxation of magnetization, while retaining the lanthanide luminescence (Shintoyo et al., 2014; Long et al., 2018a). Therefore, one alternative strategy consists of synthesizing heterotrinuclear Zn_2Dy complexes (Oyarzabal et al., 2015; Sun et al., 2016) in which the lanthanide ion is sandwiched between two bis-phenoxide moieties. This results in

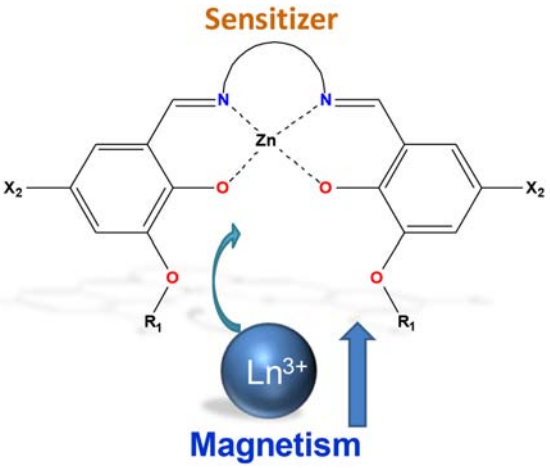

FIGURE 1 | General scheme showing the combination of compartmental Schiff-base complex and Ln^{3+} ions.

an enhancement of the axial crystal-field. The five-membered ring constituted by four methoxy oxygen and one solvate, or counter-ion, defines a basal plane (hard plane) almost perpendicular to the Zn^{2+}-Dy^{3+}-Zn^{2+} arrangement. Numerous complexes with various counter-anions and co-ligands that exhibit SMM behavior and Dy^{3+}-based luminescence associated with remanent emission from the ligands, have been reported (Costes et al., 2015, 2016). To this point, we have recently described an example of a luminescent trinuclear complex $[(ZnL^1Cl)_2Dy(H_2O)]_4[ZnCl_4]_2\cdot H_2O$ that shows a zero-field slow relaxation of magnetization that could be observed for up to 30 K (Boulkedid et al., 2018). The compound exhibits the typical Dy^{3+} emission, but the presence of four different crystallographically independent dysprosium sites precludes the extraction of the energy difference between the ground and first excited doublets. Luminescence reveals however a large total crystal-field splitting of about 1,500 cm^{-1}, indicating that such systems may have great potential if the relaxation occurs through higher excited Kramers doublets.

Schiff-base ligands could also be employed to introduce further functionalities. For instance, implementing chirality, opens the field to new properties that result from the crystallization in non-centrosymmetric structures. One can cite for instance Natural Circular Dichroism (NCD), Second-Harmonic Generation (SHG), Circular Polarized Luminescence (CPL) as well as magneto-optical cross-effects that result from the interplay with magnetism, such as magneto-chiral dichroism and Magnetized Second-Harmonic Generation (MSHG) (Train et al., 2011). In addition, the crystallization in appropriate non-centrosymmetric space groups paves the way toward advanced electrical properties such as piezo/pyroelectricity and ferroelectricity. With this in mind, we reported chiral $[ZnL^2Dy(OAc)(NO_3)_2]$ complexes based on the enantiopure Schiff base ligands *R*,*R* or *S*,*S*-HL_2 = phenol,2,2′[2,2-diphenyl-1,2-ethanediyl]bis[(E)-nitrilomethylidyne]-bis(6-methoxy) (Long et al., 2015). Each enantiomer crystallizes in the polar

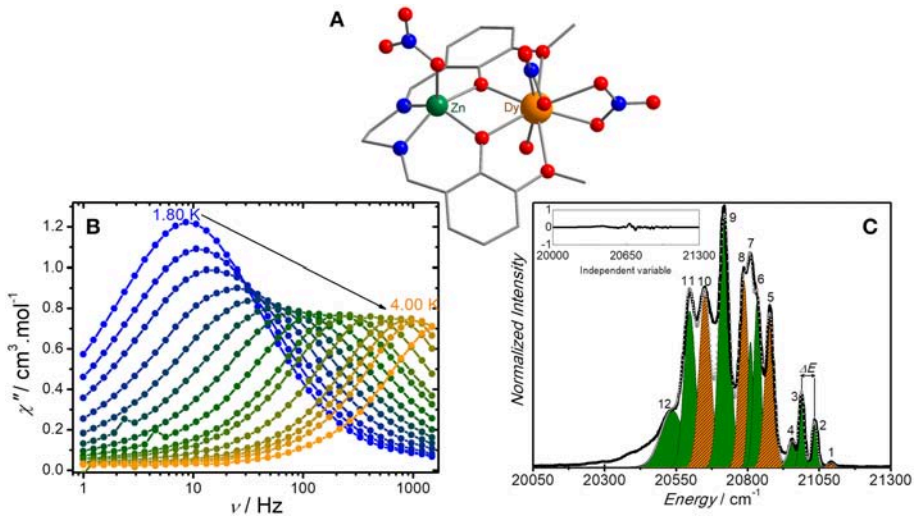

FIGURE 2 | (A) Crystal structure of the dinuclear $[Zn(NO_3)L^1Dy(NO_3)_2(H_2O)]$ complex. **(B)** Frequency dependence of the out-of-phase susceptibility (χ") obtained under a 900 dc field. **(C)** Magnification of the $^4F_{9/2} \rightarrow {}^6H_{15/2}$ emission transitions in the 20,050–21,300 cm^{-1} region (at 14 K) Multi-Gaussian function fit components arising from the first $^4F_{9/2}$ Stark sublevel to the $^6H_{15/2}$ multiplet in the energy interval. The fits regular residual plots ($R^2 > 0.98$) are shown in inset (Long et al., 2012, 2016b).

$P2_1$ space group, with two crystallographically inequivalent homochiral Zn^{2+}/Dy^{3+} complexes, in the asymmetric unit. Apart from the typical dysprosium luminescence and slow relaxation of the magnetization that have been correlated and compared with results obtained from *ab initio* calculations, the compounds exhibit a ferroelectric behavior up to the decomposition of the material at 300°C, making it the highest temperature at which a switchable polarization has been observed for a molecular ferroelectric. Such robust chiral molecular compounds may represent alternative candidates for high-temperature ferroelectrics (Hang et al., 2011).

CONCLUSIONS AND FUTURE OUTLOOK

Schiff-bases represent an interesting class of ligands from which to design luminescent lanthanide SMM. Their infinite diversity and flexibility make them ideal candidates to face the challenges in the field and to obtain air-stable luminescent SMM with high energy barriers. In a more general context, the in-depth understanding of magnetic relaxation in lanthanide-based SMM remains a challenge as this involves concepts and models in physics from the 60's, related for instance to spin-phonon coupling (Escalera-Moreno et al., 2018), which should be modernized. In this regard, photoluminescence could definitely shed light on lanthanide crystal-field splitting, to determine if the relaxation proceeds *via* the 1st or higher excited states, or involves underbarrier Raman, direct or QTM processes. Moreover, studying the vibronic coupling in high temperature SMM may be experimentally achieved by photoluminescence (emission lifetimes, *f*-*f* relative intensities…).

While the correlation between magnetism and photoluminescence should be viewed as the inception, studying the interplay between the two properties constitutes a major milestone. As both properties are intimately correlated to the electronic structure of the lanthanide ion, the coupling is expected to be strong and such a cross-effect has previously been evidenced more than 50 years ago, in paramagnetic ytterbium garnet (Buchanan et al., 1967; Grünberg et al., 1969). Thus, applying a magnetic field induces a strong modification of the emission spectrum and has been explained by the well-known Zeeman effect, that lifts the degeneracy of the Kramers doublets. Such approach was first demonstrated in lanthanide SMM, in 2016 (Bi et al., 2016) in which values of the gyromagnetic factor (that are usually difficult to experimentally obtain) were extracted, confirming the gap between the first and excited Kramers doublets. One point that needs to be addressed concerns the comprehension of the field dependence of the emission intensity as observed in others SMM (Chen et al., 2017). Such breakthroughs confirm the possibility to control both the emission intensity and wavelength by a magnetic field, which could be relevant for applications such as magnetic field sensors. However, such inductive effects may simply occur in any luminescent 4*f* paramagnetic compound, therefore, future studies should examine the existence of an interplay between the SMM property (magnetic bistability) and the luminescence. This requires circumventing synthetic issues to design systems, simultaneously exhibiting a significant magnetic remanence and coercivity at a pertinent temperature with stability over a long-time scale. This last point is of critical importance since 4*f* SMM usually shows quick relaxation of magnetization, due to the QTM. Major advances have recently been achieved in organometallic

SMM, showing magnetic bistability of up to 60–80 K (Goodwin et al., 2017; Guo et al., 2017, 2018), confirming that the design of high performing luminescent SMM with possible air-stability is within reach if suitable sensitizer ligands that are able to maximize the magnetic anisotropy, are rationally conceived.

On the other hand, introduction of chirality and other properties, resulting from the non-centrosymmetric character of the crystal structures, may be easily achieved using Schiff base ligands. Simple multifunctional molecular ferroelectrics therefore represent ideal candidates to study the coupling between the constitutive functionalities such as the magneto-electrical coupling. Designing a strong coupling between an electric and magnetic property clearly constitutes an important challenge in the field of solid-state chemistry (Fiebig et al., 2016). This indicates that molecular systems may control polarization, by applying a magnetic field and *vice versa* with prospective applications in non-volatile memories and low-consumption devices (Eerenstein et al., 2006; Cheong and Mostovoy, 2007; Mandal et al., 2015).

More generally and in order to fulfill these ambitious objectives, molecular materials also need to be integrated or shaped into more complex architectures (surfaces, films, or composites) for use in practical applications. Such strategies necessitate investigating that the considered molecular objects and their associated functionalities remain preserved. Among the characterization techniques used to investigate the latter, photo-luminescence could easily be used for this purpose. Close collaboration between chemists and photo physicists is therefore clearly necessary, in order to achieve these objectives.

C–X (X = N, O) Cross-Coupling Reactions Catalyzed by Copper-Pincer Bis(N-Heterocyclic Carbene) Complexes

*Jennifer L. Minnick, Doaa Domyati, Rachel Ammons and Laleh Tahsini**

Department of Chemistry, Oklahoma State University, Stillwater, OK, United States

Over the last two decades, N-heterocyclic carbene (NHC)–copper catalysts have received considerable attention in organic synthesis. Despite the popularity of copper complexes containing monodentate NHC ligands and recent development of poly(NHC) platforms, their application in C–C and C–heteroatom cross-coupling reactions has been limited. Recently, we reported an air-assisted Sonogashira-type cross-coupling catalyzed by well-defined cationic copper-pincer bis(NHC) complexes. Herein, we report the application of these complexes in Ullmann-type C–X (X = N, O) coupling of azoles and phenols with aryl halides in a relatively short reaction time. In contrast to other well-defined copper(I) catalysts that require an inert atmosphere for an efficient C–X coupling, the employed Cu(I)-pincer bis(NHC) complexes provide good to excellent yields in air. The air-assisted reactivity, unlike that in the Sonogashira reaction, is also affected by the base employed and the reaction time. With Cs_2CO_3 and K_2CO_3, the oxygen-generated catalyst is more reactive than the catalyst formed under argon in a short reaction time (12 h). However, the difference in reactivity is compromised after a 24 h reaction with K_2CO_3. The efficient pincer Cu-NHC/O_2/Cs_2CO_3 system provides great to excellent cross-coupling yields for electronically diverse aryl iodides and imidazole derivatives. The catalyst scope is controlled by a balance between nucleophilicity, coordinating ability, and the steric hindrance of aryl halides and N-/O-nucleophiles.

Keywords: Cu-pincer NHC complexes, Ullmann-type C–X coupling, air-assisted cross-coupling, copper-oxygen catalysts, N-aryl imidazoles, biarylethers

INTRODUCTION

The N-arylazoles and biarylethers are among the most commonly found motifs in pharmaceuticals, biologically active molecules, crop-protection chemicals, and material science. A huge number of drugs contain N-arylimidazole moieties including cyclic AMP phosphodiesterase inhibitors (Sircar et al., 1987; Venuti et al., 1988; Güngör et al., 1992; Martinez et al., 1992; Sawanishi et al., 1997), thromboxane synthase inhibitors (Iizuka et al., 1981; Martinez et al., 1992; Cozzi et al., 1993; Nicolaï et al., 1993), topical antiglaucoma agents (Lo et al., 1992), and cardiotonic agents (Hagedorn et al., 1987; Erhardt et al., 1989; Shaw et al., 1992). In this regard, transition-metal catalyzed C-heteroatom coupling reactions have become one of the most important areas in modern chemical synthesis. Several methods have been developed for the direct coupling of azole with functionalized arenes. The most common route is nucleophilic aromatic substitution of azoles with aryl halides;

however, this approach is limited to aryl halides with strongly electron-withdrawing groups (Venuti et al., 1988; Güngör et al., 1992; Cozzi et al., 1993; Ohmori et al., 1996). A second approach to N-arylazoles is traditional Ullmann-type coupling that has a broader aryl halide scope, but requires high temperatures (>150°C), polar solvents, and often stoichiometric amounts of copper or copper salts (Ullmann and Bielecki, 1901; Ullmann, 1903; Ullmann and Sponagel, 1905). To achieve milder C–N/C–O coupling conditions, efforts have focused on the use of more activated arenes such as arylbismuth (Barton et al., 1988), -tin, (Davydov et al., 2002) -lead (Lopez-Alvarado et al., 1995), -silanes (Lam et al., 2000), and -boronic acids (Lam et al., 1998; Mederski et al., 1999; Collot et al., 2000). Some of these methods are limited in scope to certain azole and arenes or produce toxic side-products, e.g., copper-catalyzed N-phenylation of indoles by triphenylbismuth bis(trifluoroacetate) or synthesis of N-arylimidazoles using *p*-tolyllead triacetate and $Cu(OAc)_2$ catalyst (Barton et al., 1988; Lopez-Alvarado et al., 1995). A significant change to the conditions and the scope of azole N-arylation was made by Chan and Lam that reported direct coupling of arylboronic acids and azoles using stoichiometric amounts of $Cu(OAc)_2$ and pyridine (or trimethylamine) at room temperature (Lam et al., 1998). A similar approach was alternatively used to synthesize diaryl ethers from phenols and arylboronic acids (Evans et al., 1998). The shortcoming of this method, use of stoichiometric amounts of copper salts and base, was later improved in the report of a diamine-copper-catalyzed N-arylation of imidazoles (Collman and Zhong, 2000). The scope has been recently extended to heterocycles and diarylethers (Lam et al., 2001; Guillou et al., 2009; Wentzel et al., 2009; Liu et al., 2010; Wang et al., 2010).

Another approach toward milder C(aryl)–heteroatom bond formation is via a ligand-accelerated Ullmann-type coupling of aryl halides and nucleophiles at relatively lower temperatures than those used in Ullmann condensation. Buchwald reported the synthesis of various N-arylimidazoles using catalytic amounts of $Cu(OTf)_2{\cdot}C_6H_6$ and stoichiometric amounts of 1,10-phenanthroline and *trans*,*trans*-dibenzylideneacetone in xylenes at different temperatures (110–125°C) (Kiyomori et al., 1999). A vital step to this method, facilitated by soluble cuprous ions, (Paine, 1987) is ligand screening to identify the most effective platform. In this regard, systematic studies were undertaken on N-, O-, and P-donor ligands as well as copper sources which has led to the development of efficient catalysts for cross-coupling of N-heterocycles and phenols with aryl halides (Arterburn et al., 2001; Klapars et al., 2001; Antilla et al., 2002, 2004; Kelkar et al., 2002; Evano et al., 2008). In addition to the catalysts formed *in-situ* from copper salts and ligands, some well-defined copper catalysts have been identified for the N-arylation of azoles and O-arylation of phenols (Gujadhur and Venkataraman, 2001; Gujadhur et al., 2001; Choudary et al., 2005; Biffis et al., 2009). Interestingly, the reports of phosphine- and NHC-supported copper catalysts in this chemistry has been limited, unlike N- and O-donor systems. To the best of our knowledge, there has been only two reports of NHC ligands in Ullmann-type coupling wherein the catalytic activity of cationic trinuclear Cu(I)-tris(NHC) and neutral mononuclear [Cu(IPr)Cl] has been assessed (Tubaro et al., 2008; Biffis et al., 2009). The trinuclear complexes presented high reactivities in C–N, C–O, and C–C coupling reactions with a low catalyst loading.

Recently, we have developed mononuclear pyridylmethyl-linked Cu(I)-bis(NHC) complexes with alkyl wingtips, Cu-$I(R)^{C\wedge N\wedge C}$, and examined their catalytic reactivity in an air-assisted cross-coupling of terminal alkynes and aryl iodides (Domyati et al., 2016, 2018). Our interest in Ullmann-type coupling was driven partly by a need to synthesize N-arylated imidazole derivatives for our pyridine-based bis(NHC) ligands with aryl wingtips. Herein, we report based-controlled, air-assisted Ullmann-type coupling of azoles and phenols with aryl halides facilitated by pincer Cu-NHC complexes (**Figure 1**).

RESULTS AND DISCUSSION

Synthesis of Copper Catalysts

The pyridine-based pincer bis(NHC) complexes containing Me, Et, and ^{i}Pr substituents were prepared via the reaction of tetrakis(acetonitrile)copper(I) hexafluorophosphate as copper source and an *in-situ* generated carbene following our previously described procedure (Domyati et al., 2016). To compare the catalytic activity of the cationic pincer Cu-NHC complexes to one of the most efficient copper-carbene catalysts known to date, [Cu(IPr)Cl] (**4**), it was prepared by modifying a published procedure (Santoro et al., 2013; Lazreg et al., 2015). In an attempt to conduct Ullmann-type coupling of azoles under ambient conditions similar to that reported previously for primary amines and N-heterocycles (Shafir and Buchwald, 2006), an *in-situ* formed copper catalyst from CuI and 2-acetylcyclohexanone (**5**) was also utilized.

Cross-Coupling Reaction Optimization

We chose the coupling of imidazole and 4-iodoacetophenone as a model reaction to determine the optimal conditions for catalysis (**Table 1**). All reactions were carried out in a 20 mL screw-cap reaction vial that was charged with reagents and 5 mL reagent-grade solvent in air. The model reaction was initially performed using **3** as catalyst for 12 h in different solvents which provided the highest yield of N-arylimidazole in DMF at 120°C (**Table 1**, entry 5). The yield increased only to a slight extent (+4%) when the reaction time was doubled indicating an almost-completed cross-coupling in 12 h (**Table 1**, entry 6). This finding and the lack of any biaryl coupling, a potential side reaction in air, makes the pincer complexes one of the most efficient, well-defined catalysts for N-arylation of imidazole (Kiyomori et al., 1999; Biffis et al.,

[e] *Under air.*

2009). The catalytic activity of the pincer Cu-NHC complexes is strictly controlled by temperature. Reducing the temperature to 60°C provided a much lower yield and no conversion occurred at room temperature (**Table 1**, entries 7-8). The model reaction was then tested using **1**, **2**, and **4** as other well-defined catalysts, however, the product was isolated at lower yields than that obtained with **3**. Interestingly, **4** provided the lowest yield, even lower than that of **3** at 5 mol% loading after 24 h (**Table 1**, entries 6, 11). The reduced catalytic activity of **4** in this reaction, compared to that reported previously for the same substrates in DMSO at 100°C, is most likely due to different solvent and/or atmosphere (Biffis et al., 2009). The cross-coupling reaction in the absence of a copper catalyst provided only 24% yield under the same reaction conditions (**Table 1**, entry 12). The optimal amount of the base was determined by the highest cross-coupling yield achieved for the model reaction using various amounts of Cs_2CO_3 (**Supplementary Figure 1**).

Furthermore, we attempted to compare the pincer complexes activity to an *in-situ* formed catalyst, **5**, reported as an efficient catalyst for the Ullman-type coupling of primary amines and N-heterocycles (Shafir and Buchwald, 2006). First, the model N-arylation of imidazole was performed using **5** under the exact same conditions reported for the coupling of non-azole substrates. At room temperature, the **5**-catalyzed reaction of 4-iodoacetophenone and imidazole afforded 63% cross-coupling yield, whereas no product was formed using **3** (**Table 1**, entries 8, 13). Although this result makes **5** a more reactive catalyst than **3**, a further study revealed its limited scope due to a substrate-dependent reactivity with other aryl halides (**Supplementary Figure 2**). The coupling of imidazole with 4-iodonitrobenzene provided 67% yield at room temperature, comparable to that of the model reaction, but no cross-coupled product was isolated for 4-(trifluoromethyl)iodobenzene. Further attempts to improve the yields by conducting these reactions at a higher temperature (120°C) revealed a moderate increase for the model substrate (**Table 1**, entry 14). However, a reverse temperature effect was found with the 4-NO_2 derivative and the conversion was reduced significantly. Additionally, temperature had no improving effect on the yield of 4-CF_3 substrate and no conversion occurred even at 120°C. Unlike pincer Cu-NHC catalysts, air did not have a noticeable effect on the cross-coupling reactions catalyzed by **5** and no clear improvement of the yield was found (**Table 1**, entry 14).

Atmosphere and Base Effect

The assistant role of oxygen in Cu-NHC catalyzed Sonogashira reaction was previously shown by the greater yield of the product in air than that under argon (Domyati et al., 2018). This effect in Ullmann-type coupling was examined by conducting the model reaction under argon using the same optimized conditions found in air. After a 12 h anaerobic reaction, the N-arylimidazole was isolated at almost half of the yield obtained under air indicating the facilitating effect of oxygen in the C–N coupling reactions catalyzed by **3** as well (**Figure 2**). Interestingly, extending the reaction time to 24 h improved the yield only to a slight extent, similar to the trend observed for the aerobic reaction. To examine the effect of oxygen concentration, the model reaction

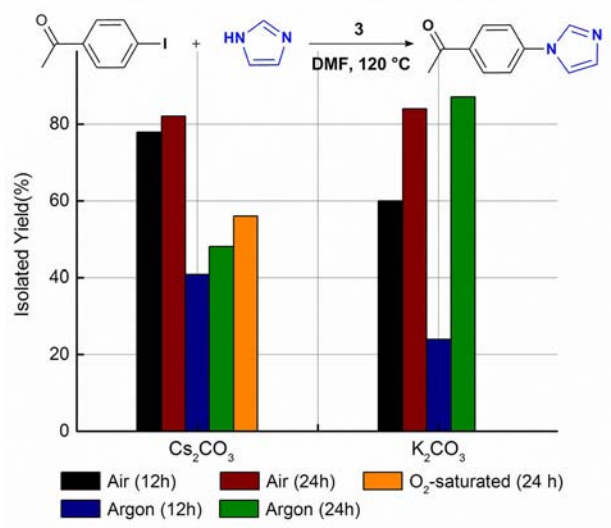

FIGURE 2 | The isolated yield of the cross-coupled product from imidazole and 4-iodoacetophenone reaction catalyzed by **3** and Cs_2CO_3 or **3** and K_2CO_3 in DMF at 120°C under an air, O_2-saturated, and argon atmosphere. Reaction conditions were as follows: aryl halide (0.5 mmol), imidazole (0.75 mmol), base (1.0 mmol), **3** (0.05 mmol), DMF (5 mL).

was performed in O_2-saturated DMF which provided a lower yield than in air but slightly more than that under argon. This indicates the significance of a certain stoichiometry of oxygen and copper to the catalytic activity, similar to that in **3**-catalyzed Sonogashira-type coupling (Domyati et al., 2018).

The oxygen-assisted cross-coupling mechanism is also controlled by the base used in the reaction. While Cs_2CO_3 provided more cross-coupled product in air than under argon in both 12 h and 24 h reaction times, the yields obtained with K_2CO_3 after 24 h were almost identical under both atmospheres. In contrast, K_2CO_3 provided a much smaller cross-coupling yield under argon in 12 h than in air supporting a slow formation of the active catalyst under anaerobic conditions. The distinct reactivity of Cu-I(R)$^{C\wedge N\wedge C}$ complexes in air from that under argon could be due to different active catalysts and potentially a different mechanism that needs to be clarified. However, the presented data support a higher cross-coupling reactivity of the air-generated catalyst in the presence of Cs_2CO_3 than that in the presence of K_2CO_3. On the other hand, the slowly-formed active catalyst under argon is more reactive in the presence of K_2CO_3 than with Cs_2CO_3. Such versatility of active catalysts controlled by simple change of the base or atmosphere is significant to the application scope of the system.

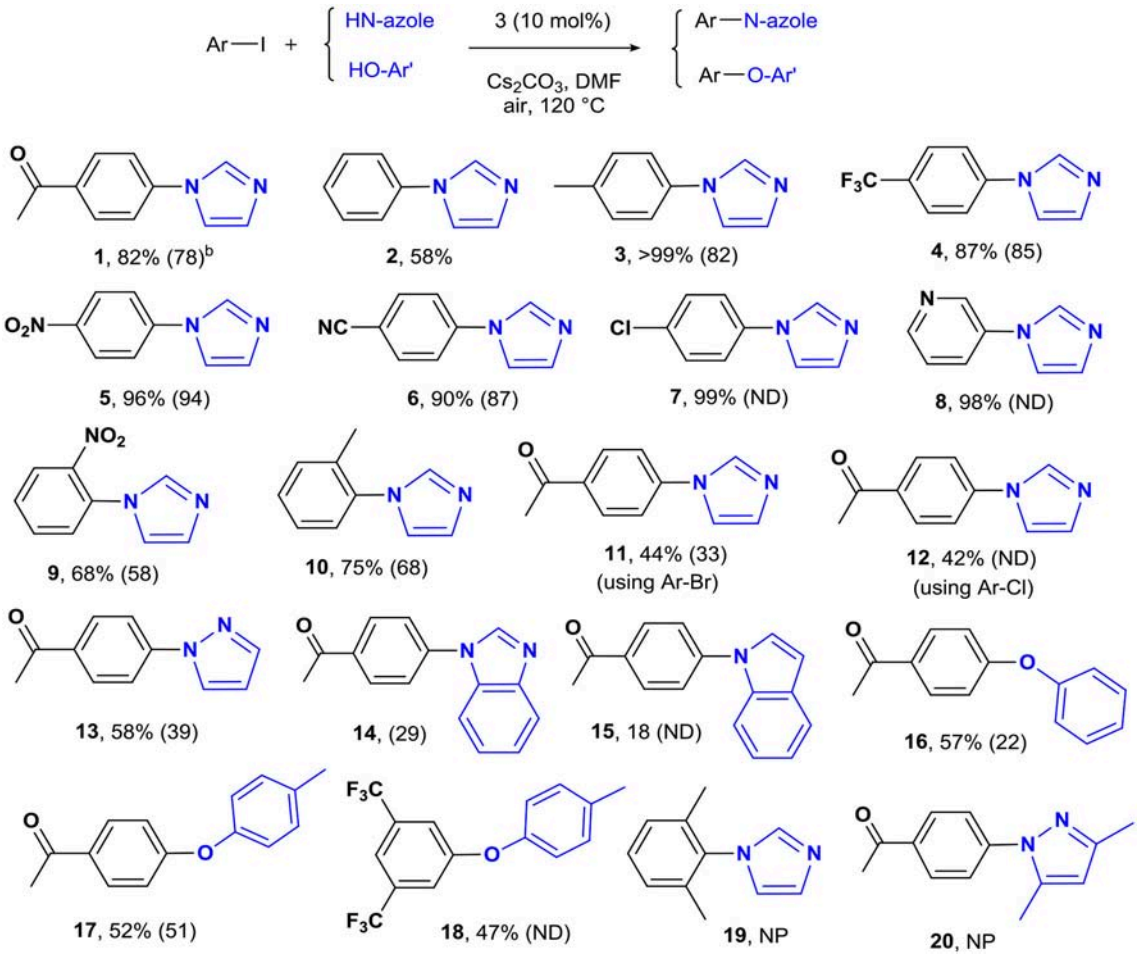
Reaction Scope

The optimized conditions were applied to a range of electronically diverse aryl halides and different N- and O-nucleophiles to explore the application scope of the pincer Cu-NHC catalysts in Ullmann-type coupling. Considering the close yields obtained for the model reaction after 12 and 24 h, most reactions were performed at both times to examine any substrate-dependent behavior in this matter. The cross-coupled products were isolated with <10% difference in yield between the two reaction times, except for the reaction of 4-iodotoluene with imidazole and 4-iodoacetophenone with pyrazole and phenol (**Scheme 1**, **3**, **13**, **16**). The coupling of *p*-substituted aryl iodides bearing electron-donating and electron-withdrawing groups with imidazole provided the corresponding N-arylimidazoles in great (82%) to excellent (>99%) yields (**Scheme 1**). An exception to this trend is the coupling of unactivated iodobenzene and imidazole that provided a moderate yield (58%) of the product in 24 h (**Scheme 1**, **2**). The less pronounced effect of the directing groups of aryl halides on the reactivity of **3** is also shown by the comparable yields of *o*-substituted substrates. While the steric hindrance of 2-iodotoluene and 2-iodonitrobenzene led to a lower cross-coupled product than their *p*-substituted analogs, their isolated yields are close with slightly higher activity of 2-iodotoluene (**Scheme 1**, **9**, **10**). The steric effects appear to play a major role in the reactivity of aryl iodides in the present system given that no product was isolated from the reaction of 2,6-dimethyliodobenzene and imidazole (**Scheme 1**, **19**). The other important parameter affecting the catalyst reactivity is the type of halide. While aryl iodides are highly reactive using **3**, the coupling of activated aryl bromides and chlorides with imidazole was achieved at moderate yields (**Scheme 1**, **11, 12**). Additionally, the coupling of imidazole with heteroaryl iodides is facilitated given the excellent yield obtained for 3-iodopyridine (**Scheme 1**, **8**). The application scope of pincer Cu-NHC complexes in Ullmann-type coupling is also controlled by the type of nucleophile used. The cross-coupling of 4-iodoacetophenone with exemplary heterocycles such as indole, pyrazole, and benzimidazole, as well as phenols provided low (18%) to moderate yields (58%) of corresponding products (**Scheme 1**, **13–18**). The reactivity pattern of nucleophiles appears to be the result of a balance between nucleophilicity and coordinating ability to the copper center controlled by steric effects in the order: imidazole > pyrazole > phenol > benzimidazole > indole. This is further confirmed by no cross-coupled product isolated from the reaction of 3,5-dimethylpyrazole and aryl iodide due to the greater steric hindrance of substituted pyrazole compared to pyrazole, despite its higher nucleophilicity (**Scheme 1**, **20**).

To clarify the scope of reactivity in O-arylation, we examined the coupling of exemplary phenol and aryl iodide derivatives bearing electron-donating and electron-withdrawing groups. Complex **3** showed good reactivity toward activated aryl iodides and phenols with moderate yields (47–57%) isolated from the phenol and p-cresol reaction with 4-iodoacetophenone and 3,5-bis(trifluoromethyl)-iodobenzene (**Scheme 1**, **16–18**). Interestingly, electron-rich aryl halide and/or electron-poor phenols shut down the reaction completely such that no cross-coupled product was isolated.

Comparison to Other Cu-NHC Catalysts

The pincer Cu-NHC complexes (**1–3**) present a new class of Ullmann-type C–heteroatom coupling catalysts with distinct structure and properties from those reported previously (**Table 2**). While complex **4** is air-stable and benefits from good solubility in less polar solvents due to charge neutrality, the



SCHEME 1 | The coupling of aryl halides and N- and O-nucleophiles catalyzed by **3**[a]. [a]Reaction conditions: aryl halide (0.5 mmol), imidazole (0.75 mmol), Cs_2CO_3 (1.0 mmol), [Cu] (0.05 mmol), solvent (5 mL), in air, 24 h. [b]Isolated yields after 24 h reaction time. The yields in parentheses are after 12 h. ND, not determined; NP, no product.

Cu-triscarbene complexes are applicable at a low catalyst loading owing to three Cu(I) ions in a molecular unit. On the other hand, pincer Cu-NHC complexes bearing small alkyl wingtips and open coordination sites can react with oxygen leading to more efficient C–X coupling systems in air than under argon. We have conducted a comparative study between pincer complex **3** and other Cu-NHC systems by taking into account the N-nucleophile substrates used in common (**Table 2**).

In contrast to **4** and the Cu-triscarbene with methyl wingtips (**Table 2**, **A**) that present a low reactivity toward aryl halides bearing weakly electron-donating groups, complex **3** is able to efficiently convert both activated, electron-poor aryl iodides and electron-rich ones (**Table 2**, entries 1, 2). In addition, **3** is able to facilitate the coupling of activated aryl bromides and chlorides with a comparable, moderate efficiency to the Cu-triscarbene complex **B**, but with a lower efficiency than that of complex **4** (**Table 2**, entries 3, 4). Regarding other azoles, **3** performs with a lower efficiency toward N-arylation of pyrazoles than other Cu-NHC complexes (**Table 2**, entry 5). To the best of our knowledge, the reactivity of other Cu-NHC complexes in cross-coupling of aryl halides with benzimidazole and indole substrates has not been reported.

MATERIALS AND METHODS

General Procedure

Imidazolium salts and Cu(I) complexes (**Figure 1**, **1–3**) were synthesized according to published procedure using standard Schlenk techniques or in an MBraun glovebox under Ar atmosphere. 1,3-Bis(diisopropylphenyl)imidazolium chloride, IPr.HCl, was obtained from TCI Chemicals. The solvents used for the syntheses were purified and distilled under N_2 atmosphere before being stored over activated molecular sieves (4 Å) in the glovebox. Tetrahydrofuran was purified by refluxing over Na/benzophenone under a N_2 atmosphere and distilled. Hexane was distilled from CaH_2 under N_2. Reagent-grade N,N-dimethylformamide (DMF), 2-acetylcyclohexanone, cesium- and potassium carbonate, and copper iodide were purchased from Sigma-Aldrich and used as received. Aryl halides were obtained from TCI Chemicals and Sigma. Flash chromatography was

performed on Merck silica gel 60 (230–400 mesh) obtained from Sigma-Aldrich. NMR spectra were measured using a 400 MHz Bruker Avance III spectrometer. NMR samples were prepared in deuterated solvents, CD_3CN, $CDCl_3$, or DMSO-d_6 containing 0.05% TMS as internal standard. Chemical shifts (δ) for ^1H and ^{13}C NMR spectra were referenced to the resonance of TMS as an internal reference or the residual protio solvent. GC/MS data were collected using Shimadzu GC-MS-QP-2010S.

Synthesis of [Cu(IPr)Cl], 4

The compound was synthesized by modifying a published procedure (Santoro et al., 2013). Under an argon atmosphere, CuCl (0.105 g, 1.06 mmol), IPr.HCl (0.300 g, 0.706 mmol), and K_2CO_3 (0.293 g, 2.12 mmol) were mixed in a reaction vial, and transferred out of the glovebox. The vial was quickly charged with 4–5 mL acetone and kept under refluxing conditions for 48 h. The reaction mixture was filtered through Celite and rinsed with 10–15 mL acetone and 6–7 mL dichloromethane. The filtrate was then concentrated under vacuum and layered with hexane. The resultant white solid was then filtered and kept under vacuum to dry completely. The solid was transferred into a glovebox and recrystallized from THF and hexane affording white crystals in 78% yield (0.270 g). ^1H NMR (CD_3CN with 0.05% v/v TMS, 400 MHz): δ = 7.56 (t, 1H; J = 7.8 Hz), 7.46–7.36 (m, 3H), 2.56 (septet, 2H; J = 6.9 Hz), 1.24 (dd, 12H; J = 6.9 Hz). ^{13}C NMR (CD_3CN with 0.05% v/v TMS, 101 MHz): δ = 146.94, 135.59, 131.47, 125.12, 124.84, 29.52, 29.33, 24.98, 23.86.

Cross-Coupling Reactions Catalyzed by 3 and 4 in Air

A mixture of copper complex (0.05 mmol) and cesium carbonate (1 mmol) was added to a 20 mL vial charged with a Teflon stir bar in the glovebox. The mixture was transferred out of the glovebox and suspended in 2 mL non-anhydrous DMF. To the resulting yellow suspension, a solution of aryl halide (0.5 mmol) in 2 mL DMF followed by a solution of azole or phenol (0.75 mmol) in 1 mL DMF was added. The vial was then sealed and placed in an oil bath with pre-adjusted temperature at 120°C for 12 or 24 h. The cooled mixture was diluted with 20–30 mL ethyl acetate and filtered over a pad of silica. The silica was washed with 30–40 mL ethyl acetate and the filtrate was placed under vacuum

until dry. The residual material was loaded on a silica gel column and eluted with mixtures of hexane and ethyl acetate to afford the corresponding product. The cross-coupling reactions were repeated twice to ensure reproducibility.

Cu-Catalyzed Coupling of 4-Iodoacetophenone and Imidazole in O_2-Saturated DMF

In an argon-filled glovebox, a 20 mL scintillation vial was charged with a Teflon stir bar, copper complex (0.05 mmol), cesium carbonate (1.0 mmol), 4-Iodoacetophenone (0.5 mmol), and imidazole (0.75 mmol). The vial was sealed with a teflon cap bearing a silicone septum and transferred out of the glovebox. To this mixture, 5 mL O_2-saturated DMF prepared by bubbling dry O_2 gas through the solvent for 20 min was added. The reaction vial was then placed in an oil bath with pre-adjusted temperature at 120°C. After reaction completion, the mixture was cooled down, diluted with 20 mL ethyl acetate, and filtered through a pad of silica. The silica was washed with 30–40 mL ethyl acetate and the solvent was then removed under vacuum. The residue was purified by column chromatography to obtain analytically pure product.

Cross-Coupling Reactions Catalyzed by CuI and 2-Acetylcyclohexanone, 5

Under an argon atmosphere, a 20 mL scintillation vial was charged with a Teflon stir bar, CuI (0.05 mmol), cesium carbonate (2.0 mmol), aryl halide (1.0 mmol), imidazole (1.5 mmol), and 3.5 mL anhydrous DMF. To the mixture, 2-acetylcyclohexanone (0.2 mmol) and 0.5 mL DMF were then added. The vial was sealed, brought out of the glovebox and kept stirring at room temperature or was placed in an oil bath with pre-adjusted temperature at 110°C. The progress of the reaction was monitored by TLC at different time intervals. Upon completion of the reaction, the reaction mixture was cooled down, diluted with 20 mL ethyl acetate, and filtered through a pad of silica gel. The silica was washed with 30 mL ethyl acetate and the solvent was then removed under vacuum. The residue was diluted with 2–3 mL ethyl acetate and purified by column chromatography using varying gradients of hexane and ethyl acetate to obtain analytically pure product.

CONCLUSION

We have developed a new protocol for the Ullmann-type coupling of aryl halides with N- and O-nucleophiles catalyzed by pincer Cu-NHC complexes bearing alkyl wingtips. Unlike other well-defined Cu catalysts that are more efficient under inert atmosphere, the pincer complexes present generally a higher reactivity in air. This could be due to different active catalysts involved in the rate-determining step of the aerobic and anaerobic reactions. The oxygen-generated active catalyst was found more reactive than the catalyst formed under argon as indicated by the higher cross-coupled product obtained in air than that under argon. The air-assisted reactivity is also affected by the type of the base in the Ullman-type coupling. The catalytic reaction in air was accelerated to a greater extent using Cs_2CO_3 than K_2CO_3 as indicated by a nearly-completed reaction and a higher cross-coupling yield achieved in 12 h. Building on these findings and by taking advantage of the air-assisted reactivity of pincer complexes, an efficient cross-coupling of aryl iodides and imidazole derivatives has been developed. The catalytic system performed with a great to excellent efficiency toward the coupling of electron-poor and electron-rich aryl iodides with imidazole, but had moderate reactivity with pyrazole and aryl bromides or aryl chlorides. Further studies to clarify the reactivity of the Cu-pincer NHC complexes with nucleophiles and to improve their efficiency toward C–O coupling reactions are currently ongoing in our group.

AUTHOR CONTRIBUTIONS

JM and DD designed and completed most of the experiments and helped with data analysis. RA helped with the synthesis of copper-NHC catalysts and some of the catalytic reactions. LT and JM co-wrote the manuscript and were responsible for discussing and revising the paper.

Luminescent nanothermometry uses the light emission from nanostructures for temperature measuring. Non-contact temperature readout opens new possibilities of tracking thermal flows at the sub-micrometer spatial scale, that are altering our understanding of heat-transfer phenomena occurring at living cells, micro electromagnetic machines or integrated electronic circuits, bringing also challenges of calibrating the luminescent nanoparticles for covering diverse temperature ranges. In this work, we report self-calibrated double luminescent thermometers, embedding in a poly(methyl methacrylate) film Er^{3+}- and Tm^{3+}-doped upconverting nanoparticles. The Er^{3+}-based primary thermometer uses the ratio between the integrated intensities of the $^2H_{11/2} \rightarrow {}^4I_{15/2}$ and $^4S_{3/2} \rightarrow {}^4I_{15/2}$ transitions (that follows the Boltzmann equation) to determine the temperature. It is used to calibrate the Tm^{3+}/Er^{3+} secondary thermometer, which is based on the ratio between the integrated intensities of the $^1G_4 \rightarrow {}^3H_6$ (Tm^{3+}) and the $^4S_{3/2} \rightarrow {}^4I_{15/2}$ (Er^{3+}) transitions, displaying a maximum relative sensitivity of 2.96% K^{-1} and a minimum temperature uncertainty of 0.07 K. As the Tm^{3+}/Er^{3+} ratio is calibrated trough the primary thermometer it avoids recurrent calibration procedures whenever the system operates in new experimental conditions.

INTRODUCTION

Lanthanide-doped upconversion materials have been extensively investigated since the 1960s and displaying numerous applications due to its exceptional photophysical properties, including narrow emission lines, large anti-Stokes shift, long lifetimes, low background autofluorescence, and low toxicity (Bettinelli et al., 2015; Savchuk et al., 2018; Brites et al., 2019). The development of synthesis strategies for nanomaterials enabled a complete upconversion nanomaterials engineering, allowing the precise control of composition, morphology, size, crystalline structure, and surface chemistry (Chen et al., 2014; Wen et al., 2018).

One of the most promising applications of upconverting materials is luminescence thermometry, in which changes in photophysical properties of a material are converted into absolute temperature (Vetrone et al., 2010; Brites et al., 2012; Jaque and Vetrone, 2012). In the

last decade, inorganic compounds doped with trivalent lanthanide ions (Ln^{3+}) have been broadly studied as reliable ratiometric luminescent thermometers. The energy level structure of these ions allows to work in the so-called transparency biological windows (Hemmer et al., 2016) in which the tissues' absorption is minimized. The Yb^{3+}/Er^{3+} couple is the most investigated upconverting dopant for a wide variety of applications, being used for bioimaging (Mader et al., 2010), photothermal therapy (Cheng et al., 2012), and for fundamental studies (Brites et al., 2016b). Albeit other approaches have been reported (Rai and Rai, 2007; Gálico et al., 2017; Brites et al., 2019), it is recognized that the wise approach for upconversion nanothermometry is based on the ratio between the integrated emission intensities of two thermally-coupled transitions. Indeed, when the emission arises from two transitions ascribed to the same emitting center with integrated intensities I_1 and I_2, originated in emitting levels $|1>$ and $|2>$ separated in energy by a ΔE value between 200 and 2,000 cm^{-1} (defined as thermally-coupled levels), the levels' population is governed by Boltzmann statistics and the thermometric parameter Δ is given by:

$$\Delta = \frac{I_2}{I_1} = B \exp\left(-\frac{\Delta E}{k_B T}\right) \quad (1)$$

where k_B is the Boltzmann constant, and the pre-exponential factor B is dependent on the degeneracies, branching ratios, spontaneous absorption coefficients, and frequencies of the I_1 and I_2 transitions (Brites et al., 2019).

In terms of calibration features, the thermal probes can be sorted as secondary and primary thermometers. While for the formers a calibration procedure is mandatory, the second kind of thermometers allow the temperature determination based on an equation of state that depends only on the material's parameters (without demanding any calibration). Recently, it has been demonstrated that any upconverting thermometer based on thermally-coupled energy levels is intrinsically a primary thermometer governed by an equation of state outcoming from Equation 1 in which the pre-exponential factor B is rewritten in terms of a known temperature value (T_0) and the corresponding ratio of intensities (Δ_0) (Balabhadra et al., 2017):

$$\frac{1}{T} = \frac{1}{T_0} - \frac{k_B}{\Delta E} \ln\left(\frac{\Delta}{\Delta_0}\right) \quad (2)$$

The seminal example of an upconverting luminescent primary thermometer is based on the integrated emission intensities arising from the $^2H_{11/2} \rightarrow {}^4I_{15/2}$ (I_H) and $^4S_{3/2} \rightarrow {}^4I_{15/2}$ (I_S) Er^{3+} transitions (Balabhadra et al., 2017). If, by one hand, the self-calibration of primary thermal probes is a great benefit (see further discussion in Brites et al., 2019), on the other hand, the typical relative thermal sensitivity S_r values of primary thermometers (**Supplementary Materials**) are limited to values of the order of $1.0\%{\cdot}K^{-1}$. Contrarily, secondary thermometers can render higher values (typically $S_r > 3.0\%{\cdot}K^{-1}$) (Marciniak et al., 2017; Brites et al., 2018, 2019). However, a new calibration is mandatory whenever secondary thermometers operate in a distinct medium and this is a serious implementation bottleneck for these devices. Thus, the wisest combination should provide the possibility of predicting the temperature through a primary thermometer displaying simultaneously a performance larger than that typical of primary thermometers.

Despite the large number of reported luminescent thermometers based on a ratio of intensities from two Ln^{3+} ions (the so-called dual-center thermometers; Brites et al., 2016a, 2019), very few are examples of double thermometers, in which the temperature is extracted from two distinct thermometric parameters. Up to now, and as far as we know, double luminescent thermometers combining two different emitting centers in the same nanostructure were reported only using Ln^{3+}-doped core@shell upconverting nanoparticles (UCNPs), in all the cases through intensity ratios (Marciniak et al., 2016; Skripka et al., 2017; Martínez et al., 2019a). Marciniak et al. combined in the same UCNP one thermometer using the Er^{3+} emission in the Yb^{3+}/Er^{3+} core with a second one using the Nd^{3+} downshifting emission in the Yb^{3+}/Nd^{3+} shell. The nanostructure was excited at 808 nm, resonantly with the $^4I_{9/2} \rightarrow {}^4F_{5/2}$ Nd^{3+} transition, and a non-radiative deactivation process populated the metastable $^4F_{3/2}$ state followed by sequential Nd^{3+}-to-Yb^{3+} and Yb^{3+}-to-Er^{3+} energy transfer processes allowing Er^{3+} upconversion emission ($^4S_{3/2} \rightarrow {}^4I_{15/2}$ and $^2H_{11/2} \rightarrow {}^4I_{15/2}$) in the green spectral range (Marciniak et al., 2016). Skripka et al. further developed the same concept exciting Nd^{3+}/Ho^{3+} and Nd^{3+}/Er^{3+} ion pairs in UCNPs upon 800 nm. Like in the previous example, the system was excited through the Nd^{3+} ions followed by sequential Nd^{3+}-to-Yb^{3+} and Yb^{3+}-to-Ho^{3+} ($^5I_6$ level emitting in the 1,180–1,340 nm spectral range) or Yb^{3+}-to-Er^{3+} ($^4I_{11/2}$ and $^4I_{13/2}$ states emitting in the 1,340–1,550 nm spectral range) (Skripka et al., 2017). More recently, we described a set of electrothermal devices combining Yb^{3+}/Er^{3+} and Yb^{3+}/Tm^{3+}-doped UCNPs of distinct sizes deposited on the top of a silver nanowires network to determine the temperature using a double thermometer combining Tm^{3+} and Er^{3+} emissions (Martínez et al., 2019a).

Here we extend the concept of this later article reporting in more detail how Yb^{3+}/Er^{3+}- and Yb^{3+}/Tm^{3+}-doped UCNPs of distinct sizes embedding in poly(methyl methacrylate) (PMMA) films can be used to fabricate self-calibrated double luminescent thermometers. Moreover, the particles' dispersion is enhanced relatively to what was published in that previous work by embedding them into polymer films (see Martínez et al., 2019b for details). This permits to study the effect on the thermometers' figures of merit of combining mixtures of UCNPs with distinct sizes (e.g., large-sized Er^{3+}- and small-sized Tm^{3+}-doped UCNPs and small-sized Er^{3+}- and large-sized Tm^{3+}-doped UCNPs).

The self-referenced nanocomposites include a luminescent primary thermal probe operating based on the ratio between the integrated intensities of the $^2H_{11/2} \rightarrow {}^4I_{15/2}$ and $^4S_{3/2} \rightarrow {}^4I_{15/2}$ Er^{3+} transitions and a secondary thermometer that uses the ratio between the integrated intensities of the $^1G_4 \rightarrow {}^3H_6$ (Tm^{3+}) and the $^4S_{3/2} \rightarrow {}^4I_{15/2}$ (Er^{3+}) transitions. The primary thermometer is used to calibrate the

secondary one (that display a higher relative thermal sensitivity and a lower temperature uncertainty), avoiding recurrent and time-consuming calibration procedures whenever the system operates in new experimental conditions. The temperature prediction in primary thermometers allows to sign changes in transitions' intensity decoupling temperature-induced changes from others resulting from distinct stimuli (*viz.* pressure, stress, etc.). Moreover, our approach of incorporating a primary self-reference thermometer is a clear step-forward toward the general implementation of luminescent thermometers as it allows the systems to be calibrated even when the conventional calibration procedure cannot be executed, as for instance, when the probes are embedded in living cells (Brites et al., 2019).

EXPERIMENTAL SECTION

Materials and Synthesis

The synthesis of the UCNPs and composite films was made accordingly to the procedures presented elsewhere (Martínez et al., 2018, 2019b), as detailed in **Supplementary Materials**. **Table 1** summarizes the composition of the films.

Operating Procedure for Temperature Calibration

The composite film's temperature is controlled by a Kapton thermofoil heater (Minco) in thermal contact with the films and is determined by a thermocouple (I620–20147, VWR), also in thermal contact with the films, with an accuracy of 0.1 K. A continuous wave laser diode (980 nm, 3×10^4 W·m^{-2}) is used to excite the films and the upconversion emission is collected and guided to the detector (Maya 2000 Pro, Ocean Optics) through a QP450-1-XSR optical fiber (Ocean Optics). The emission spectra are subsequently post-processed using a MatLab® routine to calculate the Er^{3+} and Tm^{3+} transitions' integrated areas and the corresponding error values, as already reported (Brites et al., 2016a).

The intensity-to-temperature calibration procedure is done stepping the temperature in the 299–410 K range, placing the composite films in thermal contact with the temperature controller (**Figures 1A,B**) during 5 min for each temperature step, and collecting the emission spectra. The measured temperature (using the thermocouple in direct contact with the sample's surface) is compared to the predicted temperature using Equation (2). In between the temperature steps, the temperature is stabilized for 15 min and, then, all the calibration procedure takes ∼3 h per sample. The validity of the temperature measurements performed by the secondary thermometer self-referenced using the temperature calculated by the primary one (through Equation 2) was tested imposing a sharp temperature increase in the composite films (initially at room temperature), recording continuously the time-dependent upconversion emission spectra (during 200 s), and calculating the integrated areas of the Er^{3+} and Tm^{3+} transitions and the corresponding temperature values.

RESULTS AND DISCUSSION

The temperature dependent emission spectra of $\mathbf{C_1}$ and $\mathbf{C_2}$ present the characteristic narrow emission lines ascribed to the Er^{3+} and Tm^{3+} intra-4f transitions upon 980 nm excitation (power density 3×10^4 W·m^{-2}, **Figures 1C,D**). As expected, the emission intensity is thermally quenched for large-sized UCNPs and thermally enhanced for small-sized UCNPs (Martínez et al., 2019a). For the large-sized nanoparticles, the increase of temperature induces a systematic decrease of the emission intensity. All transitions suffer thermal quenching upon temperature increase, although in distinct extents. It is well-known that the thermal quenching in micro-sized particles and bulk upconverting materials has been frequently attributed to multi-phonon non-radiative relaxation mechanisms, resulting in higher decay probabilities, and, thus, the observed trends are expected (Shen et al., 2010; Yu et al., 2016). On the contrary, intensity enhancement (or reverse quenching) with the increasing temperature observed for small-sized UCNPs is in agreement with the findings firstly reported by Jiang's group (Li et al., 2014, 2015; Shao et al., 2015, 2017), and more recently by Zhou et al. (2018). The later work explained the observed thermal enhancement of the intensity for small-sized UCNPs by heat-favorable phonons existing at the surface of UCNPs that compensate the thermal quenching, favoring the energy transfer from sensitizers to activators to pump-up the intermediate excited-state upconversion process. The authors argued that the oxygen moiety chelating the Yb^{3+} ions is the key underpinning this enhancement. However, a definitive physical mechanism that fully explains this surface phonon-assisted energy transfer mechanism remains inconclusive ((Liang and Liu, 2018); Martínez et al., 2019a).

Analyzing the temperature dependence of the integrated intensities of the $^2H_{11/2} \rightarrow {}^4I_{15/2}$ (I_H), $^4S_{3/2} \rightarrow {}^4I_{15/2}$ (I_S), and $^1G_4 \rightarrow {}^3H_6$ (I_G) transitions upon increasing the temperature, we observe an increase of I_S and I_H and a marginal decrease of I_G (**Figure 2A**) for $\mathbf{C_1}$, whereas the opposite occurs for $\mathbf{C_2}$: I_S decreases, I_H is roughly constant and I_G increases (**Figure 2B**). The thermometric parameter of the Er^{3+}-based primary thermometer is defined as $\Delta_P = I_H/I_S$, whereas that of the Er^{3+}/Tm^{3+}-based secondary thermometer is defined as $\Delta_S = I_G/I_S$. Observing the temperature dependence of the intensity ratios from the primary and secondary thermometers, we notice a clear steep increase in the Δ_S ratio compared to the Δ_P one (**Figures 2C,D**). This indicates an improved in the S_r values for the dual-center secondary thermometer, in line to what is observed before, as detailed next.

The maximum relative thermal sensitivity of the primary thermometers in $\mathbf{C_1}$ and $\mathbf{C_2}$ (1.31 and 1.19%·K^{-1}, respectively) (**Figures 3A,B**) and the minimum temperature uncertainty (0.15 and 0.18 K, respectively, all at 300 K) (**Figures 3C,D**) are comparable to the values reported for Er^{3+}- based thermometers (Brites et al., 2019). Moreover, the relative thermal sensitivity of the primary thermometers (**Figures 3A,B**) is independent on nanoparticle's dimensions, in line with our previous observations (Balabhadra et al., 2017; Brites et al., 2019). The relative thermal sensitivity of the secondary

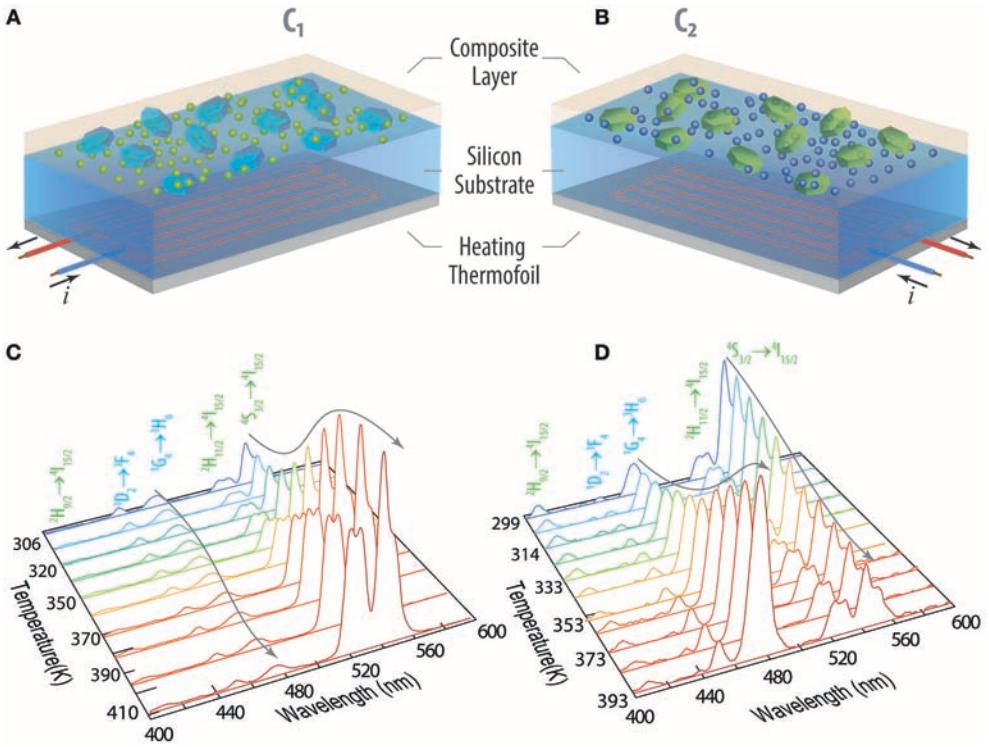

FIGURE 1 | Schematic representation of the nanocomposites **(A)** C_1 and **(B)** C_2. The electrical current flowing in the heating thermofoil is used to control the local temperature of the UCNPs in the composite layer. The temperature dependent emission spectra upon 980 nm excitation is presented for **(C)** C_1 and **(D)** C_2 within the 299–410 K range. The Er^{3+} and Tm^{3+} transitions are depicted in green and blue, respectively.

thermometers presents the typical functional forms observed for dual-center luminescent thermometers (**Figures 3A,B**) (Brites et al., 2016a) with maximum values of 2.96%·K^{-1} (C_1 at 300 K) and 2.28%·K^{-1} (C_2 at 350 K), corresponding to minimum temperature uncertainties of 0.07 K at 300 K (C_1) and 0.09 K at 350 K (C_2). There is an improvement in the relative thermal sensitivity values by a factor of up to 2.3 (in C_1), relatively to the same parameters calculated for the primary thermometer and the most advantageous combination of UCNPs is the mixture of large-sized Tm^{3+} -doped and small-sized Er^{3+} -doped UCNPs (**Figure 3**).

Comparing the performance of C_1 with those of other double luminescent thermometers in the literature, we conclude that the sensitivity values are the largest reported so far. Whereas, the system reported by Marciniak et al. presents a maximum relative sensitivity of 2.1%·K^{-1} at 370 K (Marciniak et al., 2016) that reported by Skripka et al. don't present values higher than 1.1%·K^{-1} (Skripka et al., 2017), meaning that the composite films reported here presents an increase of 40% with respect to these results. Moreover, in comparison with the system developed by us using the same design principle (Martínez et al., 2019a), the nanocomposites studied here present

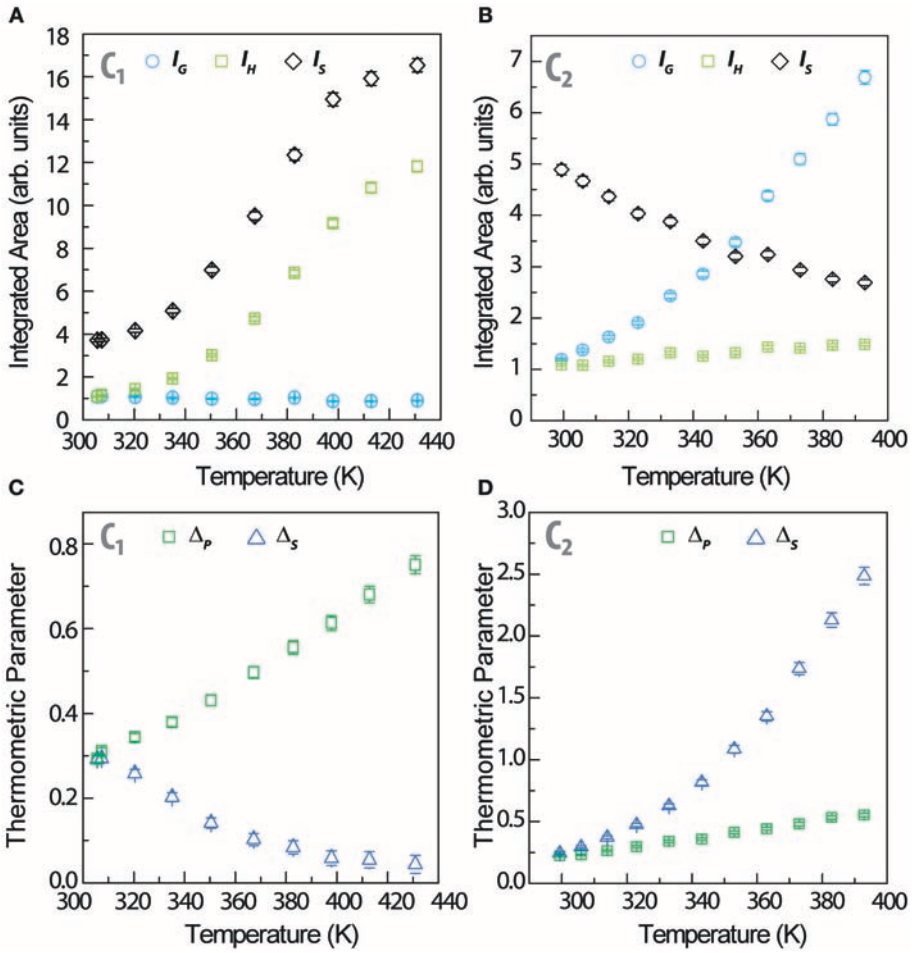

FIGURE 2 | Temperature dependence of the integrated areas of I_H, I_S (Er^{3+}) and I_G (Tm^{3+}) for **(A) C_1** and **(B) C_2**. The corresponding Δ_P and Δ_S thermometric parameters are presented in **(C)** and **(D)**, respectively.

comparable sensitivity values for the primary thermometer and about half of the sensitivity value for the secondary one. We ascribe these differences in performance to the encapsulation of the UCNPs in the PMMA that resulted in a smoother temperature enhancement of the Tm^{3+} emission of small-sized nanoparticles, in comparison with that observed previously for similar nanoparticles deposited directly on silver nanowires and exposed to the air (Martínez et al., 2019a). This is a remarkable relative thermal sensitivity tuning-up that we will exploit in a future work.

As the nanocomposite films combining the Er^{3+} and Tm^{3+} UCNPs permit to define one primary (Δ_P) and another secondary thermometric parameter (Δ_S), in what follows we show how that the first parameter (that follows Equation 2, section Er^{3+}-based primary thermometers) can be used to calibrate the secondary thermometer (section Self-referenced Er^{3+}/Tm^{3+} secondary thermometers).

Er^{3+}-Based Primary Thermometers

Despite the opposite behavior of the temperature dependence of the integrated areas of the Er^{3+} transitions for small (<10 nm) and large-sized (>100 nm) UCNPs, the ratio $\Delta_P = I_H/I_S$ always grows with the increasing temperature, irrespectively of the nanoparticle size and morphology (nanospheres or nanocrystals). To predict the temperature through Equation 2, the ΔE and Δ_0 values must be calculated for each UCNP by independent measurements (and not as fitted parameters of Equation 1). There are distinct strategies reported in the literature for extracting these parameters (Brites et al., 2019). The energy gap ΔE is evaluated deconvoluting the emission spectra at room temperature by a set of Gaussian peaks and evaluating the position of the $^2H_{11/2} \rightarrow {}^4I_{15/2}$ and $^4S_{3/2} \rightarrow {}^4I_{15/2}$ transitions' barycenter (**Supplementary Figure 1**), whereas Δ_0 is the thermometric parameter corresponding to the temperature T_0. It can be evaluated measuring the excitation power dependence of the thermometric parameter (Debasu et al., 2013), or just assuming the initial value of Δ_P at T_0 (room-temperature), when there is no excitation laser-induced heating (low excitation power density values 3×10^4 $W{\cdot}m^{-2}$). Notice the dissimilar T_0 values are consequence of distinct operating ambient conditions during the spectra acquisition. The ΔE and Δ_0 parameters for large- and small-sized Er^{3+}-doped UCNPs

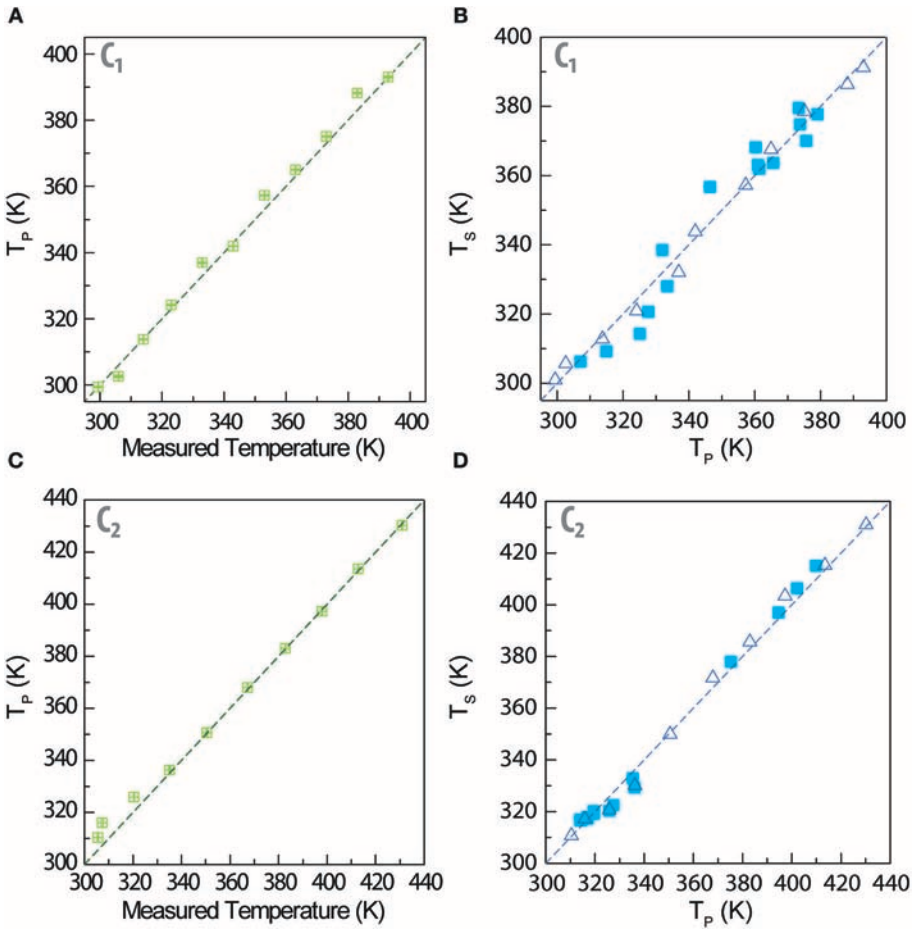

FIGURE 3 | Temperature dependence of the relative thermal sensitivity of primary and secondary thermometers for **(A)** C_1 and **(B)** C_2. **(C,D)** Temperature dependence of the corresponding temperature uncertainties, respectively.

TABLE 2 | ΔE (cm^{-1}), Δ_0 and T_0 (K) values of the primary thermometer in C_1 and C_2.

Composite film	ΔE	Δ_0	T_0
C_1	780 ± 15	0.222 ± 0.006	299.4 ± 0.1
C_2	749 ± 15	0.293 ± 0.008	305.6 ± 0.1

are presented in **Table 2**. The calculated ΔE values are similar for both composite films within the corresponding experimental errors and are in good agreement with those reported in the literature (Carnall et al., 1977).

In **Figures 4A,C** we compare the temperature calculated through Equation (2) (T_P) with that measured by a thermocouple in direct contact with the sample's surface. The remarkable agreement observed in both nanocomposites demonstrates that the primary thermometric parameter Δ_P permits to determine the temperature of the films using Equation (2), in excellent agreement with the values that are measured by a control temperature probe in contact with the nanocomposite's surface. These results validate the use of the ratio of intensities of the $^2H_{11/2} \rightarrow {}^4I_{15/2}$ and $^4S_{3/2} \rightarrow {}^4I_{15/2}$ Er^{3+} transitions for primary thermometry, as it has been systematically observed since the initial purpose of some of us (Balabhadra et al., 2017; Brites et al., 2019). Moreover, the relative thermal sensitivity of the primary thermometers in $\mathbf{C_1}$ and in $\mathbf{C_2}$ are only determined by the ΔE values (Equation 1 and **Supplementary Equation 1**) listed in **Table 2**, and that depend on the size and on the composition of the Er^{3+}-doped UCNPs. The maximum S_r values are comparable to those reported for other luminescent thermometers based on Er^{3+}-doped UCNPs (Brites et al., 2019).

Self-Referenced Er^{3+}/Tm^{3+} Secondary Thermometers

The secondary luminescent thermometer based on the Δ_S parameter determines the temperature (denoted by T_S) using the phenomenological calibration curve described by **Supplementary Equation 3** and presented in **Supplementary Figure 2**. In **Figures 3B,D** that temperature T_s is compared with that extracted from Equation (2) using the Δ_P values (T_P). It is remarkable that we calculate

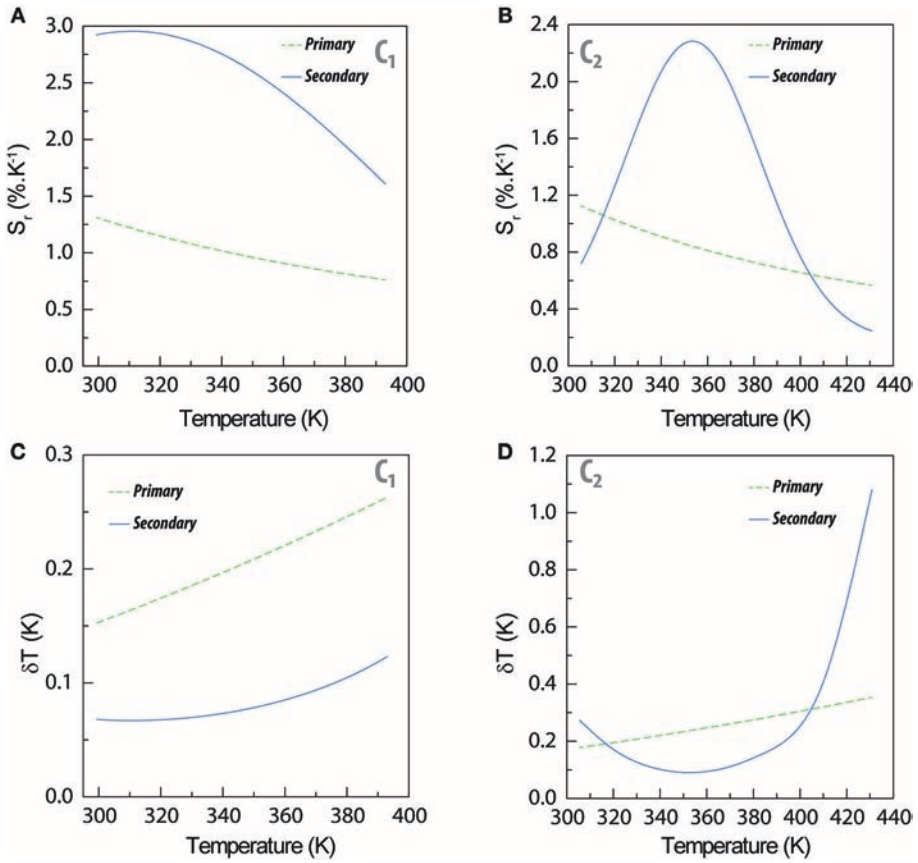

FIGURE 4 | Temperature measured by a thermocouple in contact with the composite films (*x*) vs. the temperature calculated using Equation 2 (T_P, *y*) for **(A) C_1** and **(B) C_2**. Calculated temperature T_P (*x*) vs. calculated temperature T_S (*y*) using the calibration curve of the Er^{3+}/Tm^{3+} secondary thermometer (T_S, y) for **(B) C_1** and **(D) C_2**. In (**B**,**D**), the open and solid symbols correspond to the calibration points and validity checks, respectively, as detailed in Experimental section. The straight lines correspond to $y = x$ in all the plots.

similar temperature values (T_P and T_S, based on the two thermometric parameters Δ_P and Δ_S), that agree very well with the values measured by the thermocouple in contact with the nanocomposite's surface. The temperature predicted through Equation 2 (primary thermometer) is used to calibrate the secondary thermometer (presenting a higher relative thermal sensitivity) enabling its self-referencing and not requiring the presence of an external thermocouple to set the calibration temperature during a large time period (3 h, as mentioned above).

To exemplify that the nanocomposite's temperature control can waive the record of an intensity-to-temperature calibration curve, we design a validity check experiment that consists in record the time-evolution of the emission spectra during 200 s, calculating the corresponding Δ_P and Δ_S values (the temporal evolution of the emission spectra is presented in **Supplementary Figure 2**). For each emission spectrum, we convert Δ_P into temperature using Equation (2) (**Figures 3B,D**) and Δ_S into temperature using **Supplementary Equation 3**. The results are presented as solid symbols in **Figures 3B,D**. We observe an excellent agreement between the conventional calibration and the validity check points, meaning that both calibration procedures are similar within the experimental error. Moreover, the temperature values calculated from both intensity ratios are statistically similar to those measured with the conventional calibration procedure, with an incredible gain in terms of time efficiency, because the heating ramp recording is more than 50 times faster than the conventional temperature stepping procedure.

The step forward presented in this work relatively to what was reported previously by us (Martínez et al., 2019a) is the comparison of the thermometric performances of the secondary thermometers formed by mixtures of large-sized Tm^{3+}- and small-sized Er^{3+}-doped UCNPs (**C_1**) with small-sized Tm^{3+}- and large-sized Er^{3+}-doped UCNPs (**C_2**). As expected, the functional form of S_r is the same for both composites, and for UCNPs deposited directly over a Ag-nanowires network (Martínez et al., 2019a), because it results from the phenomenological function used for fitting Δ_S, **Supplementary Equation 3** which is the same in all the three examples. Moreover, in the temperature range studied the S_r

values of $\mathbf{C_1}$ and $\mathbf{C_2}$ varies, respectively, between 1.65 and 2.93%·K^{-1} and 0.72 and 2.28%·K^{-1} (**Figures 4A,B**). These values are consistent with the changes on the integrated areas presented in **Figures 2A,B** showing that the performance of the secondary thermometer is essentially determined by the temperature enhancement observed in the integrated areas of the transitions of the small UCNPs. Furthermore, the combination of small Tm^{3+}-doped and large Er^{3+}-doped UCNPs resulted in a narrower S_r peak for $\mathbf{C_2}$ (in comparison with $\mathbf{C_1}$), that in that is comparable with that reported by us previously for UCNPs deposited directly over a Ag-nanowires network (Martínez et al., 2019a). The incorporation of the UCNPs into the PMMA film resulted in a decrease of the maximum S_r value and in the temperature at which it occurs (**Supplementary Figure 4**), in comparison with our previous work (Martínez et al., 2019a). This is consequence of the thermal dependence of the integrated area of the $^1G_4 \rightarrow {}^3H_6$ transition, that growths about seven times for $\mathbf{C_2}$ whereas in our previous work it increases about 18 times in a comparable temperature range (Martínez et al., 2019a). Thus, we conclude that the transitions originated in the small-sized Tm^{3+} particles are determining the performance of these devices (**Figure 4**). The observed changes in the integrated areas of small -sized UCNPs resulting from their embedding into PMMA are still not entirely understood, needing further experimental evidences (specially in what concerns the incorporation of UCNPs in other hosts). Work is in progress along this research line.

CONCLUSIONS

In this work, we combined a primary thermometer and a secondary thermometer rendering to self-referenced double thermometric systems in the same composite film with relative thermal sensitivity comparable with the largest ones reported yet for secondary thermometers. To illustrate this concept, Ln^{3+}-doped $NaYF_4$ and $NaGdF_4$ nanoparticles (Ln = Yb, Er, Tm) of distinct sizes were embedded in two PMMA films. The nanocomposites' inner temperature reference is the primary thermometer based on the $^2H_{11/2} \rightarrow {}^4I_{15/2}$ (I_H) and $^4S_{3/2} \rightarrow {}^4I_{15/2}$ (I_S) Er^{3+} transitions, univocally assigning each emission spectrum to the corresponding temperature using Boltzmann equation. We attest that the system is a primary thermometer comparing the predicted and measured temperature values and observing an excellent agreement between both. The secondary thermometer is based on the temperature dependence of a ratio of intensities involving one emission intensity that is thermally quenched (large-sized UCNPs) and another one that is thermally enhanced (small-sized UCNPs). The maximum relative thermal sensitivity of this thermometer is 2.96%·K^{-1} and the minimum temperature uncertainty is 0.07 K (both at 300 K), among the highest performance values reported so far for luminescent dual thermometers. Moreover, the maximum S_r value corresponds to a 2.3-fold improvement, with respect to the Er^{3+}-based primary thermometer.

This highly sensitive thermometer can be calibrated using a conventional temperature-stepping procedure, taking a total of 3 h, or using the primary thermometer to calibrate it. We validate the resulting calibration curves recording the emission spectra in a heating ramp and observing a good agreement between the temperature values calculated from the primary and the secondary thermometers independently. Although in our previous work (Martínez et al., 2019a) we adopted this faster method to calibrate the secondary thermometer, here we demonstrate that conventional and fast calibration procedures are equivalent and, thus, the external temperature control is not mandatory to calibrate the self-referenced system taking only 200 s, that constitutes a procedure more than 50 times faster than the conventional calibration.

Finally, we stress that the procedure described here of incorporating an inner self-referenced temperature probe (Er^{3+} doped UCNPs) is general and can be applied for any system that require thermal calibration. Such dual systems present the critical advantage of the secondary thermometer being more sensitive than the primary. Since the secondary thermometer can be calibrated "*in situ*," this avoids conventional methods of calibration, and opens the way for applications in biological media, particularly at the cell level. This strategy will certainly pave the road for the future routinely use of self-calibrated dual luminescent thermometers based on UCNPs, allowing to avoid long calibration procedures that require sophisticated temperature controllers, without sacrificing the temperature readout error.

DATA AVAILABILITY

The raw data supporting the conclusions of this manuscript will be made available by the authors, without undue reservation, to any qualified researcher.

AUTHOR CONTRIBUTIONS

CB, LC, and EM conceived the project. EM synthesized the particles and performed all measurements. CB, EM, and LC discussed the project, analyzed the data, performed the calculations, and prepared all figures. RU and CR contributed with the experimental set-up and discussion of the project. The manuscript was written with contributions from all authors.

FUNDING

Work was partially developed in the scope of the project CICECO–Aveiro Institute of Materials (Ref. FCT UID/CTM/50011/2019), financed by Portuguese funds through the Fundação para a Ciência e a Tecnologia/Ministério da Educação e Ciência (FCT/MEC). Financial support of FCT (PTDC/CTM-NAN/4647/2014 and POCI-01-0145-FEDER-016687) is also acknowledged. This work was supported and performed under the auspices of the Brazilian agencies CAPES, CNPq, and Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP) through Grants #2011/19924-2, #2012/04870-7, #2012/05903-6, #2015/21290-2, and #2015/21289-4. CB

acknowledge the grant financed by the SusPhotoSolutions project CENTRO-01-0145-FEDER-000005. EM acknowledge, respectively, the post-doctoral FAPESP fellowship #2015/23882-4 and BEPE #2018/12489-8.

ACKNOWLEDGMENTS

Authors acknowledge the funding institutions and the parent institutions were the work was performed. CICECO–Aveiro Institute of Materials, University of Aveiro, and Department of Quantum Electronics, Institute of Physics Gleb Wataghin, UNICAMP.

Reversible Control of the Mn Oxidation State in $SrTiO_3$ Bulk Powders

*Haneen Mansoor, William L. Harrigan, Keith A. Lehuta and Kevin R. Kittilstved**

Department of Chemistry, University of Massachusetts Amherst, Amherst, MA, United States

We demonstrate a low-temperature reduction method for exhibiting fine control over the oxidation state of substitutional Mn ions in strontium titanate ($SrTiO_3$) bulk powder. We employ $NaBH_4$ as the chemical reductant that causes significant changes in the oxidation state and oxygen vacancy complexation with Mn^{2+} dopants at temperatures <350°C where lattice reduction is negligible. At higher reduction temperatures, we also observe the formation of Ti^{3+} in the lattice by diffuse-reflectance and low-temperature electron paramagnetic resonance (EPR) spectroscopy. In addition to Mn^{2+}, Mn^{4+}, and the Mn^{2+} complex with an oxygen vacancy, we also observe a sharp resonance in the EPR spectrum of heavily reduced Mn-doped $SrTiO_3$. This sharp signal is tentatively assigned to surface superoxide ion that is formed by the surface electron transfer reaction between Ti^{3+} and O_2. The ability to control the relative amounts of various paramagnetic defects in $SrTiO_3$ provides many possibilities to study in a model system the impact of tunable dopant-defect interactions for spin-based electronic applications or visible-light photocatalysis.

INTRODUCTION

The oxide $SrTiO_3$ is a classic perovskite-type member of the valuable ABO_3 semiconductor family. The promising properties such as a large tunable dielectric constant, structural phase transitions, superior charge storage capacity and tunable electronic structure have made $SrTiO_3$ an exciting candidate for a wide range of multifunctional applications (Weaver, 1959; Faughnan, 1971; Mattheiss, 1972; Müller and Burkard, 1979; Kamalasanan et al., 1993). Although in ambient conditions it exhibits a wide band gap and low electron mobility, introducing impurity dopants and intrinsic defects radically influence the conductivity and optical properties of the host material (Wild et al., 1973; Kozuka et al., 2010). The function of a semiconductor is intimately related to the chemistry and physics of native and targeted defects. The rich defect chemistry enabled by native oxygen vacancies (V_O) in semiconductors such as $SrTiO_3$, $PbTiO_3$, and $BaTiO_3$ has been correlated with numerous functions including ferroelectricity, visible-light photocatalysis, and multiferroics. These V_O defects can donate up to two electrons to the host lattice. Transition metal dopants may also impart additional functionality that result from partially-filled d-orbitals. For example, Cr^{3+} dopants, and Rh^{3+} dopants in $SrTiO_3$ can reduce protons to generate H_2 gas using visible light that creates an oxidized dopant ion and a conduction band electron, e_{cb} (Ishii et al., 2004; Sasaki et al., 2009; Kato et al., 2013). However, undesirable defects such as Cr^{6+} can form to maintain charge neutrality, but limit the photochemical efficiency by serving as a trap for the e_{cb}. These types of

high-valent defects can be removed by either post-synthetic annealing under reducing atmospheres (Zuo et al., 2010; Tan et al., 2014; Lehuta and Kittilstved, 2016), co-doping the host lattice with additional *n*-type dopants (Chan et al., 1981; Kato and Kudo, 2002; Wang et al., 2014), irradiating with UV light (Wang et al., 2006), or applying a large electrical bias (La Mattina et al., 2008). Of these, the only potentially "green" reduction source could be UV irradiation from the sun. However, we note that the reported photoreduction step using a 400 W Hg-lamp in Cr:$SrTiO_3$ powders was of the order of tens of hours. The realization of a fast, low-energy method to modulate the oxidation state of transition-metal dopants in $SrTiO_3$ and related metal oxide semiconductors could impact various fields such as visible-light photocatalysis, sensing, and spin-based electronics. To this end, recent studies on the photodoping of colloidal Cr:$SrTiO_3$ nanocrystals show promise (Harrigan and Kittilstved, 2018).

We previously studied the effect of a relatively low-temperature $NaBH_4$ reduction reaction on the oxidation state of Cr dopants in $SrTiO_3$ and related Sr_2TiO_4 bulk powders (Lehuta and Kittilstved, 2016; Lehuta et al., 2017). In those studies, we observed an order of magnitude *increase* in the Cr^{3+} concentration by EPR spectroscopy that we attributed to the reduction of EPR-silent high-valent Cr^{4+} and Cr^{6+} ions. The increase in the Cr^{3+} concentration in *n*-type $SrTiO_3$ presents an interesting scenario where the Cr^{3+} ion has a dual role of being an electron donor and a paramagnetic ion ($S = 3/2$). In addition, these observed changes are quantitatively reversible upon annealing the powders in air.

An isoelectronic analog of Cr^{3+} is Mn^{4+}, which is known to also occupy the Ti^{4+}-site in $SrTiO_3$. Although additional defects are required to maintain charge neutrality in Cr^{3+}:$SrTiO_3$, Mn^{4+} in the B-site of $SrTiO_3$ is an isovalent dopant. Amongst the transition-metal doped oxides, Mn:$SrTiO_3$ has recently received extensive attention due to its complex and unique behavior than intrinsic $SrTiO_3$. The concurrent doping of Mn and oxygen vacancies in $SrTi_{1-x}Mn_xO_{3-\delta}$ is reported to promote ferromagnetic ordering, dielectric permittivity and possible metallic behavior (Savinov et al., 2008; Choudhury et al., 2011, 2013; Middey et al., 2012; Thanh et al., 2014). These observations make nonstoichiometric Mn:$SrTiO_3$ a highly attractive candidate for spin-based electronics applications. Although not completely understood, the results are attributed to the interplay of redox-active Mn ions and the intrinsic charge compensating defects. In this regard, quantitative research is challenging due to a lack of experimental control over the interactions, and the complexity of Mn ions present in multiple oxidation states. Herein we report on the nature of the oxidation state of Mn ions and associated defect centers in bulk Mn:$SrTiO_3$ powders. We utilized various dopant-specific spectroscopic probes to elucidate the Mn oxidation state including EPR and diffuse-reflectance spectroscopies. We extend the use of $NaBH_4$ as a solid-state reductant to monitor changes in the three, unique Mn-related species as well as oxygen-related defects and "self-doped" Ti^{3+} ions. Comparison to other studies of reduced Mn:$SrTiO_3$ and noticeable absences of certain EPR-active Mn-centers is also discussed. We also observe a new signal in reduced samples that we attribute to superoxide anions, O_2^-.

MATERIALS AND METHODS

Chemicals

TiO_2 (>99.5%, Aeroxide P25 powder, Acros Organics), $Sr(NO_3)_2$ (>99%, Acros Organics), $Mn(NO_3)_2{\cdot}4H_2O$ (analytical grade, Acros Organics), $NaBH_4$ (≥98%, white powder, MP Biomedical), MgO (Fisher Science Education), and ethanol (200 proof, ACS/USP grade, Pharmco-Aaper) were used as received.

Synthesis of Bulk Mn-Doped $SrTiO_3$

Bulk powders of $SrTi_{1-x}Mn_xO_{3-\delta}$ (abbreviated Mn:$SrTiO_3$) were synthesized by a conventional solid-state reaction method, where x is the nominal concentration of Mn ($x = 0.001$) and δ is the concentration of oxygen vacancies. Briefly, $Sr(NO_3)_2$, $Mn(NO_3)_2{\cdot}4H_2O$, and TiO_2 were mixed in the desired stoichiometry and ground with a mortar and pestle for about 10 min. The mixture was then transferred to a porcelain combustion boat and placed in the center of a tube furnace inside a quartz insert. The reaction mixture was heated in air for 6 h at 1,000°C, reground for 10 min, then heated again for an additional 16 h at 1,000°C.

$NaBH_4$ Reductions and Reoxidation

Chemical reductions of the bulk powders were carried out using a modified version of reduction previously described by our group for Cr:$SrTiO_3$ (Lehuta and Kittilstved, 2016). For each reduction,

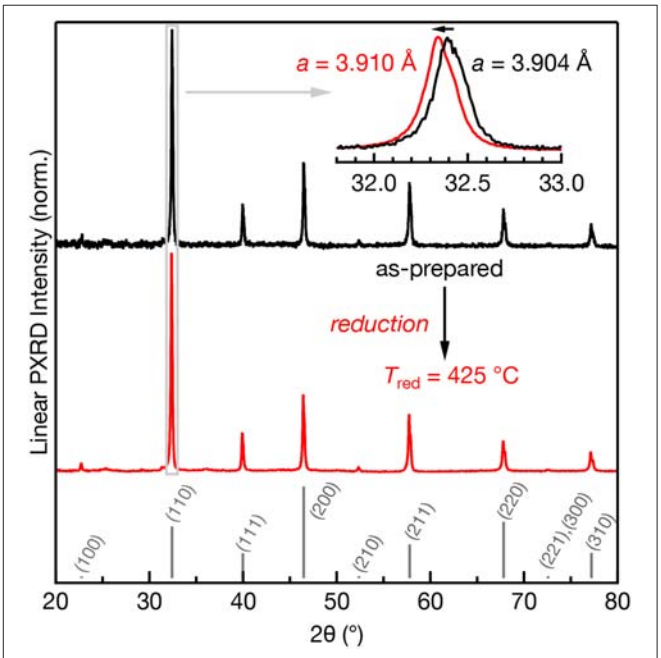

FIGURE 1 | Powder XRD patterns of 0.1% Mn:$SrTiO_3$ before (black) and after T_{red} = 425°C (red). The calculated pattern for $SrTiO_3$ (cubic phase) is shown in gray as sticks (Yamanaka et al., 2002). Inset: expanded region of the (110) diffraction peak clearly showing a shift to lower 2θ after T_{red} = 425°C.

an amount of powder was mixed in a 1:1 mole ratio with $NaBH_4$ using a mortar and pestle for 5 min and then placed in a porcelain combustion boat in the middle of a quartz insert in a tube furnace. The atmosphere in the quartz insert was continuously purged by a controlled flow of Ar gas monitored by a rotameter (Matheson 7300). The samples were heated at temperatures ranging from 300 to 425°C in 25°C increments under Ar flow for 30 min. After reducing, samples were cooled under Ar to room temperature, washed and centrifuged alternately with deionized water and ethanol to ensure complete removal of $NaBH_4$. After washing, samples were dried in an oven at 100°C for 2 h.

Reoxidation was performed by aerobically annealing the reduced samples until the physical color of the sample reversed to Mn:$SrTiO_3$ as-prepared sample.

Characterization

Powder X-ray diffraction (XRD) patterns were collected at room temperature using a Bragg-Brentano configuration with Cu K-α source (Rigaku SmartLab SE Diffraction System with cross-beam optics and D/Tex 250 Ultra 1D Si strip detector). X-band quantitative EPR spectra were collected at room temperature in 4 mm quartz EPR tubes (Wilmad-Glass) in a double rectangular resonator cavity (Bruker Elexsys E-500 with ER 4105DR cavity). Room temperature quantitative EPR spectra were collected consecutively on chemically perturbed samples (either oxidized or reduced) and an as-prepared sample using identical sample placement and instrument settings (Eaton et al., 2010). The resonance field positions in the EPR spectra for each paramagnetic Mn center were simulated using the "resfields" function in EasySpin using the reported EPR parameters from literature and referenced below (Stoll and Schweiger, 2006). Low-temperature X-band EPR spectra were measured at 77 K on powders using the perpendicular mode of a dual-mode resonator cavity with a quartz finger dewar insert (Bruker Elexsys E-500 with ER-4116 cavity) ensuring the sample height exceeded the cavity height for quantitative analysis. Diffuse-reflectance spectra were collected with an integrating

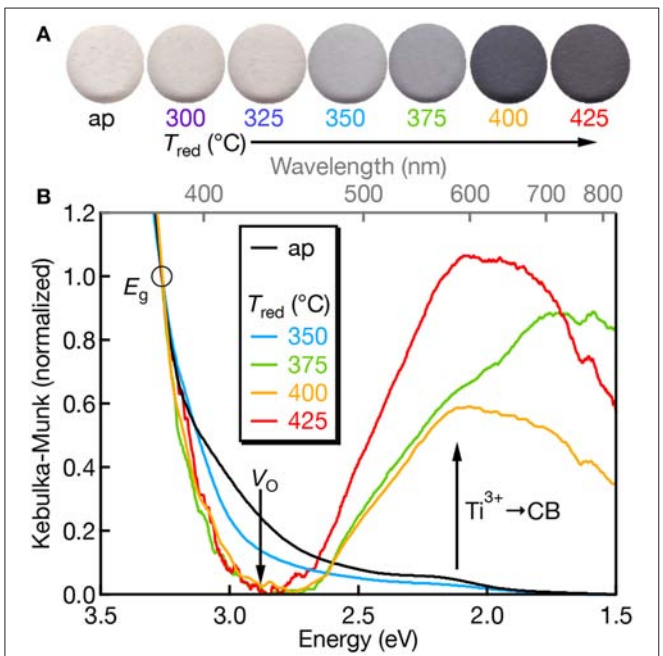

FIGURE 2 | (A) Scanned color images of Mn:$SrTiO_3$ powders as a function of T_{red}. **(B)** Diffuse-reflectance spectra of Mn:$SrTiO_3$ as a function of reduction temperature (as-prepared = black; T_{red} at 350°C (blue), 375°C (green), 400°C (orange), and 425°C (red), respectively). Data were normalized at 380 nm (3.26 eV; denoted by the circle) after setting the lowest y-value in the spectrum as the "zero." The T_{red} = 400°C spectrum was smoothed for presentation.

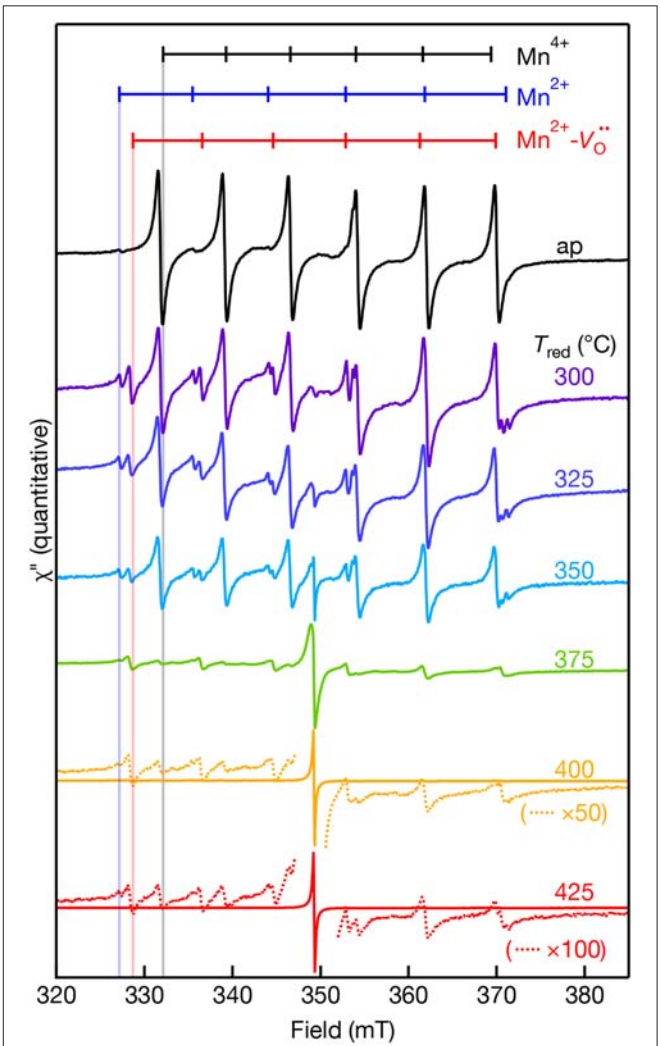

FIGURE 3 | Room temperature X-band EPR spectra of 0.1% Mn-doped $SrTiO_3$ bulk powder before (as-prepared, black) and after $NaBH_4$ reduction for 30 min at various temperatures (300–425°C). The dotted lines in the 400 and 425°C spectra are selected regions of the spectra that are multiplied (×) by 50 and 100, respectively. The calculated resonance fields for the hyperfine-split transitions of Mn^{4+} (black), Mn^{2+}-$V_O^{\cdot\cdot}$ (red), and Mn^{2+} (blue) in $SrTiO_3$ are shown as vertical markers. The calculated resonance fields were simulated for each Mn center observed in the EPR with EasySpin (see characterization). Data were collected on the same day in a double-resonator cavity equipped with an as-prepared sample in the 2nd resonator and used to standardize sample intensities.

TABLE 1 | Summary of EPR parameters for the Mn centers observed in the as-prepared and chemically treated samples reduced at various low temperatures.

EPR center	Observed in this work	*g*-value	$\|A\|$ (x10^{-4} cm^{-1})	References
Mn^{4+}	As-prepared (strong) reduced (weak)	1.994	69.4	Müller, 1959
Mn^{2+}	As-prepared (weak) reduced (strong)	2.004	82.3	Azzoni et al., 2000
[a]Mn^{2+}-$V_O^{\cdot\cdot}$	Reduced (weak)	$g_{\|\|} = 2.003$	76	Serway et al., 1977
Mn^{3+}-$V_O^{\cdot}$	Not observed	$g_{\|\|} = 7.945$ $g_{\perp} < 0.4$	37.3	Serway et al., 1977
O_2^-	Reduced (strong)	2.003	–	this work

The g-values and |A| obtained in this work are corroborated with previous reports in the literature.
[a]*An additional large axial component to the zero-field splitting was also estimated, D = 0.544 cm^{-1}.*

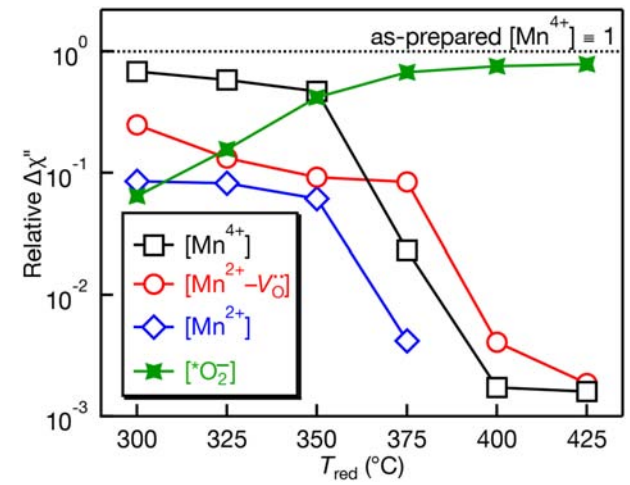

FIGURE 4 | Relative EPR peak intensities plotted on a log scale as a function of $NaBH_4$ reduction temperature (T_{red}) for Mn:$SrTiO_3$. The peak intensities are normalized vs. the intensity of the Mn^{4+} EPR signal in the as-prepared sample. Quantitative measurements performed using a dual-cavity EPR resonator (see characterization section).

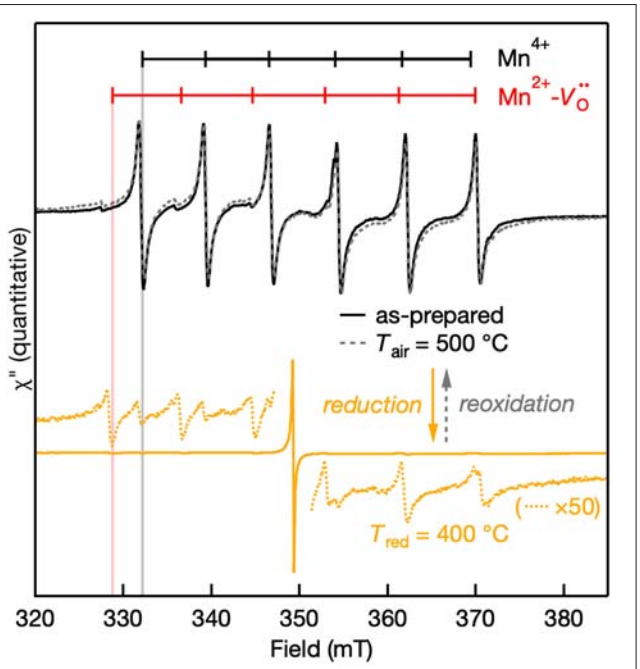

FIGURE 5 | Quantitative reversibility of the EPR signal of Mn:$SrTiO_3$ bulk powder as-prepared (solid black line), after T_{red} at 400°C (solid orange line), and after T_{air} at 500°C for ~1 h (gray dotted line). The weak Mn^{4+} and Mn^{2+} features after $NaBH_4$ reduction are still observed in the 50× scaled spectra (orange dotted lines).

sphere (Ocean Optics ISP-REF) coupled by fiber optics to a CCD-based spectrophotometer (Ocean Optics USB2000+ VIS-NIR). The optical density between the absorption minimum and the absorption at 320 nm was adjusted by diluting the powders with MgO.

RESULTS AND DISCUSSION

The room temperature powder XRD patterns of as-prepared and reduced (T_{red} = 425°C) Mn:$SrTiO_3$ are shown in **Figure 1**. All samples designated Mn:$SrTiO_3$ contain nominally 0.1% Mn content. Both the as-prepared and reduced samples indicate the presence of the cubic phase of $SrTiO_3$ (Mitchell et al., 2000). However, a clear *increase* in the lattice parameter is observed after reduction. This result is consistent with other observations and has been attributed to both changes in ionic size and electronic effects after reduction of the lattice (Janotti et al., 2012). For example, the reduction of both Mn ions ($Mn^{4+} \rightarrow Mn^{2+}$) and lattice cations ($Ti^{4+} \rightarrow Ti^{3+}$) would result in larger ions leading to lattice expansion (Shannon, 1976). No appreciable secondary phases were observed after low-temperature chemical reduction despite clear spectroscopic changes in the samples (*vide infra*).

The electronic structure of Mn:$SrTiO_3$ is dependent on the nature of the Mn-ion speciation (i.e., oxidation state(s) and first-coordination sphere). Mn^{4+} has a d^3 electronic configuration yielding a $^4A_{2g}$ ground state when substituted at the Ti^{4+}-site in $SrTiO_3$. The physical appearance of the Mn:$SrTiO_3$ as-prepared (oxidized) powders is off-white and gradually turns to black with increased reduction temperature as shown in **Figure 2A**. The black appearance of $SrTiO_3$ has been previously observed and indicates reduction in the $SrTiO_3$ lattice resulting in self-trapped electrons localized at Ti^{3+} sites (Tan et al., 2014; Lehuta and Kittilstved, 2016). The diffuse-reflectance spectra corroborates

the assignment of the black color to excitations from Ti^{3+} to conduction band states also referred to as a metal-to-metal charge transfer (MMCT) transition in the near-IR region (Khomenko et al., 1998). In the Mn:$SrTiO_3$ powder this MMCT appears at T_{red} between 350 and 375°C. The sub-bandgap tailing absorption at ∼2.9 eV has been assigned to excitations from the valence band to V_O's with different charge states (Mitra et al., 2012). With increasing T_{red}, the relative intensity of the V_O-related transitions decreases and disappears at T_{red} = 375°C and is consistent with electron accumulation in the V_O states. Both spectral changes observed here for Mn:$SrTiO_3$ with increasing T_{red} are similar to our recent study on chemically-reduced Cr:$SrTiO_3$ (Lehuta and Kittilstved, 2016).

We also do not observe Mn-centered transitions from the diffuse-reflectance spectra which we attribute to either (1) low concentrations of Mn^{3+} or Mn^{4+}, which have spin-allowed transitions in the visible, or (2) the Mn ions are primarily in their +2 oxidation state, which only has spin-forbidden transitions when the d-electrons order in the high-spin configuration (S = 5/2, $^6A_{1g}$ ground state).

EPR-active species involving Mn ions in the +2, +3, and +4 oxidation states in $SrTiO_3$ have previously been reported (Müller, 1959; Serway et al., 1977; Azamat et al., 2012). However, Mn^{3+} exhibits large zero-field splitting due to the S = 2 electronic spin state and thus, it is EPR-silent at conventional X-band frequencies (Azamat et al., 2012). The room temperature quantitative X-band EPR spectra of the Mn-doped $SrTiO_3$ samples are shown in **Figure 3** as a function of reduction temperatures ranging from T_{red} = 300–425°C. The as-prepared sample consists of two sets of sextet peaks. In accordance with the reported g-value and hyperfine splitting constant (A) of Mn^{4+} in $SrTiO_3$, the main sextet in the as-prepared sample is assigned to Mn^{4+} substituting for Ti^{4+} with an isotropic g = 1.996 and $|A|$ = 69.4 × 10^{-4} cm^{-1} (Müller, 1959). The second and much weaker set of sextets is somewhat occluded by the Mn^{4+} transitions, but the low-field resonances agree well with substitutional Mn^{2+} at the Ti^{4+} site in $SrTiO_3$ with g = 2.004 and $|A|$ = 82.30 × 10^{-4} cm^{-1} (Azzoni et al., 2000; Choudhury et al., 2013). Despite reports of both axial Mn^{2+}-$V_O^{\cdot\cdot}$ and Mn^{3+}-$V_O^{\cdot}$ complexes in Mn:$SrTiO_3$, we do not observe these complexes in the as-prepared Mn:$SrTiO_3$ sample. Hence, only the substitutional Mn^{4+} and Mn^{2+} species in an octahedral oxide crystal field co-exist in the as-prepared Mn:$SrTiO_3$ powders.

After chemical reduction with $NaBH_4$ under Ar(g) at T_{red} = 300°C, a new, third set of transitions are detected near the Mn^{2+} lines. Concomitant with the appearance of this new set of peaks is a decrease in the intensity of Mn^{4+} lines and an increase in the relative intensity of Mn^{2+}. The new set of lines agree well with the report of a substitutional Mn^{2+} center at the Ti^{4+}-site coupled to a doubly ionized oxygen vacancy (Serway et al., 1977).

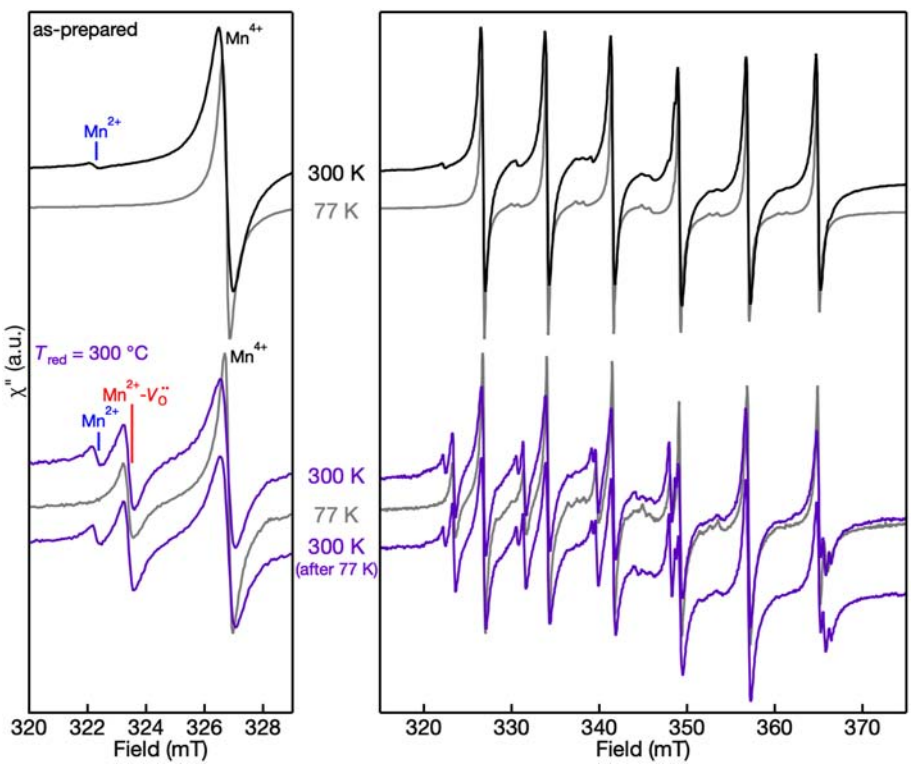

FIGURE 6 | 300 K and 77 K EPR spectra of Mn:$SrTiO_3$ powders as-prepared **(top)** and after T_{red} = 300°C **(bottom)**. **(left)** Spectra in the region of the lowest field transitions within the hyperfine structure and **(right)** full spectrum. The temperatures at which the spectra were collected are labeled in the figure. Spectra are normalized to account for the increased EPR intensity with decreasing temperature.

The reported EPR parameters of this Mn^{2+}-$V_o^{\cdot\cdot}$ complex includes a large axial component to the zero-field splitting ($D = 0.544$ cm^{-1}), $g_{||} = 2.003$, and $|A| = 76 \times 10^{-4}$ cm^{-1}. We were unable to detect any transitions at lower or higher magnetic fields likely from the low relative concentration and low nominal concentration of Mn in the lattice. The Mn^{2+}-$V_o^{\cdot\cdot}$ complex forms at low temperatures before reduction of the $SrTiO_3$ lattice at $T_{red} < 375°C$ (see **Figure 2**). One possible mechanism to explain the formation of this complex could be that oxygen vacancies may diffuse through the lattice and localize in the vicinity of Mn^{4+} substitutional sites at low temperatures. This work demonstrates that mild reduction at only $T_{red} = 300–325°C$ is sufficient to form the Mn^{2+}-$V_o^{\cdot\cdot}$ complex in bulk powders. This result contrasts with the high temperature reductions above 825°C previously used to create these centers in Mn:$SrTiO_3$ (Blazey et al., 1983; Kutty et al., 1986). In addition, we observe the co-existence of Mn^{4+} and the Mn^{2+}-$V_o^{\cdot\cdot}$ complex in the same EPR spectra at every T_{red}. This does not agree with previous single crystal studies where the Mn^{2+}-$V_o^{\cdot\cdot}$ complex was only observed when the Mn^{4+} lines were fully removed upon reduction in 5% hydrogen for 3 h at 1,000°C (Serway et al., 1977).

A new single feature centered at $B_0 \sim 350$ mT ($g \sim 2.003$) with no associated hyperfine structure was also observed in the EPR spectra after reduction. This feature increases in spectral intensity and also narrows with increasing T_{red}. This feature is similar to a feature observed in Cr:$SrTiO_3$ at $T_{red} > 375°C$ (Lehuta and Kittilstved, 2016), but has a significantly larger relative intensity compared to the dopant EPR signal in the Mn:$SrTiO_3$ sample with the same nominal dopant concentration. This feature is tentatively assigned as the EPR-active superoxide anion (O_2^-) adsorbed on the surface of $SrTiO_3$ and could form via a surface reaction between Ti^{3+} and oxygen (Bykov et al., 2013; Harrigan et al., 2016). **Table 1** below summarizes the EPR spectral parameters for previously reported Mn species in $SrTiO_3$ in the as-prepared and reduced Mn:$SrTiO_3$.

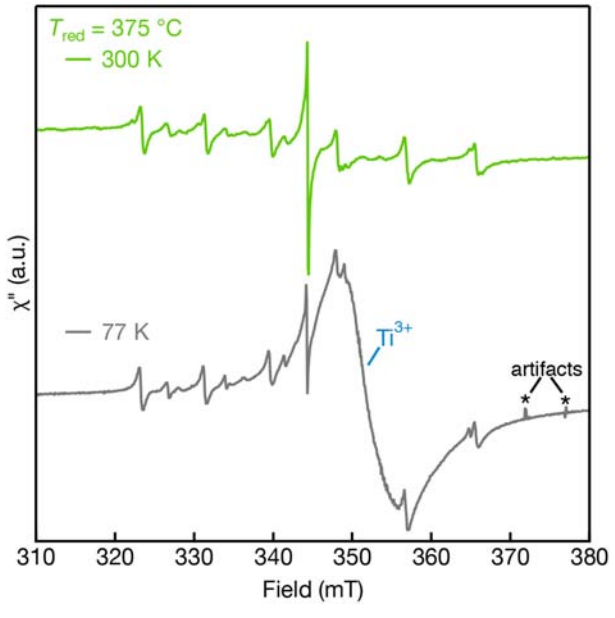

FIGURE 7 | EPR spectra of Mn:$SrTiO_3$ bulk powders reduced at $T_{red} =$ 375°C measured at 300 K (top) and 77 K (bottom). Sharp features in the 77 K spectra are attributed to artifacts resulting from bubbles that arise in the liquid nitrogen finger dewar.

The quantitative EPR spectra measured using the double resonator cavity shown in **Figure 3** was analyzed and the relative intensity of the observed EPR centers is shown in **Figure 4** as a function of T_{red}. Compared to the as-prepared Mn^{4+} signal intensity (defined as 1), a gradual decrease in the Mn^{4+} and Mn^{2+} EPR signals is observed with similar correlations in their temperature dependences. The signal for Mn^{2+} is not detected for $T_{red} \geq 375°C$. In contrast, the EPR intensity of the Mn^{2+}-$V_o^{\cdot\cdot}$ complex shows little change and is more intense than the Mn^{4+} and Mn^{2+} EPR signals for $T_{red} \geq 375°C$. The intensity of the Mn^{2+}-$V_o^{\cdot\cdot}$ complex drops by an order of magnitude after increasing T_{red} from 375 to 400°C. At the highest temperature, $T_{red} = 425°C$, the EPR intensity of the O_2^- ion is nearly 3 orders of magnitude more intense than the Mn^{2+}-$V_o^{\cdot\cdot}$ complex, indicative of substantial surface defects. Studies to identify the nature of this defect center are currently underway.

The EPR spectra of the Mn:$SrTiO_3$ powders after preparation, after $T_{red} = 400°C$, and after aerobic reoxidation at $T_{air} = 500°C$ for ~1 h are shown in **Figure 5**. The observed changes in the EPR spectra of the reduced samples revert to the as-prepared EPR spectrum by aerobically annealing the sample. The process of forming Mn^{2+}-$V_o^{\cdot\cdot}$ complex in the reduced samples is thus reversible. However, elevated temperatures and longer reoxidation times were required in contrast with the chemical reductions. Since the Mn^{2+}-$V_o^{\cdot\cdot}$ complex is a charge-neutral complex in the lattice, it is expected to be at least metastable. The apparently slower reoxidation kinetics compared to reduction kinetics suggest a metastable complex.

The 300 K (room temperature) and 77 K (liquid N_2) EPR spectra of the Mn centers in the as-prepared and $T_{red} = 300°C$ powders are shown in **Figure 6**. Two things are revealed from the EPR spectra of both as-prepared and lightly-reduced Mn:$SrTiO_3$ samples: (1) there is no evidence of self-trapped electrons at Ti^{3+} sites in the lattice based on the 77 K spectra, and (2) the EPR intensity of Mn^{2+} completely disappears at 77 K. At low temperature, the intensity of Mn^{4+} is pronounced following the typical Boltzmann statistics. In contrast, the Mn^{2+} EPR signal completely disappears at 77 K in these two samples. These results agree with a previous magnetic susceptibility and EPR study of the Mn^{2+} signal vanishing, where the behavior was attributed to increased antiferromagnetic interactions between adjacent Mn^{2+} ions with decreasing temperature (Azzoni et al., 2000). This explanation cannot be extended to describe the EPR signal of the Mn^{2+}-$V_o^{\cdot\cdot}$ complex, which does not disappear at 77 K in the $T_{red} = 300°C$ sample. To confirm the behavior of EPR signals as a function of temperature, the EPR spectrum of the reduced sample at 300 K was repeated after cooling it to 77 K and the entire spectrum is nearly identical.

The cryogenic EPR measurements were also collected for samples reduced above 350°C to reveal the effect of Ti^{3+} defects on the EPR spectra that are observed in the diffuse-reflectance spectra shown in **Figure 2**. **Figure 7** shows the 300 K

and 77 K EPR spectra of $T_{red} = 375°C$. The paramagnetic Ti^{3+} defects are not observed in the EPR performed at 300 K due to fast spin-lattice relaxation but are promptly observed at 77 K (Lehuta and Kittilstved, 2016; Harrigan and Kittilstved, 2018). At 77 K, the $T_{red} = 375°C$ sample is dominated by a broad and intense asymmetric Ti^{3+} lattice defect centered at $g = 1.94$. The appearance of this fast-relaxing defect, however, has no apparent effect on the linewidth of the Mn-centers nor the single line that we tentatively assign to surface-adsorbed O_2^- ions. We recently showed that linewidth and relaxation-dynamics of substitutional Cr^{3+} ions in $SrTiO_3$ powders and colloidal nanocrystals can be significantly altered when Ti^{3+} defects are present in the lattice through a near-resonant cross-relaxation process (Lehuta and Kittilstved, 2016; Harrigan and Kittilstved, 2018). This same behavior is not observed for any of the Mn-centers in the reduced $SrTiO_3$ powder.

CONCLUSIONS

A low-temperature chemical reduction technique has been implemented for tunability of the Mn dopant oxidation states and the related intrinsic defects in bulk Mn:$SrTiO_3$. We employed a myriad of structural and spectroscopic techniques on samples subjected to a systematic chemical reduction. Both isotropic Mn^{4+} and Mn^{2+} species were identified in the as-prepared powders. Following the thermal reduction, the samples exhibited a continuous decrease in Mn^{4+} EPR signal and an increase in the Mn^{2+} intensity, accompanied by the introduction of a Mn^{2+}-$V_o^{\cdot\cdot}$ complex. We demonstrate that our chemical treatment at merely $T_{red} = 300–325°C$ generates sufficient driving force to significantly reduce the intensity of the octahedral Mn^{4+} and Mn^{2+} dopants and form the Mn^{2+}-$V_o^{\cdot\cdot}$ complex. All the Mn peaks showed distinctive changes at low-temperature in the EPR that are readily reversible upon warming back the samples. Reductions at 375°C and above generated significant concentrations of Ti^{3+} defects that were confirmed by diffuse-reflectance and low-temperature EPR spectroscopy. All the observed perturbations in the reduced samples are entirely reversible by aerobic annealing at elevated temperatures. We also observe an intense spectral feature in the EPR spectrum in heavily-reduced Mn:$SrTiO_3$ powders that we attribute to O_2^- ions at the surface. This fast and effective strategy offers a general low-temperature reduction process that allows tunability and control over the rich dopant-defect chemistry in transition-metal doped $SrTiO_3$ materials.

Molecular Orbital Insights of Transition Metal-Stabilized Carbocations

*Hannah Goodman†, Liangyong Mei† and Thomas L. Gianetti**

Department of Chemistry and Biochemistry, University of Arizona, Tucson, AZ, United States

Transition metal-stabilized carbocations are characterized by synthetically valuable interactions, yet, to date there are no comprehensive reports of the many bonding modes that can exist between a metal and carbocation. This review summarizes developments in these complexes to provide a clear picture of their properties and reactivities. In order to strategically exploit them, we propose this summary of the different bonding modes for transition metal-carbocation complexes. These models will help chemists understand the orbital interactions involved in these compounds so that they can approach their synthetic goals most effectively. Multiple transition metals and carbocations will be discussed.

Keywords: metal complexes, carbocation, bonding model, metal-carbocation interaction, molecular orbital interactions

INTRODUCTION

The structures, properties, and reactivities of organometallic complexes depend mostly on their ligand environment. Ligands are used to improve catalyst efficiency and accelerate the discovery of new reactivity modes. We will use M. Green's seminal model for Covalent Bond Classification (CBC method) (Green, 1995; Parkin, 2007) to define 2-center metal-ligand interactions of organometallic compounds as $ML_lX_xZ_z$, where the ligand atoms are classified as L, X, and Z ligands (**Figure 1A**). L-type ligands are Lewis bases that donate two electrons to form a dative L → M bond (e.g., PR_3, NR_3, OR). X-type ligands donate one electron, requiring oxidation of the metal center to form classical covalent M–X bonds (e.g., H^-, RO^-, Cl^-). Z-type ligands are Lewis acids that accept a pair of electrons from the metal to form a dative M ← Z bond (e.g., SO_2, BR_3). Since transition metals (TMs) are typically defined as electron-deficient species, the majority of ligands that have been developed are electron-rich Lewis-basic moieties (L- and X-types) that aim to complete the valence shell of the transition metal (also known as the 18 electron rule). However, transition metals also exhibit Lewis-basic character from metal-to-ligand back-donation from partial filling of their upper valence d shell. Organometallic chemists have recognized how this basicity can be used to promote interactions between a TM and a Lewis acid moiety, where the acid acts as a σ-acceptor (L-type) and not a σ-donor (Z-type) ligand.

The first example of Lewis acid–metal coordination was reported in 1970 (Shriver, 1970), yet the incidence of M ← Z complexes remained scarce for several decades. The scope of Lewis acids acting as σ-acceptor ligands has been significantly extended over the last two decades with the development of ambiphilic ligands—ligands that contain both electron donor (L-type) and acceptor (Z-type) groups (Amgoune and Bourissou, 2011; Braunschweig and Dewhurst, 2011; Owen, 2012, 2016; Bouhadir and Bourissou, 2016; Jones and Gabbaï, 2016). Transition metals exhibit similar ambiphilic character since they contain both filled and empty d-orbitals. When ambiphilic ligands are used, the metal center coordinates to the L-type moiety of the ligand and the degree of coordination to the Lewis acid moiety is increased (**Figure 1B**). The Z-type ligand can stabilize a

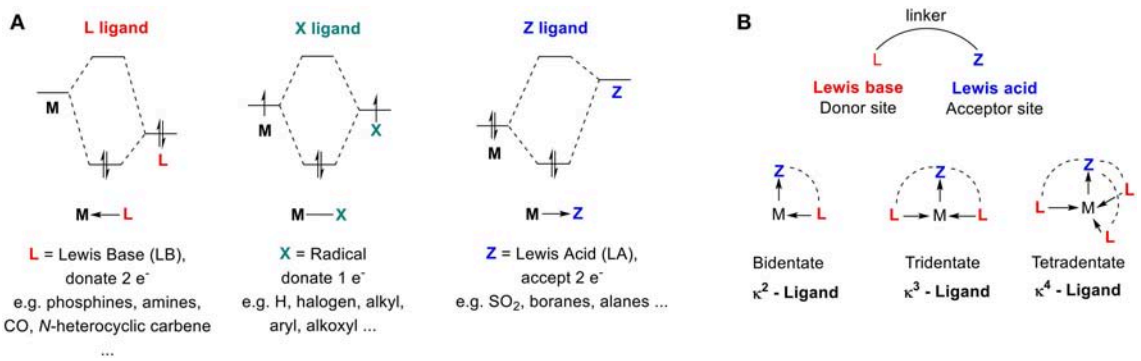

FIGURE 1 | (A) Simplified orbital diagrams associated with M—L, M—X, and M—Z interaction. **(B)** Schematic representation of ambiphilic ligands.

vacant orbital of the transition metal center while drawing electron density from the filled d-orbitals because of its σ-accepting properties. This interaction determines the electronic properties and reactivities of the metal (You et al., 2018). The synthesis, coordination chemistry, and reactivity of ambiphilic ligands and their metal complexes have been extensively studied and well-summarized in several recent reviews (Amgoune and Bourissou, 2011; Braunschweig and Dewhurst, 2011; Owen, 2012, 2016; Bouhadir and Bourissou, 2016; Jones and Gabbaï, 2016). Surprisingly, none of these reports have mentioned carbocations as Lewis acid Z-type ligands, and they neglect to examine the interactions between transition metals and persistent carbocations.

In organic chemistry, carbocations are ubiquitous. The field of carbocation chemistry has rapidly developed since its conception in 1901 when Norris discovered the first stable carbocations, triphenylmethyl ions (PH_3C^+) (Norris, 1901; Norris and Sanders, 1901) Carbocations have been identified as key intermediates in many organic reactions, including electrophilic aromatic substitutions, unimolecular nucleophilic substitutions, addition-eliminations, and many rearrangements (Olah, 2004). The significance of carbocations as reactive intermediates in acid-mediated reactions was also highlighted when Professor Olah was awarded the Nobel Prize in Chemistry to in 1994 for his contributions to carbocation chemistry (Olah, 1995). The diverse applications of carbocations in organic chemistry is outside of the scope of this review, but interested readers are encouraged to consult the many reviews published on their synthesis and applications.

This review focuses on organometallic complexes that contain a carbocation (Z-type ligand), within their first coordination sphere. In 1972, Olah proposed carbenium and carbonium ions as two distinct types of carbocations that are differentiated by their structures (Olah, 1972). The "classical" trivalent carbenium ion contains an sp^2-hybridized electron-deficient carbon atom (**Figure 2A**), while the "non-classical" carbonium ion is defined as a penta- (or higher) coordinate carbon that involves a 3-center-2-electron bond (**Figure 2B**; Winstein and Trifan, 1952; Olah, 1972). This review focuses on classical carbenium ions, which we will refer to as carbocations.

Carbocations can be transient, extremely reactive species, or they can be long-living, isolable, and storable. They gain stability from filled p orbitals or π-systems α to a sp^2 hybridized carbon, which creates resonance and delocalizes the positive charge over multiple atoms (**Figure 2A**). Their thermodynamic stability can be described in term of their pK_R^+ value, which is defined by the equilibrium between the cationic species and its corresponding carbinol (**Figure 2C**; Deno et al., 1955) A larger pK_R^+ value correlates to a more stable carbenium or, specifically, one that is resistant to nucleophilic attack by water. Examples of persistent carbenium ions and their pK_R^+ values are shown below (**Figure 2D**; Breslow and Chang, 1961; Ritchie, 1986; Amyes et al., 1992; Sørensen et al., 2014).

GENERAL BONDING CONSIDERATIONS

The bonding mode for most of the Z-type ligands described in the literature is unambiguous (Amgoune and Bourissou, 2011; Owen, 2012). In these models, there is a localized empty p orbital that acts as a σ-acceptor for a filled metal-based d orbital on either a group 13 or a hypervalent, heavy group 14 element (**Figure 1A**). However, this bonding model becomes more complicated when considering carbocation-containing species since the empty sp^2 hybridized orbital is often involved in an extended π-system that can act as an L- or X-type ligand. In order to discuss the bonding model of carbocations in depth, it is important to remind the reader about an important concept—donation and backdonation. This concept is represented by the Dewar-Chatt-Duncanson model (**Figure 3A**) with regard to metal-olefin interactions (Nelson et al., 1969; Mingos, 2001; Frenking, 2002). The filled π-orbital of the olefin donates electron density to the metal center via an interaction with an empty metal-based d orbital. This donation (L-type) is supplemented by backdonation from a filled metal-based d orbital into the empty π*-orbital (Z-type). **Figure 3A** shows how the complex can be described either as a metal-olefin adduct from modest backbonding (resulting in an L-type ligand), or as a metallacyclopropane derivative due to extensive backbonding (where the olefin serves as an LZ ligand, otherwise known as an X_2 ligand). The equivalence

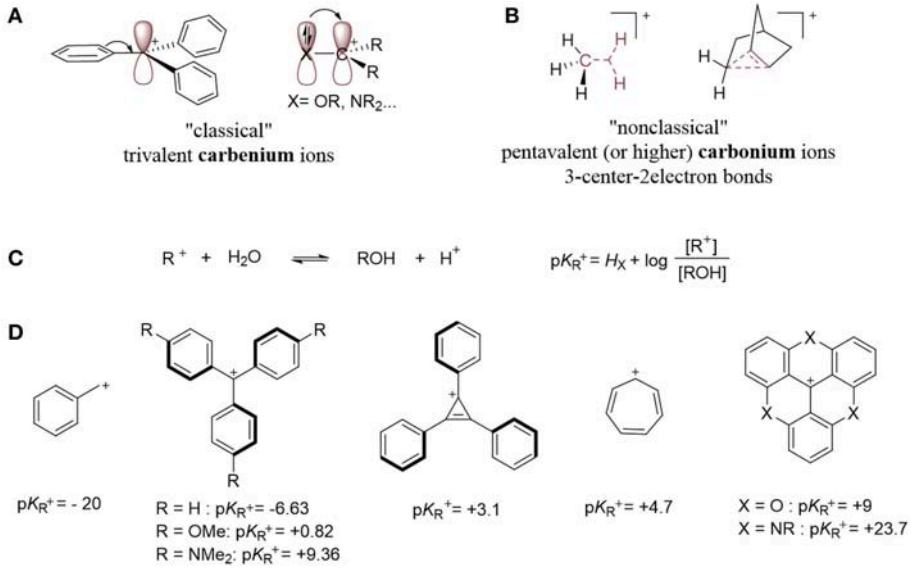

FIGURE 2 | (A) Examples of carbenium ions. **(B)** Examples of carbonium species. **(C)** Determination of carbocation stability: pK_{R+}. **(D)** Examples of carbocations and their pK_R^+ values (Breslow and Chang, 1961; Ritchie, 1986; Amyes et al., 1992; Sørensen et al., 2014).

between an LZ and X_2 system comes from the fact that both types require the involvement of two metal orbitals (**Figure 3B**; Parkin, 2007). Similar to the relationship between Fischer carbenes and Schrock alkylidenes (Fischer, 1976; Schrock, 2001, 2005; Shrock, 2002), the "triplet" state of the ligand becomes accessible only if the empty orbital is sufficiently low in energy. However, both bonding descriptions represent extreme cases of this model and most reported olefin complexes are more accurately described as a hybrid, with varying degrees of backdonation (**Figure 3A**, LZ′). The extent of backdonation strongly depends on the nature of the metal center. For example, a metal with a pair of electrons residing in a high energy orbital will favor strong backbonding interactions because of energy matching. Since it is impossible to predict which model is preferred without further spectroscopic or structural analysis, Parkin introduced the LZ′ designation, where Z′ refers to an unspecified degree of backbonding (Parkin, 2007). Examples of these types of ligands are C_2H_4 and CO. In order to describe the bonding mode for carbocation-containing ligands, we will employ this Z′ classification.

Another important concept is the equivalent neutral class (**Figure 3C**; Parkin, 2007) the classification of the ligand changes with the presence of any charge or delocalization of charge. A donor ligand with x-electrons bound to a cationic metal center is equivalent to a donor ligand (x-1)-electrons bound to a neutral metal center (i.e., $[ML]^+ \equiv [MX]$, so $X^+ \equiv Z$). Due to the cationic nature of the ligand of interest, this notation will be used to differentiate between partial backdonation (Z') and strong backdonation/charge delocalization (X^+).

Carbocation species can form either σ- or π-complexes depending on whether they are carbenylium (R_2C^+) or carbenium (R_3C^+) moieties. Carbenylium R_2C^+ ions possess a half-filled sp^2 orbital that can participate in σ-bonding with a metal center. They also have an empty p orbital, which is available for backdonation (**Figure 4A**). Using the CBC method, R_2C^+ can be described as an XZ′ ligand. These molecules are analogous to LZ′ carbenes R_2C: (vide supra, $L^+ \rightarrow X$). These carbenes can be classified in two ways, depending on the extent of π-backbonding from the metal center: either as a "Fischer carbene," which is an L-type ligand due to weak backdonation, or as a "Schrock alkylidene," which is an X_2 ligand because of strong backdonation (Parkin, 2007). A similar description for the interaction between a carbenylium R_2C^+ and a metal center can be used that also depends on the extent of π-backdonation. Stabilization of the empty p orbital by an alkyl substituent will result in no backdonation; in this case, R_2C^+ is a pure X ligand (i.e., $X = L^+$ for comparison with a Fischer carbene). On the other hand, no stabilization results in extensive backbonding so that R_2C^+ is classified as and XZ ligand (i.e., $XZ = X_2+$ for comparison with a Schrock alkylidene). Types of interactions between these extreme configurations can also be observed (XZ′ function, **Figure 3A**), as illustrated by our olefin model.

Carbenium R_3C^+ moieties only possess an empty p orbital, resulting in the formation of π-complexes (**Figure 4B**). For consistency in our discussion, we describe their bonding modes, differentiated by the extent of interaction between the metal orbitals and carbon's empty 2p orbitals. These modes of interaction range from: (1) no C^+ interaction, (2) weak interactions, and (3) full hybridization of the carbon. The persistent carbenium ions that will be discussed are stabilized by resonance with an adjacent π-system. Therefore, the ligand is considered ambiphilic, since it acts both as a σ-donor through its electron rich π-system (L-type ligand) and as a π and/or σ-acceptor through its empty π*-system and p orbital (Z-type ligand). Again, the bonding mode depends on the electron

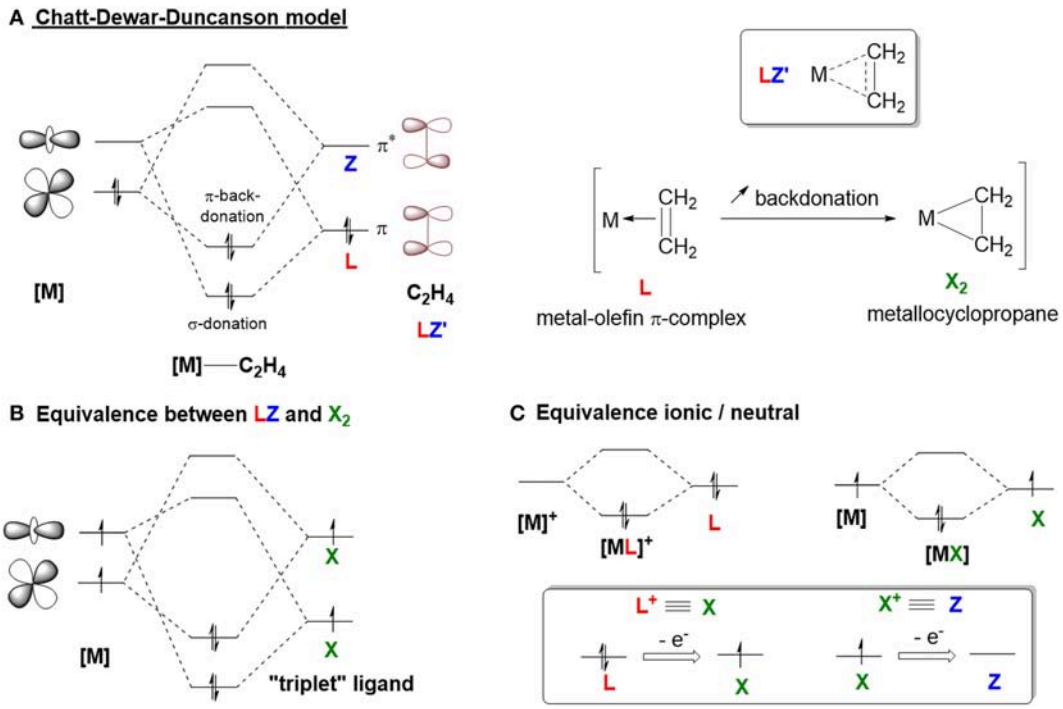

FIGURE 3 | (A) Chatt-Deward-Duncanson model. **(B,C)** Covalent bond classification equivalency.

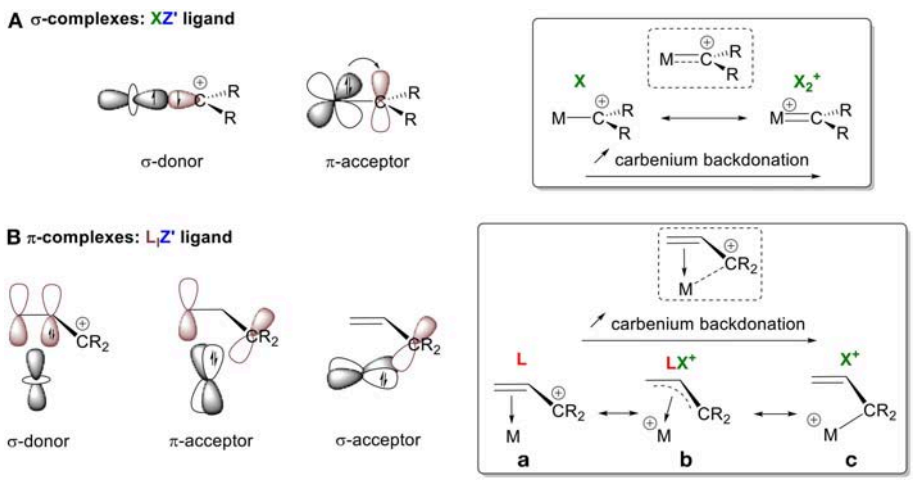

FIGURE 4 | Orbital interactions between a carbenium ion and a metal center in **(A)** σ-complexes, **(B)** π-complexes.

accepting ability of the ligand framework. In the absence of σ-backdonation from the metal, the carbenium species acts as an L-type ligand and does not interact with the metal center. In the absence of σ-backdonation from the carbenium, interactions between the filled π-system and the metal center will be the main orbital interactions, leading to a η^2 coordination mode with an L-type ligand (**Figure 4B,a**). As the interaction between the metal and the empty p orbital of the carbenium increases, the allyl cation acts as an LX^+ ligand through π- and/or σ-backdonation, resulting in η^3 bonding (**Figure 4B,b**). In the presence of extended σ-backbonding into the p orbital of R_3C^+, the M-C^+ interaction will govern the bonding mode leading to full hybridization of the carbon and a η^1 coordination mode (**Figure 4B,c**). This simplistic model is used to introduce the notion of Z′ and relative backdonation into carbenium π-complexes. A more relevant bonding view of each example system will be further discussed in their corresponding sections. This will allow us to address how the Z′ character of a carbenium

ligand is affected by the nature of the metal, its d electron count, its coordination environment, and the π-systems that stabilize the C^+ atom.

σ-COMPLEXES

As stated in the initial bonding discussion, σ-bonded carbenium complexes are in equilibrium with a carbene-bonded cationic metal. Carbenylium cations and Fisher carbenes have similar bonding modes and are considered π-acceptors. By analogy, cyclopropenylium ions are XZ'-type ligands and Fisher carbenes are LZ'-type. However, carbocations donate one electron as σ-donors while carbenes donate two electrons as σ-donors. Carbene complexes are prevalent, well-discussed species in literature so we will not focus on presenting the extensive progress in the field of carbene chemistry. Interested readers are encouraged to review articles on this subject (Ofele et al., 2009; Melaimi et al., 2010; Martin et al., 2011; Moerdyk and Bielawski, 2013). Instead, we will use selected examples to generalize bonding interactions between carbenium ions and metal centers in a σ-manner, and highlight how this bonding model is affected by the nature of the R groups on the carbenium and the metal and its ligands (L_n).

Cyclopropenylium Cations

Cyclopropenylium cation ($C_3H_3^+$) is the smallest member of the Hückel aromatic system (Breslow, 1957; Breslow and Chang, 1961). It exhibits considerable thermodynamic stability from aromaticity and resonance with 2 π-electrons delocalized over three conjugated 2p orbitals. The symmetry of its π-system imparts enormous stability relative to typical carbocations. Its protonated analog, cyclopropene, is a strained three-membered ring that is hugely thermodynamically unstable. The stability of the cation relative to the instability of the neutral species has elicited great interest in chemists and inspired synthetic and theoretical studies for decades. Cyclopropenylium cations were first synthesized by Breslow (1957) when he synthesized triphenylcyclopropenylium cation (Breslow, 1957). This was the first experimental verification of aromaticity in non-benzenoid molecules and it offered an important lesson: the energetic debt from ring strain can be compensated by aromatic stability (Breslow and Chang, 1961). Although the cation has been widely investigated since its discovery, the number of metal-bound cyclopropenylium complexes is not as abundant. A thorough review of this topic was presented by Komatsu and Kitagawa (2003).

The first isolated σ-bound cyclopropenylium-metal complexes were reported in 1978 in consecutive articles by Gompper and Bartmann (1978) and by Weiss and Priesner (1978) following two different approaches.

Approach 1: Bartmann reported the synthesis of dicarbonyl(η-cyclopentadienyl)(σ-2,3-diphenylcyclopropenyl)iron salts **2** from the nucleophilic attack of a coordinatively unsaturated metallate, sodium dicarbonyl(η-cyclopentadienyl)ferrate salt, to various cylcopropenium ions **1** (**Figure 5A**). While the formation of NaX (X = cyclopropenium counter ions) is a strong driving force for this reaction, the neutral compound **2** is highly strained and reactive from loss of aromaticity. Stability from aromaticity was easily restored by abstraction of the R_2 group (e.g., Ph, He, H, Cl) with appropriate abstracting agent E (e.g., HCl, I_2, $[(Ph)_3C^+][BF_4^-]$), resulting in the σ-bound cyclopropenylium ion complexes **3** (Gompper and Bartmann, 1978).

Approach 2: Weiss and Priesner proposed that the neutral cyclopropenylidene complex **4**, first reported by Öfele (1970), is in resonance with the Zwitterionic form **5,** where a metallate anion is bound to a cyclopropenylium moiety (**Figure 5B**; Weiss and Priesner, 1978). With the aid of a strong Lewis acid, bound anionic ligand X^- can be exchanged with a non-coordinating anion (e.g., $^-$OTf), leading to the formation of transition metal-substituted cyclopropenylium system **6**. A variety of cyclopropenylidene complexes have since been reported. Their synthesis typically follows one of three routes: (1) oxidative addition of dihalocyclypropenes followed by halide abstraction (Öfele, 1970; Konishi et al., 1978; Weiss and Priesner, 1978; Yoshida, 1982; Miki et al., 1988), (2) reaction of the cyclopropenyl salts with lithium adducts (Rees and von Angerer, 1972; Gompper and Bartmann, 1978; Konishi et al., 1978; Yoshida, 1982; Miki et al., 1988; Tamm et al., 1995; Schumann et al., 1997), or (3) cyclopropenylidene transfer (Yoshida, 1982; Gade et al., 2000; Kozma et al., 2013). These carbene species have been extensively discussed and were thoroughly reviewed by Herrmann in 2009 (Ofele et al., 2009). The bonding mode of cyclopropenylidene complexes is unambiguous and well-established by carbene chemistry and, therefore, will not be presented in this review.

As discussed, the extent of π-backdonation depends on the energies of the overlapping orbitals. Substituents on the ring alter the XZ bonding mode for this ligand because of the impact they have on the extent of electron donation and π-backdonation to the ring. In their initial report, Gompper and Bartmann synthesized complexes of substituted cyclopropenium ions with $[Fe(Cp)(CO)_2]$ (Gompper and Bartmann, 1978). They measured strength of the interaction between the iron atom and the carbon atom of the C_3 ring with IR spectroscopy and found the stretching frequencies of the CO moiety bound to iron in **3a-c** showed a clear blueshift of the $\nu_{(CO)}$ between R = Ph, R = ^{t}Bu, to R = NEt_2 (**Figure 5C**), which is consistent with a decrease in π-backdonation from the metal into the CO ligand. This decreased electron density on the metal center is a result of the increased π-accepting ability of cyclopropenylium ligand, which correlates to a lower pK_R^+ value (**Figure 5C**). These trends support the XZ-type bonding model discussed in the first part of this review (vide supra, **Figure 4A**) and is analogous to the cyclopropenylidene complexes summarized in Herrmann's review: complexes bearing cyclopropenylidene ligands with two amino substituents showed the most σ-donor/least π-acceptor ability, and those containing two phenyl groups show the least σ-donor/most π-acceptor ability (Ofele et al., 2009).

This also supports our claim that that CR_2^+ acts as an XZ′ ligand with different degrees of Z-type interactions. More precisely, complexes with $C(C(NR_2)_2)_2^+$ ligands are best described as X-type ligands with little or no π-backdonation,

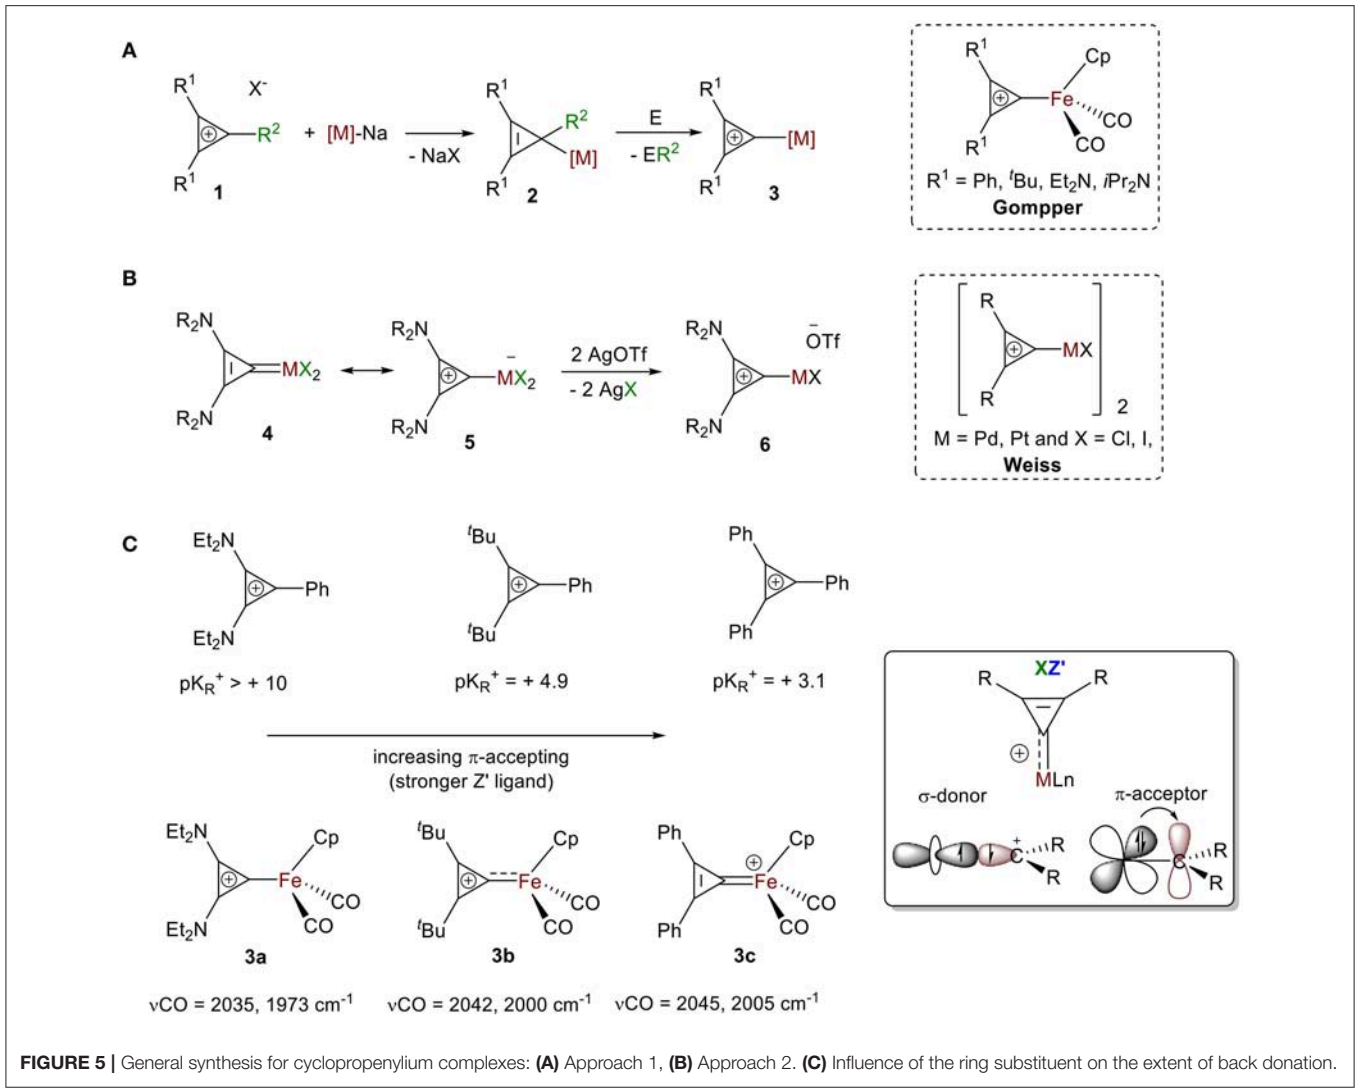

FIGURE 5 | General synthesis for cyclopropenylium complexes: **(A)** Approach 1, **(B)** Approach 2. **(C)** Influence of the ring substituent on the extent of back donation.

while complexes containing $^{+}C(CPh_2)_2$ ligands are more appropriately represented as X_2^{+} ligands because of their large Z-type interaction.

Arylenium Cations

Over the past decade, cationic gold(I) complexes have become some of the most efficient and versatile catalysts for the functionalization of C-C bonds (Echavarren and Nevado, 2004; Olah, 2004; Fürstner and Davies, 2007; Hashmi and Rudolph, 2008; Li et al., 2008; Jia and Bandini, 2015; Harris and Widenhoefer, 2016; Hopkinson et al., 2016; Zi and Toste, 2016; Shahzad et al., 2017). These complexes are typically formed from gold carbenes or from α-metallocarbenium ions. They contain a gold atom that is bound to a formally divalent carbon atom and are applied in a variety of gold-catalyzed transformations. The electronic structure of these cationic complexes is dependent on the extent of π-backbonding from the gold atom to the C_1 carbon atom (**Figure 6A**). The bonding mode of gold carbene/carbenium complexes has been extensively discussed, and much of gold carbene complexes' behavior can be understood by applying the bonding model developed by Toste and Goddard (Benitez et al., 2009). According to this model, the L–Au–C bonding network is comprised of three sets of orbital interactions: (1) a three-center, four-electron σ-hyperbond that donates electron density from filled sp^x orbitals on the carbene's carbon atom to gold's empty 6s orbital (**Figure 6A,b**), (2) two orthogonal π-bonds that donate electron density from the metal's filled 5d orbitals to the ligand's π-acceptor orbitals (**Figure 6A,a**), and (3) the carbene's π-acceptor orbitals (**Figure 6A,c**). It follows that greater σ-donation from the ligand (L) results in a weaker σ component of the Au–C_1 bond and greater π acidity of the ligand results in weaker Au-C_1 backdonation.

Cationic gold(I) complexes have been extensively studied, so this review will focus only on what we consider to be one of the most intriguing species present during gold catalysis: the *gem*-diaurated carbocation species (a carbocation that is stabilized by two gold atoms through Au-Au contacts) (Hashmi, 2014). The abundance of cationic *gem*-diaurated species discovered in gold-mediated catalysis (Harris and Widenhoefer, 2016)

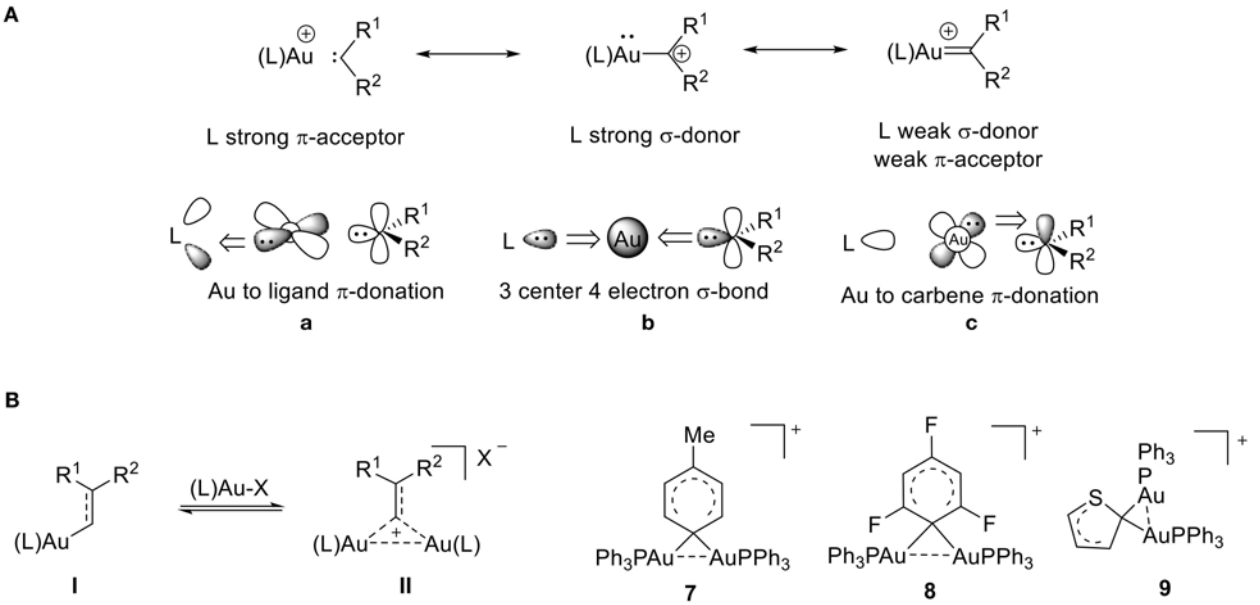

FIGURE 6 | (A) Bonding model for gold-carbene resonance structures. **(B)** *Gem*-diaurated carbocation species.

helped researchers conclude that an equilibrium exists between the vinyl gold(I) species **I** and the *gem*-diaurated species **II** (**Figure 6B**; Roithová et al., 2012; Harris and Widenhoefer, 2016). Further, the substituents R^1 and R^2 influence this equilibrium. A balance of stability and reactivity is required to observe this diaurated species **II**; otherwise, **II** can form a catalyst-poisoning thermodynamic sink, rendering the equilibrium irreversible (Roithová et al., 2012). In order for efficient catalysis to take place, the equilibrium must be reversible, and the *gem*-diaurated species **II** is actually a less reactive off-cycle species than the corresponding vinyl gold(I) species **I** (Brown et al., 2012; Zhdanko and Maier, 2013). This can be rationalized by the fact that the *gem*-diaurated species **II** is stabilized through Au-Au interactions, which makes it less reactive than the unstabilized vinyl gold(I) species **I**.

The tolyl complex **7** represents the first 1,1-diaurated carbocation derived from benzene (Nesmeyanov et al., 1974) and the cation of perchlorate salt **8** provided the first crystallographic evidence for 1,1-diauration (**Figure 6B**; Rafael et al., 1988). According to its X-ray data, complex 8 shows an Au-C-Au bond angle of 79.3°, Au-C bond lengths of 2.16 Å, and a relatively short Au···Au distance of 2.76 Å. The two [$AuPPh_3$] units in the diaurated thienyl complex **9** have identical phosphorus environments based on the ^{31}P NMR, which shows only one peak. The structure includes a short Au···Au distance of 2.81 Å and a small Au-C-Au angle of 82.5° (Porter et al., 2003), which shows a strong aurophilic interaction (Schmidbaur, 1990; Mond et al., 1995; Stephen et al., 2012), that is consistent with other reports of diaurated compounds (Osawa et al., 2008; Seidel et al., 2010). The literature range of Au-Au distances for gem-diaurated compounds is 2.72 to 2.85 Å.

π-COMPLEXES

Cyclic Carbocations

Cyclopropenium Cations

The first π-complexes with cyclopropenium cation were synthesized by Hayter (1968). His brief report included the synthesis of only one cyclopropenium-ligated complex, [(π-C_5H_5)Mo(π-C_3Ph_3)$(CO)_2$], and its characterization by ^1H NMR. The NMR spectrum showed a complex multiplet centered at $\delta = 7.2$ ppm with peak intensity ratio 5:17 for the phenyl substituents of the cyclopropenium ring (Hayter, 1968). Since Hayter's report, other isolated cyclopropenylium-metal complexes were reported; Komatsu et al. summarized these in an extensive review published in 2003 (Komatsu and Kitagawa, 2003). To the best of our knowledge, no new π-complexes of this type have since been reported.

The reactions of cyclopropenylium cations with low valent metal centers can lead to (η^3-cyclopropenyl)- (Chiang et al., 1979; Hughes et al., 1986, 1993; Lichtenberger et al., 1993; Ghilardi et al., 1995), (η^2-cyclopropenyl)- (Mealli et al., 1982), and (η^1-cyclopropenyl) (Gompper and Bartmann, 1985) metal complexes. The hapticity of the product depends on the ring's substituents, the metal, and the other ligands on the metal (**Figure 7**).

To better understand which coordination mode will be favored in each of these complex types, the molecular diagrams of C_3R_3 and the frontier orbitals for ML_n fragment ($n = 2$–5) (Jorgensen and Salem, 1973) are shown in **Figures 8A,B** respectively. The cyclopropenyl ring can either act as a: (1) σ-donor with its filled a_2'' orbital; (2) π-acceptor with its empty e'' orbital, if bound in an η^2 or η^3 coordination mode; or

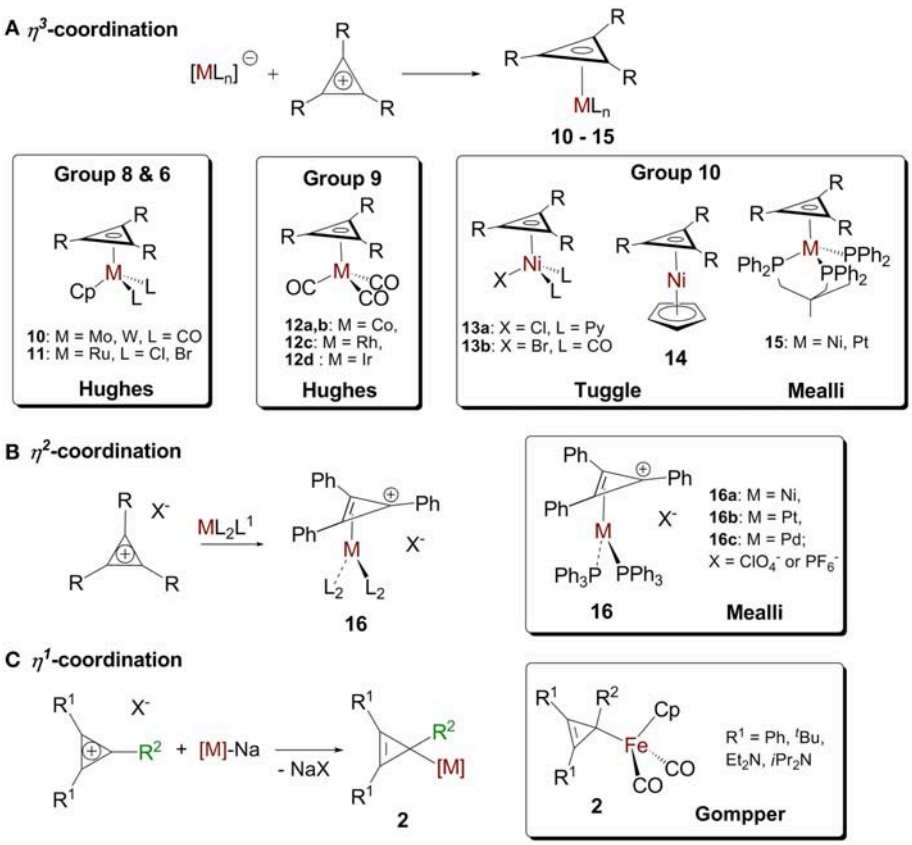

FIGURE 7 | (A) η^3-cyclopropenium complex. **(B)** d^{10} (η^2-cyclopropenium) ML_2 complex and the "Ring-whizzing" phenomenon. **(C)** η^1-cyclopropenium complex.

(3) σ-acceptor with one of the empty e″ orbitals if bound in an η^1 fashion. The coordination mode and the ring-metal interaction are determined by the d electron count of the metal and by the ligand environment of the metal fragment as established by a molecular orbital approach developed by Hoffmann et al. (Jemmis and Hoffmann, 1980). In short, the ML_n group will adopt the position that maximizes stabilizing bonding interactions. For the following discussion, the molecules will be arbitrarily split into neutral fragments, C_3R_3 and ML_n.

η^3 *coordination*

Cyclopropenium-metal complexes are prepared from the reaction between a cyclopropenium cation and a metal precursor, often a salt leading to the formation of a neutral species (**Figure 7A**; Donaldson and Hughes, 1982). We will model η^3 coordination in cyclopropenium complexes with an ML_3 d^9 fragment, $Co(CO)_3$. When the ML_3 fragment is bound to the ring in this way (**Figure 8c.1**), the a_2'' and e″ orbitals of the cyclopropenium moiety are symmetrical to the high-lying empty $2a_1$ orbital and the partially filled 2e orbital. In this case, coordination will optimize the number of metal-ring interactions, resulting in one σ- and two π-orbital interactions. If the $[Co(CO)_3]^-$ fragment moves off of the center of the ring and coordinates to it differently, part of the π-backdonation between the e orbitals will be lost. Evidence of the η^3 bonding model for $(C_3R_3)Co(CO)_3$ was confirmed experimentally by Lichtenberger et al. by photoelectron spectroscopy (Lichtenberger et al., 1993). This bonding model is applicable to complexes with the general formulas $(C_3R_3)ML_3$ (where M = Co, Rh, Ir) (Chiang et al., 1979) and $(C_3R_3)ML_2X$ (where M = Ni, Pt, Pd; X = anionic ligand; L = neutral ligand) (Mealli et al., 1981, 1983; Miki et al., 1988; Kuchenbeiser et al., 2008). Since d^9 ML_3 and d^5 ML_5 complexes are isolobal, this η^3 bonding is also appropriate for complexes with the general formula $(C_3R_3)ML_3X_2$ (where M = Ru) (Ditchfield et al., 1993; Morton and Selegue, 1999) and $(C_3R_3)ML_4X$ (where M = Mo or W) (Hayter, 1968; Drew et al., 1981; Hughes et al., 1985).

In general, the bonding mode in cyclopropenium-transition metal complexes depends on the metal involved. Strong π-backdonation from the metal to the carbocation increases the Z-type character of the ligand. It follows, then, that the distance between the metal and the C_3 ring decreases while the $\Delta G^{\ddagger}$ of rotation around their bond increases. If the metal in one of these complexes is coordinated to CO ligands, the bond between the metal and CO ligand increases in length, which results in a distinct shift in the $\upsilon_{(CO)}$ relative to that of the free CO-coordinated metal complex.

Infrared spectroscopy is the most powerful tool for monitoring reactions of metal carbonyls and for assignment of their structures, since the $\upsilon_{(CO)}$ absorptions are easily

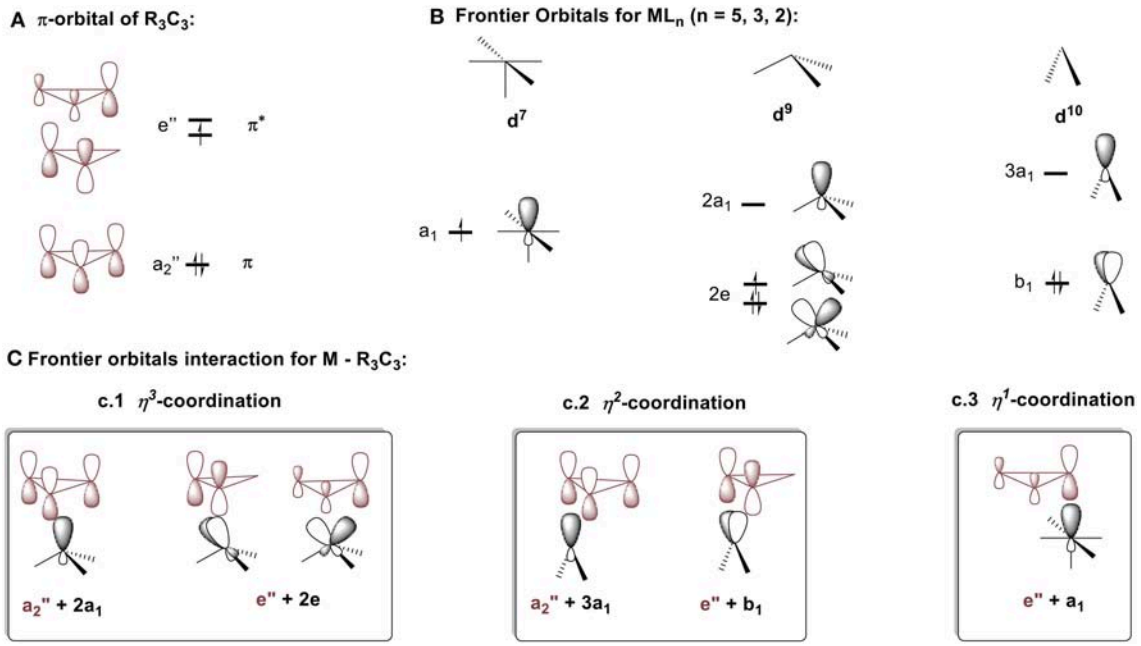

FIGURE 8 | Descritpion of bonding mode between cyclopropenium and metal fragments. **(A)** π-orbital of R_3C_3. **(B)** Frontier orbitals ML_n ($n = 5, 3, 2$). **(C)** Frontier orbitals interaction for M – R_3C_3: (c.1) η^3-coordination, (c.2) η^2-coordination, (c.3) η^1-coordination.

TABLE 1 | Compiled M-C_3 ring distance data (Churchill et al., 1984) and IR frequencies for CO in selected π-complexes.

altered by changes to the molecular structure and charge of a carbonyl complex. It is unsurprising, then, that ion pairing between the cyclopropenium cation and a metal carbonyl anion results in significant changes in the $\upsilon_{(CO)}$ region, due to strong perturbation of the geometry of the anion. This characteristic is the result of π-backbonding, since CO is a π-acceptor ligand. When the $\upsilon_{(CO)}$ decreases as a result of decreasing bond strength, the strength of the M-C bond increases. As the M-C_3 distance decreases, the M-CO distance increases; therefore, a longer M-C_3 distance corresponds to a shorter M-CO distance and a decrease in $\upsilon_{(CO)}$ relative to free CO (2143 cm^{-1}).

The $\upsilon_{(CO)}$ of a complex is affected by the nature of the substituents on the C_3 ring (**Table 1**). When the ring substituents are changed from phenyls to t-butyls in the otherwise identical cobalt carbonyl complexes (**12a** and **12b**, respectively), the $\upsilon_{(CO)}$ decreases and the metal-centroid bond distance increase significantly as a result of the increase in electron donation from the substituent, consistent with an increase in pK_R^+ values (**Table 1**). It is worth mentioning that no metal complexes are reported with tris(amino)cyclopropenylium cations, suggesting that these are inadequately π-accepting (**Table 1**, $pK_R^+ > 10$) (Ciabattoni and Nathan, 1969; Moss et al., 1986; Bandar and

Lambert, 2013; Jiang et al., 2015). The nature of the metal also affects the electronic configuration of the complex (**Table 1**). As expected, larger metals (Co to Ir in complexes **12b−12d**) provide better orbital overlap. More π-donation between the metal and the ring is observed from Co to Ir, which is consistent with the increase in $\upsilon_{(CO)}$. Finally, the extent of the back donation from the metal to the ring is dependent on the π-accepting ability of the other ligand bound to the metal. The nickel complexes in the table below (13a, 14, and 15) illustrate this: the trisphosphine (**15**) is a stronger π-accepting ligand than either Cp or two pyridines and a chloride (**14** and **13a**, respectively), and an increase in the M-$C_{centroid}$ is observed. This suggests that the backdonation into the C_3 ring is most significant in **13a**.

Tuggle and Weaver determined an important factor of the electronic transitions in their $[(\pi\text{-}Ph_3C_3)NiCl(py)_2]\cdot py$ compound **10c** by comparing the UV-Vis spectra of their metal complex to that of the free ligand. Since the spectra showed no appreciable differences in their $\pi \rightarrow \pi^*$ transitions, they concluded the principle bonding interaction in the metal complex is not involved in the $\pi \rightarrow \pi^*$ transition (Tuggle and Weaver, 1971a). Later, they studied an analogous mixed nickel sandwich **11**, $[(\pi\text{-}Ph_3C_3)Ni(\pi\text{-}C_5H_5)_2]$, and considered the metal's interactions with each ring separately. They presented two possibilities for the cyclopropenyl moiety's interactions were presented: 1) overlap of a hybridized metal a_1 orbital (with $3d_z^2$, 4s, and $4p_z$ contributions) with the a_1 combination of the C_3 pπ orbitals; and (2) back-donation from the metal e orbitals to the e antibonding combination of the ring pπ orbitals. Importantly, they concluded that the back-donation was likely directed toward the formally positively charged C_3 ring and not toward the cyclopentadiene (Tuggle and Weaver, 1971b). This finding is consistent with our conclusions above regarding M-C_3 distance and $\upsilon_{(CO)}$.

Prior studies by Hughes et al. measured the free energy of activation ($\Delta G^{\ddagger}$) for cyclopropenium ring rotation in Mo, Ru, Co, Rh, Ir derivatives (Hughes et al., 1993), which provided quantitative correlations between electronic and steric effects of ancillary ligands. Comparison of these experimental $\Delta G^{\ddagger}$ values showed a significant increase in the rotational barrier of C_3 rotation about the metal-C_3 axis with descending group, which agreed with their prior findings in η^3 complexes (Co < Rh < Ir) (Hughes et al., 1993) and with general observations made for rotational barriers of olefin and 1,3-diene complexes of transition metals (Mann, 1982).

η^2 *coordination*

We will model η^2 coordination with a d^{10} ML_2 fragment, $Ni(PPh_3)_2$. In this case, only two frontier orbitals are suitable to interact with the ring (**Figure 8c.2**). According to Hoffmann and Mealli's calculations, the low energy levels consist of four closely spaced levels, $b_2+1a_1+a_2+2a_1$, which are identifiable with the $e_g + b_{2g} + a_{1g}$ set of typical square planar ML_4 systems (not shown in **Figure 8B**) (Jemmis and Hoffmann, 1980; Mealli et al., 1982). Higher in energy is b_1, which is hybridized out away from the L groups and toward the cyclopropenium ring. Even higher in energy is $3a_1$, which is cylindrically symmetrical and is also hybridized away from L groups. The b_1 orbital is the HOMO of a d^{10} ML_2 fragment and the $3a_1$ orbital is the LUMO. The high lying empty $3a_1$ orbital can interact with the filled a_2'' orbital of the ring and the filled b_1 metal orbital can undergoes back donation with one of orbital of e″ set of the $C_3R_3^+$ (**Figure 8A**). It is worth mentioning that π interaction between the low lying b_2 metal orbital and the other component of the e″ orbital is present but much weaker. The loss of this π interaction is compensated by the metal fragment sliding in an η^2 coordination mode to optimize the π interaction that involves the frontier b_1 orbital of the metal. This bonding type will described for complexes of the type $[(C_3R_3)ML_2]^+$ (M = Ni, Pt, Pd) and $[(C_3R_3)ML_4]^+$ with a d^8 metal due to the isolobal relationship of d^8 ML_4 and d^{10} ML_2 complexes.

The clearest indication of η^2 bonding is unequal distances between the metal atom and any of the three carbons in the ring. McClure and Weaver's platinum complex in 1973 was the first report of this unsymmetrical bonding (McClure and Weaver, 1973). In their complex, **16b** $[Pt(C_3Ph_3)(PPh_3)_2][PF_6]$ (McClure and Weaver, 1973), the Pt atom is 2.09 Å away from 2 of the cyclopropenium carbons, while it is 2.48 Å away from the third carbon. McClure concluded that his complexes are more closely related to the η^2-cyclopropene resonance form and less like the η^3 complexes Weaver synthesized earlier and that the coordination geometry and bond lengthening could be described with the bonding mode of olefins to zerovalent transition metals (McClure and Weaver, 1973).

In 1982, Mealli et al. published an important report on a phenomenon in which an ML_n unit migrates inside the periphery of a cyclic polyene. They called this unique fluxionality "ring-whizzing" (Mealli et al., 1982). Mealli compared three complexes **16** $[(Ph_3C_3)M(PPh_3)_2]X$ (where M = Ni (**16a**), Pt (**16b**)or Pd (**16c**) and X = ClO_4^- or PF_6^-) by ^{13}C NMR and by computational studies informed by their X-ray structure data. They determined that the $(Ph_3P)_2M$ unit progressively moved over the face of the cyclopropenium cation. This movement was used to chart the reaction path from one η^2 geometry, with the $(Ph_3P)_2M$ unit positioned below one C-C bond, to an equivalent η^2 geometry. They concluded that a smaller distance between the metal and one of the carbons in the ring resulted in increased tilting and twisting of the phenyl group directly connected to it. These geometric changes caused longer exocyclic C-C distances because of the decreased conjugation between the phenyl groups and the cyclopropenium ring (Gompper and Bartmann, 1985).

η^1 *coordination*

We will model the η^1 coordination mode with a d^7 ML_5 fragment, $[Fe(CO)_2Cp]^-$ (Gompper and Bartmann, 1978). The frontier orbital of this fragment has two electrons in the a_1 hybrid metal orbital that will interact with one component of the e″ cyclopropenium set. The low-lying filled e set of the metal will only have a small interaction with the e″ of the ring. The metal-ring interaction that contains only one σ molecular orbital will be strengthened if the fragment slides into an η^1 mode (**Figure 8c.3**). This type of interaction is consistent with the model C described in **Figure 4B**.

While synthesizing the first σ-complexes in 1978 (vide supra), Gompper and Bartmann synthesized a neutral intermediate (η^1-cyclopropenyl)iron $(C_3R_3)Fe(CO)_2Cp$ complex **2** (**Figure 7C**; Gompper and Bartmann, 1978). This coordination mode is rare and is mostly reported as intermediate compounds in the reaction path to the formation of cyclopropylenium σ-complexes and will not be further discussed.

To conclude, (1) d^7 ML_5 complexes interact with $C_3R_3^+$ with a single σ-type orbital, resulting in η^1 coordination for $[(C_3R_3)ML_5]$ complexes, (2) d^{10} ML_2 complexes have one σ and one π orbital interaction with $C_3R_3^+$, supporting a η^2 bonding mode in complexes with the formula $[(C_3R_3)ML_2]^+$, and (3) d^9 ML_3, and isolobal fragments (vide supra) have one σ and two π orbital interactions with the $C_3R_3^+$, resulting in an η^3 mode of coordination in complexes with the formula $[(C_3R_3)ML_3]$.

Arylenium Cations

Carbocations with conjugated π systems are one of the most common types of carbocation encountered in organic reactions, and iron was one of the earliest metals used to stabilize these carbocations (Olah et al., 2009). In general, the π orbitals of the carbocation can accept the backdonation of filled d orbitals on the metal atom, so the carbocations act as LX′ ligands. **Figure 9B** shows several representative carbocations with π-allylic systems complexed to an iron (**17** and **18**) in addition to π-allylic systems complexed to platinum (**19**), chromium, molybdenum, or tungsten (**20**) and **an** arenium cation stabilized by Os complexation **21** (Green et al., 1977; Mayr et al., 1993; Winemiller et al., 1997). All of these complexes are consistent with the orbital models in **Figure 9A**.

In addition, these metal-stabilized arylenium cations can be easily characterized by their ^{13}C NMR spectra. For example, complex **19** is featured with a typical resonance around 112 ppm for the central carbon of the η^3-C_3 system, along with two terminal carbon atoms of the allyl group around 82 ppm (Green et al., 1977). The osmium π-complex **21** was also characterized with three ^{13}C resonances in the range of 75–85 ppm, indicating that the metal binds to the arenium system in an η^3 fashion (Winemiller et al., 1997). Interestingly, studies showed that order of average reactivity of **20** toward nucleophiles was **20a**>**20b**>**20c** (Mayr et al., 1993), which can be rationalized with the orbital model in **Figure 9A**. Increasing the atomic radius leads to stronger backdonation of filled d orbitals on the metal atom (W>Mo>Cr) resulting in a metal π complex that is more stable and less reactive.

Carbocations α to Cyclic π-Systems

Another extensively studied carbocation-metal complex is α-metallocenylmethylium cation (Hill and Richards, 1961; Davis et al., 1971; Gleiter et al., 2007; Bleiholder et al., 2009; Minić et al., 2015, 2017; Espinosa Ferao and García, 2017; Muratov et al., 2017; Preethalayam et al., 2017; Fomin et al., 2018). Two different resonance structures have been proposed: (1) the cation acts as an L-type ligand by donating its filled p orbital electron density to the metal center, and (2) the cation acts as an LX^+ ligand by donating its filled p orbital electron density to the metal center through carbenium backdonation (**Figure 10A**). Consequently, some bending of the sp^2-hybridized carbocationic center toward the metal atom has always been observed, which indicates the formation of double bond.

Carbenium α to Cyclopentadienyl

α-ferrocenyl carbenium ions were first observed by Richards and Hill (1959) through solvolysis of the corresponding ferrocenyl carbinyl acetate (Richards and Hill, 1959). Since then, a wide range of α-ferrocenyl carbenium ions have been synthesized and characterized under acidic conditions through their corresponding precusors (**Figure 10B**). **Figure 10B** shows some examples of reported α-ferrocenyl carbenium ions, such as tetrafluoroborates of ferrocenyl diphenyl cyclopropenium ion **24** (Sime and Sime, 1974), α,α'-diferrocenyl methylium ion **25** (Cais et al., 1978), ferrocene-annelated allylium ion **26** (Lukasser et al., 1995), and ferrocenyl diphenyl methylium ion **27** (Behrens, 1979), along with their geometric parameters as derived from X-ray diffraction studies. There is consistent bending of the C6 atom of the fulvene ring toward the iron atom in all of these complexes, but the bending angle (α) and Fe-C6 distance (d) vary considerably.

In **24**, the positive charge of the carbenium center is delocalized into the cyclopropenylium ring, which results in a bending angle of 6.8° with an Fe-C6 bond length of 2.96 Å. In **25**-**27**, an increase of the angle (α) and a reduction of the Fe-C6 distance (d) is observed. These geometric changes can be rationalized by the orbital model in **Figure 10A**. The π acidity of the C6 center depends on the identity of R^1 and R^2. Greater electron density in the carbenium center results in less π acidity, which results in weaker π backdonation and a conformation like **23b** with a smaller bending angle. For example, the π systems in **24** and **26** increase the electron density of their C6 centers, yielding smaller bending angles.

$[(\eta^6\text{-}C_5H_4C(C_6H_5)_2)]Cr(CO_3)$ (**28b**) was the first η^6-fulvene complex studied by X-ray analysis (**Figure 11A**). This data experimentally confirmed the predicted tendency toward strong bending of C6 (Andrianov et al., 1975). The neutral complex **28b** shows a bending angle of 28.4° with a Cr-C6 bond length of 2.55 Å, which can be explained by the HOMO obtained from extended Hückel calculations is shown in **Figure 11D** (Albright et al., 1978). The bending of C6 causes a bonding interaction between C6 and the Cr-centered e_s orbital (Albright et al., 1978). X-ray studies of various fulvene-$Cr(CO)_3$ complexes with different substituent groups at C6 (**28a**-**e**, **Figure 11A**) showed the strongest bending in the unsubstituted fulvene ligand (**28a**) and only a small amount of tilt angle for **28e**, which contains a conjugated 6π-electron system at the C6 atom of the fulvene ligand (Behrens, 1979; Lubke et al., 1983). Fulvene-$Cr(CO)_3$ complexes with different groups at C6 also showed an impact on the CO chemical shift of ^{13}C NMR and stretching frequencies by IR (Lubke et al., 1983). The bending angle and C6-Cr distance changes are consistent with the above α-ferrocenylmethylium ions. In general, electron-donating groups increase the electron density of the C6 center, thereby increasing σ-donation and decreasing carbenium backdonation, resulting in smaller tilt angle (α), larger CO chemical shift (δ) and lower $\upsilon_{(CO)}$.

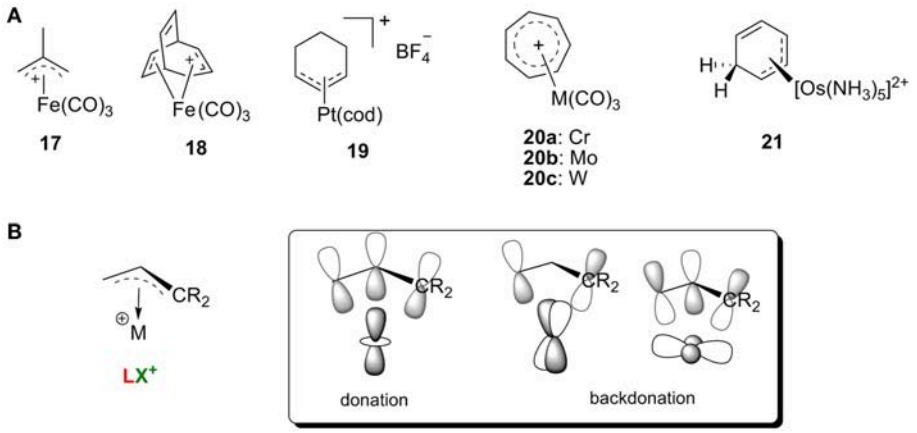

FIGURE 9 | (A) Selective transition metal-stabilized carbocations with conjugated ϕ-system, and **(B)** the correlating orbital model.

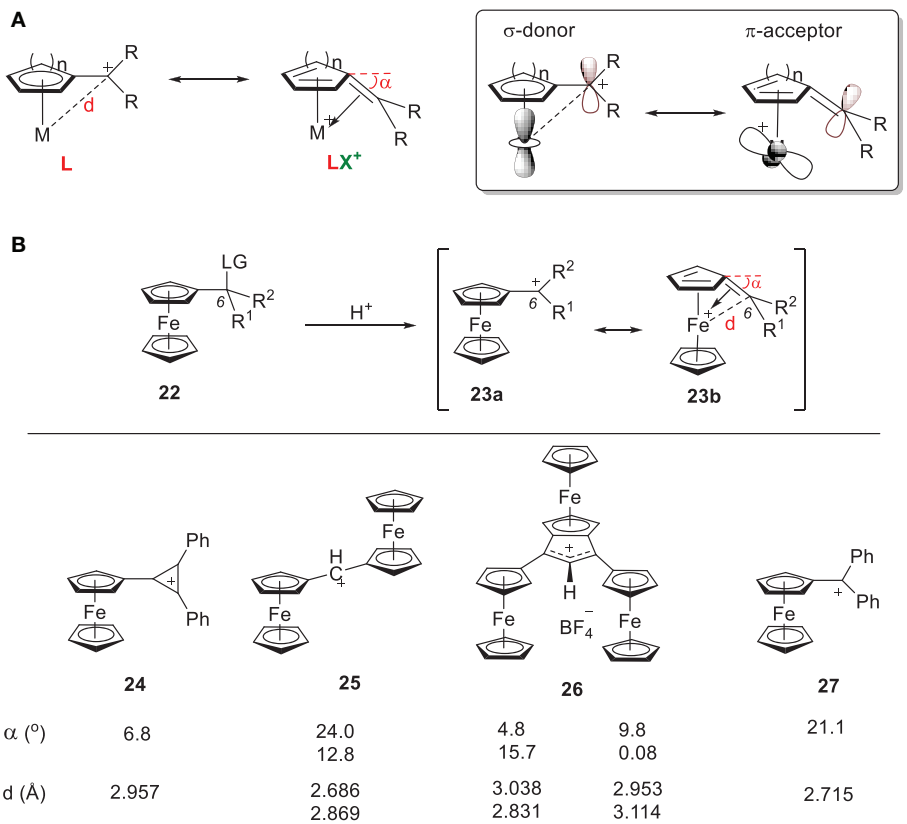

FIGURE 10 | (A) Two resonance forms of α-metallocenylmethylium cation and their orbitals. **(B)** Selected α-metallocenylmethylium cations and their general approach.

X-ray studies also showed that α-metallocenyl methylium cations show an increased metal-fulvene interaction with an increase in the metal's molecular mass. The bending angles for complexes **29a** (Kreindlin et al., 2000), **29b** (Kreindlin et al., 1987), and **29c** (Rybinskaya et al., 1989) are 22.7°, 38.2°, and 40.8°, respectively, (**Figure 11B**), which indicates a dramatic increase in metal-fulvene interactions. This is because a larger atomic radius leads to more overlap of filled metal d orbitals with the carbenium p orbital, resulting in strong carbenium backdonation and a large tilt angle (**Figure 10A**).

The effect of ligands has also been studied with DFT calculations (**Figure 11D**; Gleiter et al., 2007). We can see from MO diagrams that electron-rich ligands favor interactions with metal and carbenium centers [**Figure 11C,** Cp (**30**) > benzene (**31**) > CO (**32**)]. According to the orbital model, the electron-rich ligand can increase the electron density on the

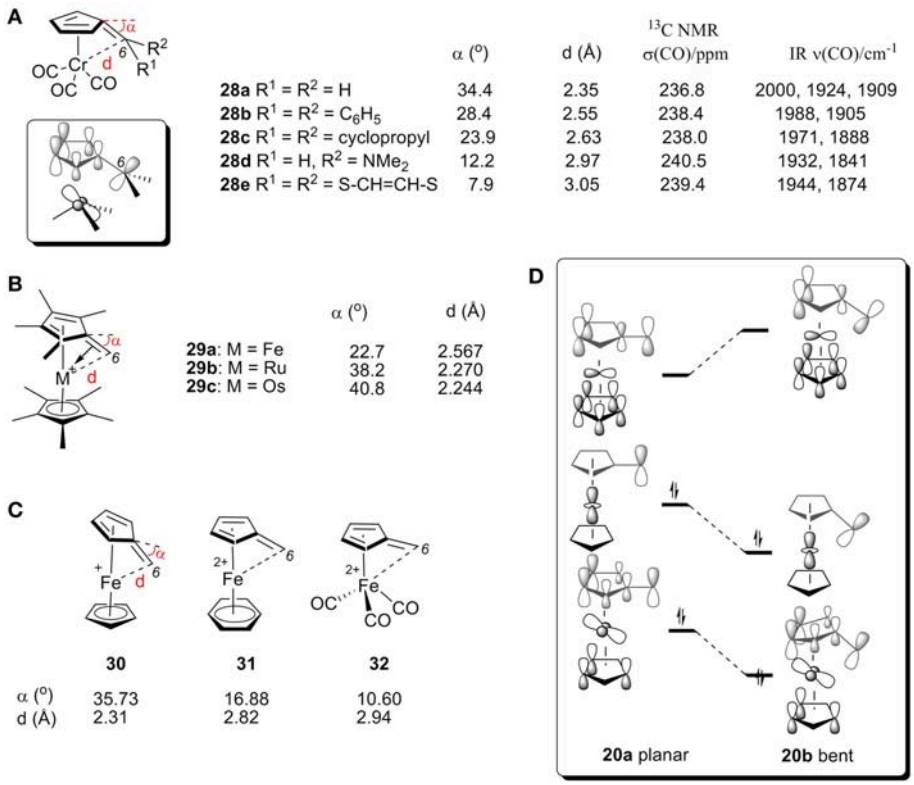

FIGURE 11 | (A) X-ray, ^{13}C NMR, and IR data for CO of complexes **28**. **(B)** Geometric parameters of complex **29** by X-ray analysis. **(C)** Geometric parameters of complexes **30-32** by DFT calculations. **(D)** Diagram between the frontier orbitals of a planar and bent α-ferrocenyl methylium ion.

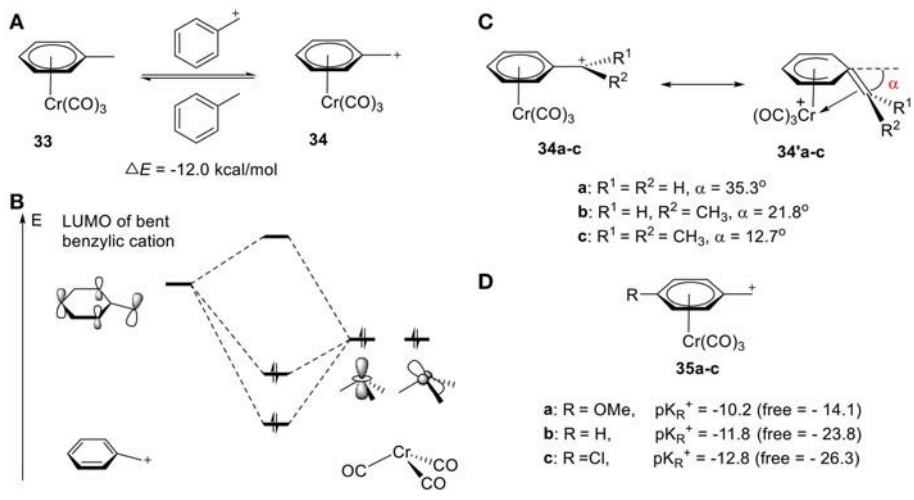

FIGURE 12 | (A) Chromium-stabilized carbocations. **(B)** Selected stabilizing orbital interactions between $Cr(CO)_3$ and benzylic cation. **(C)** Two resonance forms of Chromium-stabilized benzylic cations according to DFT calculation. **(D)** pK_R^+ values of different Cr-stabilized benzylic cations.

metal atom, resulting in carbenium backdonation and a large tilt angle.

Figure 11D shows the correlated frontier orbitals of a planar (left) and a bent structure (right) of α-ferrocenyl methylium ion (Gleiter et al., 2007; Bleiholder et al., 2009). When the bending angle increases, the LUMO is destabilized and the HOMO is stabilized, which can be rationalized by the increased bonding interaction between the C6 p orbital and the metal d-orbital of the HOMO and an increased antibonding interaction between the C6 and metal orbitals of the LUMO. As a result, electron density is transferred into an antibonding orbital between C1 and C6, resulting in a larger bending angle (α). Additionally, increasing

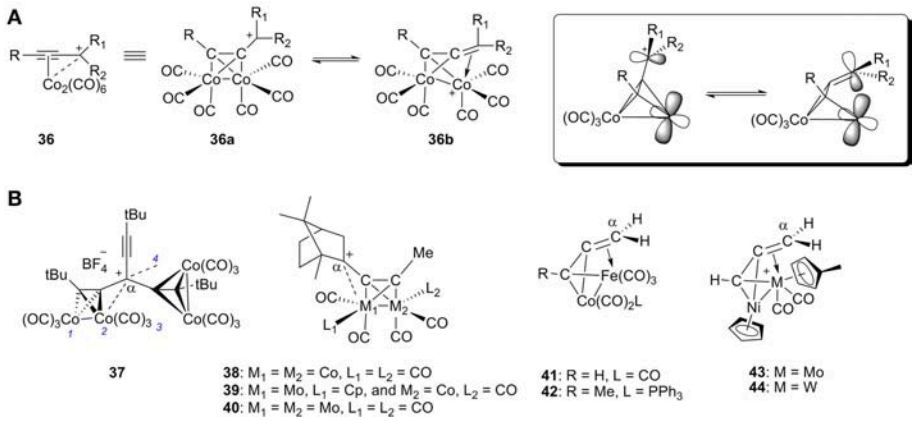

FIGURE 13 | (A) Two resonance forms of α-metallocenylmethylium cation and their orbitals. **(B)** Selected representative cationic bimetallic propargyl complexes.

the electron density of the metal center (e.g., heavier metal or electron-rich ligand) or decreasing the electron density of the carbenium center (e.g., electron-withdrawing group) will favor these interactions, leading to larger bending angle α.

Carbenium α to Aryl

Cr is well-established in its ability to stabilize carbocations, including benzylic, phenonium, and benzonorbornenyl cations (Tantillo et al., 2000; Merlic et al., 2001b; Konietzny et al., 2010; Davis et al., 2013). In 1999, the groups of Houk (Merlic et al., 1999) and Koch (Pfletschinger et al., 1999) pioneered the field through theoretical computations determining the stabilization of benzylic cations by chromium tricarbonyl. As shown in **Figure 12A**, the homodesmotic equation gives a ΔE of −12.0 kcal/mol, suggesting effective stabilization of the benzylic cation **34** by $Cr(CO)_3$ (**Figure 12A**). This stability is attributed to the other resonance form **34′**, in which the benzylic carbon bends down to coordinate to the Cr atom with an angle of 35.3°, 21.8°, and 12.7°, according to DFT calculations, for methyl, ethyl, and isopropyl cation, respectively, (**Figure 12C**; Merlic et al., 2001a). This is consistent with the substituent effects observed in **Figure 11A**. Electron-donating groups result in a smaller tilt angle (α), though steric repulsions are also likely contributive. The stability can also be rationalized in terms of orbital interactions between the hybrid fragment orbitals (Albright, 1982) of $Cr(CO)_3$ and the π molecular orbitals of benzylic cation (**Figure 12B**; Merlic et al., 2001a). In the case of the cation, the low-lying LUMO interacts strongly with the symmetric occupied hybrid metal orbitals. The overlap between the Cr and benzylic cation orbitals (especially the d_z^2-like metal orbital) is increased in two ways: (1) the distortion of the benzylic cation from planarity and, (2) shifting the chromium away from the center of the ring. Electron-donating groups can increase the electron density of C_α center and decrease carbenium backdonation, leading to a smaller tilt angle (α). These computed results are supported by the experimental pK_R^+ values of Cr-stabilized benzyl complexes **35a-c** (**Figure 12D**). The pK_R^+ increased sharply as compared to the corresponding free carbocations, indicating the stabilization of the carbocation by the Cr atom (**Figure 12D**). Additionally, more electron-deficient benzyl moieties (electron withdrawing groups) gain an even greater stabilization effect through increased π-backdonation (Trahanovsky and Wells, 1969; Cheng et al., 1993).

Carbocations α to Acyclic π-Systems (alkynyl)

Cobalt, especially cationic dicobalt propargyl complexes, have played a significant role in organic synthesis since their discovery (Nicholas and Pettit, 1971; Nicholas, 1987; McGlinchey et al., 1995; El Amouri and Gruselle, 1996; Amouri et al., 2000). In general, there are two resonance forms for this kind of propargyl cation complex **36**: (1) the cation acts as an L-type ligand by donating its filled π orbital electron density to the metal center, and (2) the cation acts as a LX^+ ligand by donating its filled π orbital electron density to the metal center with carbenium backdonation (**Figure 13A**). Both of these resonance forms provide stability to the carbocation.

A wide range of cationic dicobalt propargyl complexes or similar heterobimetallic complexes have been synthesized and characterized (**37**-**44**, **Figure 13B**; Gruselle et al., 1993; Osella et al., 1993; Melikyan et al., 1998; Chetcuti and McDonald, 2002). The propargyl cation always preferentially coordinates to one of the metal atoms in each cluster due to accumulation of positive charge. In studies of these heterobimetallic complexes, the propargyl cation prefers to coordinate to Mo and Fe instead of Co (**39**, **41,** and **42**) (Gruselle et al., 1993; Osella et al., 1993) as well as Mo and W instead of Ni (**43** and **44**) (Chetcuti and McDonald, 2002).

X-Ray Crystallography

Table 2 gives a summary of the M-C_α distance of the bimetallic complexes discussed above. In **37**, the distances between the carbocationic center and the cobalt atom are 3.07, 2.81, 3.27, and 2.89 Å, respectively, for Co1, Co2, Co3, and Co4. The 2-bornyl cation leans toward the Mo atom and the Mo-C_α distance is 2.74 Å for **39** and 2.91 Å for **40**. The preferential stabilization of the 2-bornyl cation by the molybdenum has also been rationalized with molecular orbital calculations at the

TABLE 2 | X-ray, IR, and ^{13}C NMR data for the complexes.

Complex	M-C_α distances (Å)	IR ν_{CO} (cm^{-1}) in DCM	IR ν_{CO} (cm^{-1}) in Hexane	^{13}C NMR δ(CO), ppm
37	Co1: 3.07 Co2: 2.81 Co3: 3.27 Co4: 2.89	–	–	194.4, 192.2
38	–	–	–	194.4, 192.2
39	2.74	–	–	–
40	2.91	–	–	227.1, 226.5, 223.0, 220.0
41	–	–	2,084 m, 2,041 vs. 2022 s, 2,014 m, 1,993 m, 1,981 m	210.3, $Fe(CO)_3$; 203.0, $Co(CO)_3$
42	2.20	–	2,052 vs. 2,003 s, 1,989 vs. 1,968 m	211.2, $Fe(CO)_3$; 207.3, 205.1, $Co(CO)_2$
43	–	2,049 s, 2,019 s, 1,966 m	–	–
44	–	2,047 m, 2,013 s, 1,989 w, 1,966 vw	–	–

extended Hückel level (Gruselle et al., 1993). Cations **38**-**40** do not undergo Wagner-Meerwein rearrangement as a result of their stabilization, which otherwise occurs readily for uncomplexed 2-alkynylbornyl cations. For **42**, the Fe-C_α distance is 2.195 Å. The preferential coordination of C_α with Fe has been explained by the model cluster **41** by means of extended Hückel molecular orbital calculations (Osella et al., 1993).

IR and ^{13}C NMR Spectroscopy

Table 2 also gives a summary of the IR and ^{13}C NMR data of the above bimetallic complexes. Generally, the IR ν_{CO} stretching frequencies of these cations are shifted to higher values (over 2000 cm^{-1}) compared to their corresponding neutral precusors (Osella et al., 1993; Chetcuti and McDonald, 2002). In dicobalt cation **27**, the ^{13}C NMR CO signals appear at approximately 194 ppm. Analogously, stabilization of a propargyl cation by a molybdenum center results in a shielding of the molybdenum carbonyl signals from approximately 230–220 ppm in **40** (Gruselle et al., 1993). For **41** and **42**, stabilization of a propargyl cation by an iron center shifts the carbonyl resonances to approximately 210 ppm, while the cobalt carbonyl resonances are around 203–208 ppm (Osella et al., 1993).

This stabilization can be explained in terms of orbital interactions between the metal's d orbital and the π molecular orbitals of the propargyl cation in **Figure 13A** (Gruselle et al., 1993; McGlinchey et al., 1995). The overlap between the orbitals of the metal center and of the propargyl cation (especially the d_z^2-like metal orbital) is increased by the shorter M-C_α distance, resulting from the propargyl cation bending toward the metal. The preferential coordination with a heavier metal within the heterobimetallic cations **39, 40**, and **43** is consistent with the reactivities of complex **20** and the conclusion in **Figure 9B**. However, in complexes **41**-**43**, the carbocation is bound to the lighter element, Fe. This can be explained by considering the isolobal relationship between $Co(CO)_3^+$ and $Fe(CO)_3$ (McGlinchey et al., 1995). The neutral Fe can provide more effective overlap of filled metal d orbitals with the carbenium's p orbital than Co^+, which makes the interaction with Fe more attractive. The coordination of the metal with the cation also induced higher CO stretching frequencies in IR and larger chemical shifts for CO in ^{13}C NMR.

CONCLUSION

We proposed two major bonding modes for the orbital interactions between carbeniums and metal centers in σ- and π-complexes. Most of the reported transition metal-carbocation complexes can fall into one of these two categories. In general, heavier metal atoms have larger radii, which can lead to stronger backdonation of filled d orbitals on the metal atom and greater stabilization of carbocations. In addition, electron-donating groups on the carbocations can increase the electron density of carbon center, thus increasing σ-donation while decreasing carbenium backdonation. This results in weaker transition metal-carbocation interactions. On the other hand, an electron-rich ligand can increase the electron density on the metal atom, resulting in carbenium backdonation and greater stabilization. The stabilization of carbocations by the transition metal has been unambiguously demonstrated with higher pK_R^+ values in comparison to the corresponding free carbocations.

Transition metal-stabilized carbocations have been observed and characterized throughout the last century, but there is no comprehensive summary of the bonding modes of these transition metal-carbocation complexes. To our surprise, most of this research was conducted and reported before 2000 and little attention has been given to the field during the last decades, even though much remains unknown about their properties, reactivities, and carbocation interactions with other transition metals (e.g., Pd, Rh, Ir, Ni). Because of their considerable synthetic value, it is of great importance to bring these metal-carbocation interactions back to the interest of the scientific community.

Nanoscience

Ardemis A. Boghossian

Ardemis Boghossian is a tenure-track Assistant Professor at the École Polytechnique Fédérale de Lausanne (EPFL) in Switzerland. She obtained her BEng in Chemical Engineering from the University of Michigan in Ann Arbor, MI in 2007 and her PhD in Chemical Engineering from the Massachusetts Institute of Technology (MIT) in 2012 under the supervision of Michael S. Strano. She pursued her postdoctoral studies in the laboratory of Nobel Laureate Frances H. Arnold at the California Institute of Technology (Caltech) until she started her Professorship in 2015.

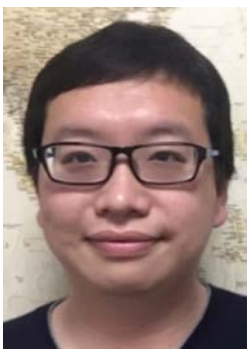
Farhat Nosheen

Dr Farhat Nosheen obtained her PhD degree in Chemistry from the Department of Chemistry, Tsinghua University, Beijing, China in 2016. Currently, she works as Assistant Professor at the Department of Chemistry, University of Education, Lahore, Jauharabad campus, Pakistan. Her research interests include synthesis, formation mechanisms, and electrocatalytic applications of noble metal based bi-and multimetallic nanostructures in fuel cells.

. Jianping Yang

Prof. Jianping Yang obtained the PhD degree in 2013 from Fudan University supervised by Professor Dongyuan Zhao. He then worked as a postdoctoral fellow at Tongji University, a visiting research fellow at the University of Wollongong and Monash University, and was promoted to full Professor in 2016 at Donghua University, China. His research interest include multifunctional materials *via* surface and interface controllable synthesis in the application of energy storage including Si-based lithium ion batteries, carbon-based sodium/potassium ion batteries, as well as in the application of environmental remediation such as catalytic reduction of nitrogen oxide exhaust, electrocatalytic abatement and adsorption of water pollutants.

Wei Luo



Dr Wei Luo is now a Professor at the State Key Laboratory for Modification of Chemical Fibers and Polymer Materials, College of Materials Science and Engineering at Donghua University. He obtained a Bachelor's degree in 2006 and Master's degree in 2009 from Nanjing Tech University, China. He obtained his PhD in chemistry in 2014 from Fudan University supervised by Professor Dongyuan Zhao. He received second prize of the Natural Science Award of Ministry of Education (the third awardee). His research interests mainly include the synthesis of functional mesoporous and nanomaterials for energy storage and conversion as well as sensors.

Lukasz Marciniak

Lukasz Marciniak received his MSc Eng in Physics (Photonics) from the Wroclaw University of Technology in Wroclaw, Poland, in 2009 and a PhD and habilitation in Physics from the Institute of Low Temperature and Structure Research, Polish Academy of Sciences, in 2014 and 2017, respectively. Holder of numerous awards and prizes (e.g. the Scholarship of Ministry of Science and Higher Education of Poland for Young and Outstanding Scientists 2015-2018, the START 2015 and START 2016 of Foundation for Polish Science FNP for outstanding young scientists, the gold medal of Brussels Innova 2015 and 2016, the Award of the Polish Minister of Science and Higher Education for his achievements in the international arena inventive in 2014, the Scientific Award of Wroclaw Department of Polish Academy of Sciences 'Iuvenes Wratislaviae' 2017 and the Scientific Award of "Polityka" 2018). He is the Principal Investigator in FNP First Team, NCS Opus, NCS Sonata, and the NSC Preludium. He has co-authored 90 publications and holds three patents with six patents applications. His current research focuses on nanocrystalline luminescent thermometry of lanthanide and transition metal ions doped inorganic structures.

Juewen Liu

Juewen Liu is currently a Professor of Chemistry and a University Research Chair at the University of Waterloo. Dr Liu is interested in bioanalytical chemistry, catalytic DNA and aptamers, and biointerface chemistry. He received a Fred Beamish Award from the Canadian Society for Chemistry (CSC) in 2014, and the McBryde Medal in 2018. He has published over 300 papers, receiving over 20,000 citations and has an H-index of 65. He is an Associate Editor of *Analytical Methods* and is on the Editorial Advisory Board of *Langmuir*.

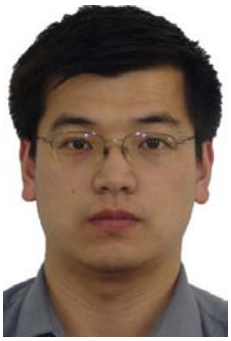
Lining Sun

Lining Sun is a Professor of Chemistry and Material Science in Shanghai University. She obtained her BSc degree from Shandong Normal University in 2002 and a PhD degree from the Changchun Institute of Applied Chemistry, Chinese Academy of Sciences at the end of 2007. From 2008 to 2009, she was an Alexander-von-Humboldt Research Fellow at the University of Regensburg, Germany. In September 2009, she joined Shanghai University as an Associate Professor, and since March 2016, she has worked as a full Professor. Her research focuses on rare-earth doped upconversion luminescent nanomaterials for sensing, bioimaging, and treatment.

Qianqian Su

Qianqian Su obtained her BE degree in Materials Science and Engineering from Shandong University. She obtained her MSc degree from Guangzhou Institute of Chemistry, Chinese Academy of Sciences and completed her PhD degree under the supervision of Professor Xiaogang Liu at the National University of Singapore. She worked as a research fellow at Fudan University with Professor Fuyou Li. Shen worked as a visiting scholar at the National University of Singapore and the University of Technology Sydney. She joined the Institute of Nanochemistry and Nanobiology at Shanghai University in 2017. Her research interests focus on the development of novel luminescent nanomaterials for biomedical applications.

Renyuan Zhang



Renyuan Zhang is an Associate Professor at the Institute of New Energy for Vehicles, School of Materials Science and Engineering, Tongji University. He obtained both his Bachelor's degree in 2004, and PhD Degree in 2010 from Fudan University, supervised by of Prof. Dongyuan Zhao. He then worked as a post-doctoral researcher at the Lab of Advanced Materials, Fudan University. His current research interests include synthesis of functional nanomaterials and mesoporous materials for catalysis, energy storage and conversion.

CuiYun Yu

Dr Cui-Yun Yu is a Professor of Pharmacy and serves as the duty director of Hunan Province Cooperative Innovation Center for Molecular Target New Drug at the University of South China. She obtained her PhD degree in Polymer Science in 2009 from Wuhan University. Dr Yu is currently leading various critical national foundations including the National Key R&D Program of China and the National Natural Science Foundation of China. Her research interests focus on the design and development of novel biomaterials for tumor targeted drug delivery. Thus far, she has published more than 30 peer reviewed papers in leading journals such as ACS Applied Materials &Interface, Biomaterials Science, Molecular Pharmaceutics.

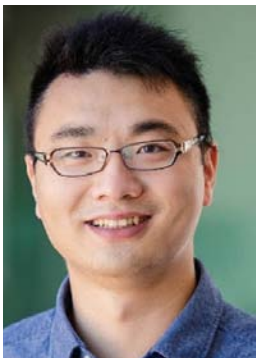
Lidan Hu

Lidan Hu obtained her PhD degree from Xiamen University in 2016. She then joined Prof. Fan Zhang's Laboratory of Nanobio in the Chemistry Department of Fudan University, as a postdoctoral fellow. In 2018, Dr Hu joined the University of South China. Her research focuses on the design, synthesis, and biomedical applications of persistent luminescence materials.

Ou Chen

Ou Chen is an Assistant Professor in the Department of Chemistry at the Brown University. He obtained his BSc degree in Chemical Physics from the University of Science and Technology of China (USTC) in 2004 and completed his PhD study in the Department of Chemistry at the University of Florida. He worked with Prof. Moungi Bawendi as a postdoctoral associate at MIT. His current research interests lie on exploring novel methodologies for generating functional nanocrystals, quantum dots and their self-assembled superstructures for energy- and bio-related applications.

Chun Xu



Dr Chun Xu obtained his PhD in Biomedical Engineering and Nanotechnology at The University of Queensland, Australia in 2016. Before that, he obtained a MDS in Oral and Maxillofacial Surgery and a BDS in Dentistry from Wuhan University, China. He is currently a NHMRC Senior Research Officer and C.J. Martin fellow at The University of Queensland. His research interest includes the synthesis of nanomaterials and their biomedical applications including drug delivery and tissue engineering.

Non-covalent Methods of Engineering Optical Sensors Based on Single-Walled Carbon Nanotubes

*Alice J. Gillen and Ardemis A. Boghossian**

École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

Optical sensors based on single-walled carbon nanotubes (SWCNTs) demonstrate tradeoffs that limit their use in *in vivo* and *in vitro* environments. Sensor characteristics are primarily governed by the non-covalent wrapping used to suspend the hydrophobic SWCNTs in aqueous solutions, and we herein review the advantages and disadvantages of several of these different wrappings. Sensors based on surfactant wrappings can show enhanced quantum efficiency, high stability, scalability, and diminished selectivity. Conversely, sensors based on synthetic and bio-polymer wrappings tend to show lower quantum efficiency, stability, and scalability, while demonstrating improved selectivity. Major efforts have focused on optimizing sensors based on DNA wrappings, which have intermediate properties that can be improved through synthetic modifications. Although SWCNT sensors have, to date, been mainly engineered using empirical approaches, herein we highlight alternative techniques based on iterative screening that offer a more guided approach to tuning sensor properties. These more rational techniques can yield new combinations that incorporate the advantages of the diverse nanotube wrappings available to create high performance optical sensors.

Keywords: optical biosensing, near-infrared sensors, single-walled carbon nanotubes (SWCNTs or SWNTs), molecular recognition, selectivity, fluorescence brightness, non-covalent solubilization

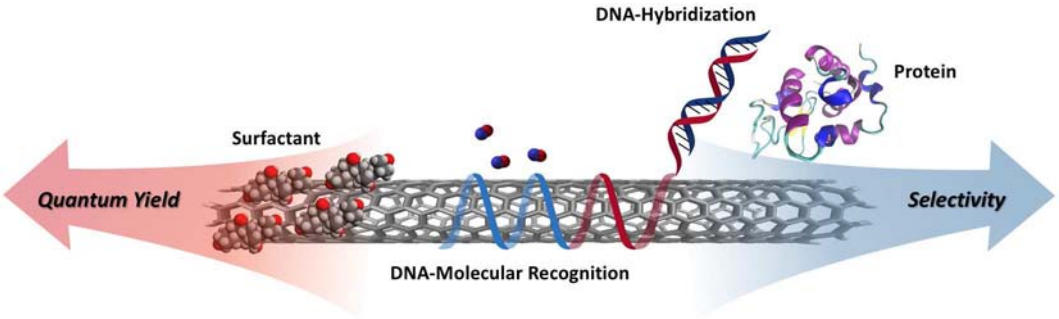
1. INTRODUCTION

Optical sensors use light as a means of contactless detection for real-time sensing. Distinct optical signals from a single device enables multimodal detection of several analytes simultaneously, a feature that is especially advantageous for remote *in vivo* biosensing applications. Fluorescence-based optical sensors require two elements for operation: a molecular recognition element that selectively interacts with the analyte of interest and an optical transducer, such as a fluorophore, that converts this interaction into a measurable optical signal.

As described in several reviews (Boghossian et al., 2011; Liu et al., 2011; Kruss et al., 2013; Pan et al., 2017), single-walled carbon nanotubes (SWCNTs) are among the most promising fluorescence-based transducers for biosensing applications. They are one-dimensional nanostructures with optoelectronic properties that are tuned by tube diameter as a result of quantum confinement. Conceptualized as cylindrically rolled sheets of graphene, SWCNTs exist with various diameters, and they can be either metallic, semi-metallic, or semiconducting, depending on the direction the sheet is rolled. In 2002, O'Connell et al. demonstrated that



GRAPHICAL ABSTRACT | Schematic illustrating the tradeoffs between quantum yield and selectivity for various non-covalent surface functionalizations.

semiconducting forms of SWCNTs dispersed in aqueous solutions emit photoluminescence at near-infrared (near-IR) wavelengths (O'Connell et al., 2002). This emission lies within the optical transparency window for biological material (Boghossian et al., 2011) which, when coupled with the nanotube's indefinite photostability and capabilities for single-molecule detection, makes SWCNTs attractive for *in vivo* continuous monitoring applications.

The use of SWCNTs as fluorescent transducers requires surface functionalization to impart optical stability and molecular recognition. Non-functionalized SWCNTs are inherently hydrophobic and exhibit a strong tendency to aggregate into bundles in aqueous solutions. Since most SWCNT preparations contain metallic nanotubes, these bundles contribute to the fluorescence quenching of semiconducting SWCNTs through the non-radiative exciton decay channels within the bundle (O'Connell et al., 2002; Maeda et al., 2004). Therefore, the bundles need to be exfoliated to generate individually suspended nanotubes in a liquid phase for most practical applications (Coleman, 2009). Specifically, this suspension allows the semi-conducting nanotubes to fluoresce in the near-IR. In addition to enabling solubilization and fluorescence, surface functionalization can also modify the nanotube surface to promote selective interactions with particular analytes of interest (**Figure 1**). The underlying mechanism for this selectivity depends on the wrapping and remains an ongoing area of research for many wrappings (Jeng et al., 2006; Hertel et al., 2010; Bisker et al., 2016; Polo and Kruss, 2016; Antonucci et al., 2017; Kruss et al., 2017; Mann et al., 2017; Zubkovs et al., 2017; Gillen et al., 2018; Wu et al., 2018; Lambert et al., 2019).

Since covalent functionalization of the nanotube surface is known to strongly affect, or even diminish, the nanotube fluorescence, non-covalent modifications are typically used for creating optical sensors. The most common approach for non-covalently separating SWCNT bundles is liquid-phase exfoliation and stabilization (Coleman, 2009). This approach typically involves using forced dispersion (with sonication, for example) in the presence of wrappings, such as surfactants, synthetic polymers, oligonucleotides, and proteins that can stabilize the suspended SWCNTs (**Figure 2**). In addition to improving the solubility of the SWCNTs, these wrappings can also impart secondary characteristics, such as enhanced bio-compatibility and improved molecular sensitivity, overcoming problems associated with the chemical inertness of raw SWCNTs (Saifuddin et al., 2013).

In this review, we present an overview of several key methods used for the non-covalent functionalization of SWCNTs. Beginning with surfactant-coated SWCNTs, we progress toward the use of biomolecules to suspend nanotubes, highlighting key advantages and disadvantages associated with each wrapping. Finally, we conclude with a consideration of new approaches aimed at overcoming some of the limitations of both surfactant- and biomolecule-suspended SWCNTs. These examples highlight emerging methods to selectively engineer improved SWCNT-based optical sensors in complex environments.

2. SURFACTANT-COATED SWCNTS

Surfactant-coated SWCNTs represent a standard comparative benchmark for nanotube suspensions, particularly with respect to achieving scalable wrapping procedures and the high quantum yields necessary for optical sensing. Historically, the first reported suspensions of individual SWCNTs were achieved using an aqueous surfactant, sodium dodecylsulfate (SDS) (O'Connell et al., 2001, 2002; Bachilo et al., 2002). The resulting isolation of the nanotubes from surrounding bundles greatly improved the optical resolution of the absorbance spectra. Additionally, the authors were able to characterize the direct band gap of individual semiconducting SWCNTs with fluorescence spectroscopy (Bachilo et al., 2002; O'Connell et al., 2002), which was first hypothesized in the early 1990s (Dresselhaus et al., 1992; Hamada et al., 1992; Saito et al., 1992) and previously detected using Raman and STEM (Wildoer et al., 1998; Kataura et al., 1999).

To prevent re-bundling and obtain a thermodynamically stable suspension, the strong cohesion energy of the isolated tubes (~120 kT nm^{-1}) must be compensated by either tube-solvent, or in the case of surfactant-suspended SWCNTs, tube-surfactant interactions (Angelikopoulos and Bock, 2012). However, SWCNT suspensions often exist in a kinetically

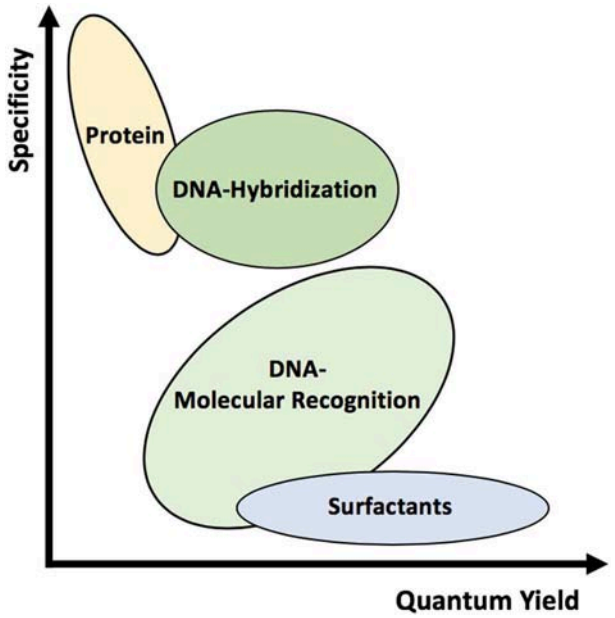


FIGURE 1 | Schematic representation of the various wrappings used to suspend SWCNTs. Different wrappings can alter the quantum yield and specificity of the complexes.

meta-stable state. Kinetic stabilization does not fully overcome the cohesion energy of the tubes; instead the surfactant creates a repulsive force between the tubes that reduces the likelihood of forming tube-tube contacts, hence slowing aggregation (Angelikopoulos and Bock, 2012). Similar to the interactions in the kinetic stabilization of colloids (Tummala and Striolo, 2008, 2009; Angelikopoulos and Bock, 2012; Kato et al., 2012; Oh et al., 2013). Previous studies hypothesized that the individual nanotubes are encased in the hydrophobic interiors of the micelle. The hydrophilic part of the surfactant molecules is believed to face outwards, creating a cylindrical micelle and a repulsive force between the nanotubes that renders a thermodynamically meta-stable suspension (**Figure 3**) (Angelikopoulos and Bock, 2008, 2012).

The use of surfactants to suspend SWCNTs has since expanded to include other anionic, cationic, and non-ionic surfactants (Hirsch, 2002; Wenseleers et al., 2004; Crochet et al., 2007; Haggenmueller et al., 2008; Blanch et al., 2010; Bergler et al., 2016; Nonoguchi et al., 2018), such as sodium cholate (SC), sodium deoxycholate (SDOC), sodium dodecylbenzenesulfonate (SDBS), lithium dodecyl sulfate (LDS), Triton X-100, and pluronic F127. Depending on the surfactant, high-quality dispersions can be achieved with large populations of individualized nanotubes (Coleman, 2009) and SWCNT concentrations >1 mg/mL. However, different surfactants have been found to vary greatly in the degree of dispersion and stability of the resulting suspensions. This variation is, in part, attributed to the interactions between the surfactant and nanotube, which result in the formation of different structures with varying degrees of surface coverage (Matarredona et al., 2003). In addition to cylindrical micelle SWCNT encapsulation, as was proposed for the SDS-suspended SWCNTs, two additional configurations include (Angelikopoulos and Bock, 2012; Xin et al., 2013) (i) Langmuir-type (random molecular adsorption) layers and (ii) adsorbed spherical and hemispherical micelles (Islam et al., 2003; Vo et al., 2016; Vo and Papavassiliou, 2017) (**Figure 3A**). The latter, spherical and hemispherical micelle formation, is adopted only by strong amphiphiles that prefer higher curvature aggregates. This formation of hemimicellar aggregates on the surface of the SWCNTs typically involves adsorption of the surfactant onto the nanotube followed by the self-assembly of the molecules, which is enabled by diffusion along the nanotube surface (Vo et al., 2016). In contrast, the former, random adsorption of the surfactant on the SWCNT surface, is adopted by weakly amphiphilic molecules [such as flavin mononucleotides (FMN)] and bile acid surfactants (including SC and SDOC) where adsorption is competitive, i.e., follows a Langmuir isotherm (Angelikopoulos and Bock, 2010, 2012; Tummala et al., 2010; Bergler et al., 2016; Xu et al., 2017).

According to both experiment and simulation, the degree of exposed SWCNT surface coverage following adsorption of surfactant molecules under all three regimes is largely dependent on surfactant concentration (Matarredona et al., 2003). Indeed, Wang et al. (2004) have shown that for Triton-X, the optimal surfactant dispersion concentration is different from the critical micelle concentration (CMC) and results from competition between maximizing surfactant adsorption on the nanotube surface and micelle-mediated depletion interactions between adjacent SWCNT bundles. Moreover, previous reports have shown vast differences in the maximum relative solubility of SWCNT complexes using the same surfactant, with an apparent dependence on the processing method and conditions. For example, suspensions made with SDBS can have maximum SWCNT concentrations of 20 mg/mL (Islam et al., 2003) or no more than ∼0.01 mg/mL (Moore et al., 2003), depending on the dispersion approach.

Another factor believed to impact the stability of surfactant-dispersed SWCNTs is the ζ-potential. When surfactant molecules adsorb onto the surface of SWCNTs, the surfactant counter-ion (commonly Na^+ or Li^+) is dissociated from the hydrophilic head group of the surfactant. These counter-ions are spatially separated from the tail group of the molecular ions, arranging in a diffuse cloud that acts as a multi-pole. As a result, surfactant-suspended nanotubes appear, from a distance, to carry an effective charge associated with this double layer, which is denoted as the ζ-potential (Coleman, 2009). This potential is equivalent to the electrostatic potential measured at the edge of the layer at the bound surfactant tail groups, and it acts as a repulsive interaction potential between neighboring SWCNTs. In a study by Sun et al. (2008), the dispersion quality of six surfactant molecules was tested. Each of the dispersion-quality metrics were found to scale well with the measured ζ-potential of the dispersion, with SDS suspending better than both SDBS and SC, corresponding to ζ-potential values of −70.0, −68.8, and −48.8 mV, respectively. These findings indicate that the dispersion quality

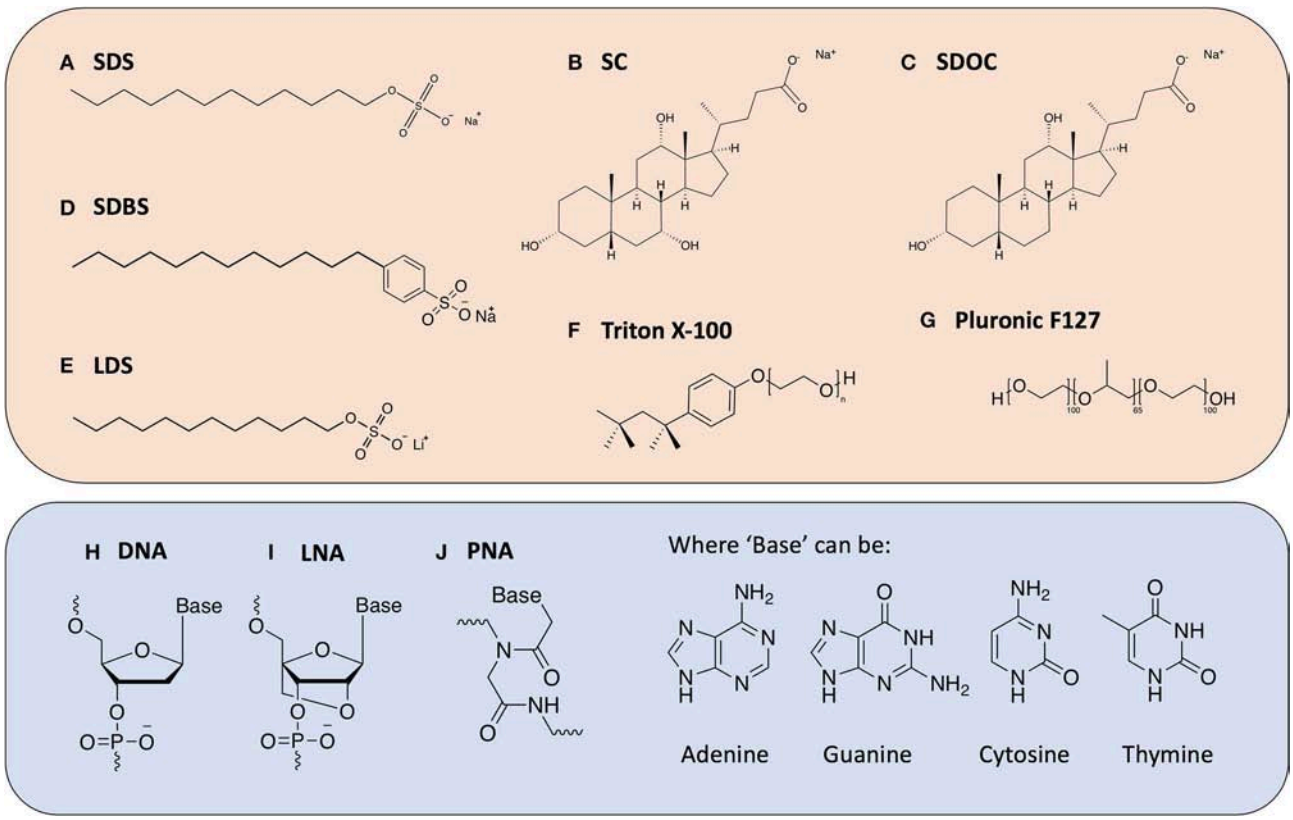

FIGURE 2 | Chemical structures of the various dispersants discussed in this review. of surfactant-SWCNTs may be controlled by the magnitude of the electrostatic repulsive forces between the coated SWCNTs (White et al., 2007; Sun et al., 2008), a property that can be tuned in order to improve the long-term stability of these solutions.

Given the dependence of maximum dispersion concentration and stability on surfactant type, we focus the remainder of our discussion on the four most commonly used surfactants for SWCNT suspension, SC, SDOC, SDS, and SDBS. These surfactants have been shown to achieve stable dispersions with suspension efficiencies above 40% (Haggenmueller et al., 2008). Despite the similar structures of SC and SDOC, which only differ by a hydroxy group, SDOC shows a marked increase in suspension yield (+17%). In addition to dispersion efficiency, the resolution of the optical absorption spectrum can be used to determine differences in the quality of SWCNT suspensions. Distinct absorption peaks are observed for both SC and SDOC, while SDS and SDBS show much broader peaks. In instances where SWCNTs are not effectively exfoliated, the van der Waals interactions between aggregated nanotubes result in broad, weak absorption peaks (Antonucci et al., 2017). This observation therefore suggests that SC and SDOC can generally yield more monodisperse SWCNTs under the studied preparation conditions. On the other hand, the broader peaks observed for SDS and SDBS indicate that these surfactants do not effectively de-bundle the nanotubes, resulting in a poorer dispersion quality despite the apparently high suspension yields.

In addition to their high dispersion efficiencies, these surfactants also benefit from a number of additional advantages. Compared to most biopolymers, these wrappings yield SWCNT suspensions that are relatively cheap and stable, and the preparation procedures are scalable enough to produce large volumes of monodisperse SWCNTs, which is an important consideration for the industrialization of nanotube sensors. Furthermore, surfactant-suspended SWCNTs typically exhibit much larger suspension (Coleman, 2009) and quantum yield values (Haggenmueller et al., 2008) compared to both protein- and DNA-suspended SWCNTs. The increased fluorescence intensity is attributed, in part, to the increased surface coverage of the surfactant on the SWCNT surface. The increased coverage results in higher levels of oxygen and water shielding, which has been shown to decrease nanotube fluorescence (Zheng et al., 2017), thereby leading to brighter SWCNT complexes. This increase in brightness is particularly important for biosensing applications, where penetration depth and sensor sensitivity have

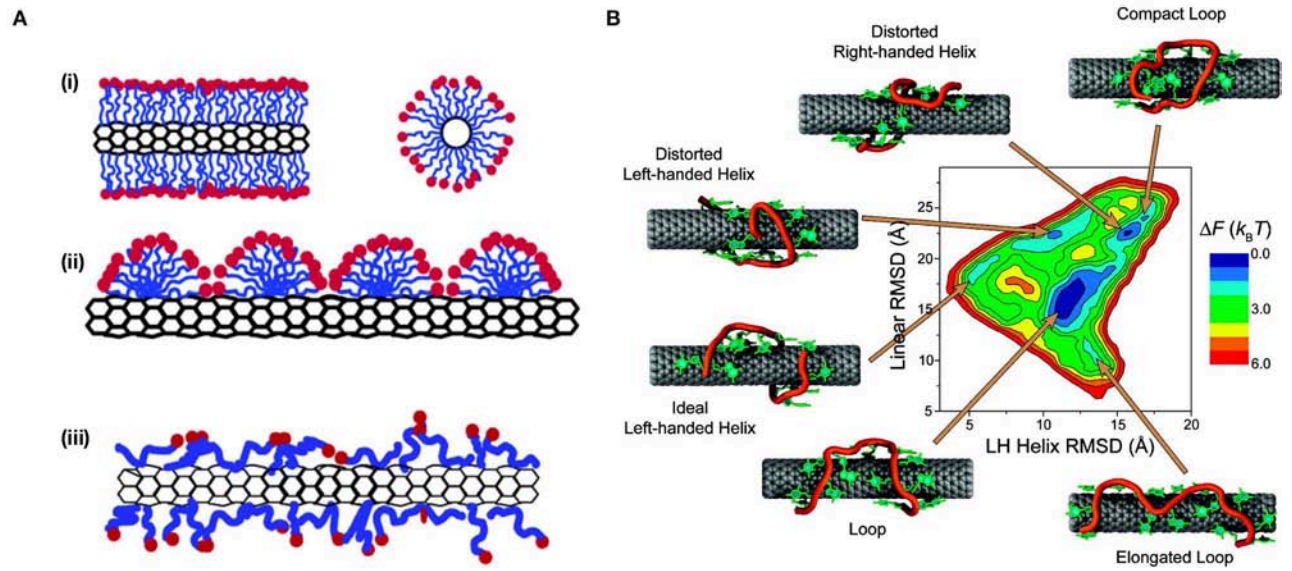

FIGURE 3 | Conformations of non-selective wrappings on SWCNT surface. **(A)** A schematic representation of the various mechanisms by which surfactant molecules interact and disperse SWCNTs. **(i)** Cylindrical micelle encapsulation; **(ii)** Hemimicellar adsorption; and **(iii)** Random adsorption. been linked to quantum yield (Yum et al., 2013; Bonis-O'Donnell et al., 2017, 2019; Beyene et al., 2018).

Toxicity is an additional metric when considering surfactant-suspended SWCNTs for *in vitro* and *in vivo* biosensing applications. Surfactants allow SWCNTs to disperse in water, the universal and biological solvent, permitting researchers to flexibly carry out a variety of environmental, biocompatibility, and safety analyses (Coleman, 2009). However, certain surfactants, such as SDS and SDBS, are known to be cytotoxic to cells even at concentrations as low as 0.05 mg ml^{-1} (Dong et al., 2008), and similar effects have been observed for nanotubes suspended with these surfactants (Dong et al., 2008, 2009). In studies performed by Dong et al. (2008) and Dong et al. (2009), neither the proliferation nor viability of the cells was affected by pristine SWCNTs in the absence of surfactant. Furthermore, conjugates of SWCNTs suspended with various concentrations of SC also showed no negative impact on cell viability and growth, and proliferation was comparable to that of untreated cells. The observed cytotoxicity of the nanotube-surfactant conjugates was therefore believed to be driven by the inherent cytotoxicity of the surfactant in the suspension (Dong et al., 2008, 2009). These studies illustrate the importance surfactant selection in overcoming challenges in toxicity. Although issues such as toxicity can be mitigated through appropriate selection of surfactant type and concentration, surfactant-suspended SWCNTs are limited for biosensing applications due to their lack of inherent selectivity. As a result, current efforts focus on the use of alternative wrappings to suspend SWCNTs, including biopolymers, such as single-stranded DNA (ssDNA) and proteins.

3. BIOPOLYMER-SUSPENDED SWCNTS

DNA is one of the most extensively studied wrappings for optical sensing applications based on Raman, fluorescence, and absorption spectroscopies (Zheng et al., 2003a; Heller et al., 2006; Enyashin et al., 2007; Zhang et al., 2011; Bansal et al., 2013; Kupis-Rozmysłowicz et al., 2016; Wu et al., 2018). The non-covalent functionalization of ssDNA is based on π-stacking of the aromatic nucleotide bases with the sp^2-hybridized side-wall of carbon nanotubes (Zheng et al., 2003a). This arrangement exposes the negatively charged sugar-phosphate backbone of the DNA, which is hydrophilic and easily solvated, toward the water, enabling suspension of the DNA-SWCNT complexes in aqueous solutions (Zheng et al., 2003a). These favorable side-wall-DNA and DNA-water interactions yield suspensions that are facile and stable at room temperature for several months (Zheng et al., 2003a). Work carried out by Zheng et al. (2003a) showed that almost any ssDNA sequence could be used to successfully suspend SWCNTs in the presence of a denaturant and mild sonication. Although atomic force microscopy (AFM) measurements and simulations show DNA to helically self-assemble around the SWCNT (Zheng et al., 2003a,b), the final binding structure has been shown to be sequence-dependent, and short ssDNA strands may also assume other configurations on the nanotube surface (Zheng et al., 2003a; Johnson et al., 2008, 2009) (**Figure 3B**). The sparser surface coverage of the DNA compared to surfactants such as SC exposes a larger carbon surface to water, resulting in a decrease in the intensity and emission energy of the SWCNT fluorescence. For example, the (7,5) chirality undergoes a bathochromic shift of 17.6 meV

(15.6 nm) when wrapped in ssDNA instead of SC due to the greater water accessibility of the DNA wrapping and the resulting increase in the local dielectric constant at the nanotube surface (Jeng et al., 2006; Li and Shi, 2014). Such changes in the local dielectric have been shown to yield an expected fluorescence shift in SWCNT emission peaks (Choi and Strano, 2007).

In addition to the facile suspension procedure and stable assembly, ssDNA benefits from additional features ideal for scale-up sensor design. DNA-wrapped SWCNT suspensions can be further concentrated to achieve dispersion yields as high as 4 mg ml^{-1} (Zheng et al., 2003a). Additionally, the nearly limitless variability in sequence length and composition, as well as the well-established chemistries available for DNA functionalization, make ssDNA an incredibly malleable polymer for tuning the characteristics of the suspended SWCNTs. For example, Zheng et al. modified DNA-SWCNTs at one end with biotin that was used for immobilization onto streptavidin-coated beads (Zheng et al., 2003a). This study demonstrates one of many biochemical approaches for controlling DNA-SWCNT behavior by specifically engineering DNA-SWCNT complexes. Furthermore, both sequence length and base composition has been shown to impact the interaction potential of ssDNA with the surface of SWCNTs (Zheng et al., 2003a; Safaee et al., 2019), which has also recently been shown to vary with SWCNT chirality (Jena et al., 2017; Safaee et al., 2019).

The ability of DNA to form chirality-specific interactions has been exploited for a variety of applications, most notably, chirality separation. Chirality separation is key for multi-modal sensing applications where each chirality selectively responds to a distinct analyte in a solution mixture. Following separation, the individual chiralities can each be functionalized with a wrapping that selectively responds to a particular analyte of interest, and the analyte is detected by monitoring the corresponding wavelength. Many separation mechanisms have been devised (Chattopadhyay et al., 2003; Krupke et al., 2003, 2004; Zheng et al., 2003a,b; Heller et al., 2004; Strano et al., 2004; Huang et al., 2005; Lustig et al., 2005; Arnold et al., 2006; Peng et al., 2006; Zheng and Semke, 2007; Tu and Zheng, 2008; Tu et al., 2009; Zhang et al., 2015) with varying degrees of success; however, a facile approach for scalable, complete and total fractionation into all the single chiralities remains elusive. Aqueous two-phase polymer (ATP) separation (Khripin et al., 2013; Ao et al., 2014, 2016; Ao and Zheng, 2015; Subbaiyan et al., 2015) has emerged at the forefront of methods currently employed in chirality separation. Briefly, an ATP system consists of two separate, but permeable, water phases of slightly different compositions that is created by polymer phase separation (Ao et al., 2016). Studies have shown that the partitioning of DNA-SWCNT complexes has a strong dependence on both the DNA sequence and SWCNT structure (i.e., chirality) (Ao et al., 2014). Moreover, this partitioning can be modulated by changing the polymer compositions of the two phases in order to rescale the hydration energies. For example, the addition of dextran (DX) to a poly-(ethylene glycol)/polyacrylamide (PEG/PAM) system pulls down DNA-SWCNTs from the top to the bottom phase (due to increased hydrophilicity) while the addition of poly(vinylpyrrolidone) (PVP) has the opposite effect. The effectiveness of this method was demonstrated in work carried out by Ao et al. (Khripin et al., 2013; Ao et al., 2014, 2016; Ao and Zheng, 2015), where over 300 DNA sequences were screened using ATP separation techniques, resulting in the isolation of 23 different chiralities.

Aside from their chirality specificity and selectivity, different DNA lengths and sequences have also shown preferences toward molecular recognition with certain analytes (**Figure 4**). Small nucleotide and microRNA sequences are promising biomarkers for a variety of pathologies, including cancer (Harvey et al. , 2017). However, current methods of detection are complex and time-consuming, leading to difficulties in their implementation for point-of-care diagnostics. An advantage of DNA-SWCNT optical sensors is the ability to engineer selectivity toward target oligonucleotides by taking advantage of DNA's natural preference for specific complementary base pairing. Many studies have demonstrated the use of DNA-SWCNTs to quantitatively detect a range of both microRNA and DNA sequences (Jeng et al., 2006, 2010; Bansal et al., 2013; Harvey et al. , 2017). Work carried out by Jeng et al. and Harvey et al. have shown that these fluorescence-based sensors are even capable of detecting single nucleotide polymorphisms (SNPs) (Jeng et al., 2010) and can be multiplexed to detect several sequences simultaneously (Harvey et al. , 2017). In the study by Jeng et al., the addition of complementary DNA is believed to increase the surface coverage of the SWCNT upon hybridization, resulting in a decrease in the effective dielectric constant of the surrounding SWCNT environment and a shifting of the SWCNT fluorescence peak. Similarly, Harvey et al. propose an underlying mechanism based on changes in dielectric constant and electrostatic charge, which can modulate SWCNT emission wavelengths upon hybridization. The fluorescence shifting observed in both studies in response to complementary hybridization is particularly advantageous for detecting diseases, such as heart and kidney disease, as well as various cancers, which can be associated with different combinations of specific microRNA sequences (Etheridge et al., 2011; Hayes et al., 2014; Mishra, 2014; Bertoli et al., 2015; Wang et al., 2016; Hamam et al. , 2017).

In addition to detecting hybridization, DNA-SWCNTs can also be engineered to detect a variety of other molecules, including neurotransmitters, sugars, and peptides (Xu et al., 2007; Kruss et al., 2017; Landry et al., 2017; Bisker et al., 2018), though the underlying mechanism of these sensors remains an ongoing area of research (Bisker et al., 2015; Ulissi et al., 2015). While certain DNA-SWCNT sensors are based on oligonucleotides that act as molecular sieves, like the $(AT)_{15}$-SWCNT sensors designed to detect NO (Zhang et al., 2011), an alternative approach is based on displacement or conformational changes of the DNA wrapping (Heller et al., 2006; Landry et al., 2014, 2017; Salem et al., 2017; Beyene et al., 2018; Gillen et al., 2018). Early studies in this area screened libraries of molecules of interest against SWCNTs suspended using several different DNA sequences by monitoring the changes in the fluorescence emission of these sensors upon addition of the analyte. Through this approach, researchers were able to identify particular sequences with an enhanced affinity to certain chemicals, such as $(AT)_{15}$ toward nitric oxide (NO) (Zhang et al., 2011) (**Figure 4B**) and

$(GT)_{15}$ toward catecholamines (Zhang et al., 2011; Kruss et al., 2017; Mann et al., 2017) (**Figure 4C**). Further studies have demonstrated that DNA length can also be used to tune the fluorescence properties of DNA-SWCNT hybrids, offering a new approach to controlling the behavior of these sensors (Jena et al., 2017; Beyene et al., 2018).

Recent studies carried out by Landry et al. and Lee et al. have shown that DNA aptamers on SWCNT scaffolds can be used to detect certain biologically relevant proteins (Landry et al., 2017; Lee et al., 2018). This label-free fluorescence detection offers many advantages over conventional immunological analytical methods, such as enzyme-linked immunosorbent assays (ELISA) or mass spectroscopy, which lack temporal resolution for real-time quantification of protein levels. Furthermore, this method obviates cumbersome purification and labeling steps typically required by more classical approaches. Both RAP1 and HIV-1 (Landry et al., 2017) and platelet-derived growth factor (PDGF) (Lee et al., 2018) were successfully detected using DNA aptamer-SWCNT complexes. Moreover, the RAP1 and HIV-1 sensors were also reported to selectively respond to their target proteins in molecularly complex environments, such as crude, unpurified cell lysates (Landry et al., 2017).

Although DNA-SWCNTs have shown improved selectivity toward small molecules compared to surfactant-SWCNTs (Zhang et al., 2013), they still lag behind their protein- and peptide-based counterparts, which offer exceptional molecular recognition. Proteins are capable of not only differentiating between molecularly similar targets, but also different chiralities of the same molecule. For example, whereas proteins, such as glucose oxidase (GOX) selectively interact with D-glucose (Zubkovs et al., 2017), sensors based on the $(GT)_{15}$ DNA wrapping interact with a family of catecholamines (Kruss et al., 2014, 2017; Mann et al., 2017). Although glucose sensors based on DNA-SWCNTs have also been developed, these sensors ultimately require the addition of GOX for specificity due to the structural similarities of competing sugar molecules. Furthermore, the underlying sensing mechanisms for protein-based sensors are often more clearly identifiable. Their sensing mechanisms are quite diverse, varying from protein charge-transfer (Barone and Strano, 2006; Zubkovs et al., 2017) to exciton quenching due to protein conformational changes (Yoon et al., 2011), both of which have been shown to alter the SWCNT fluorescence intensity.

Protein-based wrappings, however, suffer from their own disadvantages; a lack of precise control during the protein

immobilization process, for example, can result in unfavorable orientations that limit access to the active site (Mohamad et al., 2015). Similarly, structural rearrangements may occur that inhibit, or in some cases destroy, the bioactivity of these molecules (Saifuddin et al., 2013; Antonucci et al., 2017). In addition, protein-based wrappings exhibit limited dispersion efficiency, which has been shown to depend on the protein and is generally less efficient than DNA- and surfactant-based suspensions. Several methods of functionalization have been proposed (Huang et al., 2002; Jiang et al., 2004; Gao and Kyratzis, 2008; Saifuddin et al., 2013; Antonucci et al., 2017) and used to create sensors based on Luciferase-suspended SWCNTs (Kim et al., 2010), AnnexinV-suspended SWCNTs (Neves et al., 2013), and anti-uPA-suspended SWCNTs (Williams et al., 2018), for example. However, these sensors require an intermediate linker or wrapping for stability, as opposed to the non-specific adsorption possible with GOX. In fact, other protein-based glucose sensors, such as those based on glucose-binding protein (Yoon et al., 2011; Yum et al., 2013), typically require more complex conjugative chemistries compared to GOX, highlighting the importance of understanding the underlying protein mechanism when determining the most appropriate method for functionalization. Although these intermediate wrappings can improve solubilization and help maintain protein structure and function on the SWCNT surface, more complex functionalization procedures with multiple conjugation steps could limit the scalability of the sensors.

Irrespective of the improved selectivity offered by DNA and especially protein-suspended SWCNTs, these sensors suffer from relatively low quantum yields compared to surfactant-suspended nanotubes (Haggenmueller et al., 2008). The low intensities restrict the depth at which these biosensors can be implanted for use *in vivo* and *in vitro*. Moreover, studies have shown that both protein- and DNA-SWCNTs are sensitive to local variations in pH (Nepal and Geckeler, 2006; Antonucci et al., 2017) and ionic strength (Heller et al., 2006; Holt et al., 2012; Salem et al., 2017; Gillen et al., 2018). The latter poses additional challenges for biosensing applications, as these ions are often involved in biological signaling pathways (such as Ca^{2+} in dopamine regulation). Therefore, fluctuations in local concentrations throughout the day would compromise the sensing capabilities of the DNA-SWCNT complexes.

4. POLYMER ENGINEERING OF SWCNT SENSOR SPECIFICITY

The tradeoffs between surfactant-suspended SWCNTs and biopolymer-suspended SWCNTs have encouraged researchers to seek an alternative means of detection based on synthetic or bioengineered polymers. *Xeno* nucleic acids (XNAs), for example, have recently been engineered to improve the sensing capabilities of DNA-SWCNTs in ionically complex systems (Gillen et al., 2018). XNAs are synthetic alternatives to naturally occurring DNA and RNA that typically benefit from greater resistivity against nuclease degradation. Due to their modularity, nucleic acids can be readily adjusted using a variety of chemical modifications (Pinheiro and Holliger, 2012; Pinheiro et al., 2013; Ghosh and Chakrabarti, 2016; Ma et al., 2016), and XNAs can contain modifications to either the nucleobase, phosphate, or sugar in an otherwise native oligonucleotide sequence (Pinheiro et al., 2013; Pinheiro and Holliger, 2014; Anosova et al., 2016). Although XNAs were initially developed to emulate the DNA replication processes found in nature, these synthetic oligomers were quickly realized for their advantages in *in vivo* stability and specificity (Wang et al., 2005; Pinheiro and Holliger, 2014; Taylor et al., 2014; Ma et al., 2016). Larger base modifications can result in altered physico-chemical properties, such as a tendency to adopt non-standard helical conformations, but certain chemical modifications to the N7 (in purines) or C5 (in pyrimidines), sites that extend into the major DNA groove, can be reasonably tolerated without significant steric impact (Pinheiro and Holliger, 2012). Backbone modifications can also alter the physico-chemical properties of oligonucleotides. One example is peptide nucleic acid (PNA), where the sugar phosphate backbone is substituted with aminoethylglycine. This substitution results in a charge-neutral polymer that is capable of strong canonical base pairing. The type and extent of the modification depends on the intended application. For example, locked nucleic acid (LNA) can greatly improve the stability of SWCNT sensors in the presence of high ionic concentrations (Gillen et al., 2018). Previous studies showed that salt cations can alter the DNA conformation on the nanotube surface, changing the emission wavelengths (Heller et al., 2006; Salem et al., 2017; Gillen et al., 2018). Since the added methyl bridge in the backbone of LNA increases the rigidity of the polymer, LNA exhibits increased conformation stability in the presence of fluctuating salt concentrations. By modifying 25% of the sequence with a "locked" base, bioengineered sensors based on LNA have been shown to withstand over two orders of magnitude higher salt concentrations without any perturbations in fluorescence. These complexes offer a strong promise for use in ionically complex media, such as blood or urine, without compromising the biocompatibility or nearly inexhaustible sequence space offered by oligonucleotide wrappings. The added chemical modifications also carry untapped potential for further narrowing selectivity through bio-conjugative chemistries that are specific to functional groups in the desired target.

Similarly, recent work by Chio et al. has employed the use of peptoids, N-substituted glycine polymers, to serve as protein molecular recognition elements for SWCNT-based sensors (Chio et al., 2019). These peptoids draw inspiration from biological peptides, with the benefit of greater resistivity against protease degradation (Anosova et al., 2016). The tunability of these sequence-defined synthetic polymers enables greater chemical diversity by providing a larger monomer space of primary amines (Sun and Zuckermann, 2013). Although the stability of the peptoid wrapping on the nanotube surface was shown to vary depending on composition, length, charge and polarity, Chio et al. demonstrated that these sensors could be used to engineer a selective sensor for the fluorescence detection of the lectin protein, wheat germ agglutinin (WGA) (Chio et al., 2019).

In addition to peptoids and oligonucleotide derivatives, purely synthetic heteropolymers have also been used to augment sensor

properties. One such platform uses Corona Phase Molecular Recognition (CoPhMoRe) and relies on SWCNT-adsorbed heteropolymers to template preferential recognition sites for target analytes. The final structures adopted by the polymer on the surface control the selectivity of the sensor toward a target. Though the mechanism for modulating SWCNT fluorescence in response to binding is likely analyte- and polymer-specific, its precise characterization remains an area of active research (Bisker et al., 2015; Ulissi et al., 2015). Typically, the heteropolymers employed contain both hydrophobic and hydrophilic segments. The former interacts with the SWCNT surface, while the latter extends into solution to suspend the complex in aqueous solutions. CoPhMoRe-based sensors have been developed to detect neurotransmitters (Kruss et al., 2013; Zhang et al., 2013; Landry et al., 2014), vitamins (Zhang et al., 2013), and steroids (Zhang et al., 2013), as well as small molecules, such as NO and H_2O_2 (Kim et al., 2009; Iverson et al., 2013; Giraldo et al., 2015) (**Figure 4**).

Furthering the development of these sensors, Bisker et al. (2016) extended the capabilities of CoPhMoRe sensors to detect larger macromolecules, such as proteins. A variant of a CoPhMoRe screening approach was used to identify polymeric wrappings that could be used to create synthetic, non-biological antibody analogs capable of recognizing biological macromolecules. This approach yielded a selective sensor for fibrinogen based on dipalmitoyl-phosphatidylethanolamine (DPPE)-PEG (5 kDa)-suspended SWCNTs. This sensor was capable of detecting fibrinogen in a competitive binding assay in the presence of albumin, which can passivate the sensor by binding to non-specific binding sites (Bisker et al., 2016). This observation suggests that CoPhMoRe is more likely due to a combination of factors related to both the specific corona phase formed by the polymer-SWCNT complex and the unique elongated conformation of the fibrinogen protein, rather than sensing mechanisms based on aggregation, molecular weight, or protein hydrophobicity.

5. CONCLUSIONS AND FUTURE PERSPECTIVE

Since the first reported aqueous suspension of individual SWCNTs with surfactant (O'Connell et al., 2001, 2002; Bachilo et al., 2002), SWCNTs have been suspended using a variety of natural and synthetic wrappings. Polymer wrappings in particular have served the dual purpose of both solubilizing SWCNTs and regulating the selectivity of SWCNTs toward specific analytes in biological media. As a result, polymers such as DNA have become standard wrappings for optical SWCNT-based biosensing, and recent efforts have focused on modifying these polymers to improve the quantum yield, stability, scalability, and selectivity of these sensors. However, with the exception of protein-based wrappings and complementary DNA-strand hybridization, the nature of the selectivity of polymer wrappings toward specific analytes remains unclear. As a result, most DNA and synthetic polymer-based SWCNT sensors are empirically engineered through random library screening and selection. These techniques evaluate the responsivity of several different polymer-wrapped SWCNTs against a variety of analytes, and the polymer-analyte combinations that yield relatively strong fluorescence responses are used to identify suitable polymer wrappings for SWCNT-based sensing (Zhang et al., 2011, 2013). Though this approach has been quite successful in identifying wrappings that can trigger a fluorescence response toward particular analytes, the sensors often show compromised selectivity. Moreover, the polymer wrappings also yield sensors with lower stability and brightness compared to surfactant wrappings.

Studies for new SWCNT optical sensors thus far screen, at most, tens of polymers at a given time (Zhang et al., 2011, 2013), meaning they have only explored a small fraction of the near-infinite polymer sequence space. One approach to overcoming the current limitations of SWCNT sensors is to screen larger polymer libraries in order to increase the chances of identifying a polymer-analyte combination with more favorable sensing properties. An alternative approach to addressing this challenge is to implement more guided techniques, such as directed evolution (Arnold, 1997). Directed evolution uses an iterative approach to improving the properties of materials that lack a defined structure-function relationship. Though the technique is conventionally used to engineer proteins, it was recently applied to engineer DNA wrappings that were shown to improve the quantum yield of an optical SWCNT-based sensor (Lambert et al., 2019). Combined with computational methods, such guided approaches can be used to identify trends between polymer sequence and sensor properties, with the goal of ultimately understanding the underlying mechanism for selectivity and designing molecular probes in a rational and predictive manner.

Noble metal nanostructures are being used broadly as catalysts for energy conversion in fuel cells. To overcome the future energy crises, fuel cells are anticipated as clean energy sources because they can be operated at low temperature, their energy conversion is high and their carbon release is almost zero. However, an active and stable electrocatalyst is essential for the electrochemical reactions in fuel cells. Therefore, properties of the nanostructures greatly depend on the shape of the nanostructures. Individual as well as interaction properties are greatly affected by changes in the surface area of the nanostructures. By shape controlled synthesis, properties of the nanostructures could be further enhanced by increasing the surface area or active sites for electrocatalysts. Therefore, an efficient approach is needed for the fabrication of nanostructures to increase their efficiency, activity, or durability in fuel cells by reducing the usage of noble metals. Different types of hollow nanostructures until now have been prepared including nanoboxes, nanocages, nanoshells, nanoframes (NFs), etc. NFs are the hollow unique three-dimensional structure which have no walls—they only contain corners or edges so they have large surface area. In electrocatalytic reactions, the molecules involved in the reaction can easily reach the inner surface of the nanoframes, thus noble metals' utilization efficiency increases. NFs usually have high surface area, greater morphological and compositional stabilities, allowing them to withstand harsh environmental conditions. By considering the current challenges in fabrication of noble metal based alloy NFs as electrocatalysts, this review paper will highlight recent progress, design, and fabrication of noble metal alloy NFs through different strategies—mainly photocatalytic template, electrodeposition, Kirkendall effect, galvanic replacement, chemical/oxidative etching, combination of both and other methods. Then, electrochemical applications of NFs in fuel cells toward formic acid, methanol, ethanol, oxygen reduction reaction as well as bifunctional catalyst will also be highlighted. Finally, we will summarize different challenges in the fabrication of highly proficient nanocatalysts for the fuel cells with low cost, high efficiency and high durability, which are the major issues for the highly commercial use of fuel cells in the future.

INTRODUCTION

Noble metal nanostructures are being used broadly as catalysts for energy conversion in fuel cells. To overcome the future energy crises, fuel cells are anticipated as clean energy sources. Noble metals such as platinum (Pt) as well as palladium (Pd) are the most important and effective catalysts in fuel cells, but increasing the catalyst efficiency as well as cost reduction of catalysts is a great challenge. By tuning the size, composition, and morphology, electrocatalytic activity could be enhanced (Ding et al., 2012; Wang et al., 2013, 2015a; Zhang et al., 2018b). Recent research efforts have been focused on (1) the addition of cheap transition metals to decrease the cost and improve the electronic effect of Pt, (2) tuning the morphologies with high index facets, ultrathin walls and 3D surface accessibility, (3) NF architecture which shows the 3D surface with high catalytic surface area as well as large utilization of precious metals, (4) composition segregation of Pt on the edges and corners of NFs to increase the Pt usage. Furthermore, it is very necessary to fabricate the novel nanocatalyst with both higher activity as well as stability.

Pt content could be reduced without compromising the catalytic properties by changing the solid nanostructures into hollow nanostructures with ultrathin walls and with controlled surface composition. The advantage of hollow structures over the solid particles is that Pt atoms in solid nanoparticles are unexploited because they cannot participate in electrocatalytic reactions. However, the empty interior of nanocages and nanoframe allows the reactants to interact with 3D interior and exterior surfaces in catalytic reactions (Fang et al., 2015). Moreover, atomic scale ultrathin walls below 2 nm can further improve the electrocatlytic applications. In previous studies, a lot of hollow as well as nanocage structures have been fabricated, but NF architectures—especially bi-and multimetallic NFs—have not received more attention. Attaining NFs with controlled size, highly open structure, 3D surface area, control thickness, and stable shell is a more difficult task. In recent years, some groups have been interested in the atomic scale synthesis of bi- and multimetallic NFs due to their excellent electrocatalytic activity as well as durability in fuel cells. In this review, we will highlight the state-of-the-art accomplishments on NFs and will discuss the growth mechanism, which includes the photocatalytic template method, electrodeposition, Kirkendall effect, galvanic replacement reaction, oxidative/chemical etching, and others. In previous years, researchers have fabricated the single component noble metal hollow, nanocages and NFs, but few have focused on the fabrication of noble metal based bimetallic and multimetallic NFs for fuel cells.

SYNTHETIC METHODOLOGIES FOR NANOFRAMES

Photocatalytic Template Synthesis

Template based synthesis has been widely employed for the synthesis of various hollow nanostructures (Bai et al., 2011). Photocatalytic-based hard and soft template synthesis has been used by a few groups to synthesize Pt nanocages. For example, Shi et al. developed Pt nanocages by using the liposomes as a template in which photocatalyst molecules were present. In this protocol, firstly hydrophobic Sn^{IV} octaethylporphyrin (SnOEP) has been integrated into unilamellar liposomes. After that, platinum seeds were formed due to photo-catalytic reduction of Pt salts and converted in the form of dendritic Pt-nanosheets. Then these dendritic nanosheets combined with each other inside the bilayer and evolved into nanocages. The dendritic nanosheets after combining with each other adopted the spherical structure of the liposomal template with a 2 nm thick wall and 200 nm nanocages. The synthesized Pt nanocages contain hollow voids and additional porosity, which may be beneficial for extensive applications (Shi et al., 2015). Moreover, Wang et al. developed 3D Pt nanocages by simple photocatalytic template procedure. The synthetic procedure was carried out in the presence of TiO_2 NPs that not only worked as photocatalyst but also as template. In synthesis, Pt uniform interlinked branches first formed by the increased amount of Pt precursors and reducing the intensity of light. Then, these nanobranches were photo-deposited on a TiO_2 template by irradiating the UV light without any surfactants or capping agents. After template removal, 3D Pt nanocages were attained with high surface area as well as more active sites showing them to be an active catalyst for MOR. By the photocatalytic template method, nanocages of different shapes and sizes could be synthesized by varying the exposure of light, amount of metal precursors, and size of template (Zhu et al., 2015).

Electrodeposition Method

The electrodeposition method consists of the deposition of a substance on substrate by introducing an electric current. This method is used for the fabrication of solid particles with very low porosity. However, for the creation of metal based NFs, this technique is also coupled with other strategies like chemical etching as well as electroleaching. For instance, Moghimi et al. developed FeNi NFs by the electrodeposition and electroleaching technique (Moghimi et al., 2013). The electrodeposition technique combined with chemical etching could be employed to fabricate various NFs. For example, Torimoto et al. synthesized Au NFs by the preferred electrodeposition of Au on the edges and corners of Ag cubic particles treated with the 1-octanethiol, and then chemical etchants (hydrogen peroxide and sulfuric acid) were used to chemically etch Ag particles. In this method, Ag has been used as a template, and dissolution of Ag template has not been observed during the deposition process of Au. This strategy could be used for the fabrication of NFs where simultaneous dissolution of the template needs to be avoided during electro-deposition of second material. Moreover, electrodeposition favors the formation of metal NPs irrespective of metal and their reduction potential. This method has rarely been used for synthesis of noble metal-based alloy nanoframes (Okazaki et al., 2009).

Kirkendall Effect

The Kirkendall effect is a vacancy mediated technique which is based on the net mass flow of faster diffusing species, and it is balanced by the opposing flow of vacancies. This method is useful for the synthesis of hollow and porous NCs because

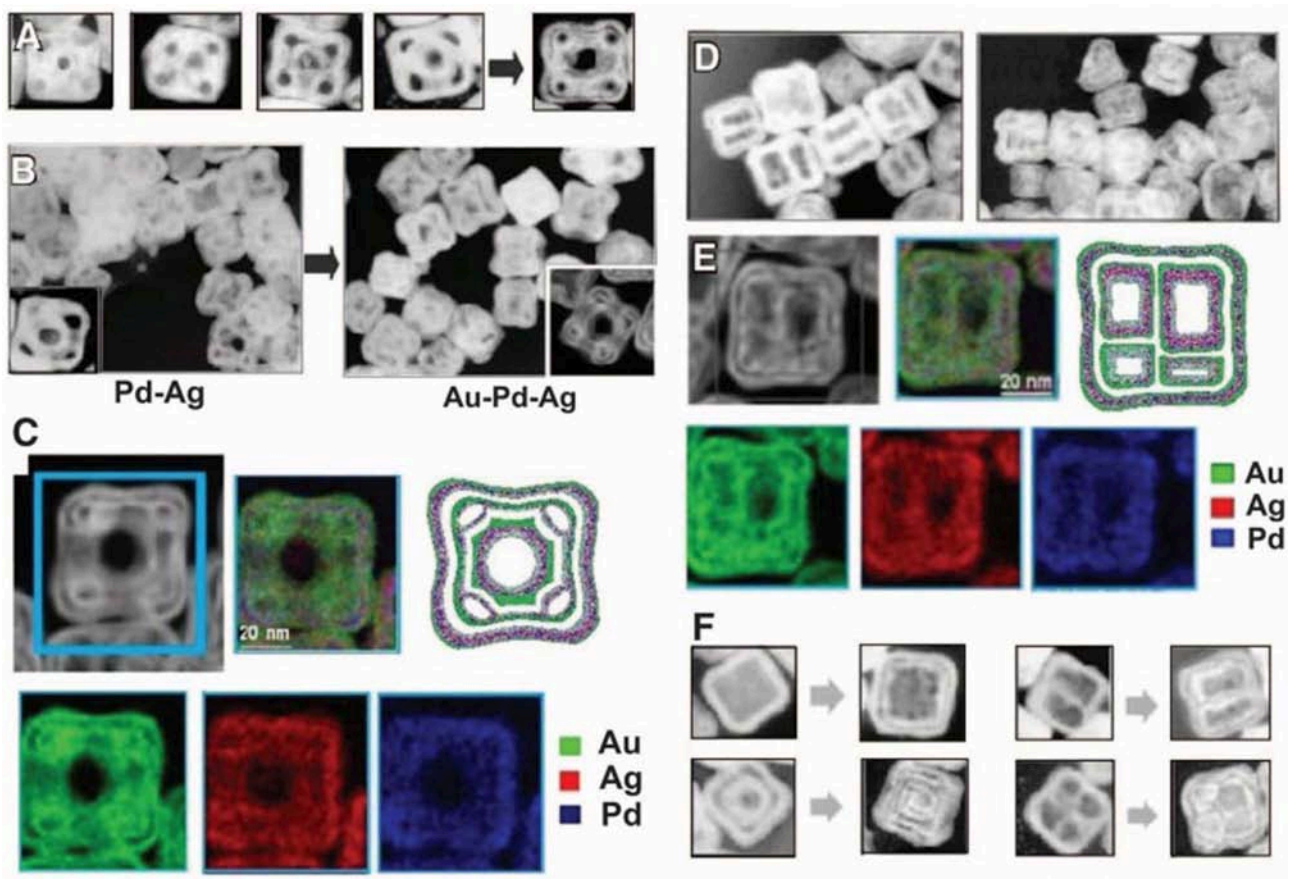

FIGURE 1 | (A) TEM images illustrating the stages of formation of hollow nanostructures by sequential action of galvanic replacement and Kirkendall effect. **(B)** TEM images showing the nanostructures dominated by galvanic replacement using palladium (left) and by Kirkendall effect using gold (right). **(C)** HAADF-STEM image and corresponding EDX elemental maps. **(D)** TEM images of multichambered NPs. **(E)** HAADF-STEM detail and corresponding EDX elemental maps. **(F)** TEM images of different structures produced by sequential action of galvanic replacement and Kirkendall effect. it is a diffusion procedure. González et al. used sequential galvanic replacement reaction or the Kirkendall effect at room temperature to synthesize polymetallic hollow nanocrystals (NCs) with complicated shapes and compositions such as trimetallic Pd-Au-Ag nanoboxes (González et al., 2011), as shown in **Figure 1**. Han et al. developed the Cu_3Pt NFs with unique morphology by a transformation process. The Kirkendall effect is not commonly used for noble metal alloy NFs, so we will focus more on other methods.

Galvanic Replacement Reaction

The galvanic replacement reaction is extensively employed to synthesize metal NCs with hollow interiors such as nanocages, nanoboxes, and NFs. The template oxidizes and dissolves during the galvanic replacement reaction, meanwhile metal ions reduce, and deposit on the template surface. The discrepancy of the two metals in redox potential is the driving force of the galvanic replacement. However, the structure of the NCs may be controlled by tuning the metal to salt ratio, quantity and the shape of the template. The same sacrificial template facets have the simultaneous removal of template and the deposition of atoms on all the facets. In the template containing distinct facets, the galvanic replacement reaction adopted the facet selectively. Atoms are dissolved at higher surface energy and deposited on the lower energy facets. In addition, template based, and one pot strategy are the two main methods to carry the galvanic replacement reaction (Xia et al., 2013).

Template Based Galvanic Replacement Method

Ag metal has a lower reduction potential in comparison with the other metals such as Pd, Au, etc. Due to this property, it is easy to remove the atoms by the galvanic replacement reaction, and it makes Ag the most efficient sacrificial template for the synthesis of hollow nanostructures. For instance, Mahmoud and El-Sayed have developed the double shell nanocages of different sizes with controlled thickness and used the Ag as template (Mahmoud and El-Sayed, 2012). In this protocol, the Ag template has been employed because at elevated temperatures single-crystalline Ag particles formed, which may produce the single

crystalline hollow structures in cases where the lattice of Ag and other metals match well. The size of templates was controllable from a few to 250 nm, which produced the hollow structures of different sizes. Synthesis of Ag template could be done with high yield. PVP is a good capping agent for Ag NC synthesis and it is appropriate for other metals as well, therefore the capping of the Ag template is also suitable for the synthesis of hollow structures and prevents their aggregation. In addition, the bowl-like morphology of PtAuAg nanocages was synthesized by using the seed mediated and galvanic replacement procedure (Xu et al., 2018) in which Ag seeds were used as a template. However, experiments in different optimized conditions were able to fabricate the structures which have time dependence and also depend on cetyltrimethylammonium chloride (CTAC). Due to their structure and synergetic effect of Pt, Au, and Ag, the final PtAuAg nanocatalyst exhibits higher catalytic performance. Furthermore, similar to the Ag template, Pd NCs were also used as sacrificial templates for the fabrication of PdPt hollow nanocages via the galvanic reaction as well as the co-reduction method. In another report, Xia et al. developed PdPt nanocages through a co-reduction approach along hollow centers by a combination of galvanic replacement by using Pd nanocubes as a sacrificial template and K_2PtCl_4 in presence of citric acid. Meanwhile higher concentrations of bromide and $PtCl_4^{-2}$ at elevated temperatures accelerated the galvanic replacement and produced PdPt alloy nanocages (Zhang et al., 2011). However, by replacing the citric acid with the ascorbic acid (AA), PdPt nanodendrites were gained because of the faster depletion of Pt precursors and the decreased rate of the galvanic replacement reaction. For instance, Han et al. have fabricated PdPt octahedral and cubic nanocages with hollow interiors containing porous walls by using Pd octahedra and cubic NCs as sacrificial templates. Change in the ratio of AA could control the galvanic replacement reaction and gives the PdPd alloys with distinct shapes (Hong et al., 2012a).

In addition to metal templates, metal oxide NCs have also been used as a template. Chen et al. fabricated flower shaped PdCu nanocages by utilizing the corner etched Cu_2O octaherda as a template through a facile and simple procedure. By adding the H_2PdCl_4, Cu_2O were hybridized to generate the Cu_2O@PdCu core shell, and etching of Cu_2O was done by $NH_3.H_2O$. These flower shaped nanocages of PdCu were used for the MOR that shows the higher catalytic activity, excellent stability, and more poison tolerance. These alloy nanoarchitectures were developed by the galvanic reaction and disproportionation reaction (Chen et al., 2018). Similar work is also reported by the other research group, where they used Cu_2O as a sacrificial template and distinct reducing agents to gain the cubic PtCu nanocage by redox reactions (Tian et al., 2014).

One-Pot Galvanic Replacement Method

Using the pre-synthesized templates like Pd or Ag in the synthesis of hollow nanostructures has more limitations as the synthetic procedure requires more steps such as template synthesis, shell growth as well as template removal, which limits the practical use. Use of the noble metals like Pd or Ag as sacrificial template also wastes the expensive materials and the final morphology is limited to the initial shape of the parent templates. Alternatively, to synthesize metal alloy NFs through one pot procedure is more difficult as compared to monometallic NCs because the insertion of the second metal makes the reduction more difficult. The standard reduction potential of noble metals is higher in comparison with the non-noble metals, while for the alloy NC synthesis the reduction potential difference among the two metals should be decreased. For this purpose, some ligands could be used in order to decrease the reduction rate of the two metals. Another way to reduce the reduction potential is to combine the metal cations with coordinating agents like halide ions, which more strongly coordinate with the noble metals. In one report, Huang et al. (2009) introduced iodide ions to the mixture of $Pd(acac)_2$]/[$Pt(acac)_2$] in solution of DMF, which produced $[PdI_4]^{2-}$ as the most dominating precursors, and Pd reduced the Pt ions early. Furthermore, cubic $PtCu_3$ nanocages were also developed by optimizing the reduction rate by the addition of cetyltrimethylammonium bromide (CTAB) as well as Pt and Cu species. From the above explanations, it is noticed that the CTAB in oleylamine works as a co-reductant, which tuned the Pt and Cu species reduction speed, and Cu ions are reduced before the Pt ions while the reduction rate of the Cu pair is more negative than the Pt pair (Xia et al., 2012).

Similarly, Zhang et al. reported the synthesis of PtCu yolk-cage like NCs through glycine mediated reduction kinetics. By changing the amount of glycine, morphology as well as composition of the NCs were controlled, and in this method glycine is used as a co-reductant and surface controller. Glycine may coordinate with the metal ions and when the medium is aqueous it strongly coordinates with Pt^{4+} instead of Cu^{2+}. Subsequently, platinum ions' reaction to reduced copper nanocrysrtals by galvanic replacement leads to a Pt–Cu yolk cage structure. As compared to hollow structures or nanocages, NFs are open, have 3D surface accessibility and more active sites (Zhang et al., 2013). In addition to the above examples of nanocages, we also fabricated the single crystalline octahedral PtCu NFs, which involve the synergetic effect of OH and amine groups of ethanolamine and concentration of glycine also effect the reduction rate. However, here it was also observed that the coordinating ligands changed the reduction rate of metals and make galvanic replacement reaction more feasible (Nosheen et al., 2013) (**Figures 2a,b**). The same method was also adopted by Zhang's group, and they vary the time of reaction as well as temperature to gain the multiple twinned NFs. It is very rare to fabricate the multiple twined noble metal NFs (**Figures 2c,d**). Twin defects in the metal nanoarchitecture would modulate their electronic structure as well as surface reactivity and could enhance the catalytic performance. In case of twin configuration, the decahedron is the most compact pentagonal cyclic twined shape along the D_5h symmetry and shows excellent catalytic applications. It is also observed that the twin defects act as a nucleation site which induces the generation of a highly anisotropic design and, as a result of symmetry breaking of the crystal lattice, gives more active sites for electrocatalysis. In addition, unique 5-fold twin PtCu NFs were also fabricated along nanothorn protruding from their edges. Meanwhile time dependence experimental analysis shows that

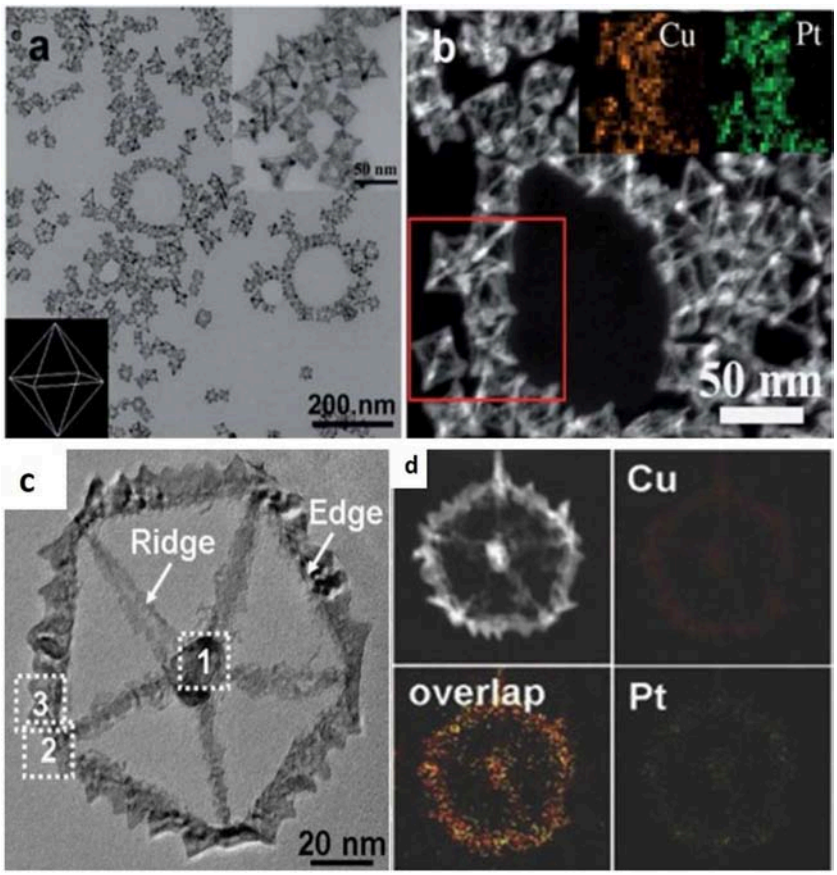

FIGURE 2 | (a) TEM image of as-prepared octahedral Pt-Cu nanoframes the top-right inset shows a high-magnification TEM image of octahedral Pt-Cu nanoframes, and the bottom-left inset shows the corresponding model image. **(b)** HAADF-STEM image of octahedral Pt–Cu nanoframes; the inset shows the selected-area (red rectangle) element analysis maps of Pt (green) and Cu (orange). pure Cu nanooctahedra were first generated. For the fabrication of anisotropic 5-fold twin PtCu NFs, galvanic replacement reaction among the Cu nanodecahedra as well as Pt precursors in solution and site-specific co-deposition of Pt as well as Cu atoms played a key role. Interestingly, these 5-fold twin PtCu NFs showed the excellent catalytic activity in terms of ORR as well as MOR in alkaline systems (Zhang et al., 2016).

Similarly, Huang et al. (2019) have developed the 3D RD $Pt_{26}Cu_{74}$ bound with multiple index facets through a facile solvothermal strategy. In this synthetic procedure, L-proline in combination with CTAC acted as a co-structure directing agent and modulated the nucleation as well as crystal growth rate. In comparison with the $Pt_{18}Cu_{82}$, $Pt_{50}Cu_{50}$, and commercial Pt/C catalyst, these $Pt_{26}Cu_{74}$ NFs showed a more enhanced catalytic performance toward ORR and HER because of their highly open nanostructure and synergetic effect of two metals. Polyhedral NFs like catalyst shows a more active and stable performance as compared to other NFs structures. For instance, Ding et al. fabricated the rhombic dodecahedral RD PtCu NFS along a highly open nanostructure in higher yield by the facile one pot method. In the synthetic procedure, a higher concentration of cupric chloride, and the combined use of glucose and oleylamine/oleic acid are responsible for the fabrication of PtCu NFs. TEM analysis proved that the formation procedure depends on initial formation of Cu nanoarchitectures and galvanic replacement of Cu nanoarchitecture with the Pt. Because of their highly open structure, these PtCu NFs showed excellent catalytic performance for MOR in comparison with the Pt/C as well as Pt catalysts (Ding et al., 2015).

Chemical/Oxidative Etching

Etching can be defined as the selective removal of definite facets of NCs as well as less stable metals through alloys with modification of remaining atoms in order to control the shape, size, and composition. The porosity of NCs could be controlled by etchant strength and other conditions of reaction. However, most important advantage of etching process is to regulate the selectivity and rate of etching. Other parameters like the power of etchant, which consists of the chemical potential, concentration, and reaction temperature also play an important role, but selective etching includes a difficult mechanism, and it is more challenging to construct the open structure with a 3D surface by

selective etching. Chemical etching has some disadvantages like surface atoms that may be removed on haphazard positions and an etching procedure that is sometimes very strong and is difficult to stop, meaning the structure could be damaged. In previous years, a lot of etchants have been used to fabricate nanoframe and nanocage structures (Xiong et al., 2005; Au et al., 2008; Zeng et al., 2009; Zhang et al., 2010; Wu et al., 2012; Xie et al., 2012). Moreover, it is a big challenge to control the etching process, and great efforts are still required to discover the path to choose a suitable etchant for the corrosion process. In addition, NFs gained by the etching method depend on precise anisotropic elemental distribution. However, compositional anisotropy of different components on the corners, edges, or facets is linked with geometrical elemental segregation (Liu et al., 2015).

Two Step Etching

The formation of Pt and Pd based NFs is accomplished by the template-mediated growth of Pt atoms followed by the removal of template with acid etching or thermal annealing. Shape can be controlled by tuning the etching as well as regrowth rate. For instance, Wang et al. (2017b) fabricated palladium NFs by excavating the solid palladium NCs. In this synthetic procedure, etching, and regrowth steps are controlled. Different regrowth rates at corners/edges/faces and etching of Pd atoms at specific sites can be controlled by tuning the rate of etching and regrowth. Without reductant, etching rules over the process, which results in conversion of NCs with more defined structures like octahedral to cuboctahedral NCs. However, when a small quantity of reductant (HCHO) is used, the regrowth rate at corners and edge sites could be controlled, which is equivalent to the etching rate, but the regrowth rate at the face site is lower compared to the etching. So, palladium NFs can be gained if etching occurs on the faces only. By following this synthetic procedure, solid Pd cubic, octahedral, cuboctahedral, and concave cubic structures have been carved to analogous NFs. These excavated Pd NCs with a frame-like structure display excellent activity as well as durability in terms of formic acid oxidation reaction. Park and co-workers fabricated cubic Pt NFs and utilized Pd NPs as a template. Site selective coverage of bromide ions induced the selective deposition of Pt on edges/corners and Pt cubic NFs can be gained by discriminating etching of Pd cubes by using acid and H_2O_2 (Park et al., 2016).

Nanoframes With Twinned Boundaries, High Index Facets, and Ultrathin Walls

The twin defects, ultrathin shell, and composition control could increase electrocatalytic properties. Zhang et al. synthesized nanocages by depositing a small number of atom layers of Pt as shell on Pd with more regular facets and etching the Pd template. On Pd NPs, Pt atoms were grown which are tuned from 1 to 6 atom layers by the maintained reaction conditions which effect the growth, diffusion, or dissolution behavior of Pt and Pd atoms (Zhang et al., 2015a). However, in the case of many structure sensitive reactions, introducing defects like twin boundaries may reduce the activation energy and enhance the catalytic performance. Therefore, concern has been focused toward the icosahedron, which has a higher density of twins in one NC. One icosahedron has 20 tetrahedrons in it and an individual tetrahedron is linked to another along the twin boundary, which endows the icosahedral nanocage as an efficient catalyst. He et al. (2016) have deposited Pt layer that is a few layers thick on the Pd to produce the icosahedral core shell NPs, and then by discriminating etching of Pd, icosahedral Pt enriches nanocages with layers that are a few atoms thick and defects were gained. In 2016, (Wu et al., 2014) synthesized platinum-based icosahedral nanocages which had a surface bounded by [111] facets as well as twin defects/boundaries and ultrathin walls of up to six atom layers. However, nanocages were derived from $Pd@Pt_{4.5L}$ icosahedra by selective etching of the Pd core by using $FeCl_3$ as well as KBr etchants. In the etching process, the multiple twinned structure was reserved and the Pt atom in the outer layer ws restructured to keep the original twinned structure with the ultrathin wall (Wang et al., 2016).

Nanoframes With Compositional Segregation

Nanoscale compositional segregation, also called compositional anisotropy, has received more attention for the design of nanocatalysts because this procedure leads to 3D NCs with larger surface area as well as precise size and facet control. Depending on this procedure, the Pt component could be fully accessed by reactants and excellent electrocatalytic properties are obtained (Stamenkovic et al., 2006; Li et al., 2018).

In comparison to homogenous alloys, compositional segregation offers a stronger electronic effect of distinct metals, and many Pt sites are available. According to the structural as well as chemical perspective, the main benefit of the compositional segregated Pt NCs is that it allows the formation of highly open nanoarchitectures, nanocages, or NFs, which are the most promising class of nanostructure, with a 3D surface area as well as interconnected edges with high surface area and improved applications in fuel cells. Now researchers are focusing on the synthetic procedure for gaining compositional segregated Pt based nanocatalysts with distinct morphologies. Moreover, many of the previous synthesized Pt dependent NPs with hollow, cage, and frame structures are homogeneous cubic, octahedral, rhombic dodecahedral, etc. But reports on the fabrication of shape controlled with highly compositional segregated features have not been considered more. Moreover, it should be pointed out that in the previous reported analysis, compositional segregated Pt based nanomaterials have a deficiency in structure control, which is vital for the fabrication of noble metal NFs with more advanced applications. However, the synthesis of highly compositional segregated NFs with complex structures is still challenging. For the first time, Chen et al. fabricated rhombic dodecahedra Pt_3Ni NFs with 2 nm thin edges from $PtNi_3$ polyhedron by the erosion of Ni followed by annealing. In this strategy, etching was conducted by dissolved oxygen present in air instead of harsh etchants or applied voltage. The open frame structure with surface crystallinity, segregated Pt-skin and 3D structure augmented the availability of the reactants for both inner and outer surfaces. As compared to commercial Pt/C, the open framework design displayed the phase segregation Pt skin

structure, which exhibited a 36-fold enhancement in terms of ORR (Chen et al., 2014).

Another group has explained an effective procedure for the synthesis of tetrahexahedral PtNi NCS (THH PtNi NCs) as well as rhombic dodecahedral PtNi NCs (RDH PtNi NCs) with more segregated features (Ding et al., 2016). It has been reported for the first time that THH PtNi NCs have been gained in a simple organic solution system. These THH PtNi NCs as well as RDH PtNi NCS were simply obtained by tuning the ratio of oleylamine and oleic acid while keeping the other conditions constant. The synthetic procedure demonstrated that the use of dodecyltrimethylammonium chloride (DTAC) as well as changing the ratio of oleylamine, oleic acid plays important part for the synthesis of THH PtNi NCs and RDH PtNi NCs. However, by simple acetic acid treatment and removal of Ni template, the THH and RDH PtNi NFs were obtained. Due to their highly compositional segregated design, these solid PtNi NCs were transformed into the PtNi NFs which showed the more open feature. These PtNi NFs presented higher performance toward ORR and for alcohol oxidation due to enhanced consumption of Pt (**Figure 3**). Another group has proposed the synthesis of tetrahexahedral (THH) PtNi NFs by the removal of the Ni component of tetrahexahedral (THH) PtNi NPs by using carbon monoxide (CO). They demonstrated that the Ni was removed from the [100] direction by using CO molecules. However, these Pt_3Ni NFs possess a 3D open structure, high index facets and thin segregated Pt layer. Furthermore, Co could be produced from the carbon support through thermal treatment in the presence of oxygen. This approach could be used for the preparation of industrial level nanocatalysts (Wang et al., 2017a). In the same way, Luan et al. also fabricated Pt-Ni Tetrahexahedral NFs by Co etching.

Chen et al. (2019) studied the reaction procedure of seeded co-reduction for the fabrication of PtNi seeded core frame structures. By controlling the shape of seeds, rhombic dodecahedra structures were obtained by depositing the Pt on their corners and edges. Different Pt salts and the ratio of Pt and Ni salts affected the shapes of seeds as well as the final morphology. Moreover, the Ni core of these hierarchical nanoarchitectures could be etched by the acetic acid which forms the concave structure and finally hollow NFs. In addition, the morphology and composition of the product could be manipulated by controlling the rates of etching and interdiffusion between two metals. The final Pt_3Ni NFs are more stable in acidic environments and show distinct electronic properties that are different from the primary core frame nanoarchitectures because of the alloying of Pt with Ni. However, this seeded co-reduction strategy can be extended for the fabrication of other Pt-based complex core frame rhombic dodecahedral NPs. Moreover, hollow NFs used low acetic acid etching, which provides a simple means to change the phase segregation of bimetallic polyhedra for hollowing out the alloyed structure with more unique morphologies. Stamenkovic et al. explained that the 3D Pt anisotropy of PtNi rhombic dodecahedra can be controlled by changing the ratio between Pt or Ni salts; as a result, hollow, and excavated NFs can be gained after Ni corrosion. In excavated NFs, at the interior of excavated NFs Pt rich sheets were extended while hollow NFs had voids inside Pt rich edges.

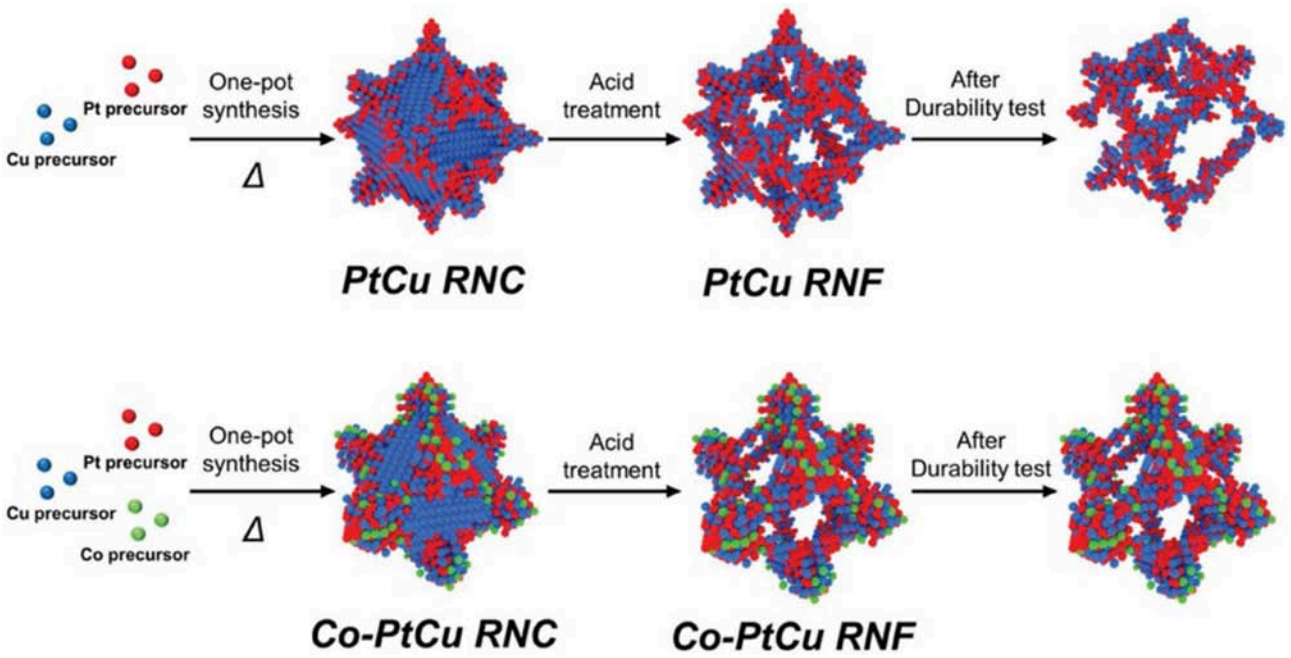

FIGURE 4 | Schematic illustration for the formation process of Cu@PtCu rhombic dodecahedral nanocrystals (PtCu RNC), PtCu rhombic dodecahedral nanoframes (PtCu RNF), Co-doped Cu@PtCu rhombic dodecahedral nanocrystals (Co-PtCu RNC), and Co-doped PtCu rhombic dodecahedral nano-frames (Co-PtCu RNF). Adapted with permission from Kwon et al. (2018b) Copyright 2018, WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim.

The excavated NFs had higher ORR performance which was due to the higher Ni amount in the near surface and the stretched 2D sheet-like structure within the NFs, which exposed Pt sites (Becknell et al., 2017).

In another example, Pt was coated on the surface of Cu nanocubes in order to synthesize the rhombic dodecahedral NFs (RD NFs). Moreover, growth in the [100] direction of Cu nanocubes leads to the RD. However, with the addition of Pt salts [100], vertices of Cu-CuPt rhombic dodecahedra NCs could be stretched to the spiny CuPt RD NCs. By removing the Cu content from the seed, CuPt RD as well as spiny CuPt RD NFs were gained. Because of their open frame design, both of these NFs showed a higher catalytic performance (Lyu et al., 2017).

The additional component to the binary catalyst serves as an efficient and robust means of structural as well as compositional stability of electrocatalyst. Kwon et al. (2018b) reported that the insertion of Co to PtCu alloy NFs gives ternary PtCuCo rhombic dodecahedral NFs along the reinforced vertex of PtCuCo ternary NFs. The Pt deposited on the edges of the Cu template leads to the formation of PtCu alloy, and then this PtCu alloy enables the *in situ* decay of the third constituent, i.e., Co that penetrates into the PtCu segment to make the desired PtCuCo phase. Furthermore, the final Co-doped PtCu rhombic dodecahedral NFs (Co-PtCu rhombic nanoframe) display the vertex strengthened structure, suggesting that the deposition of Co-occurs in the region of the vertices of PtCu NFs (**Figure 4**). Similarly, Huang et al. (2018) fabricated the PtCuNi rhombic dodecahedra NFs (NFs) by a two-step etching method. Firstly, PtCuNi concave rhombic dodecahedra formed by oxidative etchant and then PtCuNi NFs formed through the acid etchant. By controlling the reaction time and Ni precursors, PtCuNi solid rhombic dodecahedra seeds' shape can be controlled. To investigate the evolution of PtCuNi NF, atomic ratios, particle size, and morphology of ternary Nfs are precisely examined. In another report, Ye and co-workers (Ye et al., 2017) synthesized the $Pt_4PdCu_{0.4}$ NFs by the Cu-assisted deposition etching process, and these NFs showed improved electrocatalytic properties due to structural and electronic effects.

One Pot Etching

Using pre-synthesized templates like Pd or Ag NPs in the synthesis of hollow nanostructures has some limitations. (1) The synthetic procedure requires more steps such as template synthesis, shell growth as well as template removal, which limits practical use. (2) Most of the synthetic procedures utilize pre-synthesized templates, which are based on the noble metals like Pd or Ag as sacrificial template and waste expensive materials. (3) The resultant shape of hollow nanocages and NF structure is limited to the initial shape of the pre-synthesized templates. So, in order to overcome these disadvantages, for the tuning of surface energies, nanoscale phase mixing or segregation, *in situ* template formation has been proposed for the fabrication of novel hollow NCs. For the synthesis of a wide variety of binary and multimetallic NPs with more defined morphology, one pot synthesis is more preferable. Moreover, binary NCs are metastable, allowing the synthesis of NCs *in situ* phase segregation or even the removal of template leads to the hollow nanoarchitectures to be accomplished in one step.

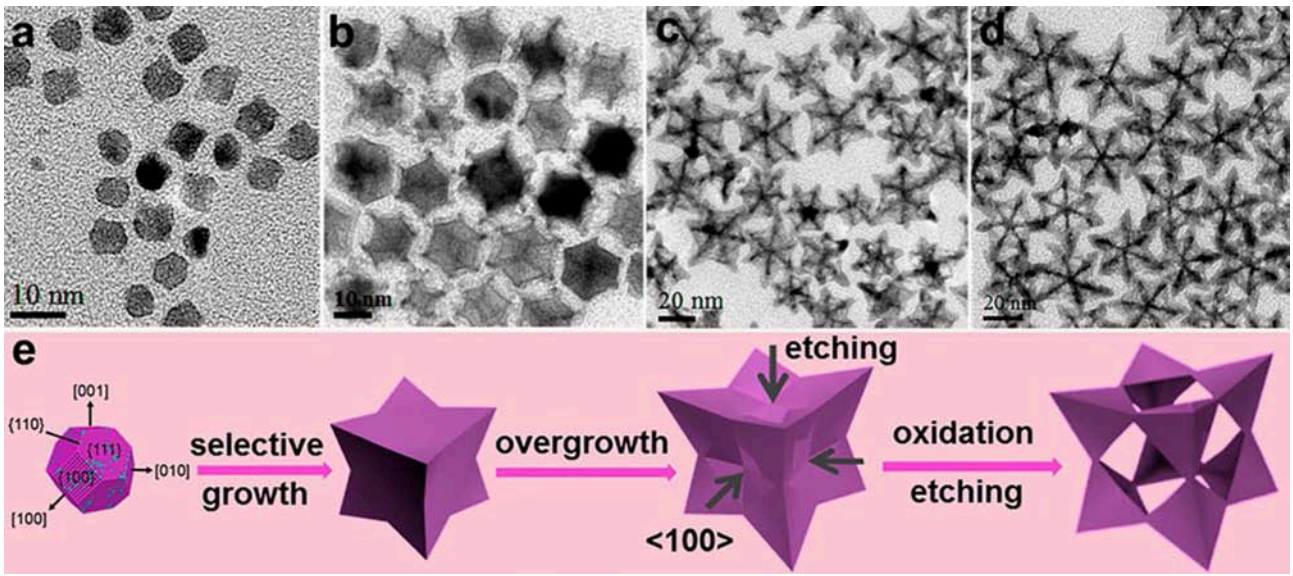

FIGURE 5 | Representative TEM images of the intermediates obtained at different reaction time during the synthesis of concave $PtCu_2$ octopod nanoframes: **(a)** 0.5, **(b)** 1, **(c)** 12, and **(d)** 18 h, respectively. **(e)** Schematic of the major steps involved in the formation of $PtCu_2$ CONFs. Adapted with permission from Luo and Shen (2017) Copyright 2017, American Chemical Society.

Carbon corrosion and leaching of transition metals during electrochemical cycling may degrade the catalyst and may decrease its durability. To overcome this problem, an active and stable catalyst is needed. Currently, polyhedral PtNi NFs have been fabricated and show the promising electrocatalytic performance for fuel cells. However, these NF catalysts have been mostly developed by the multi-step synthetic procedure, which made cost saving massive production a big challenge toward practical applications. So, engineering of self-supported as well as high-performance NF catalysts through one pot procedure is of great importance. To synthesize stable and active catalysts, Luo and Shen described a one-pot procedure for the construction of concave $PtCu_2$ octopod NFs (CONFs) with higher index facets in which CTAB is used as a structure directing agent. The CONF nanoarchitectures meet the critical design requirements for more efficient nanocatalyst-like highly open nanoarchitectures with 3D catalytic surface and a stepped surface composed of multiple index facets which showed enhanced catalytic activities. The self-supported CONFs catalyst removed the carbon erosion and facilitated the reaction by enhanced mass transport. Furthermore, CONFs are assembled by the eight symmetry feet that showed excellent physical and electrochemical stability. The evolution mechanism indicates that the octopod NFs formed from solid octapods by sequential erosion, and the overgrowth from concave cubic structure to concave octopods is comparatively slow (**Figure 5**) (Luo and Shen, 2017).

By using the one pot solvothermal strategy, Huang et al. (2018) reported 3D PtCu alloy nanocages with an open structure, large exterior and interior surfaces that are accessible for the reactants. Arginine and cetyltrimethylammonium chloride (CTAC) performed as the co-structure directing agent as well as the stabilizer. In this method, Cl^-/O_2 and oleylamine served as the etchant and co-reductant, respectively. These frame-like nanocatalysts showed greater activity and stability.

Structurally Fortified Nanoframes

More definite 3D NF design displays well-defined features like corners, edges, and facets but they degrade in harsh conditions (Park et al., 2018). However, the catalytic active surface could be preserved by the fortification of the most vulnerable sites, such as vertices through alloying and heterostructure formation, and the insertion of supported materials into NFs to maintain the overall higher surface area of the structure without losing the surface area of the exposed sites. For the formation of NFs, higher surface energies and vertices of NFs are vulnerable to the structural degradation in the chemical etching process as well as in electrocycling tests. Many groups reported the synthetic procedure in order to reduce the vulnerability of vertices by the growth of additional metals on the active vertices, which results in hetronanostructure formation at the vertices or at the alloying of vertices. However, sometimes etching and galvanic replacement reaction could take place in one process. For instance, Wu and co-workers grew Au islands on vertices of PtNi NFs. They used a protocol based on the selective galvanic replacement reaction and preferred etching, in which the role of etching was more obvious for NF synthesis. The etching was regulated by dimethylglyoxime as Pt was stable to dimethylglyoxime, therefore NFs with protected Pt edges were obtained even after etching. During MOR, the overgrowth Au sites impeded the structural deformation of PtNi NFs and the catalytic activity of Pt_3Ni NFs with the 10% Au remains unchanged after the 3,000 cycles.

Insertion of Structural Support Into the Nanoframes

The inherently weak NFs can be brutally damaged when subjected to long cycling time in electrochemical reaction, due to which a reduction in electrocatlytic performance may be observed. Hence, fabrication of NFs with strong structure support is most important and challenging. We have synthesized PtCu ultrathin NFs by the one-pot method, and these ultrathin NFs were abbreviated as hexapod backbones with thin stretchers (thinHBS). In addition to thinHBS, some other partially etched complex polyhedral hollow structures have also been synthesized. $CuCl_2$ and NaI were responsible for etching to modify the shape, whereas ethanolamine, and amino acids stabilized the [111] the domains. The combination of growth and the etching process smoothly controlled the shape. The transmission electron microscope image showed a two-dimensional picture which looks exactly like hexagonal snowflakes, and the adjacent trunks have a few stretchers which are attached to the trunks symmetrically. The trunk length was found to be 40 nm, the diameter was 5 nm and thickness of the stretchers was about 1.3 nm. The synthesized structures may be beneficial for electrocatlytic applications with enhanced activity and stability owing to ultrathin stretchers and internal trunks which provide support for stability (**Figures 6a–d**).

Moreover, trimetallic catalysts are more active and stable than bimetal alloys. In a recent study, Kwon et al. (2018a) explained the idea of a dendrite@frame-like nanostructure in which the outer PtCuNi NFs are supported by inner PtCu dendrite. Moreover, branches network as well as attached joints can reinforce the multiframe structure and could maintain the same structure during harsh conditions. In order to boost the consumption of Pt, it is necessary to have a more active PtNi alloy part for both the interior support as well as for the outer multiframes. Furthermore, the presence of nanopores in multiframes can be advantageous to entrap the gaseous reactant into nano-confined space and can show higher catalytic performance. Burst reduction and deposition of Ni after the PtNi alloying/dealloying created multiple PtNi bridges among the PtNi and superimposed interfused multiframes. By the Ni erosion, PtNi multiframes with embedded PtNi dendrites of 72 nm were gained. However, these PtNi multiframes showed a higher electrochemical active surface area and ORR performance owing to porous, more active sites, and higher index facets. Similarly, Park et al. (2017a) fabricated firm robust PtCuNi NFs, supported with an interior PtCu dendritic structure. In the formation process, first a PtCu cubic dendritic structure was formed, which evolved into PtCu@Ni dendrite@shell structures after constant deposition of Pt on the surface, and after etching process, PtCu@PtCuNi dendrite@frame (PC@PCN) formed. The detailed process showed that the morphological development into rhombic dodecahedral NCs requires Pt for the growing Ni layer (**Figures 6e–k**).

Other Uncommon Methods

In addition to the above-mentioned methodologies, a cage/frame nanostructure has been developed by the other synthetic procedures such as control decomposition kinetics, long chain alcohol (Jeyadevan et al., 2014), Ostwald ripening (Zhang et al., 2018a), etc.

Nanoframes Other Than Pt and Pd Metals

Noble metal NFs other than Pt and Pd, including gold (Au), ruthenium (Ru), iridium (Ir), and silver (Ag), have also been synthesized, but these NFs commonly have not been used for electrochemical applications in fuel cells. For their synthesis, etching, the galvanic replacement reaction and Kirkendall effect strategies were used. To cover the NFs' synthesis for all types of noble metals, we have also included a short description of noble metal NFs other than Pt and Pd.

Ultrathin triangular gold NFs have been synthesized through the etching process by Xue's group. In this strategy, Ag nanoprisms were used as the sacrificial template and $HAuCl_4$ was continuously introduced to the solution for the deposition of gold on the Ag nanoprisms. Hydroxylamine was used as the reducing agent, and after deposition of gold on the surface of Ag prism, etchants (H_2O_2+NH_4OH) were used to completely remove the Ag prism for the synthesis of ultrathin NF. H_2O_2 oxidized the Ag atoms and NH_4OH prevented the formation of other particles like AgOH and Ag_2O by dissolving the oxidized silver. Etchants were slowly added into the solution because their rapid introduction may destroy the frame structure (Shahjamali et al., 2013). In another example, ultrathin Au NFs with a thickness of 1.6 nm have been synthesized by using the Ag template with decahedral shape, twinned pentagonal rods, and icosahedra to fabricate analogous NFs. H_2O_2 was used as an etchant for the dissolution of Ag (McEachran et al., 2011).

Rhodium cubic NFs have been synthesized by Xia and co-workers, in which Pd nanocubes have been used as seeds and deposition of Rh at the edges-corners of Pd seeds occurred due to the adsorption of Br^- on facets and converted them into bimetallic Pd-Rh core-frame concave cubes. By selective etching of Pd and continuous growth of Rh, they were converted into Rh NFs (Xie et al., 2012). Another group reported the fabrication of Ru NFs by using truncated octahedal seeds, which are converted to PdRu core-frame octahedral structure that are finally converted into Ru octahedral NFs with 2 nm thick frame walls by the selective dissolution of the Pd core by etching (Ye et al., 2016). Very recently, the same group also synthesized Ru cuboctahedral NFs with the face centered cubic (fcc) phase and walls that were a few atomic layers thick by a combination of etching and the galvanic replacement method (Zhao et al., 2019). In addition to monometallic nanoframes, bimetallic nanoframes of Au, Ag, Ru, and Ir have also been synthesized. For instance, Ag/Au nanoshells with voids and pores have been fabricated by utilizing silver NPs as sacrificial templates in the presence of H_2O_2 as an etchant (Wu et al., 2012). Zhang's group fabricated Rh-based RhCu nanooctahedron frames/C, RhPdCu nanopolyhedral frames/C, and RhNi porous nanopolyhedral frames/C by using 3d metals like Cu and Ni as the sacrificial template by selective etching (Zhang et al., 2015b).

Ir-based multi-metallic double layer NFs (DNF) with NF@NF structure were developed by Lee et al. By controlling the kinetics of two types of iridium salts and salts of transition metals like

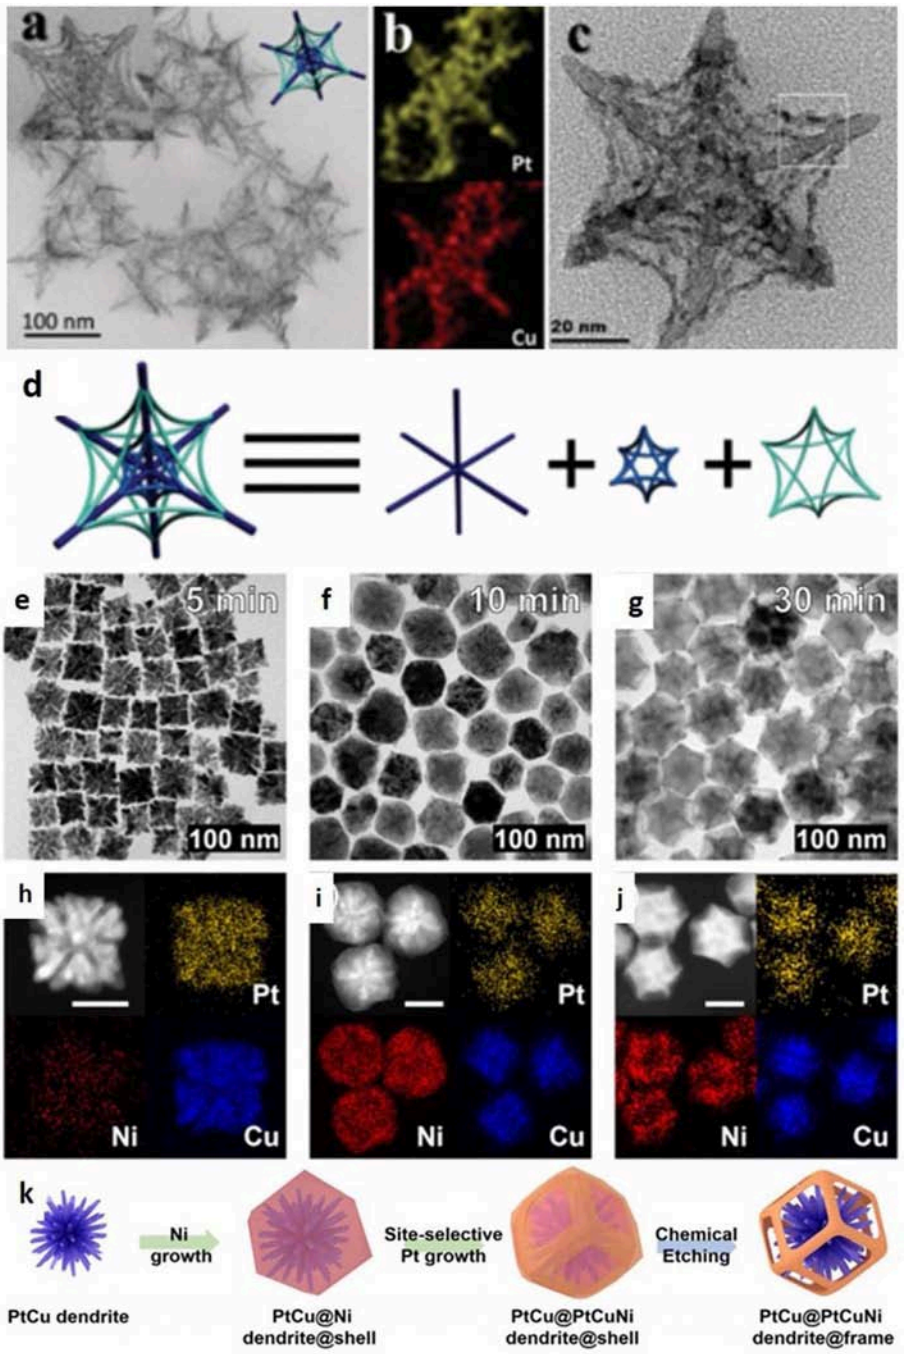

FIGURE 6 | (a) TEM images of hexapod backbones with thin stretchers (thinHBS). **(b)** Element mapping results of thinHBS. **(c)** HRTEM image of thinHBS. **(d)** The anatomic structure of thinHBS. Ni and Cu, firstly core shell alloy@alloy formed in one step and then these structures converted into rhombic dodecahedral IrNiCu DNF by preferential etching. Single-metal NFs formed by the addition of only one type of Ir salt, which showed that for the formation of double layer NFs, two kinds of Ir-metal precursors are important. The structure of Ir-based NCs have also been converted to other double layer NF morphologies, including octahedral NFs and CuNi@Ir core-shell structures, by changing the experiment conditions. The synthesized IrNiCu double layer NFs have been used for an oxygen evolution reaction (OER) in

acid medium, which showed enhanced activity as compared to commercial Ir/C. These NFs also showed good stability toward OER that could be due to the frame which stops the growth and aggregation of NPs (Park et al., 2017b).

Galvanic replacement reaction has also been used for noble metals other than Pt and Pd by many groups to synthesize monometallic and bimetallic hollow structures, nanocages, and NFs of different morphologies by using an Ag template of desired shapes (Zeng et al., 2009; Lai et al., 2015). Colloidal gold nanorings (Au NRs) with high monodispersity were synthesized with the one pot method by galvanic replacement by Du and Wang. PVP was used as coating on the cobalt nanoparticles, and then these PVP-coated nanoparticles generated a one-dimensional assemblage of cobalt nanoparticle chains which were used as the sacrificial template and galvanically replaced by Au to form Au NRs (Hu et al., 2014). Li's group reported single crystalline octahedral AuAg alloy nanoframes by the one pot galvanic method in which polyhedral truncated Ag NPs formed in solution (Hong et al., 2012b). The same group has also developed Ru-Cu nanocages and core-shell Cu@Ru NCs by a one-step galvanic reaction (Chen et al., 2016).

An Au@Ag core-shell, Au@void@AuAg nanoshell, and Au@void@Au NF have been reported by Neretina's group. Au@Ag core-shell structures produced a noble metal rattle shape by galvanic reaction where a moveable core was present in the hollow shell. Gold, platinum and palladium templates of Wulff structures were firstly converted into core/shell structures by the reduction of silver ions, which were further converted by the replacement of silver with gold.

The Wulff-shape core could be restricted in a nanoshell/cage/frame by adjusting the shape of the shell, epitaxial correlation to substrate, and the replaced amount of shell. These structures could be considered important as there is a precise gap between the core and shell. The internal side of these structures consist of the core, shell as well as substrate, which may offer good functional potential. Furthermore, the core present in the shell may provide protection and it is also linked with the surrounding reactants due to a porous cage or frame, which may be beneficial for many applications (Hajfathalian et al., 2016). González's group used a sequential galvanic replacement reaction and the Kirkendall effect at room temperature to fabricate double-walled AuAg hollow nanoboxes (González et al., 2011).

In addition to the above-mentioned methods, some other methods have also been used to synthesize hollow structures. Hollow rutehenium (Ru) octahedral (Oh) nanocages have been developed by *in situ* formed metastable copper octahedrons. Core shell Cu-Ru NPs with meta stability formed by the co-decomposition of copper and ruthenium precursors formed, and a consequent dissolving of copper core dissolution of the core Cu produced hollow octahedron shaped Cu-doped Ru nanocages. These frame structures were also used as electrocatalysts for OER (Yoon et al., 2014). Gu et al. fabricated AuAg shells and porous AuAg NFs by using citrate capped silver nanoparticles by the galvanic replacement reaction. The AuAg nanoshells formed in the presence of $AuBr^{2-}$ and porous AuAg NFs formed in the presence of $AuCl^{4-}$. The $AuBr^{2-}$ was also used to synthesize Au@AuAg rattles (Bai et al., 2015). Qin's group reported a method to synthesize Ag@AgAu core-frame cubic structures by the co-reduction of two metals in the presence of ascorbic acid (Sun and Qin, 2015).

Electrochemical Properties

In electrocatalytic reactions, there is contact between the reaction and active sites of metal. This interaction is due to various energy levels of the outermost electrons, and the electron transfer takes place to reduce the overall energy of the system. The procedure is generally completed by bond breaking and formation, which include chemical sorption and generation of intermediate species. The metals' d band center in relation to the Fermi level is considered a significant tool for measuring the power of interaction with reaction species. The d band center of the metals could be modified by fabricating alloy nanostructures or heterogeneous atomic layers, which could improve the electrocatalytic properties. The shifts in d band center values could be ascribed to the transfer of charge or lattice change owing to the addition of more than one metal. In case of alloying, the enhancement in electrocatalytic properties could be credited to charge conversion from the transition metal atoms of less electronegativity to the more electronegative platinum atoms, and another reason is the shortening of the platinum-platinum bond distance, known as compressive strain. It may happen due to the variations in elements size of different metals. However, the charge transfer as well as strain may cause the downshifting of d-electronic states of platinum surface atoms relative to the Fermi level of alloys, and hence may reduce the poisoning effect of the oxygen reduction's intermediate species.

Moreover, it has been observed that the occurrence of different kinds of transition metals in the alloy nanostructures provide a chance for maneuvering O_2 species on different surface sites and facilitate an additional bi-functional process to accelerate the oxygen reduction kinetics. For improved electrocatalytic performance, alloy NFs with platinum-skin, platinum-skeleton, or frame have been developed as promising candidates. For example, Han and co-workers have synthesized a Pt-Cu alloy octahedral Nfs (PtCu AONFs) having spiny nano-thorns on the tops by the one-step method. The insertion of nickel ions was crucial for NF formation. The synthesized PtCu AONFs showed enhanced activity and stability for ORR. The mass and specific activities were 2.8 and 2.6 times that of commercial platinum-carbon catalysts (Zhu et al., 2019). Furthermore, these PtCu AONFs also showed better results for MOR than Pt/C. In case of PtCu alloy, the surface electronic structure of pure platinum was modified and the electrocatalytic properties enhanced toward oxygen reduction reaction because of a drop of adsorption energy between platinum and oxygen species.

Effect of Surfactants on Electrochemical Properties

For the shape control of nanoparticles, surfactants are usually used, which may also be adsorbed on the exposed crystal facets and thus affect their electrochemical performances. In short, the surface covered with surfactant may suppress the catalyst performance. To overcome this problem, removal of surfactant

is necessary. Until now, different kinds of treatments have been developed for the removal of surfactants. First, a simple washing procedure is performed, followed by separation through centrifugation, and then the following treatments:

(i) Thermal annealing: The catalysts are heated in furnace at high temperature in air.
(ii) Chemical washing: The catalysts are dispersed in acetic acid for a suitable time, followed by washing through centrifugation to remove unwanted impurities.
(iii) UV-Ozone treatment. Catalyst is deposited on the glassy carbon electrode, which is then irradiated with UV-Ozone to remove the surfactants after drying in air.
(iv) Electrochemical cyclic voltammetry is used to remove the surfactants covered on the surface of the catalysts.

APPLICATIONS IN FUEL CELLS

Liquid Fuel Oxidation Reaction

In the polyelectrolyte fuel membrane cells (PEMFCS), gaseous hydrogen fuel is replaced by liquid fuels like methanol in direct methanol fuel cells (DMFC), formic acid in the direct formic acid fuel cells (DFAFC) and ethanol in direct ethanol fuel cells (DMFC) (Park et al., 2017a). For the small portable electronic devices, liquid fuels are more suitable because of their easily exchangeable fuel cartridges, higher energy density as well as faster charging rate. Because of their higher number of advantages, which are described above, the use of liquid FCs presents more challenges. The main issue is the partial oxidation of liquid fuels which leads to the sluggish oxidation reaction kinetics, and it causes a reduction in the number of transferred electrons. In DMFC, <30% of the energy can be exploited as electricity. Another major issue is the crossover of fuel molecules from anode to cathode through diffusion by the proton exchange membrane in the cell. Due to the crossover mechanism, it not only reduces the overall cell voltage but also contaminates the cathode catalyst. Due to the partial oxidation of liquid fuel, it forms CO which adsorbs on the surface of the cathode catalyst and effects the ORR performance of the cathode in cell operation. This procedure is called CO poisoning. However, Pt-based alloys are more familiar, tolerate CO poisoning and show the excellent catalytic performance. Mostly, previous studies explained the strategies to synthesize the hollow nanoarchitectures which showed higher electrocatalytic properties.

In addition to the above electroxidation reactions, the hydrogen oxidation reaction (HOR) is also an important reaction in fuel cells. HOR is a rapid one-electron oxidation route that occurs at anode. Until now, noble metals like Pt-, Pd-, Ir-, and Rh-based monometallic and alloy structures have been used as electrocatalysts for HOR, but currently no paper is available on noble metal nanoframes, which is why we will not focus on HOR applications in fuel cells. For deeper understanding of HOR, the reader is directed to related review papers (Cong et al., 2018; Davydova et al., 2018).

Formic Acid Oxidation Reaction (FAOR)

DFAFCs are the devices which catalyze the reactions among formic acid at the anode and O_2 at the cathode and change the chemical energy into electricity (Ye et al., 2017). In recent decades, for the energy source formic acid is usually used as a fuel in DFAFCs, which have received more attention. Moreover, formic acid is liquid at room temperature and is the most promising fuel. It replaced molecular hydrogen and assisted storage as well as transportation. DFAFCs show higher power density, faster oxidation rate, and higher cell potential with mild fuel crossover.

In case of FAOR, the main limitation for the Pt catalyst is struggle among the direct dehydrogenation path and indirect oxidation path, which produce CO_2 directly and CO as an intermediate, respectively. So, enhancement of the direct pathway is necessary to assist the detachment of CO from the surface. In addition, surface as well as electronic structure play significant roles in the half reaction. However, separation of Pt atoms with others not only suppresses the indirect path but is also helpful for the CO stripping from the platinum surface. In case of alloys, atomic separation is gained, which not only tailors the surface electron densities but also stimulates direct dehydrogenation. However, synthesis of stepped atoms on the surface provides additional chance for enhanced CO stripping. Thus, fabrication of open structures and alloy formation are vital for efficient and durable catalysts for FAOR.

Wang et al. fabricated Pd NFs with more defined morphology by directly excavating the solid NCs. However, in comparison with the solid Pd catalyst, these NFs display good activity as well as durability toward FAOR because of their 3D open structure. Pd NFs displayed high activity in comparison to the Pd octahedra catalyst and a 7.5-fold increase for peak current. Because of their 3D open structure, there is a larger fraction of edges and corner atoms, which lead to good catalytic performance in terms of FAO. Moreover, the long-term stability of catalysts is estimated by the durability test as depicted in **Figure 7A**. It is noted that the nanostructure of Pd NFs were balanced and showed good stability after 1,000 cycles of durability tests (Wang et al., 2017b).

In another report, Nosheen et al. (2013) used the one pot method for the fabrication of single crystalline octahedral PtCu NFs in an aqueous system. When compared with the platinum black and platinum/carbon catalyst, these octahedral PtCu NFs showed good specific activity toward FAOR due to their exclusive frame structure and combined effect of Pt and Cu (**Figure 7B**). Furthermore, comparison of electrocatalytic properties of Pt and Pd-based nanoframes toward FAOR, MOR, EOR, ORR, and bifunctional electrocatalysis is given in **Table 1** for better understanding.

Methanol Oxidation Reaction (MOR)

In the case of DMFCs, MOR occurs at the anode with the multistep reaction, and it depends upon adsorption as well as oxidation of methanol on the catalyst. For the MOR, Pt is usually used as a catalyst due to its higher activity toward adsorption of methanol. In addition, pure Pt surface suffers from CO poisoning, which reduces the catalytic performance. Researchers

have focused on the fabrication of Pt-based nanocatalysts, which not only reduces the CO poisoning but also displays good activity and stability. For instance, Luo and Shen (2017) fabricated the PtCu NFs along higher index facets by the one pot method, which showed good catalytic performance. In addition, by tuning the ratios of Pt as well as Cu precursors, two different octopod NFs like $PtCu_2$ concave octopod NFs and ultrathin PtCu octopod NFs were synthesized. Because of their 3D surface area and higher index facets, these $PtCu_2$ concave octopod NFs displayed good catalytic performance and more CO tolerance. Regarding MOR, these $PtCu_2$ concave octopod NFs showed a 7-fold enhancement in activities as compared to the commercial Pt/C catalyst. However, in a severe environment of electrocatalytic reaction, these $PtCu_2$ concave octopod NFs are more conserved as shown in **Figures 8A,B**. In another report (Zhang et al., 2013), PtCu nanocages were developed by using the glycine mediated reaction kinetics, which showed good activity and stability for the MOR in comparison to the Pt/C and Pt black catalysts. The current density value specific activity of PtCu yolk-cage nanoalloy was 2.8 mA cm^{-2}, which was four- and 6-fold higher than Pt black and Pt/C, respectively. Similarly, Ding et al. fabricated rhombic dodecahedral PtCu NFs by using the one pot method. In comparison with the Pt/C as well as Pt black, these PtCu NFs presented good catalytic performance toward MOR due to their highly open nanostructure and synergetic effect among two metals (Ding et al., 2015). Moreover, Xia et al. (2012) synthesized the $PtCu_3$ nanocages by the one pot method in organic solution. Toward MOR, these $PtCu_3$ nanocages depicted excellent catalytic activity when compared to solid PtCu NPs as well as with single component Pt catalysts. The excellent catalytic performance was due to the special nanostructure as well as the synergetic effect among Pt as well as Cu. In addition to Pt metal, Pd alloy NFs have also been used for MOR. For instance, Chen et al. have synthesized the PdCu flower-like nanocage by using the galvanic reaction and disproportionation reaction, and in the synthetic procedure Cu_2O octahedra were used as template. These PdCu flower shaped nanocages showed more catalytic activity in comparison with the Pd NPs in terms of MOR, which was 2.7 times greater than the commercial Pd/C. The higher catalytic properties were because of their large surface area and effect of Pd and Cu metals. In addition, these PdCu nanocages have shown good stability as well as excellent poison tolerance. For MOR, the presence of 10% Au on Pt_3Ni NFs may increase the catalytic activity, and the structure was preserved even after 3,000 cycles. The Pt skinned surface of NFs that is formed via the etching process is the cause of enhanced durability, which prevented further etching of the Ni content. Furthermore, the addition of Au islands to the PtNi frame could fade the bindings of poisonous and adsorbed species on the surface, which may further enhance durability **Figures 8C,D**.

Ethanol Oxidation Reaction (EOR)

Ethanol is also a type of liquid fuel and used in direct ethanol fuel cells. For instance, Wang et al. developed 3D Pt_4Ni NFs as well as $PtNi_4$ porous octahedra by the corrosion of $PtNi_{10}$ solid nanoctahedra and compared their ethanol electrooxidation under alkaline media. Current density values at the −0.1 V in the positive scan are the 5.50 and 5.90 $mAcm^{-2}$ for the $PtNi_4$ porous $PtNi_4$ octahedra and Pt_4Ni NFs which both display a higher value as compared to the commercial Pt/C value (4.01 $mAcm^{-2}$). However, the corroded Pt_4Ni NFs as well as the $PtNi_4$ porous octahedra electrocatalyst were confirmed by mass activities, which are shown in the **Figures 9A,B**. The mass activity of Pt_4Ni NFs exhibited an improvement factor of 4.5 vs. $PtNi_{10}$ octahedra, and in the case of Pt_4Ni porous octahedra the improvement factor was 4.1, which are much better as compared to the commercial Pt/C.

According to these analyses, it is proved that ethanol electrooxidation displays improved catalytic activities after corrosion from solid $PtNi_{10}$ nanoctahedra to Pt_4Ni NFs as well

TABLE 1 | Comparison of electrocatalytic properties of Pt and Pd-based nanoframes toward FAOR, MOR, EOR, ORR, and bifunctional electrocatalysis.

as $PtNi_4$ porous octahedra. Among these, Pt_4Ni NFs showed outstanding catalytic performance because of their higher surface area to volume ratio. In addition, $PtNi_4$ porous octahedra, a transparent structure with more voids and Pt-rich surface, shows superior catalytic activity. That is why the corroded nanocatalyst is superior to parent NCs in which mostly Pt atoms are buried inside, as shown in **Figure 9**.

Oxygen Reduction Reaction (ORR)

Pt-based nanocatalysts have been the most promising electrocatalysts toward ORR. But the main issue for platinum oxygen reduction is due to their lower abundance as well as higher price of Pt (Escudero-Escribano et al., 2018; Wang et al., 2018b). It is necessary to improve the efficacy of Pt atoms in catalysis by reducing Pt usage and to improve the ORR activity which is gained by both the surface and electronic structure. In terms of surface structure, hollow as well as open nanoarchitectures like nanocages and frames boost the number of Pt atoms on the edges and show higher activity for electrocatalysis. However, electronic effects act as another way for tuned ORR activity. As mentioned in the previous studies, the best method to tune the electronic structure is the alloying of Pt with other metals. In addition, Pt and Pd work differently, accumulate more electrons at Pt sites and may improve the catalytic performance in terms of ORR. However, noble metal-based NFs show higher catalytic activity and durability as compared to others. Park et al. (2016) reported the fabrication as well as catalytic activities of Pt cubic NFs with wall thickness <2 nm. The as synthesized Pt cubic NFs displayed a 6-fold enhancement in ORR mass activity over 20,000 cycles of repeated potential sweeping in comparison with Pt/C.

The morphology-based catalytic activities of several PdPt NCs in terms of ORR were studied, and their results have been compared with the commercial catalyst. For instance, Hong et al. synthesized nanocages of different shapes and compared them with the Pd@Pt core shell as well as NCs without hollow structure and commercial catalyst, and the as synthesized hollow structures showed enhanced ORR properties (Hong et al., 2012a). Similarly, Zhang et al. (2015a) developed Pt cubic and octahedra nanocages having [100] and [111] facets, respectively, which showed higher electrocatalytic activities in terms of ORR.

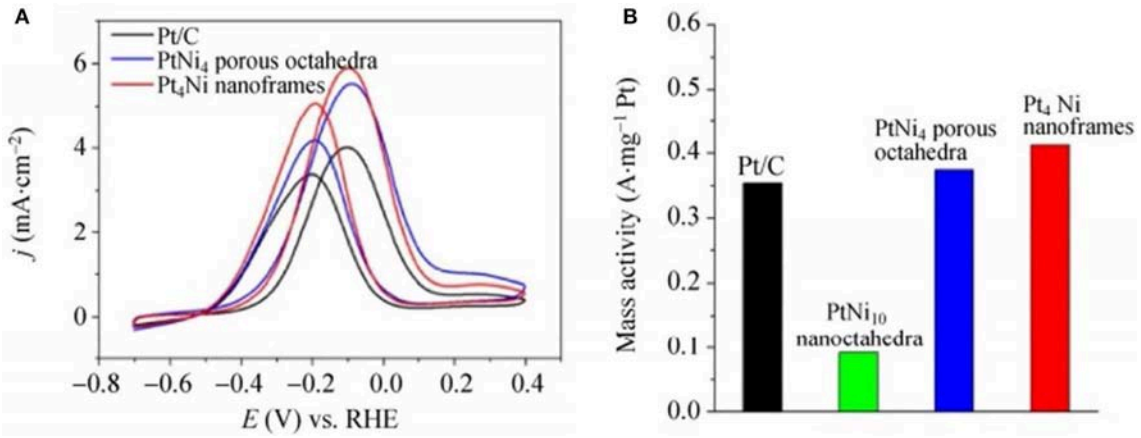

FIGURE 9 | Cyclic voltammograms of commercial Pt/C, $PtNi_4$ porous octahedra, and Pt_4 Ni nanoframes in **(A)** 0.5 M KOH + 1 M ethanol (scan rate: 50 mVs^{-1}); the current density was normalized to the ECSAs. **(B)** Mass activities measured at −0.1 V for ethanol oxidation on commercial Pt/C and three Pt-Ni catalysts; the current density was normalized to the weight of Pt loaded on the working electrode. However, in case of many structure sensitive reactions, introducing defects like twin boundaries may reduce the activation energy and enhance the catalytic performance (He et al., 2016). For example, Pt-enrich few atom thick nanocages showed the mass activity 7 times larger in comparison with the Pt/C catalyst as well as 4 times larger when compared with the PdPt core shell/C catalyst. However, specific activity of Pt-enrich nanocage/C was 10 times that of the Pt/C catalyst and 3.5 times that of the PdPt core shell/C catalyst. By accelerated degradation testing, the stability of Pt-enriched nanocage/C was also studied. Pt-enriched nanocage/C displayed nearly no degradation after 10,000 cycles and icosahedral Pt-enriched nanocages were stable after accelerated degradation testing.

In addition, Wang et al. (2016) benchmarked the ORR performance of Pt based icosahedral nanocages in contrast to the Pt/C catalyst. The mass as well as specific activities of Pt icosahedral nanocage showed 6.7 and 10-fold enhancement, respectively, which is ascribed to the exposure of [111] facets, twin defects, and higher distribution of Pt. However, mass activity of Pt icosahedral nanocages was enhanced 4 times after 5,000 cycles of ADT when compared with the commercial catalyst before the durability tests.

In addition to single metal NFs, fabrication of Pt based bi-and multimetallic alloy NFs could display superior activity in terms of ORR. So, alloying of Pt with transition metals like Co, Cu, Ni, etc., could induce the compressive strain on NPs' surface because of shorter Pt-Pt distance as well as downshifting of d-band center of the Pt. Additionally, downshift of the d-band center weakens the adsorption of OH species that are intermediate to ORR, facilitates the dissociation of water molecules from catalyst surface and increases the ORR reaction rate of NPs.

Dhavale and Kurungot (2015) developed a CuPt nanocage via the galvanic displacement reaction. These CuPt NCs display 2.9-fold and 2.5-fold higher levels of mass activity as well as specific activity toward oxygen reduction reaction at 0.9 V vs. reversible hydrogen electrode. In addition, stability of CuPt nanocages was investigated by a durability test under alkaline conditions. So, CuPt NCs have higher surface area and provide additional active sites for the dissociative adsorption of oxygen and improved the ORR performance. The combination of Pt and Cu play a very important role in facilitating the dissociative adsorption of O_2. Similarly, rhombic dodecahedral Cu_3Pt NFs synthesized by the Han group are more active toward the ORR as compared to the CuPt core shell nanostructure (Han et al., 2014).

For instance, uniform PtCu alloy hollow cubic NFs were synthesized by Wang et al., and these 3D nanoarchitectures show the larger specific as well as mass activities and improved durability toward ORR in comparison with the Pt nanocubes, commercial Pt/C as well as Pt black catalyst under alkaline solution (Wang et al., 2018a).

Lyu et al. (2017) developed the CuPt alloy RD as well as spiny CuPt RD NFs. The 3D hollow structure of both sets of NFs and abundant surface defects make them active catalysts. Toward ORR, spiny RD NFs have shown the specific activity of 1.3 and 3 times as compared to the RD NFs and Pt/C catalyst. Huang et al. (2019) have fabricated 3D RD $Pt_{26}Cu_{74}$ NFs bound with multiple index facets that were synthesized by the effective facile robust solvothermal synthetic procedure. Due to exclusive morphology and the combined effect of the two metals, these $Pt_{26}Cu_{74}$ catalysts have shown higher activity as well as stability toward ORR in comparison with the $Pt_{18}Cu_{82}$, $Pt_{50}Cu_{50}$ NC, and Pt/C catalysts.

Controlling the structure at the atomic level can tune the catalytic performance of materials and may enhance the activity as well as durability. Han et al. developed highly active and durable Pt_3Ni NFs as catalysts with a 3D surface and 2 nm thin platinum skin. Both internal and external surfaces of frames are available for reactants, the and presence of segregated platinum skin demonstrate the excellent ORR activity. These Pt_3Ni NFs have exhibited enhanced mass activity and specific

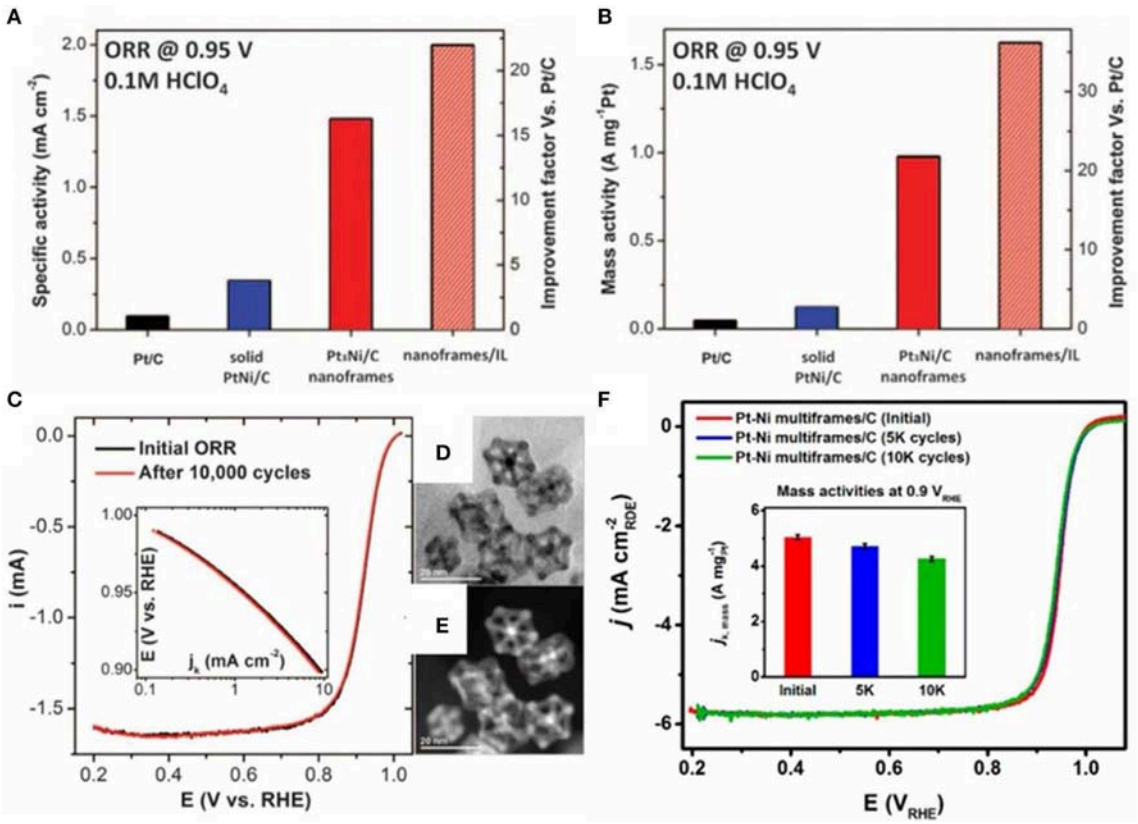

FIGURE 10 | Electrochemical properties of Pt3Ni nanoframes. **(A,B)** Specific activities **(A)** and mass activities **(B)** measured at 0.95 V, and improvement factors versus Pt/C catalysts. Because of the high intrinsic activity of the Pt3Ni nanoframes, the ORR activity values are given at 0.95 V in order to avoid the extensive error margin at 0.9 V introduced by the close proximity of current values to the diffusion-limited current. (2018a) Copyright 2018, American Chemical Society.

activity that are 36 and 22 times those of the Pt/C, respectively. Furthermore, the frame structure was retained after 10,000 cycles, even during harsh electrochemical conditions as exhibited in **Figures 10A–E** (Chen et al., 2014). In another report, dendrite implanted PtNi multiframes display the ECSA of 73.4 m^2gPt^{-1} and mass activity of 1.51 A $mgPt^{-1}$ that is the 30 time higher than the Pt/C catalyst. It is noted that the ECSA as well as ORR performance of these dendrite embedded PtNi multiframes/C are due to their porous design, several active sites, and higher index facets **Figure 10F**.

3D Pt anisotropy of PtNi RD was tuned by controlling the ratio of Pt and Ni precursors—as a result, entire hollow NFs and excavated NFs were gained. These excavated NFs display the ∼10 times greater specific as well as ∼6 times larger mass activity in terms of ORR as compared to the Pt/C and double the mass activity of hollow NFs. However, the higher activity is due to more Ni content in the near-surface region and 2D sheet structure within the NFs, which minimized the number of buried Pt sites (Becknell et al., 2017). Wang et al. explained the preferential removal of Ni components of the tetrahexahedral (THH) PtNi NPs by using the CO. These PtNi (THH) NF structures demonstrated 8-fold higher ORR mass activity than in commercial Pt/C. In another report, PtNi NFs along (THH) and RD morphologies were used for the ORR. The as synthesized PtNi (THH) NFs display more enhanced ORR activity that shows 20.9 times larger mass activity in comparison with the commercial Pt/C.

It is observed that in addition to structure, composition also plays a very important role for the enhanced catalytic performance. For instance, RD PtCuNi NF catalysts display 6-fold higher mass activity as compared to commercial Pt/C in terms of ORR. Hollow PtPdRu dendrite nanocages with porous structure not only showed 3D surface active sites from both interior and exterior surfaces but also improved the resistance to particle aggregation. In addition, mass transfer of species inside the porous nanocages also increased. However, electronic as well as strain effect of three metal components also enhanced the activity. Therefore,

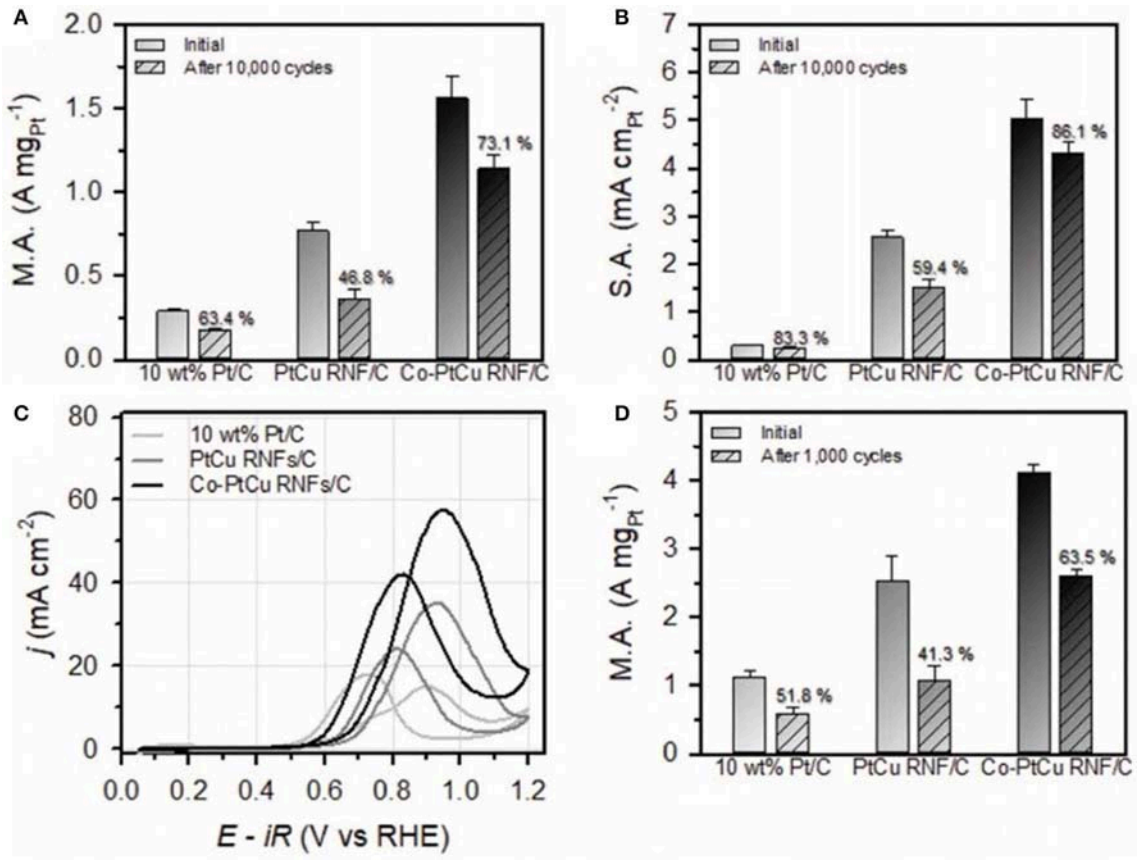

FIGURE 11 | (A,B) ORR mass and specific activities of electrocatalysts, before and after 10,000 ORR ADT cycles. **(C)** CVs of Co-PtCu RNF/C, PtCu RNF/C, and Pt/C catalysts in 0.1 M $HClO_4$+1 M CH_3 OH solution. **(D)** Mass activity of electrocatalysts for the MOR, before and after the ADTs. trimetallic dendritic nanocages accelerate the kinetics of oxygen reduction. In comparison with the Pt/C, ECSA, mass activity as well as specific activity of PtPdRu dendritic nanocage were higher (Huang et al., 2018).

The PtPdNi mesoporous truncated octahedral nanocage showed higher catalytic performance toward the ORR relative to the core shell mesoporous truncated octahedra and Pt/C catalyst due to their mesoporous surface, hollow design, polyhedral shape (Wang et al., 2019).

Bifunctional Catalysts

As mentioned above, the Pt based alloy nanoarchitectures show excellent catalytic performance toward ORR and MOR. However, the bifunctional catalysts show more importance because they function as active catalysts in both anodes as well as cathodes of DMFCs. Among different hollow structures, NFs have received more attention because of their open 3D nanoframe structure. For instance, Zhang et al. (2016) synthesized the highly anisotropic 5-fold twin CuPt NFs, which shows more ORR as well as MOR activity, with a specific activity of 1.71 mA cm_{Pt}^{-2} toward ORR and 18.2 mA cm_{Pt}^{-2} for MOR. However, the rich concave site along with a higher coordination number demonstrated superior ORR activity. The most important point in this research is that the nanothorns on the edges as well as higher index facets provided extra active surface area.

In another report, Kwon et al. (2018b) fabricated Co-doped CuPt RD NFs which displayed a higher MOR specific activity of 13.3 mA cm_{Pt}^{-2} as well as a mass activity of 4.11 A mg_{Pt}^{-1}. In addition, ORR performance was also boosted with a specific activity of 5.03 mA cm_{Pt}^{-2} as well as a mass activity of 1.56 A mg_{Pt}^{-1}. However, protruded vertices also play a most important role in boosting the durability, which is confirmed by the study with the un-doped CuPt NFs (**Figure 11**). Another example is the highly composition-segregated PtNi NFs with open frame structure transformed from solid PtNi NCs. According to the catalytic results it is proven that these PtNi NFs have shown excellent catalytic performance toward ORR as well as alcohol oxidation in comparison with the commercial Pt/C catalyst. Other Pt based nanoarchitectures have been studied which are active as bifunctional catalysts in terms of ORR at the cathode as well as other fuel oxidation reactions at the anode like formic acid, ethanol, glycerol and ethylene glycol (Ye et al., 2017).

Pt_3Ni tetrahexaherdal NFs were developed by CO etching which is highly open, stable as and has a higher index microstructure which consists of a segregated Pt thin surface and downshifted d-band center, which is revealed by the

Density Functional Theory (DFT). These NFs showed excellent catalytic performance, such as higher stability in harsh reaction conditions, which promoted direct electrooxidation of formic acid to CO_2 and enhanced ORR activities. FAOR occurs on the Pt based electrode and proceeds via a dual path mechanism. In the first pathway, direct oxidation generates CO_2 and in the second pathway there is a generation of CO adsorption and then oxidation of CO_{ads} to CO_2 at higher potentials. Very recently, Wang et al. used Co etching at higher temperatures for the fabrication of Pt_3Ni tetrahexahedron NFs by using the facile as well as efficient method. So, these NFs revealed excellent stability under prolonged electrochemical potential cycles (Wang et al., 2017a).

CONCLUSION AND PERSPECTIVES

In recent years, noble metal-based NFs have received more attention because of their special structure as well as their physicochemical properties. For controlled synthesis and advanced applications of noble metal-based NFs, great efforts have been devoted in recent years. According to this review, we explained distinct methods such as the photocatalytic template method, electrodeposition, the Kirkendall effect, galvanic replacement, oxidative/chemical etching, and other methods for the fabrication of noble metal-based alloy NFs. In addition, different shapes of noble metal-based NFs have been developed and focused with ultrathin walls, high index facets, twin boundaries compositional segregation, and inner structural support. These noble metal-based NFs show excellent performance in fuel cells.

However, for the fabrication of noble metal-based NFs still more challenges are present such as tuning the porosity, voids, elemental composition as well as the thickness of ridges and atomic arrangement. For catalytic properties, controlling the ridge thickness with segregated Pt skin of metal-based NFs is of great importance and challenging. To preserve the stability of NFs after electrocatalytic cycling is a difficult task. To improve the stability of such nanostructures, the addition of dopant, or another stable structure inside NFs may secure the atomic arrangements and stability as well. The addition of a doping material can enhance the exposed atoms on the surface. NFs with more than three or four metals and other doping materials can further increase the activities and stabilities.

Furthermore, the implementation of theoretical studies must be considered to gain an understanding of the actual basis of the catalytic properties of multimetallic NFs. Additionally, theoretical studies should focus on the calculation of surface energies of the exposed atoms. It should also calculate the binding energies of reaction intermediates and surfaces of the electrocatalyst for multi-metallic structures. Density Functional Theory studies have been used for the few faceted bimetallic structures, but for the multimetallic NFs these studies are very rare. There is an urgent need to find easy calculation strategies for understanding multimetllic NFs with complex atomic arrangements, which can help to clearly identify the reasons behind their enhancement of activity and stability. Another necessity is to understand the rearrangements of atoms at atomic scale during the process of electrocatalysis. For this purpose, *in situ* study of electrochemical reactions may be a solution for the deep understanding of phase segregation and arrangement of atoms. Additionally, these catalysts should be reproducible at industrial level and should withstand the real operating environment.

Sometimes, the thermodynamic stability of alloy phases varies during synthesis and electrochemical cycling. Few efforts have been made to perform elecrocatalysis at higher potentials and temperatures to check the stability of catalysts under real operating conditions. In addition, hollow structures show a different electrochemical active surface area at different over potentials due to mass transportation and make its use limited in real applications. At low over potential, O_2 diffuses inside the inner part of hollow structures, and at high over potential, O_2 diffuses slowly inside the voids. Some groups proposed that the use of ionic liquids in place of aqueous liquids could fill the interior void of NFs and offer more O_2 solubility that could be beneficial for a real operating environment for fuel cells.

AUTHOR CONTRIBUTIONS

FN has substantial contributions to the conception, drafting and writing of this work. AS helped in writing the draft. TA contributed to the writing and revising it critically for important intellectual content. NH reviewed it and contributed in its revision. All authors read and agreed the final version of the manuscript.

Big Potential From Silicon-Based Porous Nanomaterials: In Field of Energy Storage and Sensors

Rana Zafar Abbas Manj[1†], *Xinqi Chen*[1,2†], *Waheed Ur Rehman*[1], *Guanjia Zhu*[1], *Wei Luo*[1,3*] *and Jianping Yang*[1,3*]

[1] State Key Laboratory for Modification of Chemical Fibers and Polymer Materials, College of Materials Science and Engineering, Donghua University, Shanghai, China, [2] School of Physics and Mechanical and Electrical Engineering, Hubei University of Education, Wuhan, China, [3] Institute of Functional Materials, Donghua University, Shanghai, China

Silicon nanoparticles (SiNPs) are the promising materials in the various applications due to their unique properties like large surface area, biocompatibility, stability, excellent optical and electrical properties. Surface, optical and electrical properties are highly dependent on particle size, doping of different materials and so on. Porous structures in silicon nanomaterials not only improve the specific surface area, adsorption, and photoluminescence efficiency but also provide numbers of voids as well as the high surface to volume ratio and enhance the adsorption ability. In this review, we focus on the significance of porous silicon/mesoporous silicon nanoparticles (pSiNPs/mSiNPs) in the applications of energy storage, sensors and bioscience. Silicon as anode material in the lithium-ion batteries (LIBs) faces a huge change in volume during charging/discharging which leads to cracking, electrical contact loss and unstable solid electrolyte interphase. To overcome challenges of Si anode in the LIBs, mSiNPs are the promising candidates with different structures and coating of different materials to enhance electrochemical properties. On the basis of optical properties with tunable wavelength, pSiNPs are catching good results in biosensors and gas sensors. The mSiNPs with different structures and modified surfaces are playing an important role in the detection of biomarkers, drug delivery and diagnosis of cancer and tumors.

INTRODUCTION OF SILICON-BASED NANOSTRUCTURES

Silicon nanoparticles (SiNPs) have been remained a material of great interest with versatile and promising applications compared to the bulk material due to their physical and chemical properties (Dinh et al., 1996; Shiohara et al., 2009). SiNPs render a range of properties and series of functionalization (chemical and biological species), non-toxicity, biocompatibility and solubility in physiological fluid (Kang et al., 2009; Park et al., 2009; Wang et al., 2012). Electrical properties of silicon rely on temperature which is a conductor at room temperature. Electronic conductivity of SiNPs can be enhanced by doping of 3rd and 4th group elements of periodic table, functionalization and particle size (Anderson and Spear, 1977; Arora et al., 1982; Van Buuren et al., 1998; Veinot, 2006; Sivakov et al., 2009). SiNPs with different dyes also exhibit good photoluminescence (PL), fluorescent properties, tunable wavelength of excitation and emission, excellent photo and chemical stability (Chen et al., 2001; English et al., 2002; Shen et al., 2010; Intartaglia et al., 2012). Optical

properties of SiNPs strongly depend upon quantum confinement effect which varies with changes in particle size, concentration, and functionalization (Trwoga et al., 1998; Dancil et al., 1999; Ledoux et al., 2002). Due to these unique properties, SiNPs show numbers of applications in different fields like drug carriers, bioimaging, gas sensors, solar cells, electronics and energy storage devices.

In order to improve the performance in different applications, the structure of silicon has modified into the porous structure. On the basis of pores size, porous silicon is classified into microporous (pore diameter<2 nm), mesoporous (pore diameter 2–50 nm) and macro porous (pore diameter >50 nm). Because of alternation in the structure of silicon, a tremendous variation happen in optical properties of SiNPs which can attribute to the reduction in refractive index and enhancement in PL efficiency as compare to silicon at room temperature (Bsiesy et al., 1991; Astrova and Tolmachev, 2000; Chao, 2011; Min-Dianey et al., 2018). Surface properties also affected by varying the structure of silicon, the specific surface area per unit volume increase owing to pores in structure. Mesoporous structure of silicon improves surface to volume ratio, physical adsorption and electrical resistivity of silicon due to large void spaces (Karlsson et al., 2004; Hajji et al., 2006; Lasave et al., 2013; Azadeh et al., 2018). On behalf of these structural base properties, porous silicon nanomaterials have high potential to resolve challenges in different fields i.e. energy storage devices, sensors and biomedical applications (Yang et al., 2014a, 2016; Wang et al., 2015).

APPLICATIONS OF SILICON-BASED POROUS NANOMATERIALS

Lithium-Ion Batteries

Si as anode material has very high theoretical specific capacity 4,200 mA h g^{-1} as compare to graphite (Goodenough and Kim, 2009). In spite of high specific capacity of Si, Si as anode material has a major problem of volume expansion (up to 400%) during charging/discharging which lead to cracking of anode, electrical contact loss, unstable solid electrolyte interphase (SEI) film and finally fast fading of capacity (Yang et al., 2002; Jung et al., 2003; Baranchugov et al., 2007). Besides, the low intrinsic electrical conductivity (1.56×10^{-3} S m^{-1}) and lithium diffusivity of Si also limits its electrochemical performance. It has been noted that micro and nanostructure of silicon have good electrochemical performance as compare to bulk silicon as anode material (Ryu et al., 2004; Kim et al., 2008). The volume expansion of silicon anode material has been controlled by introducing nanostructure of silicon as Si micro/nanostructures, nanowires, hollow-structured and porous silicon (Li et al., 2000; Huang and Zhu, 2010; Xu et al., 2011; Wen et al., 2013; Cho et al., 2017; Kim et al., 2017). Spherical nano-particles of silicon having diameter of 150–200 nm was used as bulk silicon anode material which exhibited capacity higher than 500 mA h g^{-1} at current 0.2 A g^{-1} up to 100 cycles (Liang et al., 2018). To further enhance the electrochemical properties, silicon nanowires (SiNWs) on stainless steel was prepared by CVD process. SiNWs as anode

material delivered great area capacity of 7.1 cm with retention 60 % at current rate C/50 and good rate performance (Leveau et al., 2016). To accommodate volume expansion of Si anode and cycling stability, the structure of silicon was modified to the spherical hollow structure of silicon as shown in **Figure 1**. The multi-shell hollow silica microsphere (MHSM) was prepared by the sacrificial template process. MHSM as anode material delivered high capacity 750 mA h g^{-1} at current 0.1 A g^{-1} after 500 cycles. MHSM exhibited excellent cycling stability because of a porous structure which provides the easy reaction among the lithium ion and anode material and reduced the reaction path (Ma et al., 2017b). Further, three-dimensional (3D) macroporous silicon was synthesized by magnesiothermic reduction to enhance structure stability, capacity and cycle life of Si anode as shown in **Figure 2**. 3D porous silicon as anode material showed high capacity with excellent retention and cycle life (1,058 mA h g^{-1} with current rate 2 A g^{-1} after 800 cycles) (Wu et al., 2016). The structural modification in silicon anode material provided a significant improvement in electrochemical performance as compared to bulk silicon anode. The large area of nano-structure and greater voids of porous structure provided a large surface to the diffusivity of lithium ions and controlled the pulverization and compensated the electrical contact loss.

Silicon Nanostructures With Binders in LIBs

The nano-structural silicon enhanced the electrochemical performance to some extent, but a modification in silicon anode was still required. Further electrical contact loss in silicon anode due to pulverization was controlled by adding conductive additives and polymer binders in Si anode (Priyono et al., 2017; Teng et al., 2018). Conductive additives provided an electronic path in charging/discharging but after some cycles failed to contact silicon particles because conductive additives could not provide binding force Si particles

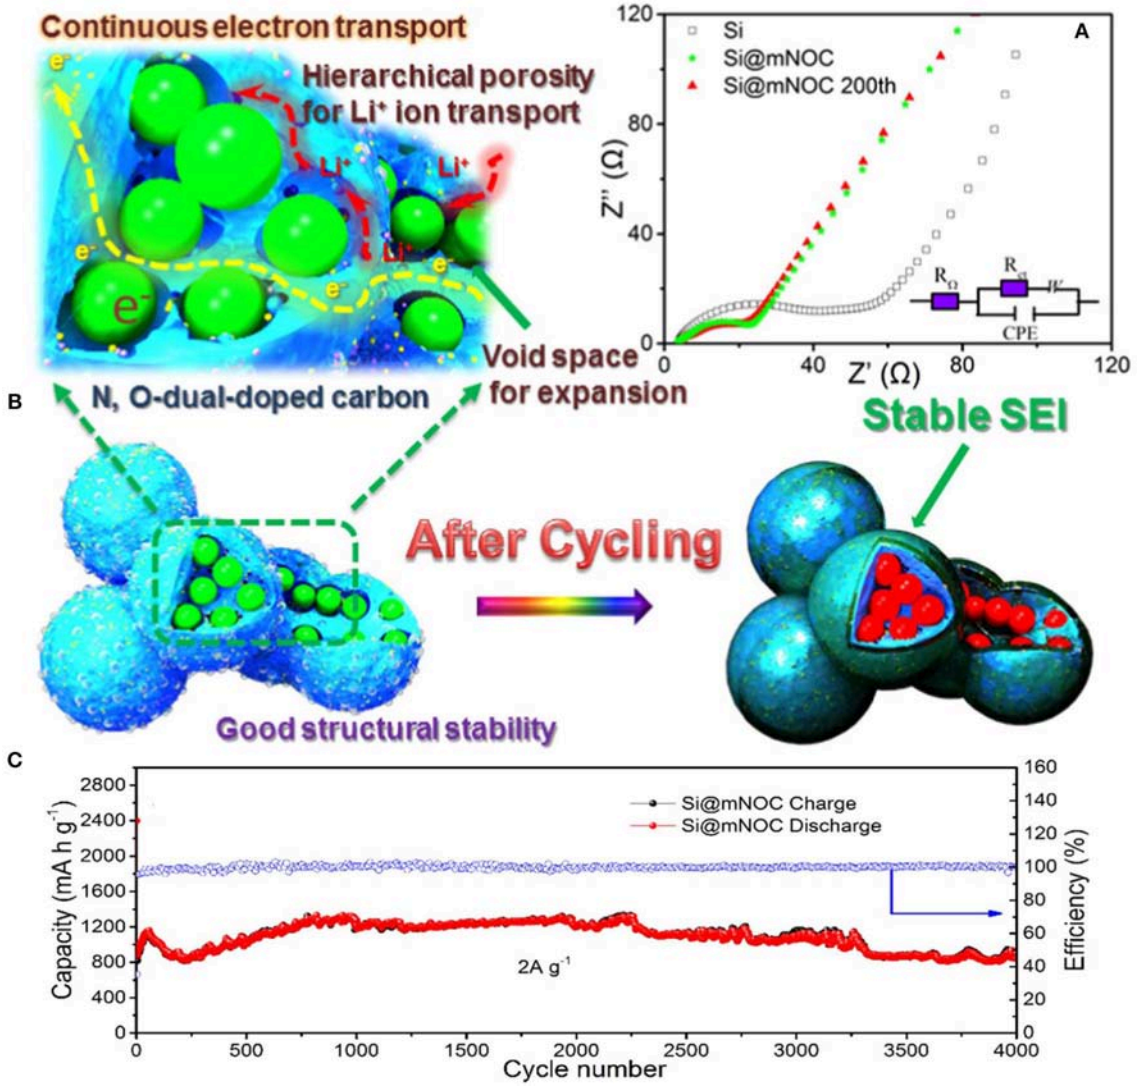

FIGURE 5 | (A) Evaluation of SEI film and surface kinetics of Si@mNOC during cycling. **(B)** Schematic representation of conductivity, stability and stable SEI film on Si@mNOC after cycling. **(C)** Cycling performance with coulombic efficiency at current 2 A g^{-1}. (Beattie et al., 2008; Renganathan et al., 2010). To overcome these issues, numbers of conductive binders were used to improve electronic conductivity and stability of Si anode for long cycle life (Lin et al., 2016; Sarode et al., 2018). By taking the advantages of self-healing ability of a material, a conductive binder was prepared by use of ureidopyrimidinone (UPy) and polyethylene glycol (PEG). By use UPy-PEG-UPy as a binder with SiNPs in anode material excellent electrochemical performance was achieved. SiNPs anode with UPy-PEG-UPy binder delivered high capacity 1,454 mA h g^{-1} over 400 cycles with the decay of 0.04 % per cycle. The self-healing ability of UPy-PEG-UPy binder maintained the good integrity of silicon anode as compared to the traditional binder (Yang et al., 2018). Electrical contact loss in Si anode has been tried to control by the chemically bonded conductive binder. The aqueous hybrid gel prepared with sodium carboxymethyl cellulose by cross-linker sodium borate and used with silicon as an anode material. Hybrid gel covalently bonded with silicon particles and also acted as a buffer for silicon particles. Si anode with gel exhibited good capacity and cycle life of 1211.5 mA h g^{-1} after 600 cycles with coulombic efficiency 88.95 % (Zhang et al., 2018). Furthermore, to enhance the electrochemical properties and stability of Si anode, a naturally derived gum Arabic (GA) polymer (as fiber-reinforced concrete) was used to control cracking of Si anode during charging/discharging as shown in **Figure 3**. Si anode with GA polymer binder delivered high capacity as compare to CMC binder 2,000 mA h g^{-1} at current rate 1C after 500 cycles and excellent cycle life with capacity

1,000 mA h g^{-1} at rate 1C over 1,000 cycles. Glycoprotein chain in GA provided good mechanical properties which behaved like a fiber in concrete and polysaccharide provided binding force due to the presence of hydroxyl groups (Ling et al., 2015). Conductive binder polymers have significantly enhanced the electrochemical properties of Si anode material and its structural integrity.

Coated-Silicon Nanostructures in LIBs

Continuous charging/discharging solid electrolyte interphase film by direct interaction between electrolyte and silicon particles is developed on silicon particles in the anode. SEI film on silicon particles acts as a barrier to further diffusion of lithium-ion and directly affects cycle life of Si anode (Yang et al., 2008; Zhou et al., 2014). Fast decay in capacity and SEI film has been controlled by a coating of different materials on silicon particles. Coating of different materials provides a barrier between direct contacts of electrolyte to active silicon which leads to decrease interfacial reaction between electrolytes to the electrode material and suppress the transformation of structure because of mechanical properties of coating materials (Kim et al., 2015). To stabilize SEI film, carbon has been used widely in the coating of silicon particles due to its good electronic and mechanical properties. Carbon coating controls the pulverization of silicon particles and prevents direct contact of the electrolyte with silicon particles (Yi et al., 2017). By leaving interior voids, unfilled pSiMPs was coated with carbon as shown in **Figure 4**. Unfilled carbon coated SiMPs as anode material delivered high capacity and excellent

All rights reserved.

cycle life (1,500 mA h g^{-1} at current rate C/4 over 1,000 cycles). Exterior carbon coating prevented the direct contact electrolyte with silicon particles and interior voids provided extra space to silicon particles during volume expansion as in **Figure 4** (Lu et al., 2015). Furthermore, Apple-like silicon@nitrogen, oxygen-doped carbon hierarchical mesoporous structure was prepared and used as anode material shown in **Figure 5**. Si@mNOC as anode material delivered good capacity and long cycle life (1,203 and 900 mA h g^{-1} at current rate 2 A g^{-1} after 2,000 and 4,000 cycles in **Figure 5C**). In Si@mNOC, the void space and mesoporous structure accommodated the volume expansion and facilitated ion transport and also controlled SEI film and improved the mechanical stability of the anode material. Nitrogen and oxygen doping improved the electronic conductivity and electrochemical

performance of Si@mNOC anode shown in **Figures 5A,B** (Yu et al., 2016). Many attempts have been taken to enhance the kinetics of ionic diffusion and electrical conductivity of coating material (carbon) by doping of different atoms (oxygen, nitrogen, and sulfur) and by using hierarchical structure (Xu et al., 2015; Wang et al., 2016).

Yolk-Shell and Core-Shell Silicon Nanostructures

Furthermore, electrochemical properties of silicon anode material enhanced by the modified structure of SiNPs and by using double coating of different materials (Ensafi et al., 2017; Jang et al., 2018; Xing et al., 2018). Herein, to improve electrochemical performance of anode material in LIBs, a series of surface and interface engineering to fabricate carbon and titanium oxide coated Si with yolk and core-shell structure have been fabricated as shown in **Figure 6** (Luo et al., 2017). First, Si@mesoporous carbon yolk-shell structure was prepared which provided extra voids inside coating as shown in **Figure 6A**. This novel yolk-shell structure led to enhance rate capability, cycle life with good specific capacity and uniform stable SEI film which exhibited good electrochemical performance (Yang et al., 2015). Second, SiNPs coated with a controllable and uniform thickness of carbon coating (2–25 nm) to form a core-shell structure. This coaxial core-shell structure enhanced the stability of anode and exhibited good specific capacity over 500 cycles as shown in **Figure 6B**. (Luo et al., 2016b). Third, Si@C coated with germanium by a simple sol-gel process and formed Si@C@Ge core-satellite NPs as shown in **Figure 6C**. Coating of germanium on Si@C exhibited high electrochemical kinetic and good structural stability as compared to uncoated Si@C (Luo et al., 2016a). Fourth, to enhance initial coulombic efficiency, lithium storage safety, and structure integrity, amorphous TiO_2 coated on SiNPs and made core-shell structure by the sol-gel process. Amorphous TiO_2 shell provided high lithium storage safety by increasing lithium kinetic because of TiO_2 showed a low resistance of Li diffusion during the electrochemical process as shown in **Figure 6D**. Amorphous TiO_2 shell acted as an elastic belt on SiNPs to control volume variation during charging/discharging and stabilized the SEI film by resisting the contact of electrolyte to active silicon which has led to high cycle life (Yang et al., 2017). Last, SiNPs coated with double layer of carbon and TiO_2 (Si@C@TiO_2) via a two-step sol-gel process. Si@C@TiO_2 composite as anode material handled conductivity, volume change during lithiation/delithiation and unstable SEI film. In Si@C@TiO_2 composite carbon enhanced electrical conductivity by providing an electronic path to electron during the electrochemical process, TiO stabilized structure integrity of anode by providing mechanical properties and controlled the SEI film by stopping the direct contact of electrolyte to silicon as shown in **Figure 6E** (Luo et al., 2016c).

Sensors

On the basis of the surface, optical and electrical properties, pSiNPs have been used for detection of different atoms, gas molecules, pH and polar/non-polar organic solvent (Harraz et al., 2014; Kashyout et al., 2015; Sarkar et al., 2018). To improve the fluorescence properties of silicon oxides, these were coated with dye molecules through different functional groups. Photoluminescence intensity depends upon concentration and size of silicon particles. The doping of different particles also affected by other organic vapors which are under examinaion (Zhang et al., 2010; Huang et al., 2015; Moret et al., 2016; Nayef and Khudhair, 2018). On the basis of fluorescence quenching of pSiNPs with other atoms, pSiNPs have been used for detection of different ions and molecules (Cu^{+2}, NO_2, Hg^{2+}, NH_3, Ag^{2+}, and ethyl carbamate) (Xia et al., 2013; Luo et al., 2018; Qin et al., 2018a,b). PL immunosensor was prepared by functionalization of porous silicon with Protein-A and bovine serum albumin (BSA) for detection of Ochratoxin A under UV Laser as shown in **Figure 7**. BSA added to active sites to blocking adsorption of protein on these sites and improve sensitivity. Functionalized-pSi immunosenor was tested under the wide range of concentrations (0.01–5 ng/ml) which was exhibited high sensitivity and high-speed detection even at low level of ochratoxin A. It was observed PL-intensity decreased as concentration of Ochratoxin A increased in sample (Myndrul et al., 2017). Carbon doped silicon nanoparticles were prepared by the mild reaction and used for detection Hg^{2+}, Ag^{2+}, and latent fingerprints. SiNPs showed good sensing ability for Hg^{2+} and Ag^{2+} by highly quenched with Hg^{2+}, Ag^{2+} and provided high range wavelength of excitation and emission. SiNPs also used as fluorescence label to detect a fingerprint on different non-porous material surfaces. In the presence of ultraviolet excitation, SiNPs provided excellent fluorescent images on different surfaces as shown in **Figure 8** (Zhu et al., 2018). SiNPs are easy to synthesize and due to numbers of properties (non-toxicity, wide range fluorescence spectra, good photoluminescence peak, solubility and large surface area) remained in great interest to apply in different fields.

Other Applications

On the basis of the surface, optical, biocompatible and nontoxic properties, pSiNPs have been used in bio-applications as Nano carriers, diagnostics and for the treatment of cancer (Vaccari et al., 2006; Donnorso et al., 2012; Haidary et al., 2012; Kaasalainen et al., 2012; Tzur-Balter et al., 2013; Yang et al., 2014b; Min-Dianey et al., 2018). The mSiNPs have great potential toward drug delivery devices due to their easy functionalization, good loading/release rate, solubility, tunable porosity and a large surface area (200–800 m^2/g) (Reffitt et al., 1999; Anderson et al., 2003; Mattei and Valentini, 2003; Horcajada et al., 2004; Salonen et al., 2005; Anglin et al., 2008; Tabasi et al., 2012; Ma et al., 2017a). In bio-applications, pSiNPs exhibit good result *in vitro* and *in vivo* conditions (Ferreira et al., 2016). The pSiNPs were prepared by electrochemical etching and coated with dextran. The pSiNPs used for theranostics of cancer on the basis of photoluminescence properties and noted that excellent uptake of pSiNPs by cancer cell and also suppress the proliferation of cancer cells *in vitro* (Wang et al., 2012). SiNPs have been used for detection of microRNAs which acts as biomarkers of various diseases. The concentration of miRNAs was measured by a decrease of SiNPs fluorescence (Ding et al., 2018). Further, pSiNPs loaded with anticancer drugs and photo

thermal agent by electrostatic assembly technique to treat the multidrug resistant cancer cells as shown in **Figure 9**. It is observed that pSiNPs leave the anticancer medicines 88.1% under different conditions and kill the multidrug resistant cancer cell. The pSiNPs as Nano carriers increased the efficiency of photo thermal therapy and chemotherapy (Xia et al., 2018). Furthermore, multifunctional pSiNPs were prepared by SPAAS click chemistry as shown in **Figure 10**. Multifunctional pSiNPs improved the rate of dissolution and cancer therapy. Uptake of multifunctional pSiNPs by tumors was enhanced due to the presence of iRGD peptide on the surface of pSiNPs and retained in tumors which suppressed tumors to further growth. Multifunctional pSiNPs exhibited well *in vivo* behavior and highest efficiency of drug delivery (Wang et al., 2015).

CONCLUSION AND OUTLOOK

In this review, we focus on the importance of pSiNPs with different structures in various fields. Silicon has much attractive material as an anode in LIBs due to their theoretical capacity (4,200 mA h g^{-1}), intercalated and electrical properties but after some cycles of charging/discharging volume of silicon changes. Continuous volume changes in silicon anode lead to fractures and affect the electrochemical properties. Solid electrolyte interphase developed on the particle by an electrolyte which leads to electrical contact loss. These challenges pulverization, electrical loss and stable SEI film by mesoporous silicon have been elaborated. It is observed that SiNPs play an important role to control volume changes in Si-anode as compare to silicon bulk. To control pulverization in Si anode further structure

of silicon particles has been modified to mesoporous, 3D and hollow spheres. By structural modification of SiNPs, a significant enhancement of electrochemical properties have been noted. Furthermore, to control volume change and improve electrical contact loss and stabilization of SEI film, SiNPs were coated with different materials (carbon, polymers other metals). Coating of different materials on SiNPs has significantly improved electrochemical properties and stabilize SEI films on particles. It is noted that the double coating of different material on particles enhanced electronic conductivity, capacity and control SEI film by stopping direct contact of electrolyte to particles. For future work, silicon anode material for commercial use still needs to be improved in volume change, stabilization of SEI film, high capacity, long cycle life, initial Coulombic efficiency and rate capability.

In biosensors and gas sensors, on the basis of optical and surface properties of pSiNPs have been used and exhibited good results. In sensors, porous silicon provides a number of void spaces to adsorption of different molecules, gases, drugs, and biomolecules. Structural dependent properties (optical, electrical and electrical properties) varies after adsorption of different molecules on the surface of porous silicon. This variation in properties are used to detect different materials. Further pSiNPs can be used to detect different compounds and biomarkers of different diseases which are still undetected.

Mesoporous structure of silicon provides a large surface area (200–800 m^2 g^{-1}), tunable optical properties and void spaces which act as good drug carriers. MSiNPs have been used as drug carriers, for therapy and detection of cancer cells due to their unique properties optical, non-toxicity, biocompatibility and surface properties. Detection and treatment of cancer tissues, tumors, and some biomarkers have been observed successfully by use of pSiNPs.

Semiconducting metal oxides with abundant active sites are regarded as promising candidates for environmental monitoring and breath analysis because of their excellent gas sensing performance and stability. Herein, mesoporous WO_3 nanofibers with a crystalline framework and uniform pore size is successfully synthesized in an aqueous phase using an electrospinning method, with ammonium metatungstate as the tungsten sources, and SiO_2 nanoparticles and polyvinylpyrrolidone as the sacrificial templates. The obtained mesoporous WO_3 nanofibers exhibit a controllable pore size of 26.3–42.2 nm, specific surface area of 24.1–34.4 m^2g^{-1}, and a pore volume of 0.15–0.24 cm^3g^{-1}. This unique hierarchical structure, with uniform mesopores and interconnected channels, could facilitate the diffusion and transportation of gas molecules in the framework. Gas sensors, based on mesoporous WO_3 nanofibers, exhibit an excellent performance in acetone sensing with a low limit of detection (<1 ppm), short response-recovery time (24 s/27 s), a linear relationship in a broad range, and good selectivity.

Keywords: mesoporous materials, WO_3, nanofibers, electrospun, acetone, sensor

INTRODUCTION

Over the past few decades, the precise monitoring of toxic polluting gases has attracted great attention in modern society in environmental protection, industrial production, health care, and so forth (Kawano et al., 2007; Wang et al., 2007; Salehi et al., 2014). Acetone is a common type of reagent which is frequently used in manufacturing industries and laboratories (Zhang et al., 2017). As a highly toxic gas, acetone is harmful to human health, and long-term exposure to acetone may cause irritation and damage to the eyes, nose, and central nervous system (Jia et al., 2014). In addition, acetone concentrations in respiration can be characterized as a biomarker in the rapid diagnosis of diabetes, because acetone concentrations exhaled from diabetes patients (1.8 ppm) are much higher than in a healthy individual (0.3–0.9 ppm) (Singkammo et al., 2015; Zhou et al., 2018). Therefore, it is of great interest and importance to develop acetone sensors with a low detection limit, fast response recovery dynamics, high sensitivity and selectivity. Among a variety of sensing-active materials used for the detection of acetone, metal oxide semiconductors (WO_3, TiO_2, SnO_2, ZnO, Fe_2O_3, etc.) have been considered as appealing candidates due to their remarkable sensitivity,

low cost, and excellent stability (Wang et al., 2010; Luo et al., 2013; Kim and Lee, 2014; Zhu et al., 2017a; Zhou et al., 2018). The sensing mechanism of semiconducting metal oxides (SMOs)-based sensors is widely accepted to be the change in conductivity when exposed in specific gas. The adsorbed gaseous analytes may cause an increase or decrease in the resistance of semiconducting metal oxides (Barsan and Weimar, 2001; Yamazoe et al., 2003; Qiu et al., 2018; Zhang Q. et al., 2018). Given that the gas-sensing process involves the adsorption–desorption and catalytic reactions on the surface of the metal oxides, a rational design and controllable synthesis of nanomaterials with high surface areas, abundant active sites, tailor-designed nanostructures and outstanding catalytic performance, are considered as promising approaches to enhance the sensing performance of the semiconducting metal oxides.

Mesoporous semiconducting metal oxides (MSMOs), as an important category of nanostructured materials, have drawn much attention because of their high surface area, uniform pore size, highly crystalline framework, numerous active sites, interconnected pore structure and large pore size. The high surface area and abundant active sites greatly facilitates the interaction between metal oxide frameworks and gaseous molecules, as well as surface catalytic reactions. In addition, the large porosity and well-connected mesostructure favors rapid and effective diffusion of gas molecules (Li et al., 2014; Luo et al., 2016b; Ma et al., 2018). Therefore, MSMOs are regarded as promising candidates for gas sensing. To date, various MSMOs have been synthesized through different approaches, such as sol–gel processes, spray pyrolysis, chemical vapor deposition and precipitation reactions (Du et al., 2011; Luo et al., 2016a; Zhao et al., 2016; Channei et al., 2018; Jha G. et al., 2018; Zhang Y. et al., 2018). However, these methods usually give rise to an uncontrolled morphology and low porosity, which is not favorable for sensing performance. Additionally, a lot of work has been focused on the design and construction of various nanostructures of SMOs to improve the their sensing performance, including zero-dimensional nanoparticles (NPs) (Yang Z. et al., 2018; Zhang H. et al., 2018; Zhao et al., 2019), one-dimensional nanofibers (NFs) (Saha and De, 2013; Kim et al., 2016a; Ren et al., 2016; Nada et al., 2017; He et al., 2018; Jeong et al., 2018) and nanowires (NWs) (Wang et al., 2004; Rakhi et al., 2012; Dam and Lee, 2013; Chen et al., 2015; Li X. et al., 2017), two-dimensional nanosheets (Wang et al., 2016, 2017; Li F. et al., 2017; Kaneti et al., 2018) and membranes (Dasog et al., 2012; Barr et al., 2017; Jha G. et al., 2018; Wang W. Q. et al., 2018). Nanofibers have drawn particular attention due to their exceptionally high surface area-to-volume ratio, high porosity, superior surface permeability and accessibility, making them an attractive candidate for gas sensing (Guo et al., 2014; Jha R. K. et al., 2018; Yan et al., 2018). Electrospinning technology has been demonstrated as an effective approach to prepare micro-sized and nano-sized fibers. The structure, morphology and dispersion of functional components of the fibers synthesized by electrospinning can be well-tailored through well-controlled conditions and compositions (Wang and Hashimoto, 2018; Yoon et al., 2018; Zhang D. et al., 2018). Kim et al. fabricated semiconducting metal oxide nanofibers through a protein nanocage templating route, to detect trace amounts of target biomarkers in exhaled breath (Kim et al., 2016a). Nevertheless, up to now, it remains a great challenge to construct mesoporous structures in nanofibers with controllable pore size and morphologies, which is highly desirable for improved gas sensing performance.

Among various SMOs, tungsten oxide (WO_3), an *n*-type semiconductor with a band-gap of 2.5 eV, is a promising sensing material for the detection of gas due to its variable oxidation states and suitable band structure (Wang C. Y. et al., 2018). Herein, we adopt a facile approach based on electrospinning to synthesize mesoporous WO_3 nanofibers (NFs) with uniform and controllable pore sizes using SiO_2 nanoparticles and polyvinylpyrrolidone (PVP) as sacrificial templates, ammonium paratungstate as a tungsten precursor and water as a solvent. Due to the support of the rigid PVP species during electrospinning process, the interconnected porous structure and unique fiber-like morphology can be well-maintained after calcination in nitrogen and air, followed by treatment with hydrofluoric acid selectively etched silica particles, creating uniform mesopores in the nanofibers. The obtained mesoporous WO_3 NFs have crystalline frameworks, large uniform pore sizes of 26.3 nm and 42.2 nm, and their specific surface area and pore volume can be as high as 34.4 m^2/g and 24.1 cm^3/g, respectively. Moreover, the mesoporous WO_3 NFs based sensors exhibit superior gas sensing performance with a fast response (24 s) and recovery (27 s), high sensitivity of 23 (R_a/R_g) at 50 ppm when operating at 300°C, an ultralow limit of detection of 1 ppm, and good selectivity, which contributes to their good merits of suitable pore size, high surface area and abundant active sites located on the surface, and continuous and crystalline framework with open pore channels. Such an excellent sensing performance opens up the possibility for the mesoporous WO_3 NFs based sensor to be used in many fields such as environmental monitoring and in the rapid diagnosis of disease.

EXPERIMENTAL SECTION

Chemicals and Materials

Tetraethyl orthosilicate (TEOS), ethanol, NH_4OH solution and hydrofluoric acid of AR grade were purchased from Sino-Pharm Chemical Reagent Co. Ltd. Polyvinylpyrrolidone (PVP, $M_w \approx 40{,}000$ g/mol) was purchased from Aldrich. Ammonium metatungstate hydrate [$(NH_4)_6H_2W_{12}O_{40}{\cdot}xH_2O$, 99.5% metals basis] was purchased from Aladdin.

Preparation of SiO_2 NPs

The SiO_2 NPs with different diameters was prepared using a base catalyzed sol-gel method previously reported (Dasog et al., 2012). Typically, TEOS (10 mL) was dissolved in a solvent mixture of ethanol (10 mL), deionized water (20 mL) and NH_4OH solution (42 %, 5 mL). The obtained solution was further stirred for 1 or 2 h to yield different size SiO_2 NPs. The white precipitate was collected by vacuum filtration and washed with deionized water four times. The solid was transferred to an oven and was kept there for 24 h at 100°C to remove any residual water and ethanol.

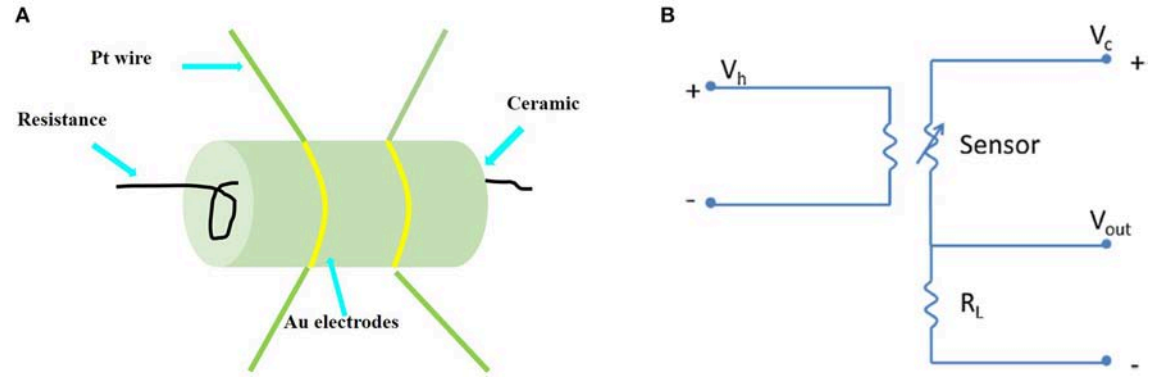

FIGURE 1 | (A) Sketch of the structure of the side-heated mesoporous WO_3 NFs based gas sensor. **(B)** Electric circuit of gas sensing measurements.

Synthesis of Mesoporous WO_3 NFs

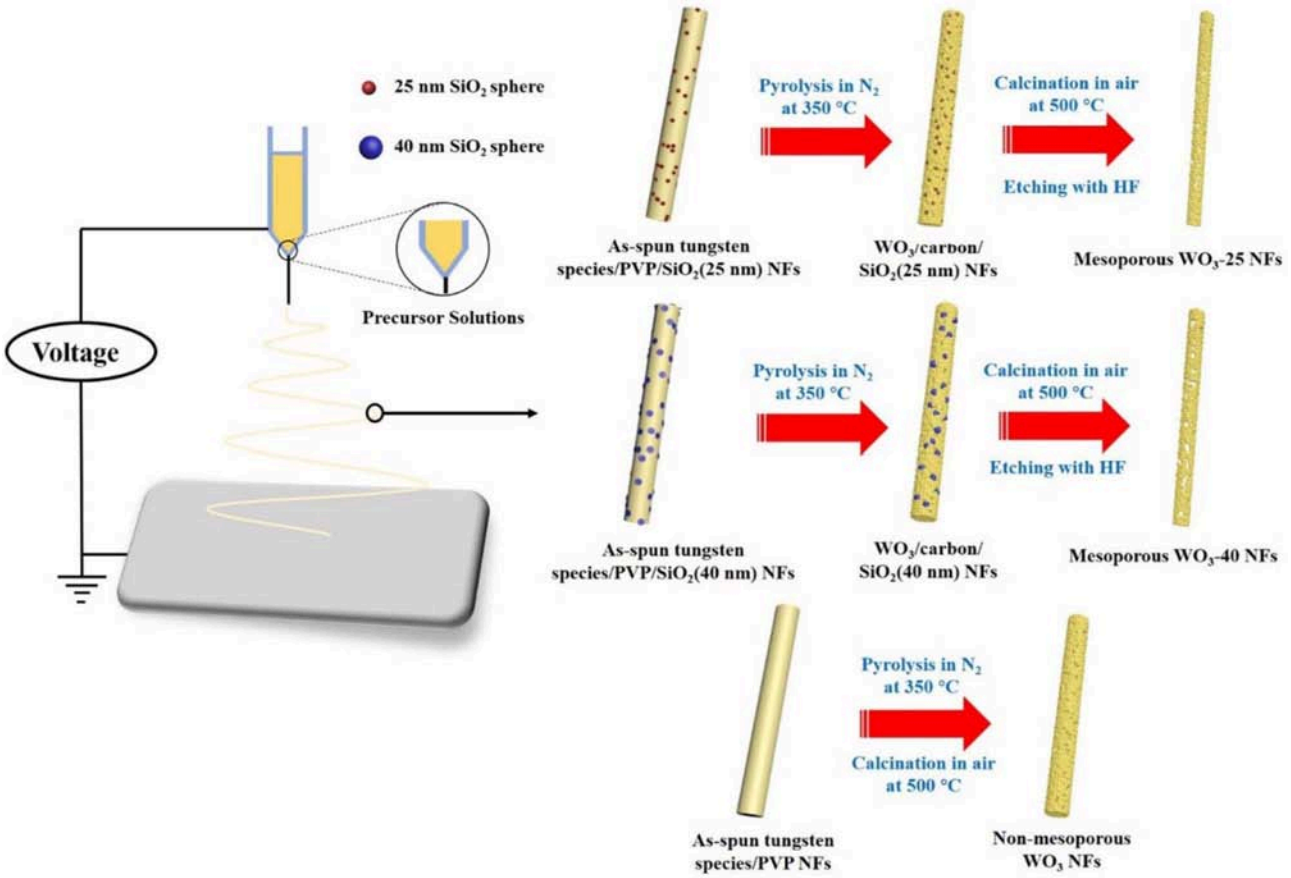
Typically, mesoporous WO_3 NFs were synthesized through an electrospinning method as follows: $(NH_4)_6H_2W_{12}O_{40}\cdot xH_2O$ (2.7 g) and PVP (3.0 g) was dissolved in deionized water (4 mL). This was followed by the addition of SiO_2 NPs (0.035 g) with a diameter of 25 nm. Then, the solution was stirred for 20 h for further electrospinning. The as-prepared gel was loaded into a plastic syringe and connected to a high voltage power supply for electrospinning. Twenty kilovolts high voltage was applied between the spinneret and the collector in a gap of 15 cm. In this way, hybrid precursor nanofibrous membranes were obtained. Then, the as-made products were heated with a ramp of 1°C min^{-1} to 350°C for 3 h in nitrogen, resulting in the carbon-supported amorphous tungsten oxide powders. The carbon species was removed and crystallization of the amorphous tungsten oxide frameworks was carried by subsequent heat treatment with a ramp of 1°C min^{-1} to 500°C in air for another 1 h. SiO_2 NPs was completely removed from the composites by treatment with a HF solution (5 wt% aqueous solution, 8 mL) for 2 h and subsequently washed with deionized water and ethanol. Finally, the obtained sample was denoted as mesoporous WO_3-25 NFs. Through the same approach, silica NPs with larger diameters (∼40 nm) were also used as a hard template to synthesize mesoporous WO_3 NFs, and the obtained samples were denoted as mesoporous WO_3-40 NFs. Control experiments, without addition of SiO_2 NPs, were performed according to the same method and procedure, and the obtained sample was denoted as a non-mesoporous WO_3 NFs.

Measurement and Characterization

Field-emission scanning electron microscopy (FE-SEM) was operated on a Hitachi S4800 (Japan) field-emission scanning electron microscope. Transmission electron microscopy (TEM) was conducted on a JEM-2100 F at an accelerating voltage of 200 kV. Wide-angle X-ray diffraction (XRD) patterns were collected on a Rigaku D/Max-2550 PC diffractometer (Tokyo, Japan) in the 2θ range of 10–90°. Nitrogen sorption isotherms were measured at 77 K with a Micromeritics Tristar 3020 analyzer (USA). Before measurements, the samples were degassed under vacuum at 180°C for at least 6 h. The Brunauer-Emmett-Teller (BET) method was utilized to calculate the specific surface areas using the adsorption data at P/P_0 = 0.02–0.20. The pore size distribution (PSD) was calculated from the adsorption branch using the Barrett-Joyne-Halenda (BJH) model. The total pore volume (V_{total}) was estimated from the adsorbed amount at P/P_0 = 0.995. The XPS were collected on an RBD 147 upgraded PHI 5000C ESCA system with a dual X-ray source. The Mg Kα (1253.6 eV) anode and a hemispherical energy analyzer were used in the measurements. All of the binding energies were referenced to the C 1s peak at 284.8 eV of the surface adventitious carbon.

Gas Sensing Performance

Side-heated gas sensors were prepared using a similar method reported previously (Zhang et al., 2009). The mesoporous (or non-mesoporous) WO_3 NFs was mixed with deionized (DI) water and ground in an agate mortar to form a paste. The mass ratio of mesoporous (or non-mesoporous) WO_3 NFs to DI water in the paste is 7:3. The paste was coated on an alumina ceramic tube printed with a pair of Au electrodes, and the thickness of the paste membrane was about 300 μm. Subsequently, the coated alumina ceramic tube was dried at room temperature for 24 h and then annealed at 300°C for 2 h with a ramping rate of 5°C/min in air. Then, a Ni–Cr alloy wire was inserted into the tube as a heater, and the working temperature could be adjusted by changing the heating voltage. Furthermore, the obtained sensor was kept at the optimal working temperature for a week before measurement to further improve the long-term stability. The assembled sensing device is depicted in **Figure 1A**. The stationary state gas distribution method was applied for testing the gas response. In the electric circuit for measuring the gas response (**Figure 1B**), a load resistor (R_L) was connected in series with a gas sensor. The circuit voltage (V_C) was set at 5 V and the output voltage (V_{OUT}) was the terminal voltage of the load resistor. Test gases (such as acetone, methanol, ethanol, toluene, formaldehyde) were injected into a test chamber and diluted with air. The gas response of the sensor is defined as $S = R_a/R_g$ (for reducing gases) or $S = R_g/R_a$ (for oxidizing gases), where R_a is the sensor resistance in air and R_g is that in the



SCHEME 1 | The fabrication process of the mesoporous WO_3 NFs by electrospinning approach.

gas tested. The response time is defined as the time taken for the variation in conductance to reach 90% of the equilibrium value after a test gas was injected, and the recovery time is the time taken for the sensor to return to 10% above the original conductance in air after releasing the test gas, respectively.

RESULTS AND DISCUSSION

The diameters of the as-synthesized SiO_2 NPs are estimated to be 25 and 40 nm from the TEM images (**Figures S1A,B**). An electrospinning technique was employed to construct mesoporous WO_3 NFs from precursor solutions containing $(NH_4)_6H_2W_{12}O_{40}{\cdot}xH_2O$, PVP, SiO_2 NPs, and deionized water, as shown in **Scheme 1**. The as-spun tungsten species/PVP/SiO_2 NFs was subjected to calcination at 350°C in nitrogen, giving rise to WO_3/carbon/SiO_2 NFs owing to the partial carbonization of the PVP species. The carbonized PVP can provide carbon support inside the frameworks, which can prevent the collapse of the fiber morphology during the crystallization process of WO_3. Finally, after further pyrolysis at 500°C in air, and selective etching with hydrofluoric acid to remove the supporting carbon species and SiO_2 sacrificing templates, mesoporous WO_3 NFs is formed as a result. By using SiO_2 NPs with different diameters, two WO_3 NFs can be obtained and denoted as mesoporous WO_3-x NFs, wherein x represents the particle size of SiO_2 NPs. For comparison, non-mesoporous WO_3 NFs was also synthesized via the same approach but without SiO_2 NPs loading.

Field-emission scanning electron microscopy (FE-SEM) observation reveals that all of the as-spun composites have a uniform fiber-like morphology with a dimeter of about 450–500 nm (**Figure 2A**; **Figures S2A, S3A**) and smooth surfaces (insets in **Figure 2A**; **Figures S2A, S3A**). After pyrolysis in N_2 at 350°C, black WO_3/carbon /SiO_2 (25 nm), WO_3/carbon/SiO_2 (40 nm), and WO_3/carbon NFs can be obtained, owing to the partially carbonization of the PVP species. Compared to the as-spun NFs, the composites retained their uniform fiber morphology, and much rougher surfaces are clearly visible in the surface (**Figure 2B**; **Figures S2B, S3B**). After complete removal of carbon and silica species by further calcination in air at 500°C and etching with hydrofluoric acid, all the WO_3 NFs also retained the fiber morphology, indicating a good thermal stability, and their diameters were decreased to 250–300 nm due to the framework shrinkage at high temperature (**Figure 2C**; **Figures S2C, S3C**). It is worth noting that the WO_3 NFs consisted of large numbers of nanograins, and boundaries can be clearly observed. An FESEM image taken along the cross-section

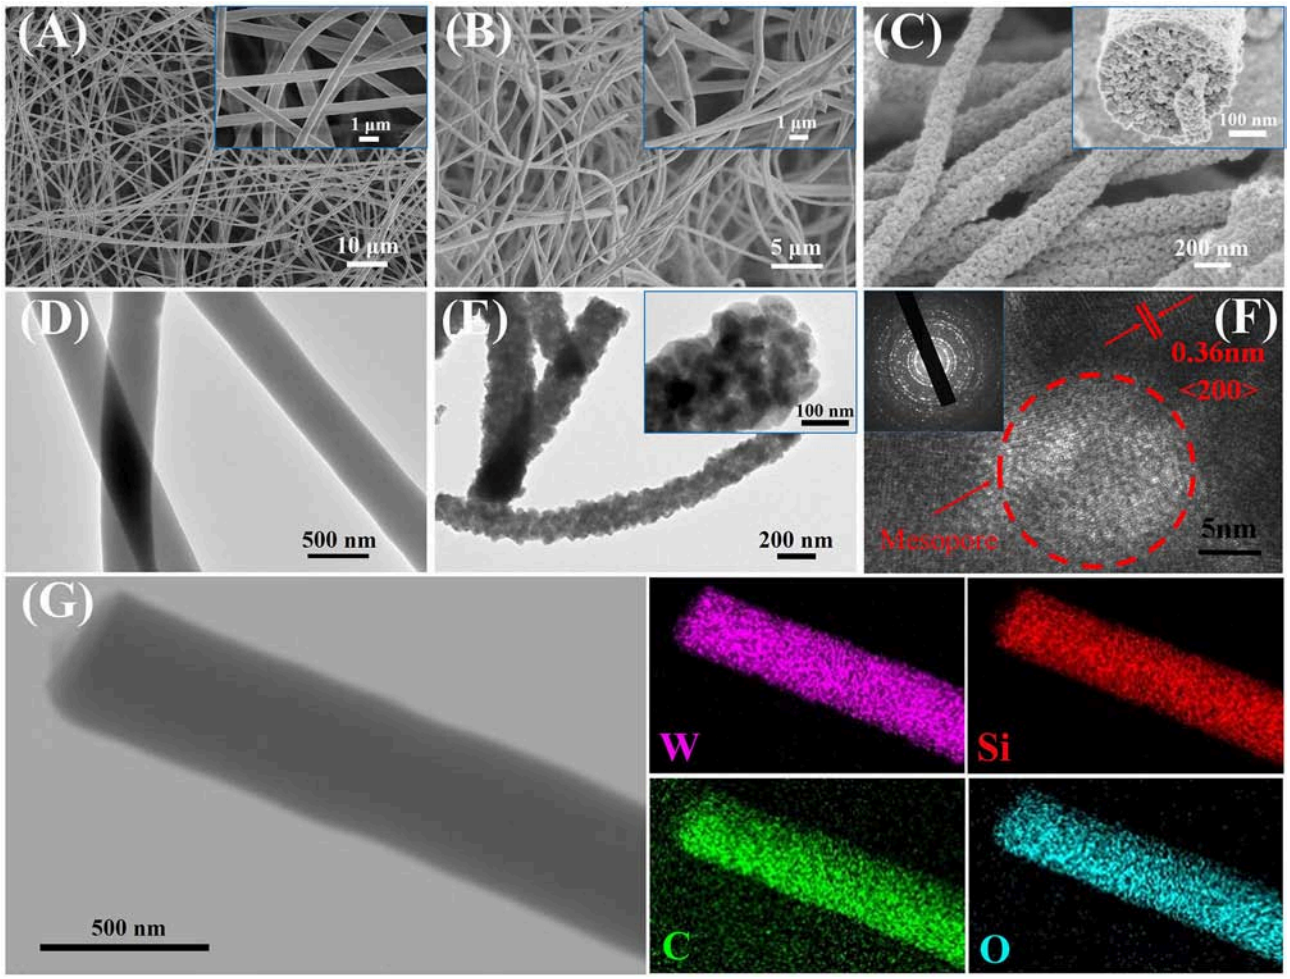


FIGURE 2 | FESEM images of **(A)** as-spun tungsten species/PVP/SiO_2 (25 nm) NFs, **(B)** WO_3/carbon/SiO_2 (25 nm) NFs, **(C)** mesoporous WO_3-25 NFs. TEM images of **(D)** WO_3/carbon/SiO_2 (25 nm) NFs, **(E)** mesoporous WO_3-25 NFs. HRTEM image of **(E)** mesoporous WO_3-25 NFs. **(F)** Scanning TEM image and the corresponding EDS mapping images **(G)** of elemental W, Si, C, and O for WO_3/carbon/SiO_2 (25 nm) NFs.

of the mesoporous WO_3-25 NFs clearly indicates the existence of mesopores around 25–30 nm (inset in **Figure 2C**), which is in good agreement with the diameter of SiO_2 nanoparticles. Due to a larger diameter of the sacrificial SiO_2 template, uniform mesopores of about 40–50 nm can be clearly visible in the SEM image of mesoporous WO_3-40 NFs (**Figure S2C**). And no obvious mesopores were observed on non-mesoporous WO_3 NFs (**Figure S3C**), attributing to the absence of the sacrificial SiO_2 template.

Transmission electron microscopy (TEM) observations further confirmed that the NFs obtained after pyrolysis at 350°C are fibrous in shape with a diameter of 400–450 nm (**Figure 2D**; **Figures S2D, S3D**). The scanning TEM (STEM) image and energy dispersive X-ray elemental mapping recorded on WO_3/carbon/SiO_2 (25 nm) NFs clearly reveals that the W, Si, C, and O elements are homogeneously distributed in entire NFs (**Figure 2G**). It suggests that the carbonized PVP molecules can provide rigid support inside the frameworks, forming a "reinforced-concrete" framework structure with WO_3 species. which can prevent the collapse of the NFs. TEM images of mesoporous WO_3-25 and mesoporous WO_3-40 NFs clearly indicate that the fiber-like morphology are well-retained, and the material consists of interconnected WO_3 nanoparticles, as well as the existence of numerous mesopores (**Figure 2E**; **Figure S2E**), which can offer abundant active sites to interact with guest molecules, greatly facilitating the diffusion of gas molecules. Additional EDS analyses of the mesoporous WO_3-25 NFs and WO_3-40 NFs were carried out as depicted in **Figures S4A,B**, respectively. The absence of peaks from Si in the EDS spectrum indicates the complete removal of SiO_2 by HF etching. Similarly, no obvious mesopores, but only WO_3 nanoparticles, were shown in the TEM image of non-mesoporous WO_3 NFs (**Figure S3E**). High resolution TEM (HR-TEM) images of mesoporous and non-mesoporous WO_3 NFs clearly show the lattice fringes of tungsten oxide with a *d*-spacing of 0.36 nm (**Figure 2F**; **Figures S2F, S3F**), corresponding

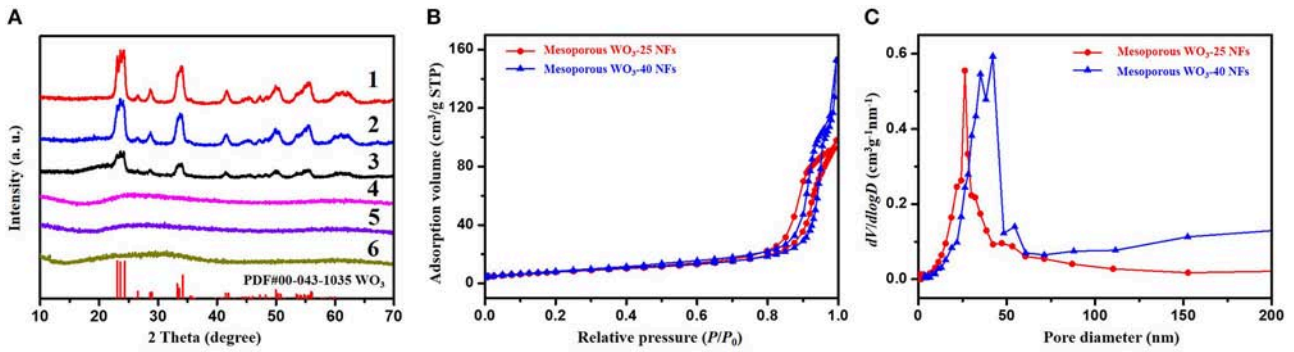

FIGURE 3 | (A) XRD patterns of (1) mesoporous WO_3-25 NFs, (2) mesoporous WO_3-40 NFs, (3) non-mesoporous WO_3 NFs, (4) WO_3/carbon/SiO_2 (25 nm) NFs, (5) WO_3/carbon/SiO_2 (40 nm) NFs, (6) WO_3/carbon NFs. **(B)** Nitrogen-sorption isotherms and **(C)** pore size distribution curves of mesoporous WO_3-25 NFs and mesoporous WO_3-40 NFs.

to the (200) planes, suggesting that the framework consists of well-crystallized and interconnected WO_3 nanoparticles. Selected-area electron diffraction (SAED), recorded on different WO_3 NFs showed well-resolved diffraction rings corresponding with the (200), (112), and (022) crystal planes of monoclinic phase WO_3 (insets in **Figure 2F**, **Figures S2F, S3F**), further confirming the crystalline feature of the scaffold.

Wide-angle X-ray diffraction (WA-XRD) patterns indicate that the WO_3/carbon/SiO_2 (25 nm), WO_3/carbon/SiO_2 (40 nm), and WO_3/carbon NFs exbibits the amorphous feature contributing to the poor crystallization (**Figure 3A**). After crystallization at 500°C, and removal of the silica nanoparticles by selective etching with hydrofluoric acid, mesoporous WO_3-25, mesoporous WO_3-40 and non-mesoporous WO_3 NFs shows well-resolved diffraction peaks in the range of 10–70°C, matching well with the crystalline monoclinic phase of WO_3 with lattice parameters of a = 0.7297, b = 0.7539, c = 0.7688 nm, and β = 90.91 (JCPDS No. 43–1,035). No diffraction peaks from other crystalline impurities are observed in the XRD patterns, indicating pure crystalline phase, which agreeing well with the HR-TEM results. The broadening of the diffraction peaks can be attributed to the small particle size of WO_3 nanocrystals (Li et al., 2014).

Nitrogen adsorption-desorption isotherms of the obtained mesoporous WO_3-25 NFs exhibit type-IV curves with H1 hysteresis loop (**Figure 3B**). The steep increase in the adsorption band at P/P_0 = 0.75–0.96 indicates mesopores with a large and uniform pore size. The pore diameter is about 26.3 nm as indicated in the pore size distributions derived from the adsorption branch of the isotherms by using Barrett-Joyner-Halenda (BJH) model (**Figure 3C**). The specific surface area and total pore volume of mesoporous WO_3-25 NFs are calculated to be as high as 34.4 m^2g^{-1} and 0.15 cm^3g^{-1}, respectively. Similarly, mesoporous WO_3-40 NFs also display type-IV curves with sharp capillary condensation steps in the relative pressure range of 0.78–0.97 (**Figure 3B**). The pore size distribution profile reveals a mesopore size of 42.2 nm (**Figure 3C**), indicating that the hard template silica nanoparticles with larger diameters result in larger mesopores. The surface area and total pore volume of mesoporous WO_3-40 NFs are approximately 24.1 m^2g^{-1} and 0.24 cm^3g^{-1}, respectively. Such a porous structure provides an amplified target-receptor interface and is beneficial for the diffusion and adsorption of large guest molecules, making it an ideal candidate for many applications involving host-guest interactions, such as catalysis and gas sensing. In addition, nitrogen adsorption–desorption isotherms of non-mesoporous WO_3-NFs show type-IV curves with H3 hysteresis loop (**Figure S5A**). The surface area and total pore volume of non-mesoporous WO_3NFs is 19.5 m^2g^{-1} and 0.17 cm^3g^{-1}, respectively. The average pore size calculated from the adsorption branch using the BJH method is about 5.3 nm (**Figure S5B**), much smaller than that of the etched samples (26.3 nm for mesoporous WO_3-25 NFs and 42.2 nm for mesoporous WO_3-40 NFs), which can be attributed to the stacked pores of small WO_3 grains.

X-ray photoelectron spectroscopy (XPS) is further used to investigate the surface composition and elemental states of the NFs before and after etching. For the WO_3/SiO_2 (25 nm) composite NFs (denoted as WO_3-25/SiO_2 NFs) before etching, four peaks corresponding to W 4f, Si 2p, W 4d and O 1s are shown in the survey spectrum (**Figure S6A**). However, after etching, the Si 2p peak at 103.3 eV disappears, indicating the complete removal of SiO_2 species by HF (Xu et al., 2015; Shi et al., 2016). The high-resolution XPS W 4d spectrum (**Figure S6B**) of the samples after etching show similar spectra and can be fitted with two peaks centering at 35.8 and 37.9 eV, which can be assigned to W^{6+} $4f_{7/2}$ and W^{6+} $4f_{5/2}$, respectively (Wang et al., 2012). These results indicate that completely oxidized W is not changed during the etching process in mesoporous WO_3-25 NFs, mesoporous WO_3-40 NFs and non-mesoporous WO_3 NFs samples. The state of O 1s indicates two types of oxygen in the surface (**Figure S6C**), lattice oxygen (O^{2-}) and adsorbed oxygen (O^- and O^{2-}). Usually, the adsorbed oxygen was more active to react with reducing gases compared with lattice oxygen, changing the concentration of main carriers (Zhu et al., 2017a).

Inspired by the unique structure of obtained mesoporous WO_3 fibers with ultra-large and controllable pore size, we tested the performance of mesoporous WO_3-25, mesoporous WO_3-40

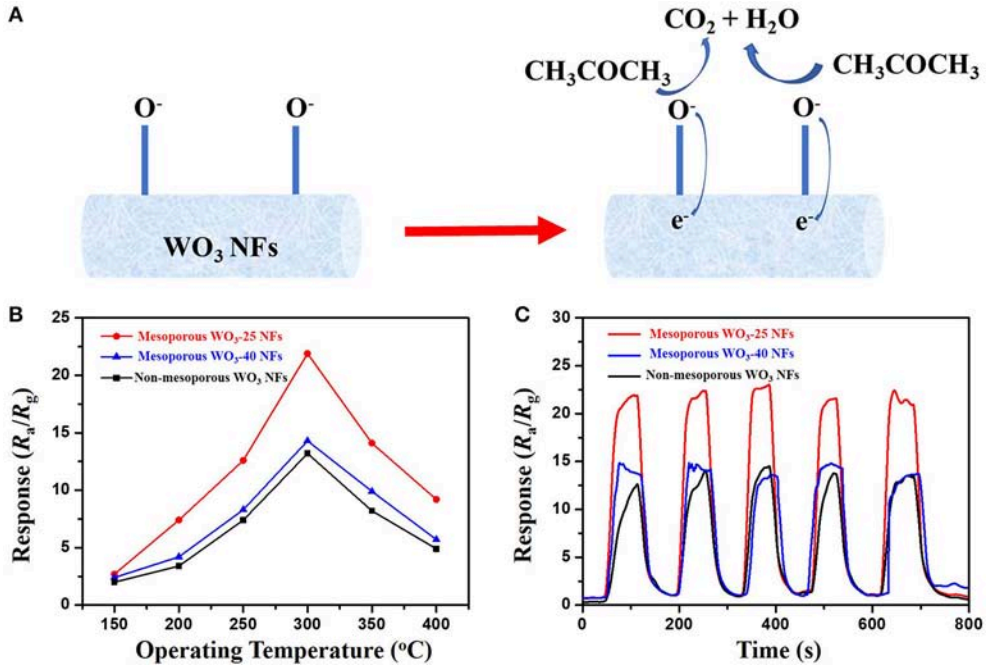

FIGURE 4 | (A) sensing mechanism of WO_3 NFs toward acetone. **(B)** responses of the mesoporous and non-mesoporous WO_3 NFs sensor to 50 ppm acetone at different operating temperatures (150–400°C). **(C)** repeating response and recovery curve of the mesoporous and non-mesoporous WO_3 NFs to 50 ppm acetone.

and non-mesoporous WO_3 NFs as sensing materials for the detection of acetone to investigate their potential application in the detection of acetone leakage and diagnosis for diabetes. The schematic diagram of sensing mechanism is shown in **Figure 4A**. In the gas sensing test, probe gases such as acetone were injected into a test chamber and mixed with air. The gas response of the sensor in this study is defined as $S = R_a/R_g$, where R_a and R_g is the resistance of the sensor in air and test gas, respectively. The response time is defined as the time required from R_a to R_a-90% × (R_a-R_g) after a test gas was injected, and the recovery time is defined as the time required from R_g to R_g + 90% × (R_a-R_g) in air after releasing the test gas, respectively. Since the sensing performances of semiconductors for a specific gas are usually dependent on the working temperature, parallel tests of mesoporous WO_3-25, mesoporous WO_3-40 and non-mesoporous WO_3 NFs based sensors were carried out toward a 50 ppm acetone gas in a range of 150–400°C to optimize the working temperature region (**Figure 4B**). It can be seen that the response of all sensors increased continuously until reaching a maximum value at 300°C and then decreased upon increase of the operating temperature. Such response behavior is due to the balance of the competition between the increase of the surface reaction rates and the decrease in the number of active sites for the adsorption of acetone at high temperatures. As a result, 300°C was adopted as the optimum working temperature for subsequent acetone detections.

In contrast, it was found that both of the mesoporous sensing materials, mesoporous WO_3-25 and WO_3-40 NFs, have shown higher responses to acetone than the non-mesoporous WO_3 NFs. Such phenomenon may contribute to the uniform mesopores and interconnected transportation channels of mesoporous WO_3 NFs resulting from the sacrificial templates including silica nanoparticles and PVP species, which provides a huge interface for the creation of active sites for acetone gas interaction, and greatly facilitates the diffusion of gas molecules in the framework. In addition, the response value increases dramatically from 13.7 for mesoporous WO_3-40 NFs to 22.1 for mesoporous WO_3-25 NFs at the same temperature, indicating that the sensitivity of the materials is closely related to its specific surface area. Mesoporous WO_3-25 NFs with a higher surface area (34.4 m^2g^{-1}) could provide more active surface sites for numerous surface reactions between guest molecules and adsorbed oxygen species on the solid-gas interface. Therefore, the response value of mesoporous WO_3-25 NFs is higher than the non-mesoporous WO_3 NFs during the operating temperature range from 150 to 400°C (**Figure 4B**), and the sensitivity of mesoporous WO_3-25 NFs is 66% higher than that of non-mesoporous WO_3 for 50 ppm at the optimal operation temperature (**Figure 4C**). Moreover, the mesoporous WO_3-25 NFs shows a response time of 24 s, much shorter than that of non-mesoporous WO_3 (67 s), as shown in the **Figure S7**. The faster response is mainly attributed to its porous structure, which could facilitate the diffusion and transport of target gas via enormous pore channels to interact with WO_3 NFs, quickly reaching the maximum sensitivity. The reversible cycles of the response curves illustrate a stable and reliable operation of acetone sensing of all the WO_3 NFs, and further confirm the consistency of mesoporous WO_3-25 NFs based sensors (**Figure 4C**). The continuous dynamic

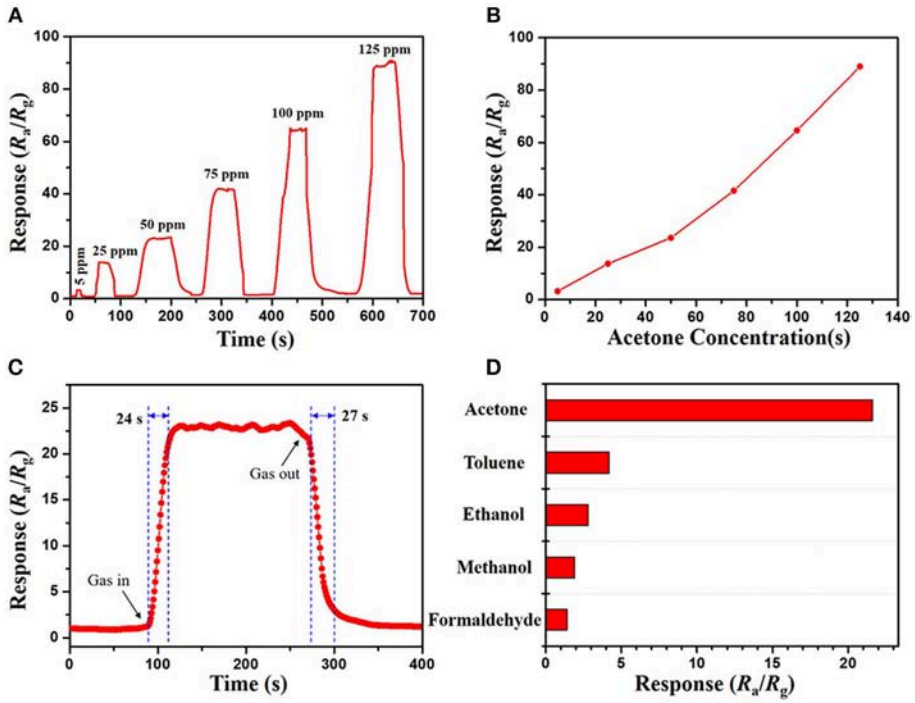

FIGURE 5 | (A) response–recovery curve and **(B)** relationships between acetone concentration and response of the mesoporous WO_3-25 NFs sensor to acetone vapors of different concentrations. **(C)** dynamic response–recovery curve of mesoporous WO_3-25 NFs sensor to 50 ppm acetone. **(D)** responses of the mesoporous WO_3-25 NFs sensor to various gases at 50 ppm.

electrical response of mesoporous WO_3-25 NFs toward different concentration of acetone (5–125 ppm) at 300°C is shown in **Figure 5A**. With the increase in acetone concentration, the response values of mesoporous WO_3-25 NFs based gas sensors rapidly increased from 3.1 at 5 ppm to 89 at 125 ppm. After aeration, the acetone molecules desorbed immediately from the surface of tungsten oxides. The response can be recovered to its initial value for all the testing concentrations, reflecting a good reversibility of the gas sensor. Surprisingly, the minimum detectable concentration can reach as low as 1 ppm (**Figure S8**). As shown in **Figure 5B**, a linear relationship between the sensing response and acetone concentrations is observed, indicating the feasibility of quantitative acetone detection by the mesoporous WO_3 NFs based sensors. As important parameters for a gas sensor, the response and recovery behaviors are also crucial for evaluating the sensing performance. The mesoporous WO_3-25 NFs based sensor exhibits a fast response of 24 s upon exposure to 50 ppm acetone and quick recovery of 27 s when acetone gas was removed (**Figure 5C**). In addition, compared with earlier reported acetone sensors, our mesoporous WO_3 NFs exhibits much better comprehensive sensing performance such as high sensitivity, low limits of detection and fast response-recovery (**Table 1**), thus becoming a promising candidate for acetone sensing in environmental monitoring and rapid medical diagnosis. Based on the aforementioned results, the predominant enhancement could mainly be explained as follows: (1) The unique hierarchical structure where uniform and controllable mesopores are well-connected with enormous transportation channels derived from PVP species, which facilitate the rapid diffusion of gas molecules. (2) The high specific surface area with abundant active sites enables the adsorption of a large amount of acetone molecules. (3) The continuous crystalline framework is also favorable for the fast transportation of charge carriers from the surface into bulk. It can therefore be concluded that the unique feature of our materials can maximize the performance of gas sensing. The selectivity of gas sensors is also an important parameter in practical applications. In this work, four kinds of typical vaporous molecules with identical concentration of 50 ppm, such as methanol, ethanol, toluene, and formaldehyde were selected as interfering gases. As illustrated in **Figure 5D**, the response value of a mesoporous WO_3-25 NFs based sensor to acetone was at least four times higher than that of interfering gases, which implies an excellent selectivity.

In summary, mesoporous WO_3 NFs with controllable pore diameters were synthesized via a facile electrospinning of an aqueous solution containing ammonium paratungstate, PVP and SiO_2 NPs sacrificing templates, followed by controlled pyrolysis at a high temperature and selective etching with hydrofluoric acid. The PVP species can provide rigid support inside frameworks, which can prevent the collapse of the unique fiber morphology and the well-connected porous structure. The decomposition of the PVP species during calcination and the etching of SiO_2 NPs was also found to contribute to the formation of interconnected transportation channels and

TABLE 1 | Comparison of acetone sensing properties of WO_3 or WO_3 based sensors with various nanostructures.

Structures	Working temperature	Acetone concentration (ppm)	Response (R_a/R_g)	Response/recovery time	References
Porous WO_3	300°C	50	12.1	4/11.7 s	Dong et al., 2016
WO_3 plate	307°C	100	~15	10/26 s	Liu et al., 2012

uniform mesopores in the framework of the fibers. The obtained mesoporous WO_3 NFs possess a tunable pore size (26.3 and 42.2 nm), high surface area and pore volume (up to 34.4 m^2/g and 0.24 cm^3g^{-1}), and a well-developed hierarchical porous structure and crystalline pore walls. Sensors based on these materials were found to have an excellent acetone sensing performance with a fast response (24 s) and recovery (27 s), a low detection limit of 1 ppm, excellent selectivity and good stability, due to their high mesoporosity, abundant active sites and the continuous crystalline framework. Based on the above-mentioned results, the obtained mesoporous WO_3 NFs holds great promise for applications in various fields such as portable miniaturized devices used for environmental monitoring, and breath analysis used for disease pre-diagnosis and home security. Moreover, it is expected that the facile and effective electrospinning approach may open up new opportunities for the design of various mesoporous metal oxide NFs with high surface areas, crystalline frameworks and greatly improved mass diffusion and transportation for application in sensors, catalysis, energy storage and conversion.

AUTHOR CONTRIBUTIONS

WL and JY conceived and designed the experiments. HX, TZ, YZ and JG performed the experiments. ML, GZ, LW, WJ, YF, MZ analyzed the data. WL and HX wrote the manuscript. XQ designed the scheme. All authors reviewed the manuscript and approved the final version.

The Impact of Cr^{3+} Doping on Temperature Sensitivity Modulation in Cr^{3+} Doped and Cr^{3+}, Nd^{3+} Co-doped $Y_3Al_5O_{12}$, $Y_3Al_2Ga_3O_{12}$, and $Y_3Ga_5O_{12}$ Nanothermometers

A new approach to enhance the sensitivity of transition metal ion based nanocrystalline luminescent thermometer is presented. It was shown that the increase of Cr^{3+} concentration in three types of garnet host namely $Y_3Al_5O_{12}$, $Y_3Ga_5O_{12}$, and $Y_3Al_2Ga_3O_{12}$ allows for significant enhancement of their performance in non-contact thermometry. This phenomenon is related to the weakening of the crystal field strength due to enlargement of average Cr^{3+}-O^{2-} distance at higher Cr^{3+} concentrations. By increasing Cr^{3+} concentration from 0.6 to 30%, the sensitivity increased by over one order of magnitude from $S = 0.2\%/^{\circ}C$ to $S = 2.2\%/^{\circ}C$ at 9°C in $Y_3Al_2Ga_3O_{12}$ nanocrystals. Moreover, it was found that due to the $Cr^{3+} \rightarrow Nd^{3+}$ energy transfer in the Cr^{3+}, Nd^{3+} co-doped system, the usable Cr^{3+} concentration, for which its emission can be detected, is limited to 10% while the sensitivity at −50°C was doubled (from 1.3%/°C for $Y_3Al_2Ga_3O_{12}$:10%Cr^{3+} to 2.2%/°C $Y_3Al_2Ga_3O_{12}$:10%Cr^{3+}, 1%Nd^{3+} nanocrystals).

INTRODUCTION

In response to the requirements imposed by technology, micro/nanoelectronics or photonics as well as by biomedical applications, new approaches to the luminescent nanothermometers (LNTs) have to be proposed to secure fast and accurate temperature sensing with submicrometer spatial resolution, and highly sensitive temperature readout (Brites et al., 2012; Jaque and Vetrone, 2012; Chen et al., 2016; del Rosal et al., 2016a,b; Dramićanin, 2016; Marciniak et al., 2016b; Suo et al., 2017; Wang et al., 2017; Gao et al., 2018; Liao et al., 2018; Liu et al., 2018; Malysa et al., 2018; Runowski et al., 2018; Zhong et al., 2018). One of the most promising one, relies on exploiting transition metal (TM) ions, whose highly temperature dependent emission is referred to emission of barely temperature dependent lanthanides ions (Marciniak et al., 2017a; Drabik et al., 2018; Elzbieciak et al., 2018; Kniec and Marciniak, 2018; Marciniak and Trejgis, 2018; Trejgis and Marciniak, 2018). Materials which could be applied as real time temperature sensors in biomedicine, must also accomplish some other important requirements like sufficient sensitivity to temperature changes, high stability, low cytotoxicity (Brites et al., 2012; Jaque and Vetrone, 2012; Benayas et al., 2015) and operation in spectral range of optical transparency windows of biological tissues (Anderson and Parrish, 1981; Jaque and Jacinto, 2016). Because the transition metal ions based luminescent nanothermometers meet abovementioned flagship demands, they

can be considered as distinctively attractive research area. However, in order to be applicable, the thorough understanding of the correlation between structure of the host material and the thermal quenching of luminescence has to be studied. In our previous work (Elzbieciak et al., 2018), we have shown that by appropriate adjustment of the stoichiometry of the host matrix, relative sensitivity of Cr^{3+} ions-based luminescent thermometer can be intentionally modulated. The presented tuning occurred as a result of modification of the metal-to-oxygen ionic distance, which modified the strength of the crystal field (CF) (Struve and Huber, 2000; Xu et al., 2017). Therefore, taking advantage from the fact that CF influences the position of $^4T_2$ parabola, the activation energy, responsible for determination of thermal stability of luminescence, can be deliberately reduced. Efficient thermal quenching of the luminescence intensity is beneficial for sensitive luminescent thermometry. As it was already presented (Marciniak and Bednarkiewicz, 2016; Marciniak et al., 2016a, 2017b; Azkargorta et al., 2017), significant changes of the CF strength may also result from rising the concentration of active or passive dopants. Recently, Deren et al. (2012) showed that the increase of the Cr^{3+} concentration in $Y_3Ga_5O_{12}$:Cr^{3+} causes the diminishment of $^2E \rightarrow {}^4A_2$ narrow emission band and enhancement of $^4T_2 \rightarrow {}^4A_2$ band's intensity. Lowering the CF strength by growing number of Cr^{3+} ions, which is related with the elongation of the M-O distance, should relevantly enhance the relative sensitivity to temperature changes of such Cr^{3+} based luminescent thermometer. These observations motivated us to verify this hypothesis through comprehensive investigations of the impact of Cr^{3+} concentration (0.01–50%) on the temperature sensing capability in $Y_3Al_5O_{12}$, $Y_3Al_2Ga_3O_{12}$ and $Y_3Ga_5O_{12}$ nanocrystals.

EXPERIMENTAL

Nanopowders of (0.1; 0.5; 2; 5; 10; 20; 50%) Cr^{3+} and (0.1; 0.5; 2; 5; 10; 20; 50%) Cr^{3+},1% Nd^{3+} doped $Y_3Al_5O_{12}$, $Y_3Ga_5O_{12}$ and (0.06; 0.3; 1.2; 3; 6; 9; 12; 30%) Cr^{3+}, (0.06; 0.3; 1.2; 3; 6; 9; 12; 30%) Cr^{3+}, 1%Nd^{3+} doped $Y_3Al_2Ga_3O_{12}$ garnets were synthesized by the modified Pechini method (Pechini, 1967). Whole synthesis procedure was analogous as described in our earlier work (Elzbieciak et al., 2018). In brief, in order to obtain metal nitrates, calculated amount of yttrium oxide and neodymium oxide were dissolved in deionized water with addition of ultrapure nitric acid. After triple recrystallization process, yttrium or yttrium and neodymium nitrates were mixed together with aluminum, gallium and chromium nitrates. Afterwards, aqueous solution of citric acid and PEG was added to the mixture, than it was stirred for 3 h. In order to form a resin the obtained solution was heated for 1 week at 90°C.

All the synthesized materials were annealed for 16 h at 850°C. The following starting materials were used for synthesis: yttrium oxide (Y_2O_3 with 99.995% purity from Stanford Materials Corporation), neodymium oxide (Nd_2O_3 with 99.998% purity from Stanford Materials Corporation), aluminum nitrate nonahydrate ($Al(NO_3)_3{\cdot}9H_2O$ Puratronic 99.999% purity from Alfa Aesar), gallium(III) nitrate nonahydrate ($Ga(NO_3)_3{\cdot}9H_2O$ Puratronic 99.999% purity from Alfa Aesar), chromium nitrate nonahydrate ($Cr(NO_3)_3{\cdot}9H_2O$, 99.99% purity from Alfa Aesar), citric acid ($C_6H_8O_7$ with 99.5+% purity from Alfa Aesar) and poly(ethylene glycol) (PEG $C_2H_6O_2$ BioUltra 200 from Sigma).

All of the obtained materials were examined by XRD (X-ray diffraction) measurements carried out on PANalitycal X'Pert diffractometer, equipped with an Anton Paar TCU 1000 N temperature control unit, using Ni-filtered Cu-K_α radiation ($V = 40$ kV, $I = 30$ mA). Transmission electron microscope (TEM) images were taken using FEI TECNAI G2 X-TWIN microscope equipped with EDS detector. Powders were dispersed in methanol solution in ultrasounds and applied for lacey type copper lattices. The studies were performed in conventional TEM microscope with 300 keV parallel beam electron energy. Images were digitally recorded using the Gatan Ultrascan 1000XP.

Excitation spectra were measured using FLS980 Fluorescence Spectrometer form Edinburgh Instruments. Temperature dependent emission spectra were measured using 450 nm excitation line from laser diode and recorded using a Silver-Nova Super Range TEC Spectrometer from Stellarnet of 1 nm spectral resolution. Temperature during the measurement was controlled using the THMS 600 heating stage from Linkam (0.1°C stability and 0.1°C set point resolution).

RESULTS AND DISCUSSION

The yttrium aluminum/gallium garnets, crystallize in cubic structure with Ia3-d space group. As it is known, structures of these materials ($A_3B_2C_3O_{12}$) provide three types of cation sites, namely dodecahedral Y^{3+} site and also octahedral (B) and tetrahedral (C) Al^{3+}/Ga^{3+} sites which, because of similarity in ionic radii and the same coordination number, could be occupied by lanthanide Ln^{3+} (A) and transition metal ions TM^{3+} (B, C), respectively. Representative XRD patterns of $Y_3Al_2Ga_3O_{12}$:Cr^{3+} nanocrystals with different chromium concentration are presented in **Figure 1a**. All the reflection peaks correspond to the reference patterns confirming phase purity of the synthesized materials even for high dopant concentration (see also Supporting Information, **Figures S1–S5**). It is worth noting that in case of YAG (**Figures S2, S3**) and YGG (**Figures S4, S5**) with doping above 20% of Cr^{3+} ions, additional peaks occur in the XRD pattern. The cell parameter, as it can be seen in **Figure 1b**, is strongly affected by the Cr^{3+} concentration. In the case of YAG:Cr^{3+}, parameter *a* increases from 11.99 Å for 0.1%Cr^{3+} to 12.16 Å for 50%Cr^{3+}. On the other hand for YGG:Cr^{3+} an opposite tendency can be found –the *a* parameter decreases from 12.09 Å for 0.1%Cr^{3+} to 12.05 Å for 50%Cr^{3+}. This is due to differences in ionic radius between host ions Al^{3+} (67.5 pm) and Ga^{3+}(76 pm) ions being substituted by a larger dopant Cr^{3+} ions (75.5 pm). When atom with shorter ionic radius is substituted by atom with longer one, as in the case of $Y_3Al_5O_{12}$, the volume of the unit cell increases, due to the local expansion of the structure. This was also confirmed by the increase of the microstrains in the YAG structure (calculated using Rietveld refinement, **Figure S7**). On the other hand, in the case of

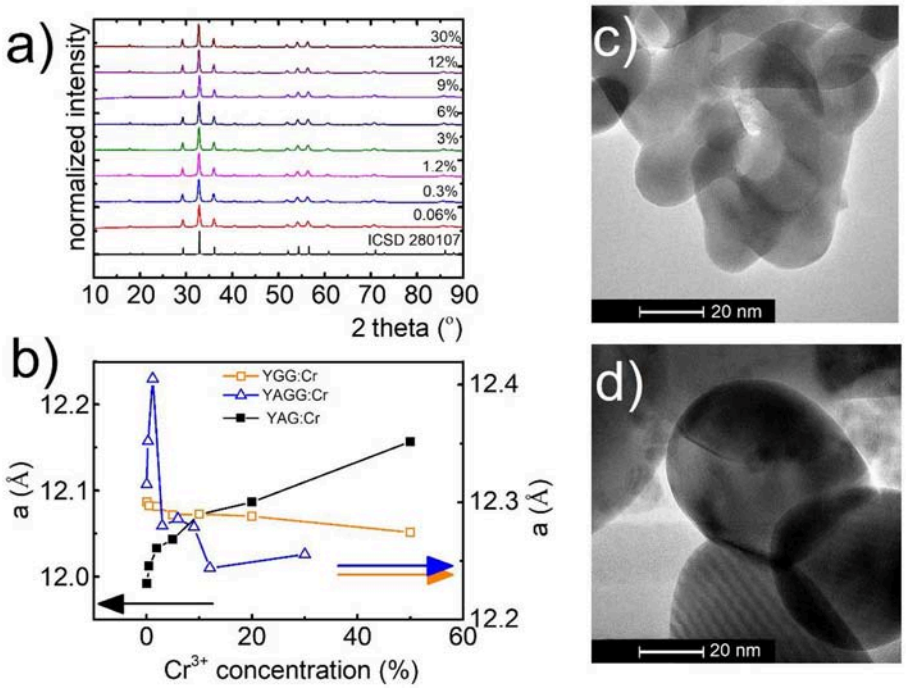

FIGURE 1 | Structural and morphological characterization of synthesized materials: XRD spectra for $Y_3Al_2Ga_3O_{12}$ **(a)** with different concentrations of Cr^{3+} ions, dependence of unit cell parameter **(a)** of YGG, YAG, and YAGG on Cr^{3+} concentration **(b)**; representative TEM images for $Y_3Al_2Ga_3O_{12}$:0.06%Cr^{3+},1%Nd^{3+} **(c)** and $Y_3Al_2Ga_3O_{12}$:30%Cr^{3+},1%Nd^{3+} **(d)** nanocrystals.

substitution of larger host ion with a smaller dopant ion, the parameter *a* and microstrains decrease likewise in the $Y_3Ga_5O_{12}$. The reduction of the cell parameter for increasing Cr^{3+} concentration observed in YAGG, is therefore a direct confirmation that Cr^{3+} ions substitute octahedral sites of Ga^{3+} ions. The average grain size of the nanocrystals, calculated using Rietveld refinement technique (around 60 nm), was in agreement with the nanoparticle size distribution determined from TEM images-70 ± 10 nm (**Figures 1c,d**, **Figure S6**). TEM images revealed good crystallization and some agglomeration of the obtained powders.

The simplified configurational coordinates diagram of Cr^{3+} is presented in **Figure 2A**. The luminescence of Cr^{3+} ions occurs through radiative depopulation of ^2E and/or $^4T_2$ states to the $^4A_2$ ground state. Due to the fact that strength of the crystal field determines the emission of Cr^{3+} ions, sharp emission line corresponding to the $^2E \rightarrow {}^4A_2$ transition and broadband emission corresponding to the $^4T_2 \rightarrow {}^4A_2$ transition can be observed in the emission spectra of Cr^{3+} ion in strong and weak crystal field, respectively. At higher temperatures, when the thermal energy is sufficient to reach the intersection point between the ^2E parabola and $^4T_2$ or $^4A_2$ parabolas, the process of nonradiative, multiphonon relaxation results in lowering of their emission intensity. Analysis of the emission spectra of $Y_3Al_2Ga_3O_{12}$:Cr^{3+} for different dopant concentration obtained upon 450 nm excitation, clearly indicates that at higher Cr^{3+} concentration the broad $^4T_2 \rightarrow {}^4A_2$ emission band localized at around 870 nm increase its intensity in respect to the $^2E \rightarrow {}^4A_2$ band at 692 nm (**Figure 2B**). Obviously, the total emission intensity decreases at higher dopant concentration due to the concentration quenching of luminescence. Nevertheless, it can be distinctly seen that $^4T_2 \rightarrow {}^4A_2$ dominates in the spectra for 30% of Cr^{3+} ions. Similar observation can be done in the emission spectra of $Y_3Al_5O_{12}$:Cr^{3+} and $Y_3Ga_5O_{12}$:Cr^{3+} nanocrystals presented in **Figures S8, S9**, respectively. However, in these cases similar trends can be observed for lower Cr^{3+} concentrations and to a lesser extent also in $Y_3Al_2Ga_3O_{12}$. Two main consequences of the lowering of $^4T_2$ state parabola can be found. First, at low dopant concentration the gradual reduction of its energy facilitates thermal depopulation of ^2E state–lowered ΔE_2 energy (the consequence of the intersection point between ^2E and $^4T_2$ parabolas). Secondly, at higher dopant concentration, when the energy $^4T_2$ state becomes lower than ^2E one, the broadband emission appears. The characteristic red-shift of the Cr^{3+} absorption bands localized around 400 nm and 575 nm, which can be attributed to the $^4A_2 \rightarrow {}^4T_1$ and $^4A_2 \rightarrow {}^4T_2$ electronic transitions, respectively, is a result of lowering of the CF strength (**Figures S12–S14**). In order to quantify the observed change of the crystal field strength in the examined nanocrystals, the Dq/B parameter was calculated for each of the samples as follows (Casalboni et al., 1994):

$$Dq = \frac{E\left({}^4A_2 \rightarrow {}^4T_2\right)}{10} \quad (1)$$

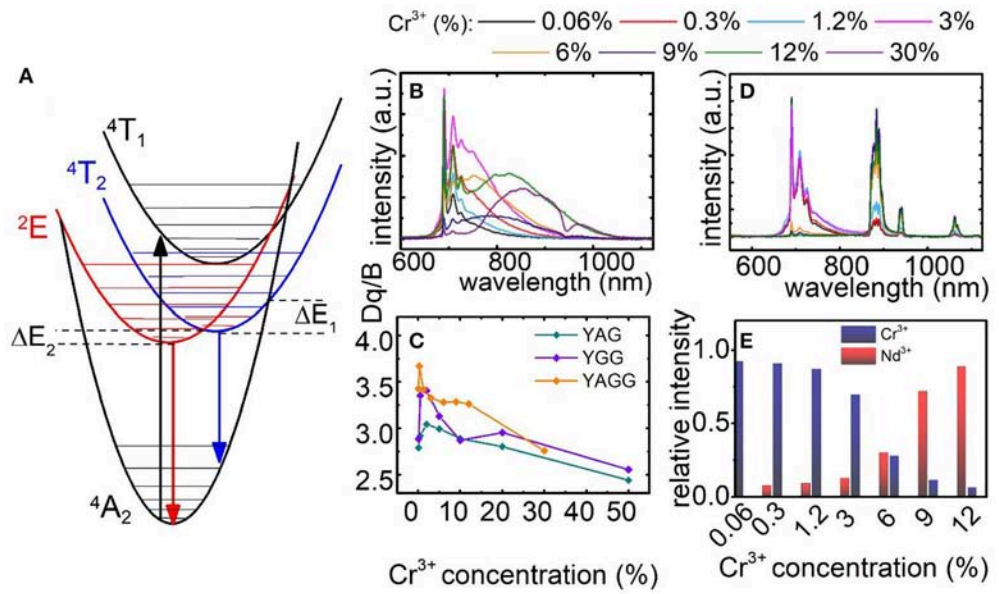

FIGURE 2 | Configurational coordinates diagram of Cr^{3+} ions **(A)**; comparison of normalized emission spectra for $Y_3Al_2Ga_3O_{12}$: xCr^{3+} **(B)** and for $Y_3Al_2Ga_3O_{12}$: xCr^{3+}, 1%Nd^{3+} nanocrystals **(D)**; dependence of Dq/B parameter **(C)** and Cr^{3+}/Nd^{3+} ratio at $T = -150°C$ **(E)** on Cr^{3+} concentration.

$$\frac{Dq}{B} = \frac{15\,(x-8)}{\left(x^2-10x\right)} \tag{2}$$

where x could be defined as (Casalboni et al., 1994):

$$x = \frac{E\left(^4A_2 \rightarrow {}^4T_1\right) - E\left(^4A_2 \rightarrow {}^4T_2\right)}{Dq} \tag{3}$$

As it can be observed in **Figure 2C** the Dq/B gradually decreases with Cr^{3+} concentration from 2.79 to 2.44 for $Y_3Al_5O_{12}$; from 2.88 to 2.55 for $Y_3Ga_5O_{12}$ and from 3.42 to 2.76 for $Y_3Al_2Ga_3O_{12}$ nanocrystals. In order to obtain self-referenced luminescent thermometer based of the Cr^{3+} emission intensity the examined nanocrystals with different Cr^{3+} concentration were co-doped with 1% Nd^{3+} ions. Emission intensity of Nd^{3+} is expected to be significantly less temperature dependent in respect to the chromium emission. Moreover, the Nd^{3+} ions emit in the first (band around 880 nm attributed to the $^4F_{3/2} \rightarrow {}^4I_{9/2}$ electronic transition) and the second (bands around 1064 nm and 1350 nm attributed to the $^4F_{3/2} \rightarrow {}^4I_{11/2}$ and $^4F_{3/2} \rightarrow {}^4I_{13/2}$ electronic transitions, respectively) optical window of the biological tissues making it well suited for biological applications.

Following excitation spectra, a 450 nm excitation line was chosen, which provides the condition of direct excitation of each individual optically active ion-Cr^{3+} ($^4A_2 \rightarrow {}^4T_1$) and independently Nd^{3+} ($^4I_{9/2} \rightarrow {}^2G_{5/2}$). As it was recently showed, this is an important condition to enhance the relative sensitivity of this kind of LTs (Marciniak et al., 2017a). In case of $Y_3Al_2Ga_3O_{12}$: Cr^{3+}, Nd^{3+} (**Figure 2D**) nanocrystals the presence of Nd^{3+} ion significantly quenched the Cr^{3+} emission intensity due to the $Cr^{3+} \rightarrow Nd^{3+}$ energy transfer. Therefore, the $^2E \rightarrow {}^4A_2$ emission band can be barely seen for $Y_3Al_2Ga_3O_{12}$: 30%Cr^{3+}, 1%Nd^{3+} while in the case of $Y_3Al_5O_{12}$ and $Y_3Ga_5O_{12}$ above 10% of Cr^{3+}, no chromium emission was detected (**Figures S10, S11**). Moreover, the presence of broad Cr^{3+} absorption bands in the excitation spectra when monitoring Nd^{3+} emission ($^4F_{3/2} \rightarrow {}^4I_{9/2}$ emission band), is an additional confirmation of the interionic energy transfer which takes place between dopants (**Figures S12–S14**). The change of contribution of the emission of particular optically active ions in the total emission intensity related with Cr^{3+} concentration is presented in **Figure 2E**. Initially, at low Cr^{3+} amount the $^2E \rightarrow {}^4A_2$ emission band dominates in the spectra. However, around 6% of Cr^{3+} its emission intensity equalize with Nd^{3+} amount. Above this value, the chromium emission intensity rapidly decreases. Therefore, this energy transfer strongly limits the usable Cr^{3+} concentration which can be applied for luminescent thermometry.

To understand the role of Cr^{3+} on the luminescence thermal quenching in the $Y_3Al_5O_{12}$ and $Y_3Ga_5O_{12}$ and $Y_3Al_2Ga_3O_{12}$ nanocrystals, their emission spectra were measured in a wide temperature range. The representative thermal evolution spectrum of $Y_3Al_2Ga_3O_{12}$:1.2%Cr^{3+} nanocrystals is presented in **Figure 3A**. It is clearly seen that sharp R-line of the $^2E \rightarrow {}^4A_2$ emission band is rapidly quenched at around 50°C in contrary to the $^4T_2 \rightarrow {}^4A_2$ emission. Therefore, due to this difference in the rates of thermal quenching of these particular emission bands, their luminescence intensity ratio was chosen as a temperature sensor LIR_1:

$$LIR_1 = \frac{Cr^{3+}(^4T_2 \rightarrow {}^4A_2)}{Cr^{3+}(^2E \rightarrow {}^4A_2)} = \frac{\int I(850-855)nm}{\int I(730-735)nm} \tag{4}$$

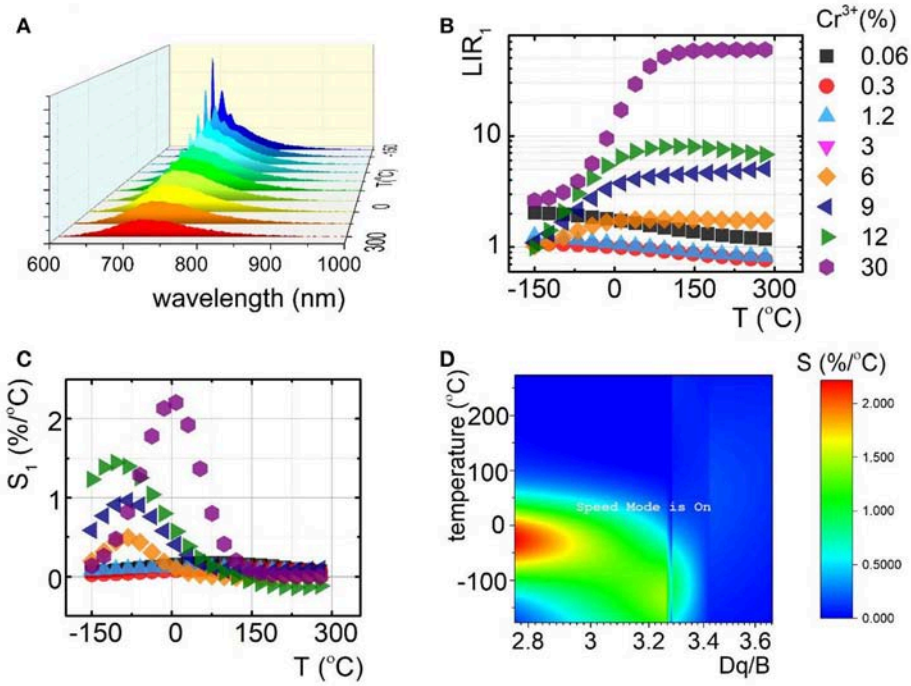

FIGURE 3 | Comparison of thermal evolution of emission spectra for $Y_3Al_2Ga_3O_{12}$:1.2%Cr^{3+} **(A)**; evolution of LIR_1 **(B)** with the corresponding relative sensitivities (S_1) **(C)** in the function of temperature; sensitivity map for different temperatures depending on Dq/B **(D)**.

At low Cr^{3+} concentration the LIR_1 decreases with temperature due to the fact that ^2E state population feeds the $^4T_2$ state at higher thermal energy. However, for higher Cr^{3+} (above 6%) different tendency can be found. Initially the LIR_1 increases up to temperatures around 100°C above which saturation of its value can be found. This effect occurs because $^4T_2 \rightarrow {}^4A_2$ band's intensity starts to play an important role in the total emission intensity. Due to the strong electron-phonon coupling, this emission band is expected to be efficiently reduced by the temperature. Therefore, its much higher rate of thermal quenching in respect to the $^2E \rightarrow {}^4A_2$ results in the enhancement of LIR_1 value. To quantitative describe the observed changes, relative sensitivity (S) of LIR_1-based luminescent thermometer was calculated according to the following formula:

$$S(T) = \frac{1}{LIR}\frac{\Delta LIR}{\Delta T}100\% \quad (5)$$

Independently from the Cr^{3+} concentration, the relative intensities reach maximal value at temperatures below 100°C. Above this value, low changes of LIR_1 are manifested as a minor value of S (**Figure 3C**). It is clearly seen that, according to our expectation, S significantly increases proportionally to Cr^{3+} content. The S_{max} at 9°C increases from 0.2%/°C for $Y_3Al_2Ga_3O_{12}$: 0.06%Cr^{3+} to 2.2%/°C for $Y_3Al_2Ga_3O_{12}$: 30%Cr^{3+} nanocrystals. Analogous tendency was found for the $Y_3Al_5O_{12}$:Cr^{3+} and $Y_3Ga_5O_{12}$:Cr^{3+} where for 10% Cr^{3+}, S_{max} equals to 2.7%/°C at −105°C and 2%/°C at −78°C respectively (**Figures S15, S16**). The observed enhancement of the rate of the thermal quenching is obviously caused by the lowering of the CF strength. The optically active ions in the heavily Cr^{3+}-doped nanocrystals are located in the lower CF sites (**Figure 3D**) which reduce the activation energy and facilitate luminescence thermal quenching. Therefore, the highest S were found for high Cr^{3+} concentration (low Dq/B values). However, above 130°C this correlation is suppressed due to the fact that above this temperature no $^2E \rightarrow {}^4A_2$ emission was observed. It is worth noting that the temperature range of high S overlaps with physiological temperature range (10–50°C) what indicates the importance of these LTs for biomedical applications.

Due to the fact that emission intensity of both $^2E \rightarrow {}^4A_2$ and $^4T_2 \rightarrow {}^4A_2$ bands decreases at higher temperatures, relative sensitivity of luminescent thermometer based on their intensity ratio is reduced. Therefore, Nd^{3+} co-dopant, whose emission intensity is expected to be less temperature dependent, were used as a luminescent reference. The luminescent properties of Nd^{3+}, Cr^{3+} co-doped nanocrystals were investigated in the analogous temperature range as in the case of singly Cr^{3+} doped counterparts. Representative thermal evolution of $Y_3Al_2Ga_3O_{12}$: 1.2%Cr^{3+}, 1%Nd^{3+} nanocrystals is presented in **Figure 4a**. According to the expectations the intensity of bands at 880 and 1,060 nm attributed to $^4F_{3/2} \rightarrow {}^4I_{9/2}$ and $^4F_{3/2} \rightarrow {}^4I_{11/2}$ electronic transition of Nd^{3+} ions, respectively, is almost independent on the temperature, while the $^2E \rightarrow {}^4A_2$ emission intensity is strongly thermally quenched. It is worth noting that at temperatures above 50°C, additional Nd^{3+} bands appears which

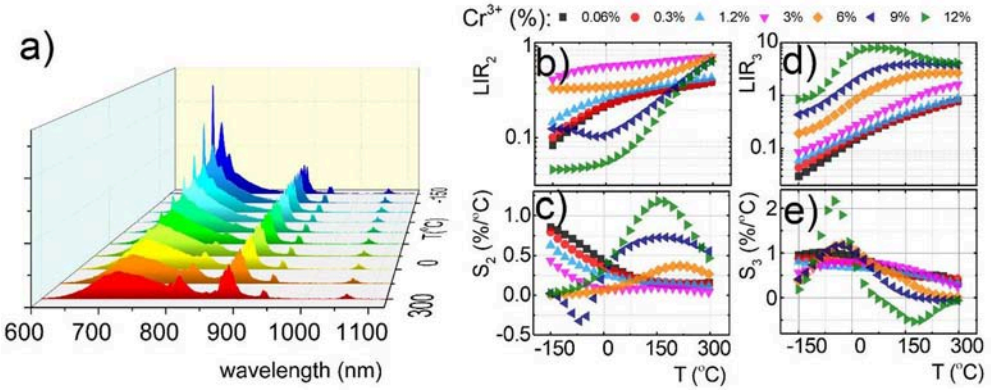

FIGURE 4 | Comparison of thermal evolution of emission spectra for $Y_3Al_2Ga_3O_{12}$:1.2%Cr^{3+}, 1%Nd^{3+} **(a)**; thermal evolution of LIR_2 **(b)**; and LIR_3 **(d)** and the corresponding relative sensitivities S_2 **(c)** and S_3 **(e)** for different Cr^{3+} concentration for $Y_3Al_2Ga_3O_{12}$:1.2%Cr^{3+}, 1%Nd^{3+} nanocrystals.

can be attributed to the $^4F_{5/2}$, $^4S_{3/2}\rightarrow{}^4I_{9/2}$ electronic transition. This band occurs at higher temperature due to the fact that population of $^4F_{5/2}$, $^4S_{3/2}$ states increases in respect to the $^4F_{3/2}$ with temperatures according to Boltzmann population. Taking advantage from these changes of the emission spectra with temperature, two types of luminescent thermometers based on the Nd^{3+}/Cr^{3+} luminescence intensity ratio have been defined as follows:

$$LIR_2 = \frac{Nd^{3+}(^4F_{3/2}\rightarrow{}^4I_{9/2})}{Cr^{3+}(^4T_2\rightarrow{}^4A_2)} = \frac{\int I(869-869.5)nm}{\int I(705-705.5)nm} \quad (6)$$

$$LIR_3 = \frac{Nd^{3+}(^4F_{5/2}\rightarrow{}^4I_{9/2})}{Cr^{3+}(^4T_2\rightarrow{}^4A_2)} = \frac{\int I(810-810.5)nm}{\int I(710-710.5)nm} \quad (7)$$

The thermal dependence of LIR_2 and LIR_3 for different concentration of Cr^{3+} ions are presented in **Figures 4b,d**, respectively. Obviously, due to the $Cr^{3+}\rightarrow Nd^{3+}$ energy transfer the usable concentration range of Cr^{3+} is strongly limited (to 12% Cr^{3+}). Independently from dopant concentration, both LIR_2 and LIR_3 increase at higher temperature due to the thermal quenching of $^4T_2\rightarrow{}^4A_2$ band of Cr^{3+} (**Figures 4b,d**). However, more rapid changes can be found for LIR_3 what is obviously related with the increase of the $^4F_{5/2}$, $^4S_{3/2}\rightarrow{}^4I_{9/2}$ emission band of Nd^{3+}. Both LIR_2 and LIR_3 are strongly modulated by the Cr^{3+} concentration. In agreement with the results obtained for singly Cr^{3+} doped systems, significant enhancement of LIR's thermal changes can be found. At heavily doped phosphors the activation energies of $^4T_2$ level is meaningfully diminished facilitating its nonradiative depopulation. Small activation energy is beneficial for enhancement of the relative sensitivity of luminescent thermometers. Therefore, these effects substantially affect the relative sensitivity of both S_2 and S_3 (**Figures 4c,e**). The highest S_2 at 150°C increases from 0.17%/°C for 0.06% of Cr^{3+} to 1.17%/°C for 12% of Cr^{3+} ions. On the other hand the S_3 at −48°C increases from 0.95%/°C for 0.06% of Cr^{3+} to 2.16%/°C for 12% of Cr^{3+} ions. Comparing these results with the **Figure 3**, evident profitable effect of the Nd^{3+} ions use as a luminescent reference can be found. The relative sensitivity for 0.06% Cr^{3+} increases from $S_1 = 0.14\%/°C$ to $S_2 = 0.17\%/°C$ and $S_3 = 0.95\%/°C$, while for 12% Cr^{3+} from $S_1 = 1.37\%/°C$ to $S_2 = 1.17\%/°C$ and $S_3 = 2.16\%/°C$. Analogous beneficial effect of high Cr^{3+} concentration can be found for $Y_3Ga_5O_{12}$:Cr^{3+}, Nd^{3+} as well as $Y_3Al_5O_{12}$:Cr^{3+}, Nd^{3+} (**Figures S10, S11**). It is also worth noting that the LIR_2 reveals high sensitivity at high temperature range (above 100°C) in contrast to LIR_3, which unveils good performance for non-contact temperature sensing at low temperatures (below 0°C). Therefore, by simultaneous employment of both of these thermometers the temperature range where high accuracy temperature readout can be achieved, is widened.

The highest recorded sensitivity ($S = 2.64\%/°C$) was found for YAG nanocrystals at −100°C for 10% of Cr^{3+} (**Figure S15B**) due to the fact of the lowest CF strength for this host material. Nevertheless, CF strength was tuned in the widest range for $Y_3Al_2Ga_3O_{12}$: Cr^{3+}, Nd^{3+} via the Cr^{3+} doping the enhancement of S_3 was the strongest in this case. The most important finding presented in this paper is that highly sensitive luminescent thermometers can be intentionally designed by the modification of the CF strength through elongation of Cr^{3+}-O^{2-} distance and enlargement of the Cr^{3+} concentration.

CONCLUSIONS

In this work, we proposed a new strategy to modulate the relative thermal sensitivity of Cr^{3+} doped nanophosphors. We considered three types of garnet matrices doped with different Cr^{3+} concentrations, with or without Nd^{3+} co-dopant. It was shown that the increase of the Cr^{3+} concentration causes elongation of the average Cr^{3+}-O^{2-} distance leading to the reduction of the crystal field strength in $Y_3Al_2Ga_3O_{12}$, $Y_3Ga_5O_{12}$ and $Y_3Al_5O_{12}$ nanocrystals. A gradual increase of the broad emission band attributed to the $^4T_2\rightarrow{}^4A_2$ spin allowed transition of Cr^{3+} is observed. Moreover, the reduction of the $^4T_2$ state energy facilitates thermal quenching of ^2E state. Therefore, the relative sensitivity of $^4T_2\rightarrow{}^4A_2$ to $^2E\rightarrow{}^4A_2$ emission intensity

increases from $S = 0.2\%/^{\circ}C$ for $0.06\%Cr^{3+}$ to $S = 2.2\%/^{\circ}C$ for $30\%Cr^{3+}$ at 9°C in $Y_3Al_2Ga_3O_{12}$ nanocrystals, from $S = 0.027\%/^{\circ}C$ for $0.5\%Cr^{3+}$ to $S = 2.7\%$ for $10\%Cr^{3+}$ at $-105^{\circ}C$ in $Y_3Al_5O_{12}$ nanocrystals, and from $S = 0.14\%/^{\circ}C$ for $0.5\%Cr^{3+}$ to $S = 2\%$ for $10\%Cr^{3+}$ at $-78^{\circ}C$ in $Y_3Ga_5O_{12}$ nanocrystals. In the case of Nd^{3+} co-doped nanocrystals, due to the $Cr^{3+} \rightarrow Nd^{3+}$ energy transfer, the usable concentration range of Cr^{3+} dopants is strongly reduced and no evidence of Cr^{3+} emission was found above 10% of Cr^{3+}. However, by taking advantage from this energy transfer and the fact that $^4F_{5/2}$, $^4S_{3/2} \rightarrow {}^4I_{9/2}$ emission intensity increases proportionally to the temperature according to the Boltzmann distribution, the relative sensitivities of luminescent thermometers defined as $^4F_{5/2}$, $^4S_{3/2} \rightarrow {}^4I_{9/2}$ to $^4T_2 \rightarrow {}^4A_2$ luminescence intensity ratio enhances from 1.3%/°C at −50°C without Nd^{3+} dopant to 2.2%/°C at −50°C for nanocrystals doped with Nd^{3+} ions $Y_3Al_2Ga_3O_{12}$: $10\%Cr^{3+}$, Nd^{3+}). The presented results confirm that the relative sensitivity of luminescent thermometers can be effectively modulated by the dopant concentration. Moreover, it was proved that the presence of Nd^{3+} dopant contributes to faster quenching of Cr^{3+} luminescence, what is favorable for highly sensitive non-contact luminescent thermometers. Our studies may be considered as a next step toward intentional designing of nanocrystalline luminescent thermometers with fully controllable thermooptical response.

Many DNA-functionalized nanomaterials and biosensors have been reported, but most have ignored the influence of DNA on the stability of nanoparticles. We observed that cytosine-rich DNA oligonucleotides can etch silver nanoparticles (AgNPs). In this work, we showed that phosphorothioate (PS)-modified DNA (PS-DNA) can etch AgNPs independently of DNA sequence, suggesting that the thio-modifications are playing the major role in etching. Compared to unmodified DNA (e.g., poly-cytosine DNA), the concentration of required PS DNA decreases sharply, and the reaction rate increases. Furthermore, etching by PS-DNA occurs quite independent of pH, which is also different from unmodified DNA. The PS-DNA mediated etching could also be controlled well by varying DNA length and conformation, and the number and location of PS modifications. With a higher activity of PS-DNA, the process of etching, ripening, and further etching was taken place sequentially. The etching ability is inhibited by forming duplex DNA and thus etching can be used to measure the concentration of complementary DNA.

INTRODUCTION

Interfacing DNA with nanomaterials has resulted in many interesting hybrids for analytical (Liu and Lu, 2006; Liu et al., 2009; Zhou et al., 2017), nanotechnology (Wilner and Willner, 2012; Pu et al., 2014; Tan et al., 2014; Seeman and Sleiman, 2017; Shen C. et al., 2017; Chidchob and Sleiman, 2018; Hu et al., 2018), and biomedical applications (Qu et al., 2000; Cao et al., 2002; Liu et al., 2015; Lu et al., 2017; Sun et al., 2018). Such applied research in turn stimulated fundamental surface and biointerface studies (Herne and Tarlov, 1997; Storhoff et al., 2002; Liu, 2012; Carnerero et al., 2017). Most of previous research focused on DNA-directed assembly (Mirkin et al., 1996; Liu and Lu, 2003; Sharma et al., 2009; Chou et al., 2014; Liu and Liu, 2017; Lin et al., 2018), or DNA-templated growth of nanomaterials (Nykypanchuk et al., 2008; Surwade et al., 2013; Wu et al., 2014; Song et al., 2015), while etching or dissolution of nanoparticles by DNA was much less explored. We reason that such studies are also important for the following reasons. First, nanoparticles were always assumed to be stable during DNA conjugation or assembly. If DNA can dissolve nanoparticles, such assumptions need to be updated and care has to be taken for long-term storage of such materials. In addition, DNA-mediated etching of nanoparticles can be a way of controlled release. Finally, it can further our fundamental understanding of DNA/nanoparticle interfaces.

Using a relatively high concentration of DNA (e.g., >1 μM), we recently observed etching of silver nanoparticles (AgNPs) by DNA oligonucleotides (Hu et al., 2019). For spherical AgNPs, poly-cytosine (poly-C) was the most effective, while the other three types of homopolymers did not display an obvious effect. The base composition of DNA is critical for etching silver-based nanomaterials.

Poly-C DNA can effectively etch AgNPs, but the required high DNA concentration and specific DNA sequence restricted its applications in analytical detection and controlled release. So far, we have studied only unmodified DNA. We reason that the effect of DNA might be further improved by introducing modifications with stronger metal ligands. Phosphorothioate (PS) modification refers to replacing one of the non-bridging oxygen atoms by sulfur (**Figure 1A**) (Huang and Liu, 2014, 2015; Huang et al., 2015a,b; Liu et al., 2018). The PS sites on DNA can bind strongly to thiophilic metals (e.g., Au and Ag) and PS-modified DNA (PS-DNA) has been used for nanomaterial synthesis (Ma et al., 2008; Farlow et al., 2013; Weadick and Liu, 2015; Shen J. et al., 2017), nanostructure assembly (Jiang et al., 2005; Lee et al., 2007; Pal et al., 2009; Shen J. et al., 2017), and biosensing (Zhang et al., 2009; Huang P. J. J. et al., 2016). We previously compared adsorption of PS-DNA with normal phosphodiester DNA (PO-DNA) on AuNPs, and concluded that the PS-DNA was more strongly adsorbed (Zhou et al., 2014). PS-DNA was also used to functionalize quantum dots (Ma et al., 2008; Farlow et al., 2013). In addition, PS modifications have been used to probe the reaction mechanism of ribozymes (Cunningham et al., 1998; Huang and Liu, 2014; Huang et al., 2015a, 2019; Thaplyal et al., 2015). All these studies took advantage of the strong affinity between PS and thiophilic metals. Since silver is also strongly thiophilic, we speculate that PS-DNA may be more effective for etching AgNPs in a less DNA sequence-dependent manner.

In this work, we systematically studied the effect of PS modifications and found that it could significantly decrease the needed DNA concentration. At the same time, the sequence of DNA was less important, making DNA-mediated etching available for many more sequences. The effects of pH, DNA length, the number and location of PS modifications and DNA conformation were also systematically studied and compared with the normal DNA of the same sequences, leading to interesting multi-stage etching and ripening process and chemically controlled etching.

MATERIALS AND METHODS

Chemicals

All the DNA were purchased from Integrated DNA Technologies (IDT, Coralville, IA, USA), and their sequences are shown in **Table S1**. Commercial citrate-capped AgNPs (20 nm diameter) were purchased from Nanocomposix (San Diego, CA, USA). Trisodium citrate and 3-(N-morpholino)propanesulfonic acid (MOPS) were obtained from Sigma-Aldrich (St. Louis, MO). Sodium nitrate ($NaNO_3$) was purchased from Mandel Scientific (Guelph, ON, Canada).

Instrumentation

UV-vis absorption spectra were recorded on a spectrometer (Agilent 8453A). The morphology of AgNPs was examined by a transmission electron microscope (TEM, Philips CM10). The etching kinetics of AgNPs were monitored using a microplate reader (SpectraMax M3). Dynamic light scattering (DLS) measurements were carried out using a Zetasizer Nano 90 (Malvern) at 25°C. Circular dichroism (CD) spectra were collected on a Jasco J-715 spectrophotometer (Jasco, Japan).

Comparison of Etching by PO and PS-DNA

In a typical experiment, a 15-mer DNA (20 μM, 35 μL) was incubated with an equal volume of AgNPs (10 μg/mL) at 37°C for 1.5 h. The final concentration of DNA was 10 μM. Then, the sample was analyzed by a spectrometer.

Effect of pH on Etching Kinetics

Typically, PO-C_{15}, PS_{14}-C_{15}, or PS_{14}-T_{15} (20 μM, 50 μL) was mixed with the AgNPs (10 μg/mL, 50 μL) in a 96-well plate. Then, 10 μL of 10 mM buffer with different pH values (citrate buffer for 4.0, 5.0, and 6.0; MOPS for 7.0 and 7.9) was added and incubated at 37°C for 1.5 h. The absorbance intensity was monitored at 395 nm every 0.5 min under the kinetic mode using the plate reader.

PS-DNA Structure Dependent Etching

First, PS-R DNA (40 μM, 17.5 μL) was mixed with 17.5 μL of its cDNA of different concentrations (5.0, 10, 20, 40, 60, 80, and 100 μM), followed by the addition of $NaNO_3$ (0.25 M, 2.0 μL). Then, the mixture was heated to 95°C for 5 min and cooled slowly to room temperature. Finally, AgNPs (10 μg/mL, 35 μL) were added and incubated at 37°C for 1.5 h. The final concentrations of the cDNA were 1.25, 2.5, 5.0, 10, 15, 20, and 25 μM, respectively.

RESULTS AND DISCUSSION

PS-DNA Mediated Etching of AgNPs

To test the effect of PS modification (see **Figure 1A** for its structure), we used the four types of 15-mer DNA homopolymers both with the normal phosphodiester (PO) backbone and with full PS modifications (each bridging phosphate contained a PS modification). Our 20 nm AgNPs had a strong surface plasmon peak at 395 nm (**Figure 1C**). Adding the normal PO-A_{15} DNA had no effect and the UV-vis spectrum retained its original shape. In contrast, the PS_{14}-A_{15} (note that a 15-mer DNA has only 14 bridging phosphates) dropped the extinction peak intensity by over 80%. From this experiment, we concluded that the sulfur atoms in the PS-DNA were the reason for the decreased extinction of the AgNPs. From TEM (**Figure 2A** and **Figures S1**, **S2A**), our starting AgNPs were monodispersed ∼20 nm spheres. After adding the PS_{14}-A_{15}, overall the AgNPs became smaller (**Figures 2B,F**), indicating its etching.

Similar experiments were also performed with the other DNA sequences, and the same observations were also made with the two T_{15} DNAs from both their UV-vis spectra (**Figure 1D**) and TEM (**Figure 2C**). The lack of etching by PO-A_{15} and PO-T_{15} is in agreement with the relatively low affinity between

these two DNA bases and silver surface (Basu et al., 2008; Wu et al., 2014).

When the PO-G_{15} was added, the extinction intensity of the AgNPs dropped by about 20% (**Figure 1E**), while a nearly 80% drop was observed when PS_{14}-G_{15} was added. At the same time, the peak red shifted by 18 nm. This suggested formation of larger AgNPs, which was confirmed by TEM (**Figure 2D**). Therefore, with this DNA concentration and reaction time, the PS_{14}-G_{15}

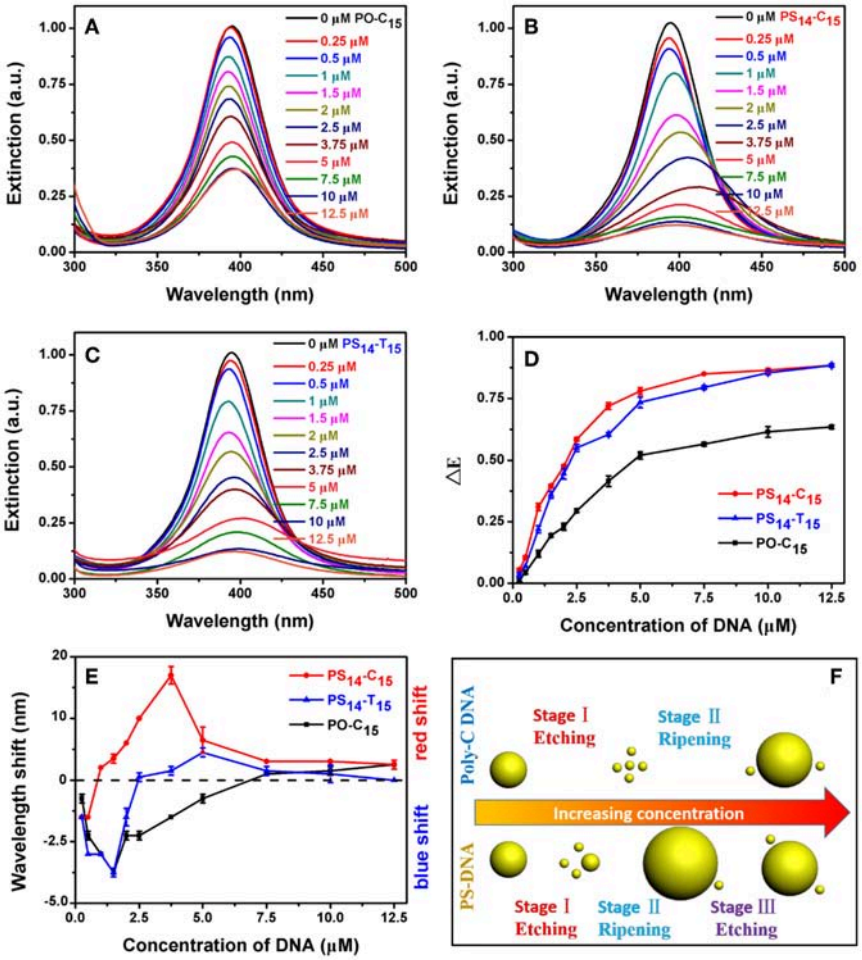

FIGURE 3 | (A) PO-C_{15}, **(B)** PS_{14}-C_{15}, and **(C)** PS_{14}-T_{15} concentration-dependent etching of the AgNPs. Relationship between DNA concentration and **(D)** dropped extinction and **(E)** wavelength shift of the AgNPs. **(F)** Comparison of the AgNPs etched by poly-C PO and PS DNA. With a stronger silver binding affinity, the PS DNA achieved the stage III reaction of further etching the larger AgNPs produced from the previous ripening stage.

helped Ostwald ripening of the AgNPs. Etching was the first step of the interaction, where the AgNPs were dissolved by the added DNA. Extensive etching and deposition of dissolved silver species on larger AgNPs (thus with lower solubility) resulted in the subsequent ripening.

The PO-C_{15} DNA was very effective in etching the AgNPs and it decreased extinction by 65% (**Figure 1F**). The extinction of the PS_{14}-C_{15}-treated sample further decreased the extinction peak to nearly 90%. Interestingly, under this condition, the ripening process caused only a 3 nm redshift, which was much smaller than that induced by PS_{14}-G_{15} (18 nm). Meanwhile, the average size of the PS_{14}-C_{15}-treated AgNPs (**Figure 2E**) was smaller than that of the PS_{14}-G_{15} treated sample (**Figure 2D**), indicating the cytosine and guanine bases also played a role on etching.

With these four pairs of DNA, we plotted the peak intensity drop in **Figure 1B**. All the PS sequences dropped the intensity by a similar value (the red bars), while a much larger difference was observed with the normal PO-DNA (blue bars). Since all the PS-DNA sequences had a significant etching effect, PS-DNA can etch the AgNPs in a less sequence-independent manner. This might be useful since etching can be general to different DNA sequences.

Comparison of PS and DNA Base Coordination

The above experiments indicated that PO-T_{15} is one of the least effective sequences for etching AgNPs. Therefore, the etching effect of PS_{14}-T_{15} should mainly come from the PS sites. PO-C_{15} is the best PO DNA and only the bases are available for etching, while PS_{14}-C_{15} is likely to be a most effective sequence overall. For PS_{14}-C_{15}, both the PS sites and the cytosine bases are likely to contribute to silver binding. Since these three sequences are representative, they were chosen for further studies. Their silver coordination sites are marked in black and red circles in **Figure 1A**.

We first studied the effect of DNA concentration. In each case, the peak intensity decreased with increase of DNA concentration (**Figures 3A–C**). At the same time, some redshifted peaks were observed at high DNA concentrations. All these experiments

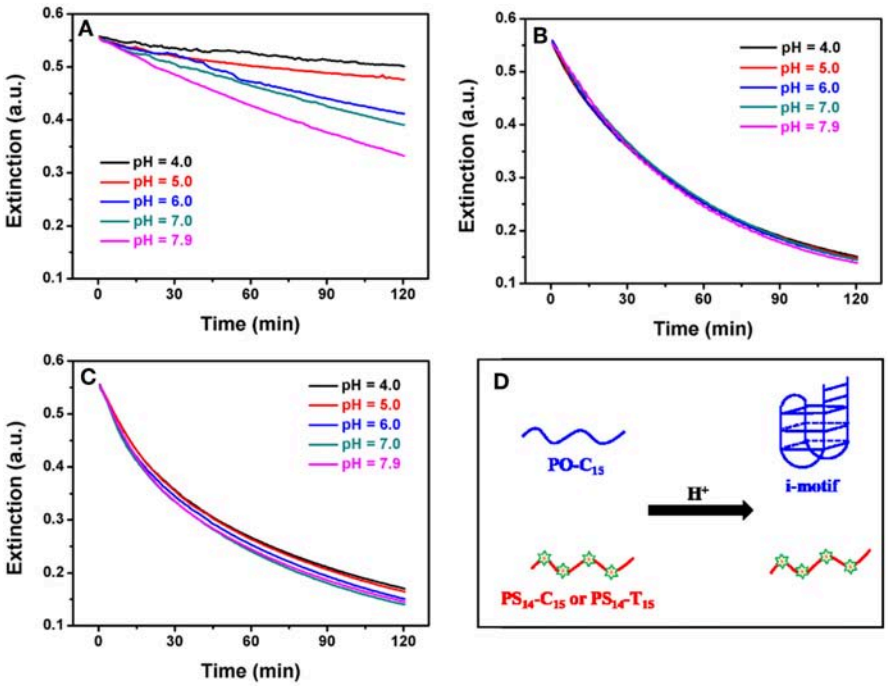

FIGURE 4 | Effect of pH on the kinetics of **(A)** PO-C_{15}, **(B)** PS_{14}-C_{15}, and **(C)** PS_{14}-T_{15} mediated AgNPs etching. Citrate buffer was used for pH 4.0, 5.0, and 6.0, and MOPS buffer was used for pH 7.0 and 7.9. **(D)** Effect of low pH on the structure of some PO and PS DNA.

were performed with an incubation time of 1.5 h, when the systems were approaching equilibrium (**Figure 4**).

By plotting the decrease of peak height against DNA concentration, we obtained their apparent binding curves (**Figure 3D**). Among these DNAs, PO-C_{15} had the lowest response with an apparent K_d of 3.87 μM. PS_{14}-C_{15} had a tighter binding with a K_d of 1.78 μM. Interestingly, PS_{14}-T_{15} had a K_d similar to that of PS_{14}-C_{15}, and thus from this standpoint, the base's contribution was minimal. Even at a relatively low DNA concentration, the base did not contribute much to etching. Adding PS modifications decreased the concentration requirement for C_{15} by 2.2-fold, while the improvement for T_{15} was close to infinity (compared to PO-T_{15}).

We then plotted the shift of peak wavelength (**Figure 3E**), where the upper half of the figure is for red shifted samples and the lower half for blue shifts. With low concentrations of PO-C_{15}, a gradual blue-shift of the AgNPs peak was observed and the maximal shift was achieved with 1.5 μM DNA, indicating etching of the AgNPs to form small particles. Then, the peak started to red shift attributable to Ostwald ripening. When the DNA concentration was more than 7.5 μM (crossing the dashed line in **Figure 3E**), the peak red-shifted relative to the original AgNPs.

For PS_{14}-C_{15}, most of their spectra were red shifted (e.g., ripening) except for the DNA concentration below 1 μM. From TEM, the overall size was indeed decreased for the 0.5 μM PS_{14}-C_{15} treated sample (**Figure S2B**). A wide size distribution with both larger and smaller AgNPs was observed for more PS_{14}-C_{15} (7.5 μM), confirming the ripening (**Figure S2C**). However, we cannot rule out slight aggregation of AgNPs occurring at the same time, which also caused the red shifted spectra. By comparing PO-C_{15} and PS_{14}-C_{15}, both showed etching at low DNA concentrations and then ripening with more DNA added. PS_{14}-C_{15} has a tighter affinity with silver allowing it to achieve the etching-to-ripening transition at a lower DNA concentration.

Interestingly, for PS_{14}-C_{15}, the red shift initially increased but later decreased when the concentration of PS_{14}-C_{15} was more than 3.75 μM (red trace in **Figure 3E**). A similar trend was also observed for PS_{14}-T_{15} despite smaller shifts compared to that of PS_{14}-C_{15}. This difference may be ascribed to their different DNA bases, suggesting that the cytosine bases of PS_{14}-C_{15} also participated in the etching process. We reason that PS_{14}-C_{15} had a complex multi-stage etching process. Low concentration of DNA contributed to AgNPs etching and further ripening (**Figures S2A–C**). Further increased PS_{14}-C_{15} DNA could further etch the larger AgNPs from the previous ripening step, which yielded the decreased red shift. The etching and thus size decrease was also confirmed by TEM (**Figure S2D**). As a result, we proposed a three-stage mechanism for PS-DNA to interact with AgNPs: etching, ripening and further etching (**Figure 3F**). For the PO-DNA, we only observed two stages (etching-ripening of AgNPs) indicating that cytosine bases alone were incapable of etching larger AgNPs, which were thermodynamically more stable than the originally used 20 nm ones. Since PS_{14}-T_{15} was also not very obvious than PS_{14}-C_{15} for this three-stage process, both cytosine bases and PS of PS_{14}-C_{15} contribute to the etching-to-ripening transition (with PS being the major contributor).

Kinetics and Effect of pH

To further study etching, we followed the reaction kinetics. Since the conformation of poly-C DNA is strongly affected by pH (Dong et al., 2014; Huang Z. et al., 2016), we also measured the etching kinetics at different pH values. For PO-C_{15}, etching was strongly inhibited at low pH (**Figure 4A**). In particular, when

pH was at 6 or lower, etching was essentially fully inhibited. In contrast, PS_{14}-C_{15} had the same rate of etching regardless of pH from 4 to 7.9 (**Figure 4B**). We fitted the kinetic data of the PS-DNA to a first-order equation and obtained a rate constant of 41.3 h^{-1}, which was much faster than the PO kinetics of 183.4 h^{-1} at pH 7.9 (the rate of the PO samples was even slower at lower pH). Since the only difference here was the base, we reason that the inhibited PO-C_{15} etching must be related to its base protonation and formation of secondary structures such as the i-motif (**Figure 4D**).

Using circular dichroic (CD) spectroscopy, a strong positive peak at around 285 nm and a small negative peak near 260 nm were observed suggesting an intramolecular i-motif structure of PO-C_{15} at pH 4.0 (the black spectrum in **Figure S3**) (Liu and Balasubramanian, 2003). Such a folded conformation could shield the bases and inhibit their interaction with AgNPs or with Ag^+. For the PS_{14}-C_{15}-mediated etching, pH had no effect on etching. Since the PS modifications could cause a reduced melting temperature compared to the PO counterpart (Gonzalez et al., 1991), the PS_{14}-C_{15} was incapable of forming i-motif at 37°C even under acidic conditions (the red spectrum in **Figure S3**). Therefore, the exposed PS and the bases in the random-coil structured PS_{14}-C_{15} could serve as the ligand for etching the AgNPs. The pH-independent etching also appeared for PS_{14}-T_{15} (**Figure 4C**), demonstrating the generality of PS-DNA-mediated etching of AgNPs.

The Number of PS Modifications and AgNP Etching

The above experiments used 15-mer DNA with full PS modification. We then varied the number of DNA length and PS modifications (see **Figure 5A** for the DNA sequences). First, the DNA length was explored. To minimize the effect of the DNA base, PS-modified poly-T DNAs were tested. The length of DNA varied from 5-mer to 15-mer, and the total PS modification was maintained to be the same (e.g., the molar concentration of PS_4-T_5 was 3.5 times of that of PS_{14}-T_{15}). The peak of the PS_{14}-T_{15} sample dropped more than that of PS_4-T_5, suggesting that longer DNA was more effective and thus the importance of polyvalent binding (**Figure 5B**).

We then varied to the number of PS modifications, while the DNA length was maintained at 15-mer. The number of PS modifications was reduced from 14 to 7, 4, 2, and 1 (**Figure 5C**). The peak intensity gradually dropped with increased PS modifications. For the poly-T DNAs with 1–7 PS modifications, the drop in the peak intensity was linearly proportional to the number of PS (**Figure S4**), further highlighting that the PS responsible for the AgNP etching. This also provided a method to quantitatively tune the extent of etching. Further increase of the PS modifications to 14 did not bring in much more changes, suggesting that seven PS modifications could be sufficient with the 1.5 h incubation time.

Finally, we explored the effect of the location of PS modifications. Compared to the uniform distribution of PS in the whole DNA backbone of PS_7-T_{15}, the 7 PS modifications in PS_{7r}-T_{15} were concentrated on the 3′-terminus of the DNA. Interestingly, the evenly distributed PS_7-T_{15} had a stronger decrease (**Figure 5D**), implying that PS coordination is more effective when they are separated.

DNA Conformation Dependent Etching

Effective adsorption of PS-DNA on AgNPs could be important for the etching process. All the above experiments used flexible single-stranded DNA oligonucleotides, while a rigid DNA structure (e.g., duplex) may hinder the attachment of DNA to AgNPs due to restricted binding sites (**Figure 6A**). To test this hypothesis, we explored the effect of DNA conformation on etching by forming duplex DNA. However, PS modifications can weaken the stability of duplex DNA as reflected from the reduced melting temperature (T_m) (Gonzalez et al., 1991). Furthermore, the A-T base pair with a PS modification showed more decreased T_m than that of the C-G base pair (Stein et al., 1988). Therefore, we designed a PS-modified random DNA (named PS-R DNA) with a high GC content (**Figure 6B**). This DNA could etch the AgNPs (the black spectrum in **Figure 6C**), and the etching efficiency was gradually inhibited with increasing dose of the complementary DNA (cDNA). The inhibiting efficacy was sharply decreased when the misDNA with a single mismatched base was added, while a full non-complementary DNA (T_{30}) had little inhibition effect (**Figure 6D**). Therefore, we can attribute the cDNA-dependent etching to the formation of the duplex DNA. In other words, single-stranded DNA is much more effective for etching the AgNPs, although the PS backbone is still fully exposed in duplex DNA. This implies that DNA needs to fold into optimal binding structures, and etching cannot take place effectively on isolated PS sites.

CONCLUSIONS

In summary, we reported that PS modifications on DNA could improve etching of AgNPs in several aspects. First, the sequence generality is significantly expanded, and the introduced PS allows essentially any DNA sequence to etch AgNPs beyond just poly-C DNA. Furthermore, the required DNA concentration decreased clearly, and at the same DNA concentration the rate of etching was much faster than that with PS modifications. The etching process also effectively took place for PS-DNA despite the low pH, which could inhibit etching induced by normal PO-DNA (e.g., poly-C DNA). At the same time, we could control the etching efficacy through changing DNA length and the number and location of PS modifications. With stronger etching efficiency, the reaction process was found to contain three stages: etching by low concentrations of PS-DNA, followed by Ostwald ripening at medium DNA concentrations, and further etching in the presence of high DNA concentrations. This work has expanded the scope of the interaction between DNA and nanomaterials, and it might lead to interesting analytical and biomedical applications. For example, etching of various silver nanostructures may produce visible color change for colormetric biosensors. These sensors might detect multiple analytes by using aptamers and by designing strategies to target the PS sites. At the same time, it also calls for attention regarding the stability of nanomaterials when designing hybrid materials

containing silver nanoparticles (and potentially other materials) with DNA.

AUTHOR CONTRIBUTIONS

SH, JW, and JL designed the experiments and wrote the paper. SH performed the experiments. PH contributed in the DNA design. All authors read and approved the final version of the manuscript.

FUNDING

Funding for this work is from the Natural Sciences and Engineering Research Council of Canada (NSERC) and the National Natural Science Foundation of China (21575166, 21876208).

Lanthanide-doped upconversion nanoparticles can convert long wavelength excitation radiation to short wavelength emission. They have great potential in biomedical applications, such as bioimaging, biodetection, drug delivery, and theranostics. However, there is little information available on their bioavailability and biological effects after oral administration. In this study, we systematically investigated the bioavailability, biodistribution, and toxicity of silica-coated upconversion nanoparticles administrated by gavage. Our results demonstrate that these nanoparticles can permeate intestinal barrier and enter blood circulation by microstructure observation of Peyer's patch in the intestine. Comparing the bioavailability and the biodistribution of silica-coated upconversion nanoparticles with oral and intravenous administration routes, we found that the bioavailability and biodistribution are particularly dependent on the administration routes. After consecutive gavage for 14 days, the body weight, pathology, Zn and Cu level, serum biochemical analysis, oxidative stress, and inflammatory cytokines were studied to further evaluate the potential toxicity of the silica-coated upconversion nanoparticles. The results suggest that these nanoparticles do not show overt toxicity in mice even at a high dose of 100 mg/kg body weight.

Keywords: upconversion nanoparticle, bioavailability, distribution, toxicity, *in vivo*, gavage

INTRODUCTION

In the last decade, lanthanide-doped upconversion nanoparticles have attracted increasing attention because of their unique advantages, such as low level of background noise, deep penetration depth, minimal photodamage, and high resistance to photobleaching (Auzel, 2004; Lu et al., 2013; Bettinelli et al., 2015; Li et al., 2015b, 2017; Jalani et al., 2018; Liu et al., 2018; Sun et al., 2018). Surface modification is typically required to make upconversion nanoparticles, UCNPs, suitable for biomedical application, which typically involves coating a hydrophilic ligand (i.e., amphiphilic polymers, proteins) or an extra hydrophilic layer (i.e., SiO_2) on their surface (Li et al., 2015a; Liu et al., 2015; Sedlmeiera and Gorris, 2015; Plohl et al., 2017). These features made UCNPs suitable for many biological and medical applications, including multimodal bioimaging, biosensing, drug delivery, photodynamic therapy, and synergetic therapy

(Lim et al., 2006; Liu et al., 2012, 2016; Yang et al., 2015; Zhou et al., 2015; Su et al., 2017; Chen et al., 2018; Green et al., 2018; Tsai et al., 2018). Despite the encouraging results that have been obtained, there are many unresolved issues relating to the biological effects of these nanomaterials.

UCNPs acting as drug carriers, contrast agents, or bioprobes have been extensively studied either in mice or in plant models (Peng et al., 2012; Liu et al., 2013; Chen et al., 2014; Wu et al., 2016). In previous studies, the majority of UCNPs toxicity assays were performed on different cell lines *in vitro* (Gnach et al., 2015; Tian et al., 2015; Wozniak et al., 2016; Wysokinska et al., 2016; Gao et al., 2017), but fewer reports focused on *in vivo* toxicity studies (Cheng et al., 2011; Wang et al., 2013; Jang et al., 2014; Lucky et al., 2016). The toxicity assays of UCNPs were routinely carried out based on the intravenous injection technique (Abdul and Zhang, 2008; Xiong et al., 2010; Zhou et al., 2011; Ramirez-Garcia et al., 2017). Very recently, Ortgies et al. developed an orally administrated lanthanide-doped UCNP for multiplexed imaging and drug delivery (Ortgies et al., 2018). It is also worth noting that oral administration of substances is a common route in scientific experiments using small animals, such as mice. However, a comprehensive study of the biodistribution and toxicity of UCNPs undergoing oral administration route was not found. Furthermore, since nanoparticles have larger sizes compared to conventional drugs, UCNPs can be poorly absorbed via the oral route. For this reason, it is important to examine whether these nanoparticles can permeate epithelial barriers, in particular the intestinal barrier. There is little information available about the bioavailability of these nanoparticles through oral exposure. Therefore, it is necessary to assess the bioavailability, distribution, and toxicity of UCNPs administrated orally.

In this study, a systematic investigation of the bioavailability, biodistribution, and toxicity of orally administered silica-coated $NaYF_4$:Yb,Er nanoparticles ($NaYF_4$:Yb,Er@SiO_2) with an average diameter of 50 nm was carried out in mice. $NaYF_4$:Yb,Er@SiO_2 nanoparticles are chosen because of their good biocompatibility, broad bioapplications, and suppression of lanthanide leakage (Liu et al., 2015). We envision that $NaYF_4$:Yb,Er@SiO_2 nanoparticles can be absorbed though Peyer's patch in intestine and then enter the blood circulation of mice. We also compare the biodistribution of orally administrated $NaYF_4$:Yb,Er@SiO_2 with that of intravenously administrated $NaYF_4$:Yb,Er@SiO_2 by TEM and inductively coupled plasma mass spectrometry (ICP-MS). The toxicity of $NaYF_4$:Yb,Er@SiO_2 is determined by several different approaches, including body weight measurement, pathology changes observation, Zn and Cu levels, serum biochemical analyses, oxidative stress, and inflammatory cytokines analysis.

MATERIALS AND METHODS

Materials

Yttrium(III) chloride hexahydrate (99.9%), ytterbium(III) chloride hexahydrate (99.9%), erbium(III) chloride hexahydrate (99.9%), oleic acid (technical grade, 90%), 1-octadecene (technical grade, 90%), Igepal CO-520 and tetraethyl orthosilicate (TEOS, 99.0%) were purchased from Sigma Aldrich. Sodium hydroxide (96%), ammonium fluoride (98%), methanol (99.5%), and ammonia solution (25–28%) were obtained from Aladdin. Nitric acid (CMOS), hydrofluoric acid (guaranteed grade), and perchloric acid (guaranteed grade) were purchased from Sinopharm Chemical Reagent Co., Ltd., Shanghai, China. All chemicals were used as received without further purification.

Characterization

The size and morphology of the nanoparticles were characterized on a low-to-high resolution transmission electron microscope (JEM-2010F, JEOL, Japan) operated at 120 kV. Powder X-ray diffraction (XRD, Nano 90ZS, Malven, Britain) measurement was performed on a 3 kW D/MAX2200 V PC diffractometer using Cu kα radiation (60 kV, 80 mA) at a step width of 8° min^{-1}. Fourier transform infrared spectroscopy (FT-IR) spectra were obtained in the spectral range from 4,000 to 400 cm^{-1} on an Avatar 370 (Nicolet, America) instrument using the pressed KBr pellet technique. The microstructure observation of Peyer's patch and liver tissue was conducted on a transmission electron microscopy (JEM-1200EX, JEOL, Japan). All biochemical assays were performed using a Hitachi 7,080 clinical automatic chemistry analyzer (Japan).

Synthesis of $NaYF_4$:Yb,Er Upconversion Nanoparticles

In a typical experiment, YCl_3 (1.56 mmol, 78%), $YbCl_3$ (0.4 mmol, 20%), and $ErCl_3$ (0.04 mmol, 2%) dissolved in deionized water were added into a 100 mL flask. The solution was then

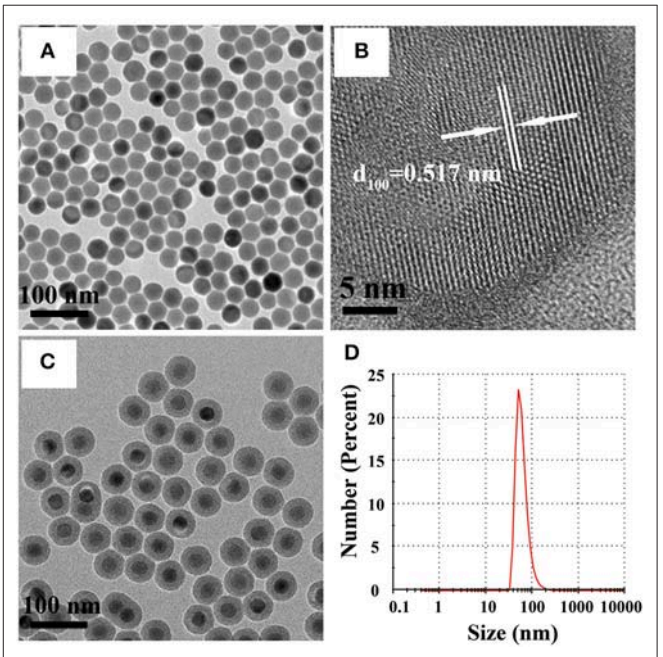

FIGURE 1 | (A,B) TEM and HRTEM images of $NaYF_4$:Yb,Er nanoparticles in cyclohexane. **(C)** TEM image of $NaYF_4$:Yb,Er@SiO_2 nanoparticles in water. **(D)** Dynamic light scattering (DLS) of $NaYF_4$:Yb,Er@SiO_2 nanoparticles in water.

heated to 110°C to evaporate water until the solution became white powder. Subsequently, 12 mL oleic acid and 30 mL 1-octadecene were added in the mixture. The mixture was then heated to 150°C and kept at this temperature for 1 h before cooling down to 50°C. Twenty milliliters of methanol solution containing NaOH (0.2 g, 1.6 mmol) and NH_4F (0.3 g, 8 mmol) was added into the flask and stirred for 30 min at 100°C to evaporate methanol. After that, the mixture was heated to 300°C and kept for 1 h under nitrogen atmosphere. The obtained mixture was precipitated by the addition of acetone, separated by centrifugation, and washed with cyclohexane. The resulting nanoparticles $NaYF_4$:Yb,Er were redispersed in 20 mL cyclohexane.

Synthesis of $NaYF_4$:Yb,Er@SiO_2 Nanoparticles

Igepal CO-520 (1 mL) was dispersed in 20 mL of cyclohexane, and then a 1.5 mL $NaYF_4$:Yb,Er nanoparticle in cyclohexane solution was added into the mixture. After stirring for 3 h, 200 μL TEOS was added and the mixture continue stirred 0.5 h. Then, 130 μL ammonia was injected into the mixture and the mixture was sealed and kept stirring for 20 h. The product was precipitated using methanol, collected by centrifugation, and washed with ethanol several times. Finally, the product was dispersed in deionized water.

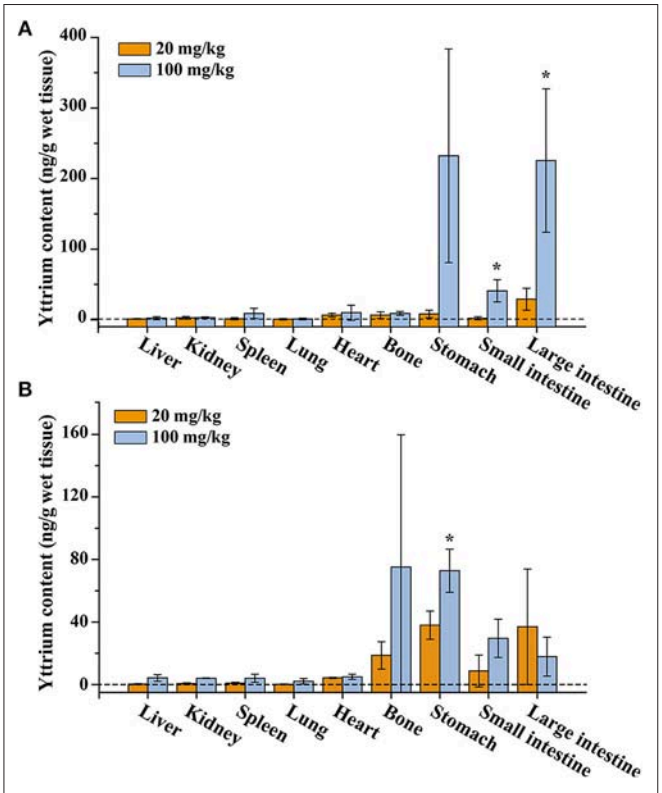

FIGURE 2 | Yttrium content in tissues of the mice after consecutive gavage administration of $NaYF_4$:Yb,Er@SiO_2 for 7 days **(A)** and 14 days **(B)**. *Significant difference between the two experimental groups ($P < 0.05$, $n = 3$).

Stability Assay

To determine the stability of $NaYF_4$:Yb,Er@SiO_2 in physiological solutions, the dissolutions of $NaYF_4$:Yb,Er@SiO_2 nanoparticles were monitored in fetal bovine serum (FBS) and simulated body fluid (SBF). SBF was prepared following the recipe in **Table S1** (Tadashi and Hiroaki, 2006). $NaYF_4$:Yb/Er@SiO_2 (0.1 mL) at a concentration of 20 mg/mL was mixed with 0.9 mL of FBS or SBF in a glass bottle. The mixture was incubated in a thermostatic shaker (150 rpm) at 37°C. After incubation for predetermined period of time, the resulting solution was centrifuged at 12,000 rpm for 15 min. The supernatant was collected and digested with 1 mL 70% HNO_3 and 0.5 mL 30% H_2O_2 at 90°C. When the solution became clear and colorless, the solution was adjusted to 8 mL by using 2% HNO_3. The content of yttrium (Y) in the solution was measured by inductively coupled plasma mass spectrometry (ICP-MS, ELAN DRC-e, PerkinElmer Co., Ltd., USA).

In vivo Experiment

All animal experiments were carried out in accordance with the guide for the animal care and use program guidelines of Shanghai University with the approval by Shanghai University. In this study, 60 mice were divided into gavage (36 mice) and intravenous administration (24 mice) groups. Six-week-old healthy male ICR mice (22–26 g) were supplied by the Experimental Animal Center, Second Military Medical University (Shanghai, China). The mice were housed in clean polypropylene cages (6 mice/cage) with the commercial pellet diet and water *ad libitum* at 22 ± 2°C and kept on a 12 h light/dark cycle. After acclimation for 1 week, four groups of mice were treated with $NaYF_4$:Yb/Er@SiO_2 (treatment group, $n = 6$) daily by gavage for 7 and 14 consecutive days with doses of 20 mg/kg bodyweight (b.w.) and 100 mg/kg (b.w.). The two corresponding control groups ($n = 6$) were treated with water daily by gavage for 7 and 14 consecutive days. In addition, four groups of mice were intravenously injected with $NaYF_4$:Yb/Er@SiO_2 (treatment group, 20 mg/kg b.w, $n = 6$) and saline (control group, $n = 6$) through mouse tail veins and sacrificed at 1 and 7 days after injection. All mice were weighed daily during the experimental period. And all experiments were repeated twice.

Biodistribution of Yttrium, Zinc, and Copper in Mice

At predetermined time points, mice were sacrificed and the contents of Y, Zn, and Cu in main organs were measured after consecutive gavage administration of $NaYF_4$:Yb/Er@SiO_2. Liver, kidneys, spleen, lungs, heart, bone, stomach, large intestine, and small intestine were collected and about 0.1–0.3 g of these organs and were digested with 70% nitric acid and hydrofluoric acid by microwave digestion system (MARS, USA). In addition, the blood samples were digested by the same method as organs. Then, perchloric acid was added into the digested solution and the mixture was heated at 200°C to remove the remaining nitric acid and hydrofluoric acid. When water was evaporated, ultrapure water was added twice. The resulting solution was

adjusted to 8 mL with 2% nitric acid solution and the metal content in solution was determined by ICP-MS.

Microstructure Observation of Peyer's Patch and Liver Tissue

Peyer's patch and liver tissue (1 mm cubes) were collected from small intestine and liver, respectively. They were subsequently fixed in 2.5% glutaraldehyde in phosphate buffer for 2 h and rinsed by 0.1 M phosphate rinsing fluid for three times. After that, the samples were post-fixed with 1% osmium tetraoxide at 4°C for 2 h and then dehydrated with ethanol and acetone as follows, 50% ethanol−15 min, 70% ethanol−15 min, 80% ethanol−15 min, 90% ethanol−15 min, 100% ethanol−20 min, and 100% acetone−20 min. Then the tissue blocks were infiltrated with embedding medium in acetone (v:v = 1:1) for 3 h, and infiltrated with embedding medium overnight. The embedded tissue blocks in embedding medium were polymerized in a dry centrifuge tube at 70°C overnight. The blocks were then cut in 50–70 nm thickness using an ultramicrotome (LKB-I, Sweden), and then counterstained with 3% uranyl acetate and lead citrate prior to TEM measurements.

Organ Index

Organ indices were calculated for major organs using the following formula: (organ weight)/(total body weight) × 100.

Histopathological Investigation

The organs including liver, kidney, lung, spleen, and small intestine were collected at each time point and fixed with formalin. The fixed organs were embedded in paraffin, sliced at a thickness of 5 μm and then placed onto glass slides. After hematoxylin–eosin (H&E) staining, the slides were investigated and photographed on an optical microscope (DM750, Leica, Germany).

Serum Biochemistry Analysis

Blood samples were collected from mice at predetermined time point and centrifuged at 3,000 rpm for 15 min. The obtained serum samples were stored at −20°C before analysis. Alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), blood urea nitrogen (BUN), and creatinine (CREA) were measured using the commercial kits (The Seno Clinical Diagnostic Products Co., Japan).

Oxidative Stress Assay

The organs including liver, lung, kidney and spleen were rinsed with saline solution at 4°C and then wiped with dry filter papers. Ten or Five percent (w/v) homogenates were prepared by homogenization of tissue in saline solution at 10,000 rpm for 3 min using a homogenizer. The supernatants

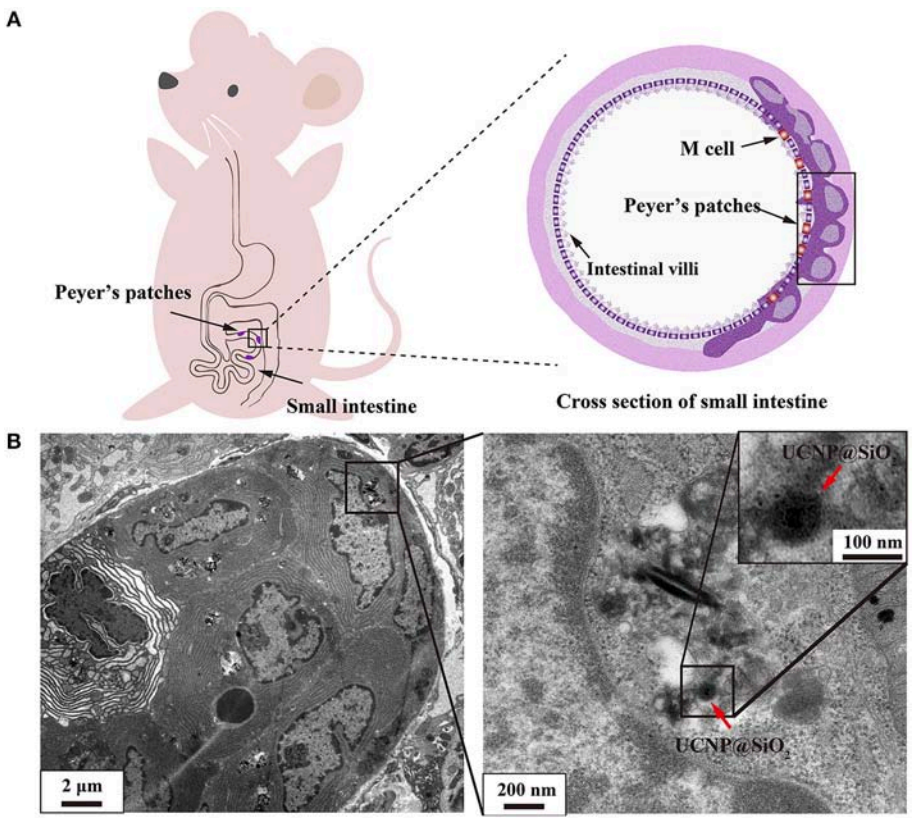

FIGURE 3 | (A) Schematic illustration of Peyer's patches in small intestine. **(B)** TEM image demonstrated that $NaYF_4$:Yb,Er@SiO_2 nanoparticles were located in Peyer's patch in small intestine of mice after 14 days' consecutive gavage administration of these nanoparticles. UCNP@SiO_2 denotes $NaYF_4$:Yb,Er@SiO_2.

were collected after centrifuging the homogenates at 3,500 rpm for 10 min. The contents of protein in the supernatants were examined by bicinchoninic acid assay (BCA protein assay kit, Nanjing Jiancheng bioengineering institute, Nanjing, China). The reduced GSH levels of the supernatants were determined by Ellman's reagent 5,5'dithiobis-(2-nitrobenzoic acid) (DTNB, Nanjing Jiancheng Biotechnology Institute, China). The lipid peroxidation indicator malondialdehyde (MDA) was estimated by the method of thiobarbituric acid reactive species (TBA, Nanjing Jiancheng Bioengineering Institute, Nanjing, China).

TNF-α, IL-6, and IL-1β Levels in Liver

The contents of TNF-α, IL-6, and IL-1β in supernatants of liver homogenates were quantified by a double-antibody sandwich ELISA commercial kit (BD Biosciences, USA). Manufacturer's protocol was followed. The absorbance was measured on a microplate reader at 450 nm (Varioskan Flash, Thermo, USA) and the contents of TNF-α, IL-6, and IL-1β were calculated based on the corresponding standard curves. The protein contents in supernatants were also determined by bicinchoninic acid assay (BCA protein assay kit, Nanjing Jiancheng bioengineering institute, Nanjing, China). The levels of TNF-α, IL-6, and IL-1β were expressed as ng/mg protein.

Statistical Analysis

All data were expressed as the mean ± standard deviation (mean ± SD) of more than three individual observations. Significance was calculated using Student's *t*-test. The difference was considered significant if $p < 0.05$. In addition, standard deviation and *p*-value were calculated by:

$$\text{Standard deviation (SD)} = \sqrt{\frac{\sum (\text{X-M})^2}{n-1}},$$

$$S = \sqrt{\frac{(n_1-1)\,SD_1^2 + (n_2-1)\,SD_2^2}{n_1+n_2-2}},$$

$$\text{p} = \frac{|M_1 - M_2|}{S}\sqrt{\frac{n_1 n_2}{n_1+n_2}}$$

X represents the data value, M refers to the average value between the data, S represents the pooled estimate of the standard deviation, n represents the number of data (Gardner and Altman, 1986).

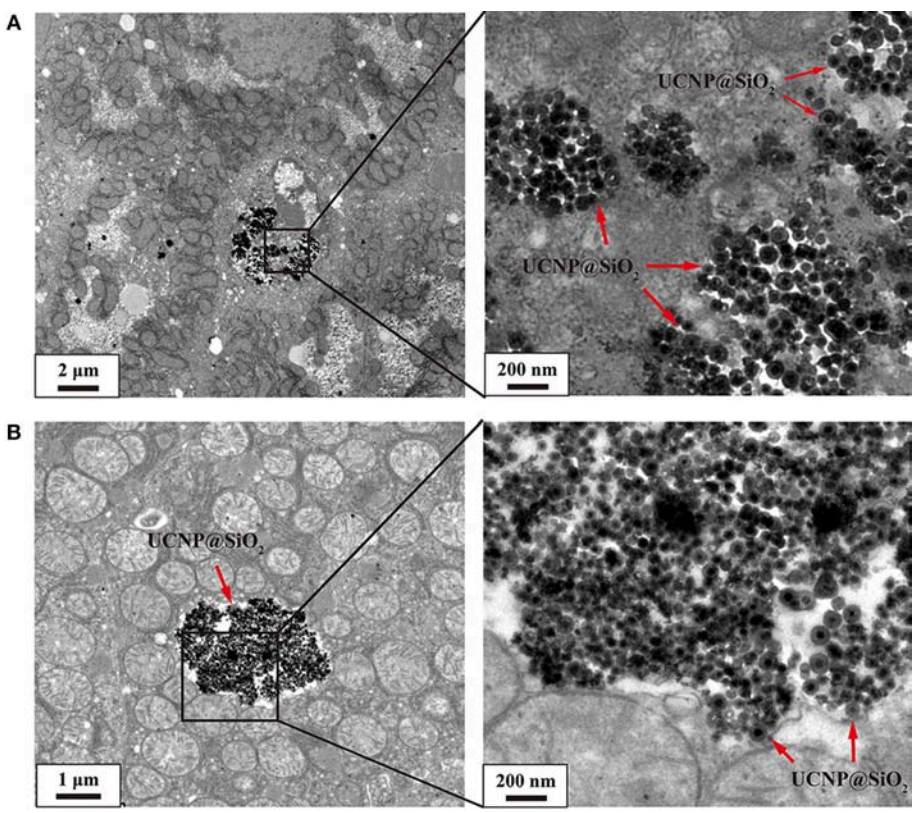

FIGURE 4 | (A) TEM image of 20 mg/kg $NaYF_4$:Yb,Er@SiO_2 intravenously treated mouse showing aggregations of these nanoparticles (red arrow) located outside of hepatocytes. **(B)** TEM image shows aggregations of $NaYF_4$:Yb,Er@SiO_2 nanoparticles (red arrow) in the cytoplasm. UCNP@SiO_2 denotes $NaYF_4$:Yb,Er@SiO_2.

RESULTS AND DISCUSSION

Characterization of $NaYF_4$:Yb,Er@SiO_2

We first characterized the morphology and size of $NaYF_4$:Yb,Er nanoparticles using a transmission electron microscope (TEM). As shown in **Figure 1A** and **Figure S1A**, uniform nanoparticles with an average diameter of around 32 nm were obtained. The obtained nanoparticles were confirmed to be single crystals with a hexagonal phase by high-resolution transmission electron microscopy (HRTEM) and X-ray powder diffraction (XRD) study (**Figure 1B** and **Figure S2**). The lattice distance of 0.517 nm corresponds to the *d* spacing for (100) plane of hexagonal $NaYF_4$. After coating with a silica layer on the surface of $NaYF_4$:Yb,Er nanoparticles, the size of the nanoparticles reached 49 nm (**Figure 1C** and **Figure S1B**). The results of dynamic light scattering (DLS) measurement show that the hydrodiameter of $NaYF_4$:Yb,Er@SiO_2 nanoparticles was around 60 nm (PDI = 0.23), confirming their mono-dispersion in aqueous solution (**Figure 1D**). The XRD pattern of $NaYF_4$:Yb/Er samples can also be indexed as a hexagonal phases of $NaYF_4$ (JCPDS file number 16-0334) (**Figure S1**). After silica coating, a broad diffraction peak at $2\theta = 22^\circ$ appeared, which can be ascribed to the peak of amorphous silica. In addition, the presence of the elements (Si, O, F, Y, Yb, Er) in the energy dispersive X-ray (EDX) spectrum also confirmed that silica shell was successfully coated onto the surface of $NaYF_4$:Yb/Er nanoparticles (**Figure S3**).

FT-IR spectra of oleic acid coated $NaYF_4$:Yb,Er and $NaYF_4$:Yb,Er@SiO_2 nanoparticles were shown in **Figure S4**. In the spectrum of oleic acid coated $NaYF_4$:Yb,Er, the peaks at 2,927 and 2,857 cm^{-1} are attributed to the asymmetric and symmetric stretching vibration of methylene (CH_2) in the long alkyl chain of oleic acid, and the 1,557 and 1,460 cm^{-1} bands are assigned to the asymmetric and symmetric stretching vibration of the carboxylic group (–COOH) in oleic acid. In the spectrum of $NaYF_4$:Yb,Er@SiO_2, the bands of Si–O–Si are located at 1,091 and 799 cm^{-1}, and the peaks at 953, 1,637, and 3,428 cm^{-1} are assigned to Si–OH, H_2O, and –OH.

Stability Assay of $NaYF_4$:Yb,Er@SiO_2 in Physiological Solution

In order to study the stability of $NaYF_4$:Yb,Er@SiO_2 under physiological conditions, the dissolved yttrium ions (Y^{3+}) of $NaYF_4$:Yb,Er@SiO_2 in FBS and SBF was monitored by ICP-MS. As shown in **Figure S5**, while the percentage of dissolved Y^{3+} in SBF was only around 0.1%, in FBS it quickly increased to around 1.2%. This result was consistent with the dissolution of Ag_2Se quantum dots, which was about 4–5% in FBS and <1% in SBF (Tang et al., 2016). Compared with naked UCNPs, these results imply that silica coating can suppress the leakage of lanthanide from nanoparticles, offering an excellent stability of $NaYF_4$:Yb,Er@SiO_2 under physiological conditions (Wang et al., 2012; Tian et al., 2015).

Stability of $NaYF_4$:Yb,Er@SiO_2 After *in vivo* Gastrointestinal Digestion

To examine the stability of $NaYF_4$:Yb,Er@SiO_2 after *in vivo* gastrointestinal digestion, we investigated the morphology and size of $NaYF_4$:Yb,Er@SiO_2 collected in feces excreted by mice orally administrated $NaYF_4$:Yb,Er@SiO_2 (100 mg/kg b.w.) by using TEM image. As shown in **Figure S6**, the morphology and size of $NaYF_4$:Yb,Er@SiO_2 was essentially not changed. This result suggest that SiO_2 coated UCNPs are also stable in the low gastric pH, which is consistent with the previous results of silica coated quantum dots (Loginova et al., 2012). This result also indicates that UCNPs with silica coating can be used to visualize the gastrointestinal tract *in vivo*.

Biodistribution of $NaYF_4$:Yb,Er@SiO_2

For the oral administration group, a relatively high concentration of Y^{3+} was detected in the gastrointestinal tract after 7 and 14 days consecutive oral exposure (**Figure 2**). In contrast, relatively low Y^{3+} concentrations were detected in several other major organs including liver, kidney, spleen, lung, heart, and bone. The concentration of yttrium in all organs

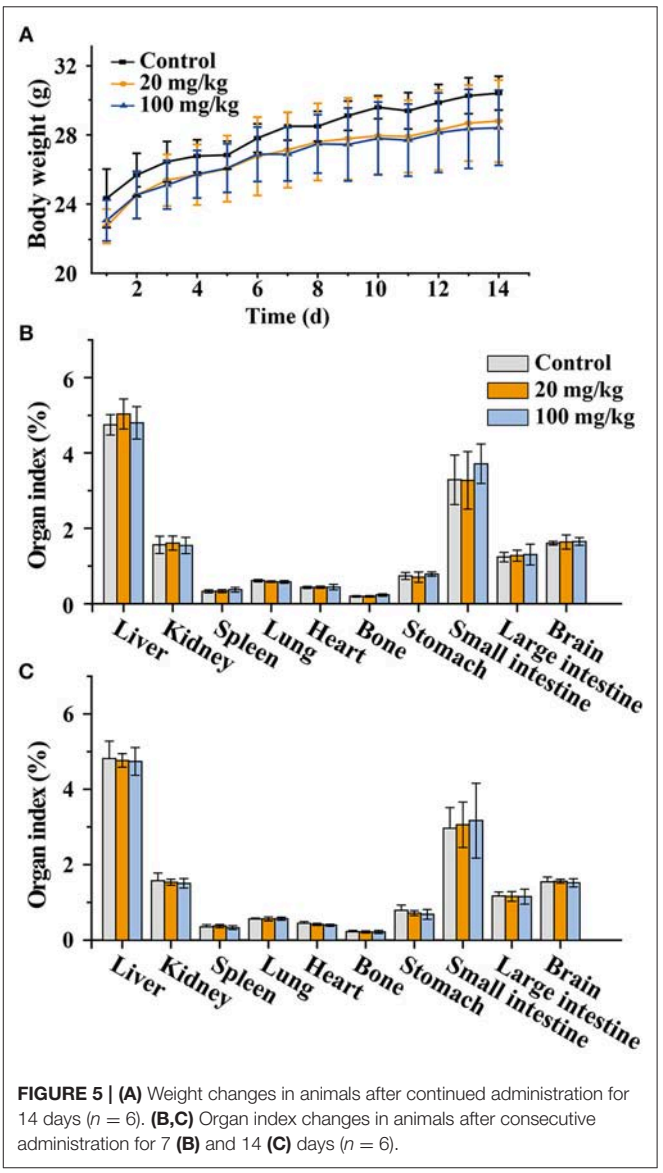

FIGURE 5 | (A) Weight changes in animals after continued administration for 14 days ($n = 6$). **(B,C)** Organ index changes in animals after consecutive administration for 7 **(B)** and 14 **(C)** days ($n = 6$).

increased to a relatively higher level at a high dose of 100 mg/kg compared with the dose of 20 mg/kg. Note that very little amount of Y^{3+} was released from $NaYF_4$:Yb,Er@SiO_2 as mentioned above, thus, it is reasonable to deduce that the Y^{3+} ion in the organs did not come from released ions of $NaYF_4$:Yb,Er@SiO_2. This may be attributed to the fact that after passing through the mouth and stomach, a small amount of $NaYF_4$:Yb,Er@SiO_2 are absorbed by the epithelium of the digestive tract and enter the blood, subsequently resulting in the accumulation of these particles in the organs.

Unlike oral administration, a very high concentration of Y^{3+} was mainly accumulated in the liver of mice after intravenous injection of these nanoparticles. With the lapse of time, the concentration of Y^{3+} decreased in liver and increased in spleen, indicating these nanoparticles follow a hepatic metabolic pathway (**Figure S7**). This result is also consistent with previous reports (Yu et al., 2017). In addition, we also examined the content of ytterbium ion (Yb^{3+}) in organs (**Figure S8**). We found that the change of Yb^{3+} content was the same as that of Y^{3+}, further indicating the good stability of those silica-coated upconversion nanoparticles *in vivo*.

Ultramicrostructure Observation of Peyer's Patch and Liver Tissue

To identify the potential uptake mechanism, we carefully examined the samples of small intestine after 14-day consecutive gavage of $NaYF_4$:Yb,Er@SiO_2 at a dose of 100 mg/kg by TEM image. It was reported that large size particles are probably absorbed by Peyer's patches through microfold (M) cells (Lundquist and Artursson, 2016). Peyer's patches are located in the mucous membrane lining of the intestine. They play a role in immunologic response (**Figure 3A**). Several studies have tested the translocation of nanoparticles in cell models (Yoshida et al., 2014; Walczak et al., 2015; Yao et al., 2015; Chen et al., 2016). However, there is no report to demonstrate this assumption *in vivo*. Here, we utilized TEM to visualize the location of the nanoparticles. As shown in **Figure 3B**, it can be clearly observed that nanoparticles are located in Peyer's patches in small intestine of mice. The size and shape of these nanoparticles were the

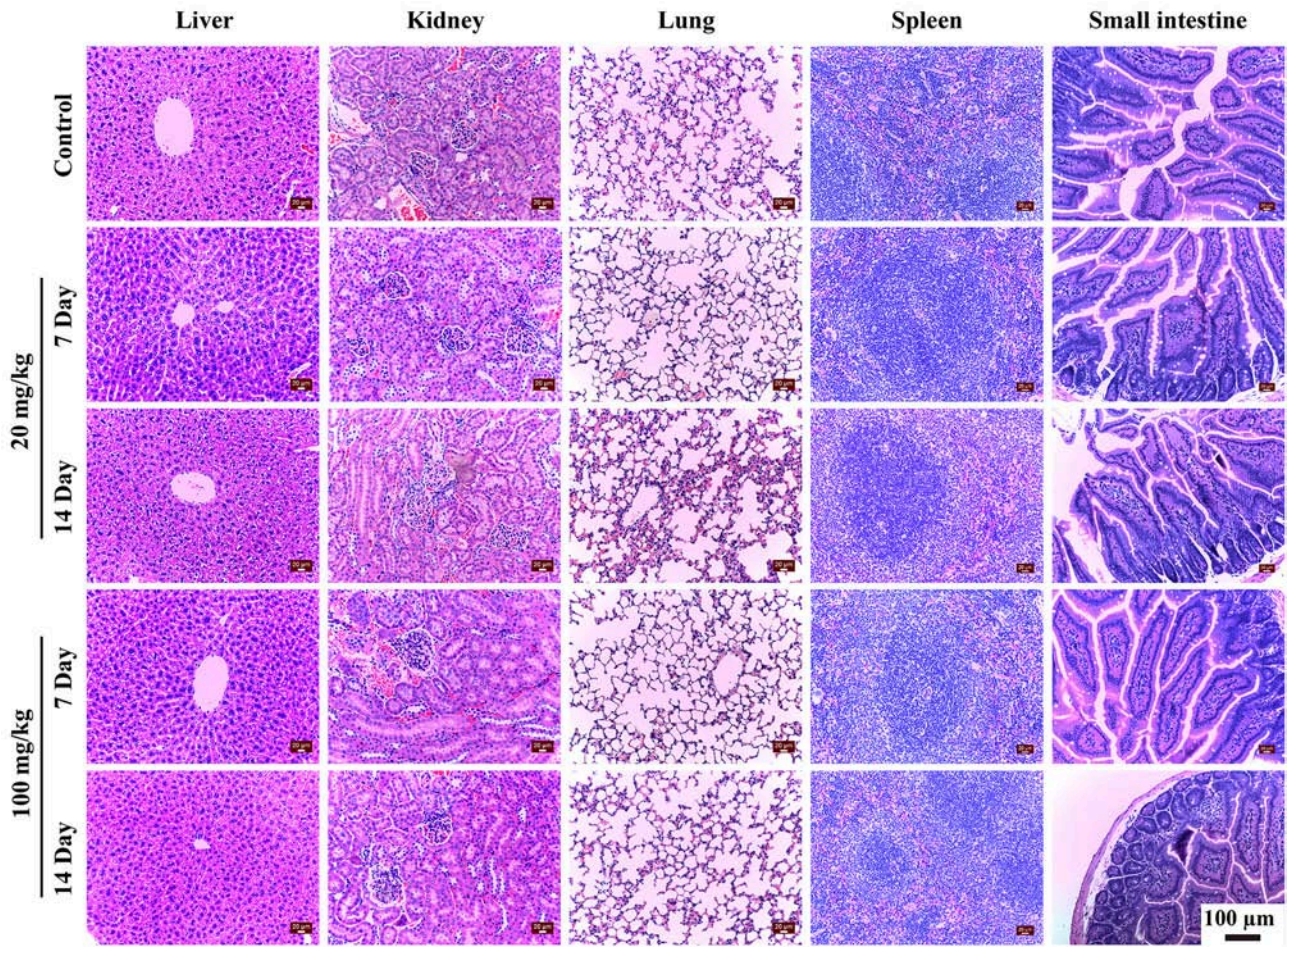

FIGURE 6 | Histopathological observation of liver, kidney, lung, spleen and small intestine of mice after 7 and 14 days' consecutive gavage administration of $NaYF_4$:Yb,Er@SiO_2 at different doses.

same as those we synthetized. This result confirms that the nanoparticles can cross small intestine through the uptake by Peyer's patches. However, due to the limited number of M cells in Peyer's patches, who compose <1 percent of the small intestine epithelial cell layer, we speculate that the bioavailability of these nanoparticles is low.

For intravenous administration, nanoparticles show a tendency to accumulate in the liver after entry into the bloodstream. As shown in **Figure 4**, a large amount of $NaYF_4$:Yb,Er@SiO_2 was observed in liver tissue at day 1 and 7 after mice were intravenously injected with these nanoparticles with dose of 20 mg/kg. This result suggests that the nanoparticles were internalized by hepatocytes.

In order to further evaluate the bioavailability of $NaYF_4$:Yb,Er@SiO_2 nanoparticles, we measured the contents of Y^{3+} in blood. For the oral administration group, the contents of Y^{3+} cannot be detected in blood after 7 and 14 days consecutive oral exposure (**Figure S9**). By comparison, relatively high concentration of Y^{3+} has been observed in blood after intravenous injection of these nanoparticles. This can be ascribed to the low bioavailability of $NaYF_4$:Yb/Er@SiO_2 nanoparticles via gavage administration route, which is consistent with the results of ultramicrostructure observation of Peyer's patch.

Body Weight and Organ Index of Mice

To evaluate the toxic effects of $NaYF_4$:Yb,Er@SiO_2 in mice, the body weights of mice were recorded every day during consecutive gavage administration. As shown in **Figure 5A**, death, obvious body weight decrease, and other signs of significant weakness were not observed in mice treated with $NaYF_4$:Yb,Er@SiO_2 over the 14-day period. The body weights of the $NaYF_4$:Yb,Er@SiO_2 treated groups increased in a pattern similar to that of the control group. Organ index is a key parameter in toxicity evaluation. Our results showed that there was no difference between the treatment group and the control group after gavage administration of $NaYF_4$:Yb,Er@SiO_2 either at a dose of 20 or 100 mg/kg (**Figures 5B,C**). These results demonstrate that $NaYF_4$:Yb,Er@SiO_2 nanoparticles have no effect on the body weight and organ index of mice.

Histological Analysis

Histological analysis of vital organs is important to evaluate whether $NaYF_4$:Yb,Er@SiO_2 could cause tissue damage, inflammation, or lesions. The analysis was performed on the liver, kidney, lung, spleen, and small intestine to investigate signs of the potential toxicity of $NaYF_4$:Yb,Er@SiO_2 at doses of 20 and

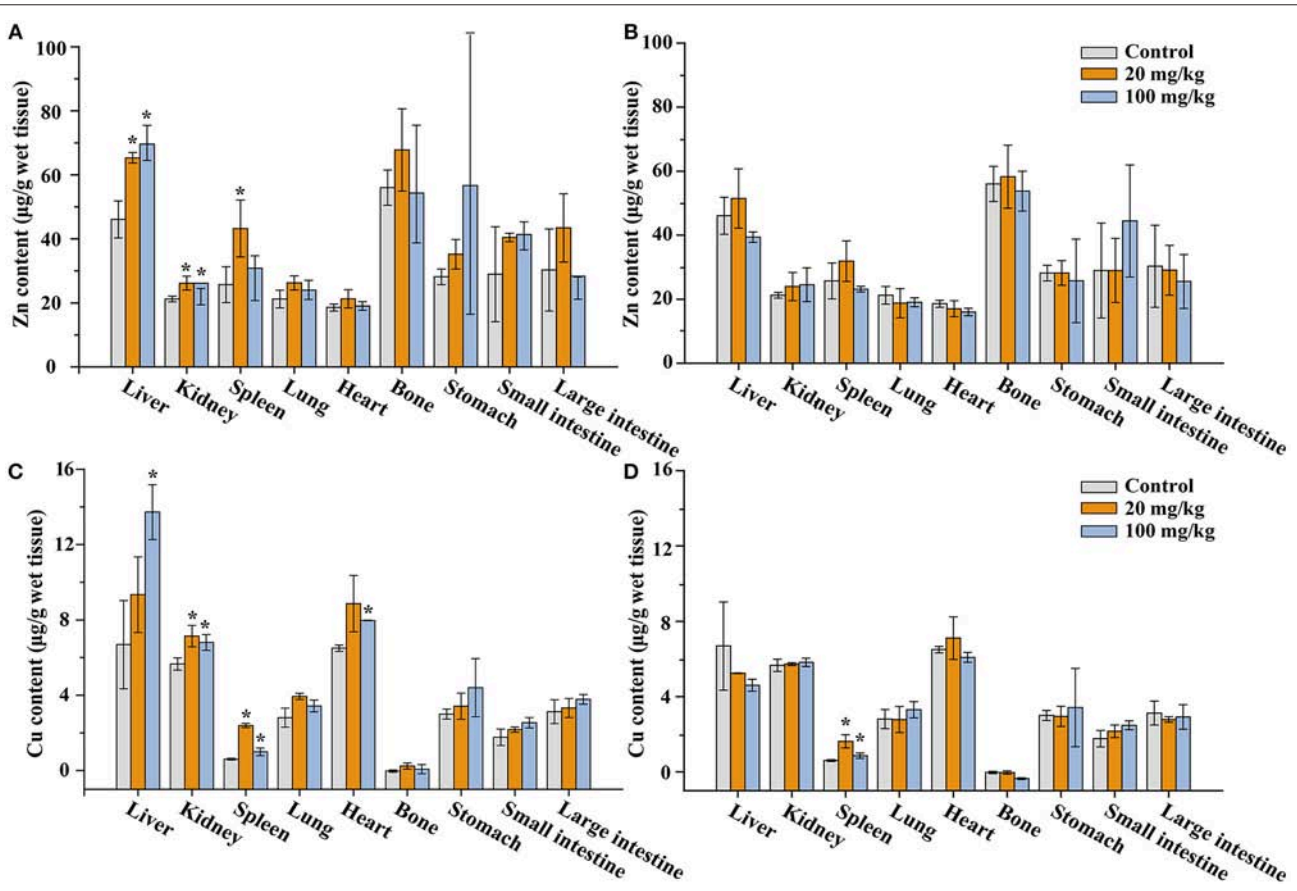

FIGURE 7 | Zinc **(A,B)** and copper **(C,D)** content in tissues of the mice after 7 **(A,C)** and 14 days' **(B,D)** consecutive gavage administration of $NaYF_4$:Yb,Er@SiO_2, respectively. *Significant difference vs. the corresponding control ($P < 0.05$, $n = 3$).

100 mg/kg for 7 and 14 days. As shown in **Figure 6**, hepatocytes were arranged in rows that radiate out from the central vein, and no inflammatory infiltrates of hepatocytes was observed in the liver samples (the first column). There was no change in the morphology of the renal corpuscles and renal tubules in the experimental and control groups (the second column). The glomerular structure was easy to distinguish and there was no sign of inflammatory infiltrates and necrosis. In addition, no pulmonary fibrosis or other abnormal phenomena was observed in the lung tissues for experimental groups (the third column). The white pulp and red pulp have normal appearance in spleen tissues (the forth column). The experimental and control mice showed normal intestine villi (the fifth column). Furthermore, the shape of the small intestine was normal, the tissue was intact, no inflammatory cells were infiltrated, and no bleeding was observed. In addition, we also conducted histological analysis on major organs (liver, kidney, lung, and spleen) after intravenous injection of $NaYF_4$:Yb,Er@SiO_2 nanoparticles into mice for 1 day. As shown in **Figure S10**, there was no obvious sign of abnormality in these major organs. Our results are also consistent with the previous study involving polyethyleneimine modified $NaYF_4$:Yb,Er nanoparticles (Yu et al., 2017). In all, these results indicate that there are no obvious difference of these organs between the experimental group and control group, and the organs of experimental group exhibited healthy structural features.

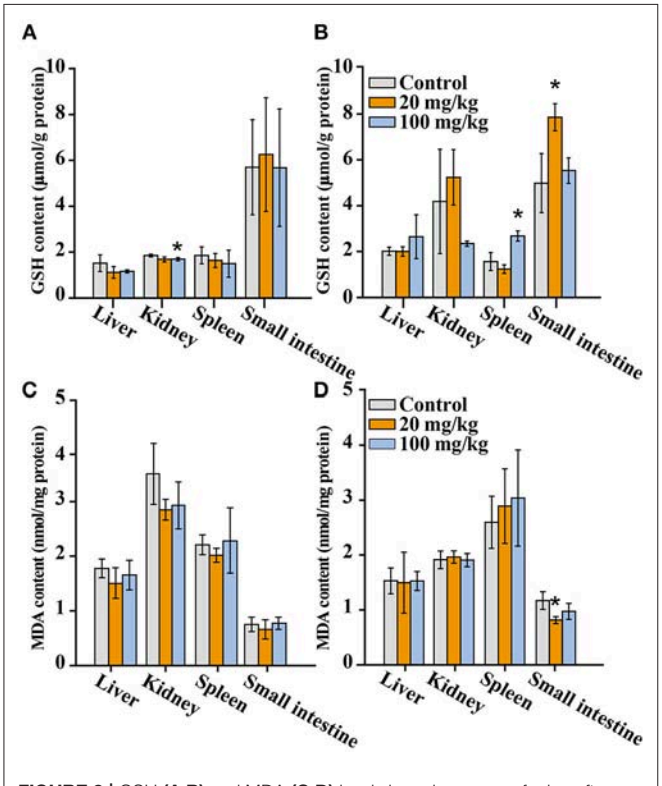

FIGURE 8 | GSH **(A,B)** and MDA **(C,D)** levels in main organs of mice after consecutive gavage administration of $NaYF_4$:Yb,Er@SiO_2 ($n = 4$). **(A,C)**: 7 days; **(B,D)**: 14 days. *Significant difference vs. the corresponding control ($P < 0.05$).

Effect of Gavage Exposure to $NaYF_4$:Yb,Er@SiO_2 on the Distribution of Zinc and Copper in Mice

The absorption of certain metal element may affect levels of essential metal elements in animals. Zinc plays a critical role in many biological functions including antioxidant defense, cell signaling, and gene expression. Copper is vital and essential to the proper functioning of organs and metabolic processes. Like all essential elements and nutrients, copper excess, or deficiency has adverse health effects.

To evaluate the influence of $NaYF_4$:Yb,Er@SiO_2 exposure, the contents of trace essential elements Zn and Cu in tissues in $NaYF_4$:Yb,Er@SiO_2-treated mice were measured by ICP-MS. Zinc levels in different organs of mice were shown in **Figures 7A,B**. After 7 days post-administration, we found that Zn concentrations significantly increase in spleen at doses of 20 mg/kg of $NaYF_4$:Yb,Er@SiO_2, and they significantly changed in liver, kidney at both doses of 20 and 100 mg/kg. However, the Zn level went back to the control level after 14-day consecutive oral exposure. In addition, copper contents in liver significantly increased at the dose of 100 mg/kg of $NaYF_4$:Yb,Er@SiO_2, while they significantly increased in kidneys, spleen and heart at both doses of 20 and 100 mg/kg $NaYF_4$:Yb,Er@SiO_2 (**Figure 7C**). Although the Cu level in spleen didn't go back to the control level, they reduced to the control level in liver, and kidney (**Figure 7D**). In addition, Zn level only significantly decreased in bone at day 1 after intravenously administration of $NaYF_4$:Yb,Er@SiO_2 at the dose of 20 mg/kg (**Figure S11A**). By contrast, Cu levels significantly increased in bone at day 1, and they significantly increased in liver, spleen, lung, heart, and stomach at day 7 (**Figure S11B**). We didn't observe the recovery in Cu level, maybe because the Cu level in mice need to take longer time to recover (i.e., 28 days) as selenium did in a previous report (Tang et al., 2016). Taken together, these results suggest that $NaYF_4$:Yb,Er@SiO_2 could slightly change the zinc and copper level of certain organs in mice. However, these changes can be recovered after a period of time.

Serum Biochemical Analyses

Serum biochemical analysis is usually used to determine whether the function of vital organs is damaged. Liver function parameters including alanine aminotransferase (ALT, IU/L), aspartate aminotransferase (AST, IU/L), alkaline phosphatase (ALP, IU/L) and kidney index blood urea nitrogen (BUN, mmol/L), and creatine (Crea mmol/L) were measured. Results showed that ALT, AST and ALP remain unchanged after consecutive administration for 7 and 14 days (**Table S2**). The BUN levels in nanoparticles treatment groups were significantly elevated at day 7, while they came back to the normal level at day 14. The Crea level in the 100 mg/kg $NaYF_4$:Yb,Er@SiO_2 group significantly declined compared with the control at day 14. In brief, $NaYF_4$:Yb,Er@SiO_2 nanoparticles induce slight

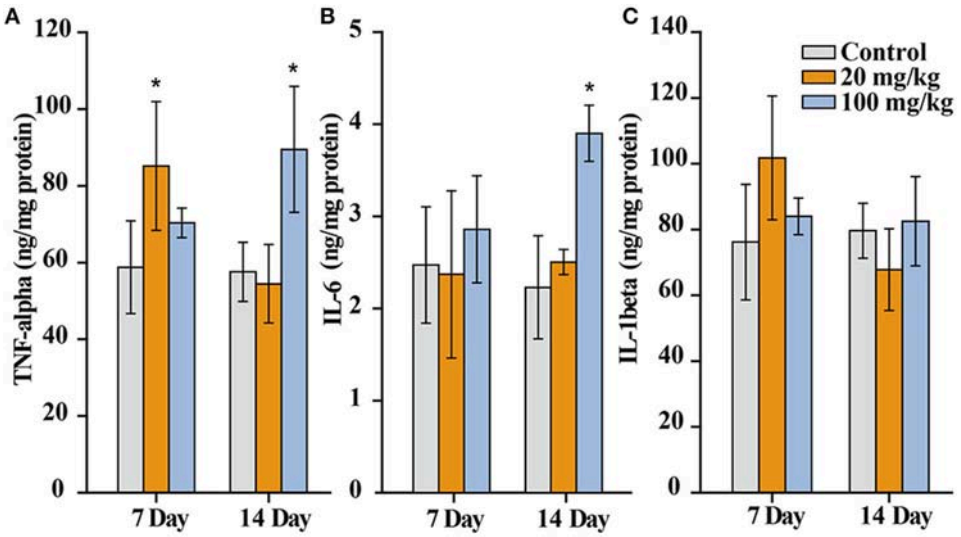

FIGURE 9 | TNF-α **(A)**, IL-6 **(B)**, and IL-1β **(C)** level in liver of mice after 7 and 14 days consecutive gavage administration of $NaYF_4$:Yb,Er@SiO_2 ($n = 5$). *Significant difference vs. the corresponding control ($P < 0.05$).

fluctuations in BUN and Crea levels after oral administration, but the levels remain in a normal range (Lu et al., 2010).

The oxidative stress is an important cause of injury or inflammation for certain organs. Therefore, we further measured the levels of glutathione (GSH) and malondialdehyde (MDA) in liver, kidneys, spleen, and small intestine. As shown in **Figure 8**, The GSH level was the highest in small intestine, reaching a value of 6 μmol/g protein, while the level in liver, kidneys, and spleen was about 2 μmol/g protein. The GSH levels in kidney (day 7), spleen and small intestine (day 14) of the 100 and 20 mg/kg $NaYF_4$:Yb,Er@SiO_2-treated group were significantly different from that of corresponding control, respectively. The MDA level in $NaYF_4$:Yb,Er@SiO_2-treated group did not show any difference with the control at day 7 after gavage administration. However, the MDA level exhibit significant difference in small intestine at day 14 with control after gavage administration of nanoparticles. In brief, it can be concluded that $NaYF_4$:Yb,Er@SiO_2 just induce slight fluctuations of GSH and MDA levels in certain organs.

Cytokines are secreted by inflammatory cells, which are involved in the immune response of the organism to foreign nanoparticles. This is the pathological basis of the occurrence and development of tissue injury. Particularly, tumor necrosis factor-alpha (TNF-alpha) is involved in inflammation and immune response. Interleukin-6 (IL-6) is involved in the pathophysiological processes of various inflammatory diseases. Interleukin-1 beta (IL-1beta) can stimulate other cytokines or inflammatory mediators, inducing the expression of immune molecules. Therefore, we detected the expression of TNF-alpha, IL-6, and IL-1beta in the liver to observe whether orally administrated $NaYF_4$:Yb,Er@SiO_2 could induce inflammation in the liver of mice. As shown in **Figure 9**, we found TNF-alpha and IL-6 are elevated in the $NaYF_4$:Yb,Er@SiO_2 (100 mg/kg) treated group compared with the control at day 14 after gavage administration, and significant difference of TNF-alpha only is observed in the 20 mg/kg treatment group at day 7. In addition, there was no difference of IL-1beta between the nanoparticles treated group and the control. Therefore, $NaYF_4$:Yb,Er@SiO_2 nanoparticles change the level of TNF-α and IL-6, while there is no influence to IL-1β after consecutive administration.

CONCLUSIONS

In this study, we systematically investigate the bioavailability, biodistribution, and toxicity of orally administered $NaYF_4$:Yb,Er@SiO_2 nanoparticles with an average diameter of 50 nm. Our results show that these nanoparticles can be absorbed by mice with oral administration and the intestinal absorption through Peyer's patch was confirmed by TEM measurement. In addition, we demonstrate that the nanoparticles with intravenous injection are trapped in hepatocytes. The biodistribution of $NaYF_4$:Yb,Er@SiO_2 is particularly dependent on the administration routes. Specifically, $NaYF_4$:Yb,Er@SiO_2 nanoparticles mainly accumulate in bone, stomach, and intestine by oral administration, while these nanoparticles mainly accumulate in liver and spleen by intravenous administration. Furthermore, our results suggest that there is no overt toxicity of $NaYF_4$:Yb,Er@SiO_2 in mice even after consecutive oral exposure for 14 days at a high dose of 100 mg/kg. Collectively, these results provide an important reference for the future medical and clinical applications of inorganic nanoparticles.

Air-Stable Na_xTMO_2 Cathodes for Sodium Storage

Yi Zhang, Renyuan Zhang and Yunhui Huang*

Institute of New Energy for Vehicles, School of Materials Science and Engineering, Tongji University, Shanghai, China

Sodium-ion batteries are considered to be the most promising alternative to lithium-ion batteries for large-scale stationary energy storage applications due to the abundant sodium resource in the Earth' crust and as a result, relatively low cost. Sodium layered transition metal oxides (Na_xTMO_2) are proper Na-ion cathode materials because of low cost and high theoretical capacity. Currently most researchers focus on the improvement of electrochemical performance such as high rate capability and long cycling stability. However, for Na_xTMO_2, the structure stability against humid atmosphere is essentially important since most of them are instable in air, which is not favorable for practical application. Here we provide a comprehensive review of recent progresses on air-stable Na_xTMO_2 oxides. Several effective strategies are discussed, and further investigations on the air-stable cathodes are prospected.

INTRODUCTION

The growing demand for large-scale energy storage applications has driven the research interest into new energy storage systems with low cost. Although lithium-ion battery (LIB) can deliver high energy and power density, the limited resource and the rising cost of lithium may restrict their application in grid scale energy storage. Recently, sodium-ion battery (SIB), which owns a similar chemical storage mechanism to LIB, has been rapidly developed as a complementary technology. As the second lightest alkali metal, sodium resource is inexpensive and almost globally available. The common abundant sodium salt such as Na_2SO_4, NaCl, and Na_2CO_3 could be obtained from marine or mineral. In addition, copper foil can be replaced by cheaper aluminum foil for anode current collector since sodium has no reaction with aluminum. Therefore, SIB has received considerable attention as a promising alternative to LIB (Dunn et al., 2011; Yang et al., 2011, 2017; Palomares et al., 2013; Pan et al., 2013; Yabuuchi et al., 2014; Han et al., 2015; Kubota and Komaba, 2015; Kundu et al., 2015; Xiang et al., 2015; Hwang et al., 2017; Luo et al., 2017; Nayak et al., 2018; Zhu et al., 2019).

The SIB system consists of five parts: cathode, anode, membrane, electrolyte and current collector, which has the same structure as LIB. **Figure 1** shows typical configuration of a SIB coin cell, in which sodium layered transition metal oxide (Na_xTMO_2) and hard carbon are employed as cathode and anode, respectively. During the charge process, the Na^+ and e^- migrates to hard carbon anode with voltage increasing. During the discharge process, Na^+ and e^- return to Na_xTMO_2 cathode reversibly with voltage decreasing. The overall reaction can be described as:

$$Na_xTMO_2 + C \leftrightarrow TMO_2 + Na_xC \quad (1)$$

Numerous cathode materials such as polyanion compounds (Tripathi et al., 2013; Zhang Y. et al., 2016), layered transition metal (TM) oxides (Roger et al., 2007; Berthelot et al., 2011; Carlier et al., 2011) and Prussian blue or Metal-Organic compounds (Fang et al., 2017; Su et al., 2017;

Qian et al., 2018) have been applied as Na^+ host materials. Layered TM oxides show a high theoretical capacity among these cathode materials (Wang et al., 2018c). In addition, taking the preparation process and cost into consideration, the layered transition metal oxides are the optimal choice for practical application because they can be easily obtained by calcining the precursors in air. As a result, the layered transition metal oxides with general formula Na_xTMO_2 have attracted more and more attention since the first report by Delmas' group in the 1980s (Delmas et al., 1980, 1981).

Most of researches about Na_xTMO_2 focused on the improvement of electrochemical properties, such as: (i) eliminating Na^+ vacancy ordering to improve rate capability; (Wang et al., 2015, 2018a; Kang et al., 2018) (ii) suppressing phase transition or surface coating to achieve long cycling life; (Wang et al., 2016c; Wang P.-F. et al., 2017; You et al., 2017; Sathiya et al., 2018) (iii) exploring oxygen ion redox mechanism to achieve high energy density (Rozier et al., 2015; Kim et al., 2017; Bai et al., 2018; Maitra et al., 2018; Qiao et al., 2018; Rong et al., 2018), and so on. However, most Na_xTMO_2 materials are hygroscopic and air-instable, which limit their practical applications because huge cost will be spent on materials' storage and transportation (Blesa et al., 1993; Franger et al., 2000; Lu and Dahn, 2001b; Caballero et al., 2002; Monyoncho and Bissessur, 2013; Duffort et al., 2015; Kubota and Komaba, 2015; Boyd et al., 2018; You et al., 2018). So in recent years, the design and synthesis of air-stable Na_xTMO_2 materials have become a hot topic. In this review, we summarize the recent progress on air-stable Na_xTMO_2 materials from structure understanding to corresponding solutions, and at the same time we address the remaining problems and challenges for further development.

STRUCTURE OF NA_XTMO_2

In Na_xTMO_2 compounds, TM layers are usually occupied by Ti, (Senguttuvan et al., 2011; Wu D. et al., 2015) V, (Hamani et al., 2011; Guignard et al., 2013; Wang et al., 2018d) Cr, (Braconnier et al., 1982; Yu et al., 2015) Mn, (Ma et al., 2011) Fe, (Blesa et al., 1993; Yabuuchi et al., 2012b) Co, (Berthelot et al., 2011; Rai et al., 2014) Ni, (Vassilaras et al., 2013; Wang et al., 2018b) Cu, (Ono et al., 2014; Jiang et al., 2018; Ono, 2018) a mixture of two (Saadoune et al., 1996; Yabuuchi et al., 2012a; Mortemard de Boisse et al., 2013; Gonzalo et al., 2014; Guo et al., 2014; Kalluri et al., 2014; Zhu et al., 2014, 2016; Chen et al., 2015; Jiang et al., 2015; Kang et al., 2015; Wang et al., 2015, 2016d; Bucher et al., 2016; Kee et al., 2016; Liu et al., 2016; Manikandan et al., 2017; Sabi et al., 2017; Song et al., 2017) or more elements (Lu and Dahn, 2001b; Buchholz et al., 2014; Li et al., 2014; Liu et al., 2015; Li Y. et al., 2015; Li Z.-Y. et al., 2015; Yue et al., 2015; Han et al., 2016a; Kang et al., 2016; Qi et al., 2016; Satyanarayana et al., 2016; Sun et al., 2016; Wang et al., 2016b; Zhang X.-H. et al., 2016; Wang L. et al., 2017; Zheng and Obrovac, 2017) The corresponding

redox potential ranges of these TM are presented in **Figure 2**. Na_xTiO_2 compound is usually used as anode material due to its low redox potential range. $Na_x(Ni_yMn_{1-y})O_2$ compound has been thoroughly investigated as cathode material because of the relatively high redox potential and theoretical capacity. (Lu and Dahn, 2001a; Fielden and Obrovac, 2015) V, Cr and Co substitution also shows a proper potential range for cathode but it may not suitable for practical application since V, Cr, and Co are expensive and toxic. Although Fe and Cu are almost electrochemical inactive when used as $LiTMO_2$ for LIB system, (Ado et al., 1997; Arachi et al., 2012) these two elements are proven to be highly active in Na_xTMO_2 as Na-ion host. (Yabuuchi et al., 2012a; Ono, 2018) Since Ni and Co resources are mostly consumed by LIB system, the abundant Fe and Cu resources with low price are suitable for Na_xTMO_2 as sodium storage materials. (Li Y. et al., 2015; Mu et al., 2015) In addition, electrochemical inactive metal ions such as Li^+, Mg^{2+} and Zn^{2+} could also be introduced into the TM layer for the improvement of electrochemical performance (Xu et al., 2014; Wu X. et al., 2015; Wang et al., 2016c). **Table 1** lists the most common metal ions for the construction of TM layers and their corresponding ionic radii with coordination number of six (Shannon, 1976). Cations with similar ionic radius can partially substitute each other to form solid solutions, and hence various Na_xTMO_2 compounds could be designed by choosing two or more proper metal ions for the TM layer to improve electrochemical performance.ta

The crystal structure of Na_xTMO_2 can be usually classified into two types, P2 and O3 (**Figure 3**). The symbols of "P" and "O" are from the abbreviation of "prismatic" and "octahedral," "2" and "3" represents the stacking arrangement per unit of O ions. For P2 type structure (usually $x = 2/3$), Na ions occupy two different prismatic sites, one shares faces between TMO_6 octahedra called Na_f sites and another shares edges between TMO_6 octahedra called Na_e sites. TM ions are surrounded by oxygen frameworks with a stacking mode of ABBA. For O3 structure (usually x = 1), all Na ions share one edge and one face with TMO_6 octahedra. The oxygen frameworks are arranged in ABCABC pattern (Delmas et al., 1980, 1981; Shu and Chou, 2008; Morris et al., 2009; Toumar et al., 2015; Zheng C. et al., 2017).

Influence of Air on Na_xTMO_2

So far, many researches have proven that the water and CO_2 molecules from air can react with Na_xTMO_2, bringing

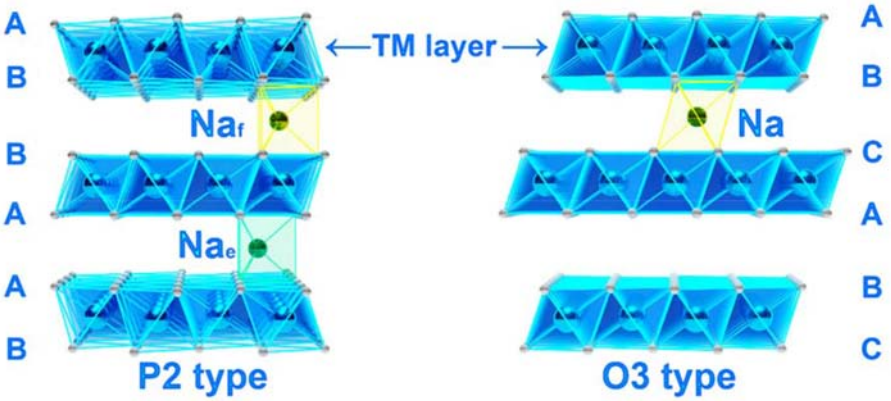

FIGURE 3 | The schematic of the crystal structure for layered sodium TM oxides, left is P2 type and right is O_3 type.

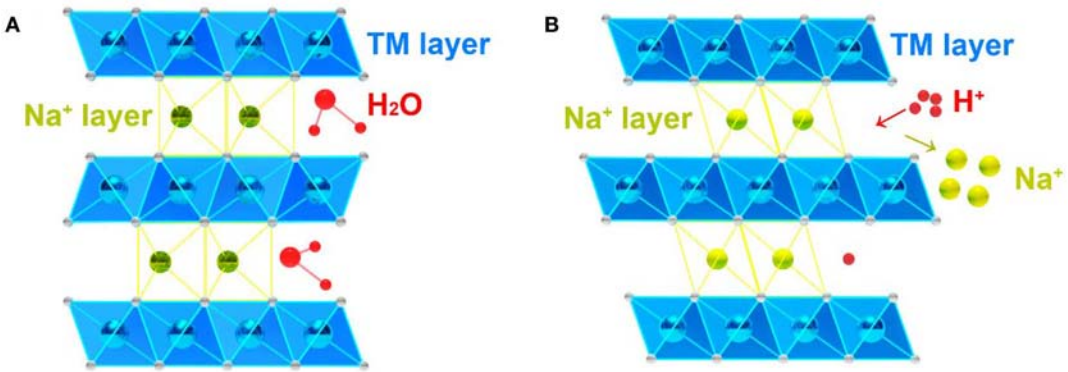

FIGURE 4 | (A) Insertion of water molecules in Na^+ layer, **(B)** Ion exchange between H^+ and Na^+ in Na^+ layer.

negative influence on its morphology, crystal structure and electrochemical performance. The water molecules are easy to react with air-instable Na_xTMO_2 by inserting into the Na layer (Le Goff et al., 1993; Paulsen and Dahn, 1999; Franger et al., 2000; Lu and Dahn, 2001b; Caballero et al., 2002; Duffort et al., 2015; Boyd et al., 2018) or exchanging Na^+ with H^+, (Blesa et al., 1993; Monyoncho and Bissessur, 2013; Kubota and Komaba, 2015; Han et al., 2016b; Yao et al., 2017) leading to the expansion of interlayer spacing and the formation of impure phase (**Figure 4**). While CO_2 can transform to CO_3^{2-} on the surface of Na_xTMO_2 (Duffort et al., 2015; You et al., 2018). These air exposed Na_xTMO_2 usually show serious capacity decay and large polarization because of: (i) the side reaction between water and electrolyte (Kawamura et al., 2006; Lux et al., 2012; Han et al., 2016b); (ii) the active-materials' surface dissolution triggered by the acid attack of proton, which is released by water molecules (Blyr et al., 1998; Thackeray et al., 1998; Benedek and van de Walle, 2008); (iii) capacity and electronic conductivity decrease caused by inactive Na_2CO_3 layer (Duffort et al., 2015; You et al., 2018). Therefore, the air-instable Na_xTMO_2 cannot maintain its original crystal structure and electrochemical property under moisture atmosphere condition.

Reaction Mechanisms of Water on Na_xTMO_2

Water molecules can insert into Na layer to form a $Na_xTMO_2{\cdot}yH_2O$ hydrate phase, which usually occurs in P2 type structure (Le Goff et al., 1993; Franger et al., 2000; Lu and Dahn, 2001b; Caballero et al., 2002; Duffort et al.,

2015; Boyd et al., 2018). In 2001, Lu et al. (Lu and Dahn, 2001b) studied the water insertion reaction mechanism for the first time in P2-$Na_{2/3}Co_xNi_{1/3-x}Mn_{2/3}O_2$ compound ($x = 1/6$ or $1/3$). Compared with the XRD patterns of pristine $Na_{2/3}Co_xNi_{1/3-x}Mn_{2/3}O_2$, two new peaks around 14° and 28° were observed after exposing $Na_{2/3}Co_xNi_{1/3-x}Mn_{2/3}O_2$ samples in humid air environment (**Figures 5A,B**). These two peaks were assigned as hydrate phase due to the insertion of water molecules in Na layers. Rietveld refinement of hydrate $Na_{2/3}Co_{1/3}Mn_{2/3}O_2{\cdot}yH_2O$ indicated that the ratio of water/Na is close to 1:1 and the oxygen atoms from water was in the 2c site of the crystal structure (**Figures 5C,D**). Franger et al. (Franger et al., 2000) investigated the influence of water soaking on α-$Na_{0.7}MnO_2$. With the increasing of water soaking time, the two peaks around 8° and 16° were vanished and four new peaks around 6.5°, 13°, 19° and 21° appeared gradually. The α-$Na_{0.7}MnO_2$ was totally transformed to $Na_{0.45}MnO_2{\cdot}0.6H_2O$ after 60 min of water soaking treatment (**Figure 5E**). In 2018, Boyd et al. compared the air-stability of P2-$Na_{0.62}Ni_{0.22}Mn_{0.66}Fe_{0.1}O_2$ (NaNMFe), P2-$Na_{0.61}Ni_{0.22}Mn_{0.66}Co_{0.1}O_2$ (NaNMCo), P2-$Na_{0.64}Ni_{0.22}Mn_{0.66}Cu_{0.11}O_2$ (NaNMCu) and P2-$Na_{0.64}Mn_{0.62}Cu_{0.31}O_2$ (NaMCu) samples. After air-exposure treatment of these four samples for 8 days, the XRD patterns of NaNMCu and NaMCu samples remained unchanged, while two new peaks around 12.5° and 25° appeared in the patterns of NaNMFe and NaNMCo samples, indicating that water can insert in the interlayer spacing of NaNMFe and NaNMCo samples (**Figure 5F**). From the STEM images of these four samples before and after air-exposure, an obvious extension in interlayer spacing could be seen after air-exposure, proving the insertion of water molecules in the interlayer spacing (**Figure 5G**). Although water molecules can insert into the interlayer spacing of P2-Na_xTMO_2 to form a P2-$Na_xTMO_2{\cdot}yH_2O$ hydrate phase, Na_xTMO_2 phase can be regenerated by heat treatment at 200 °C to remove the water molecules (Lu and Dahn, 2001b).

For most O3-type $NaTMO_2$, water molecules can release H^+ to exchange the Na^+, (Blesa et al., 1993; Monyoncho and Bissessur, 2013; Kubota and Komaba, 2015; Han et al., 2016b; Yao et al., 2017) which could be regarded as hydrolysis reaction:

$$NaTMO_2 + xH_2O \rightarrow Na_{1-x}H_xTMO_2 + NaOH \quad (2)$$

Specially, if the TM layers contain a certain amount of Ni^{2+} ions, NiO would be emerged during the air exposure treatment:

$$NaNi_yTM_{1-y}O_2 + xH_2O \rightarrow Na_{1-x}H_xNi_{y-z}TM_{1-y}O_{2-z} + xNaOH + zNiO \quad (3)$$

This hydrolysis phenomenon has been confirmed in $NaNi_{0.5}Mn_{0.5}O_2$, $NaNi_{0.7}Mn_{0.15}Co_{0.15}O_2$ and $NaFeO_2$ compounds (Blesa et al., 1993; Monyoncho and Bissessur, 2013; Kubota and Komaba, 2015; You et al., 2018). A simple way to verify this hydrolysis reaction is to analyze the change of pH value after soaking $NaTMO_2$ in deionized water due to the release of NaOH (Blesa et al., 1993). In 2013, Monyoncho and Bissessur reported that the pH of aqueous solution was higher than 12 after mixing O3-$NaFeO_2$ sample with deionized water (Monyoncho and Bissessur, 2013). In addition, compared with the XRD patterns of pristine $NaFeO_2$ sample, the 003 peak of hydrolysis $Na_{1-x}H_xFeO_2$ sample became broader and shifted to low angle (**Figure 6A**), indicating the formation of a disordered crystal structure. Wang et al. investigated the hydrolysis reaction of O3-$NaNi_{0.5}Mn_{0.5}O_2$ sample by testing the temperature after water soaking because this reaction can release heats (Yao et al., 2017). After $NaNi_{0.5}Mn_{0.5}O_2$ was added into water, the temperature of the water was increased from 24.4 to 30.8°C. In contrast to the XRD pattern of as-synthesized sample, the 003 and 006 peaks of water soaked $NaNi_{0.5}Mn_{0.5}O_2$ shifted to low angle with the generation of NiO impurity phase (**Figure 6B**). Importantly, unlike P2 type, the hydrolysis reaction between O3 type $NaTMO_2$ and water is irreversible.

Reaction Mechanisms of CO_2 on Na_xTMO_2

As mentioned above, NaOH is generated on the surface of O3 type Na_xTMO_2 during the air exposure process, then CO_2 can further react with NaOH to form Na_2CO_3 (Sathiya et al., 2012; Monyoncho and Bissessur, 2013; You et al., 2018). This reaction can be described as:

$$NaTMO_2 + xH_2O + CO_2 \rightarrow Na_{1-x}H_xTMO_2 + Na_2CO_3 \quad (4)$$

Sathiya et al. (2012) proved the formation of Na_2CO_3 on the surface of $NaNi_{1/3}Mn_{1/3}Co_{1/3}O_2$ particles. Compared to the pristine sample (**Figure 7a**), the surface showed no obvious change after 15 days air-exposure (**Figure 7b**) but became quite rough after 30 days air-exposure (**Figure 7c**). IR spectrum revealed the bands of CO_3^{2-} at 1,450 and 863 cm^{-1}, suggesting the existence of sodium carbonates on $NaNi_{1/3}Mn_{1/3}Co_{1/3}O_2$ particles' surface (**Figure 7d**). Monyoncho and Bissessur (2013) extracted the aqueous solution from the mixture of $NaFeO_2$ and water (**Figure 7e**). The XRD pattern of extracted sample matched very well to commercial Na_2CO_3, proving the reaction of CO_2 and $NaFeO_2$ compounds (**Figure 7f**).

After the formation of Na_2CO_3 on the surface, the CO_3^{2-} can even be inserted into the TM layer, forming a "CO_4" tetrahedron. Duffort et al. elucidated the mechanism of CO_3^{2-} insertion in $Na_{0.67}Mn_{0.5}Fe_{0.5}O_2$ crystal (Duffort et al., 2015). With increasing the time of air exposure, ribbon-like particles start to appear and grow longer gradually

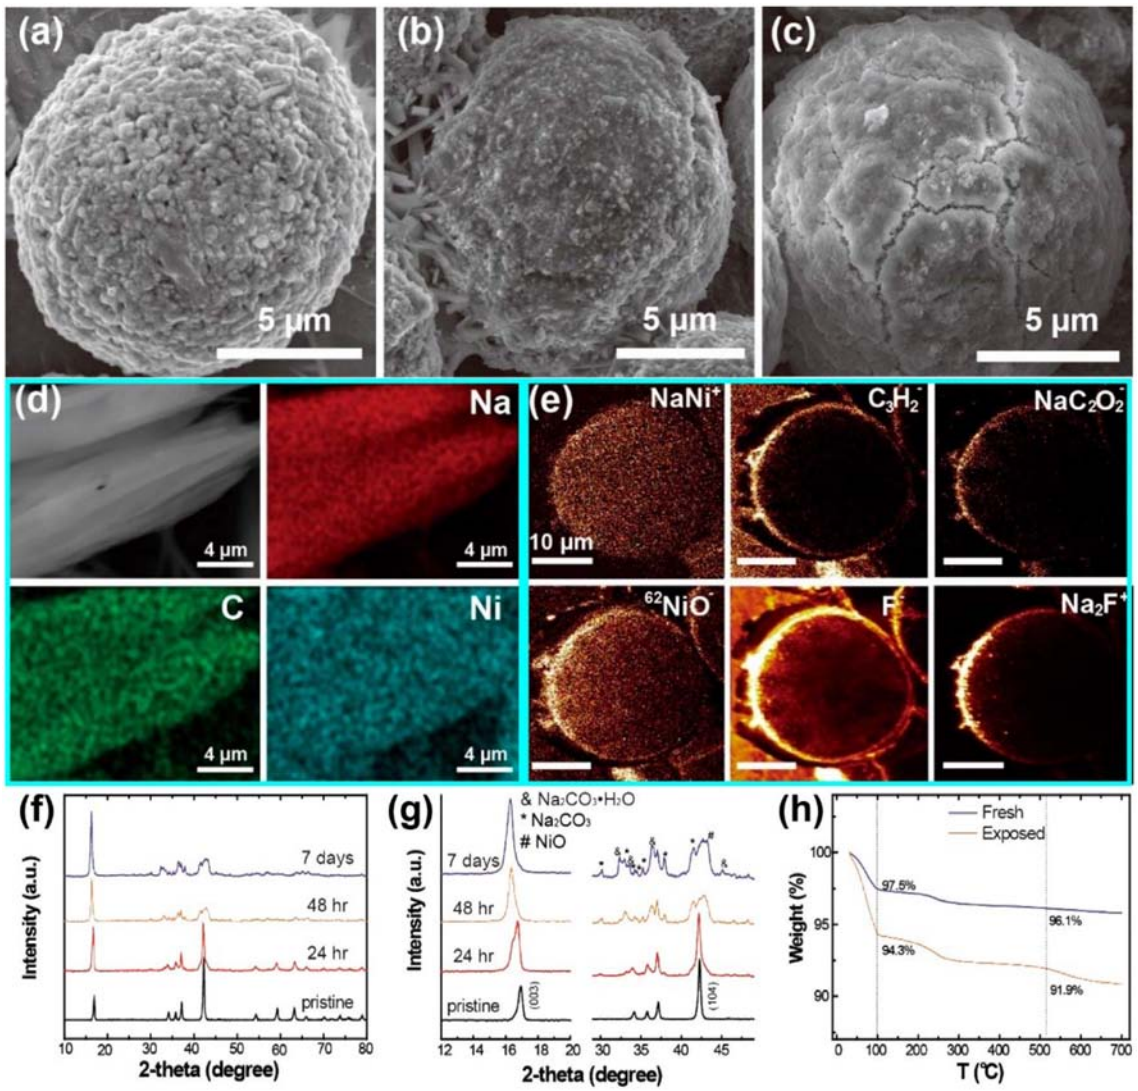

FIGURE 9 | SEM images of **(a)** pristine $NaNi_{0.7}Mn_{0.15}Co_{0.15}O_2$, **(b)** $NaNi_{0.7}Mn_{0.15}Co_{0.15}O_2$ after 24 h air-exposure, **(c)** $NaNi_{0.7}Mn_{0.15}Co_{0.15}O_2$ after 7 days air-exposure, **(d)** dendrite-like impurity in part b with the corresponding elemental mappings of Na, C and Ni, **(e)** TOF-SIMS chemical mapping of $NaNi_{0.7}Mn_{0.15}Co_{0.15}O_2$ after 24 h exposure, **(f)** XRD patterns of $NaNi_{0.7}Mn_{0.15}Co_{0.15}O_2$ samples under different air exposed time, **(g)** the enlarged peaks from part f, **(h)** TGA profiles of pristine $NaNi_{0.7}Mn_{0.15}Co_{0.15}O_2$ and 7 days exposed $NaNi_{0.7}Mn_{0.15}Co_{0.15}O_2$ samples. Reproduced with permission (You et al., 2018). Copyright 2018, American Chemical Society.

(**Figures 8a–c**). In addition, the corresponding XRD patterns of $Na_{0.67}Mn_{0.5}Fe_{0.5}O_2$ are also changed. New peak is observed around 13° after a month air exposure (**Figure 8d**), indicating the formation of hydrate phase (phase 3) and sodium-depleted P2 phase (phase 2). In Fourier difference map, the existence of large residual nuclear density is caused by the carbonate ions (**Figure 8e**) because the insertion of CO_3^{2-} leading to the changing of the nuclear density distribution (**Figure 9g**). In the TM layer, the CO_3^{2-} is combined with one C-O bond to form a CO_4 tetrahedron structure (**Figure 8f**).

Except for Na_2CO_3, other surface components are also observed. You et al. studied the surface reaction between $NaNi_{0.7}Mn_{0.15}Co_{0.15}O_2$ and air systematically by using time-of-flight secondary ion mass spectroscopy (TOF-SIMS) (You et al., 2018). The pristine sample shows a microsphere morphology, which is consisted of nanosized particles (**Figure 9a**). After 24 h air exposure treatment, the surface of this microsphere becomes smooth with the absence of nano-particles (**Figure 9b**). Finally, a thick layer of impurities is formed on the surface after 7 days air exposure (**Figure 9c**). Elements of Na, Ni, and C are distributed uniformly on the impurity surface (**Figure 9d**). The existence of $NaNi^+$, NiO, $NaC_2O_2^-$, $C_3H_2^-$, Na_2F^+, and F^- composition are confirmed by TOF-SIMS, indicating the surface degradation of $NaNi_{0.7}Mn_{0.15}Co_{0.15}O_2$ as well as the reaction between sodium carbonates and PVDF (**Figure 9e**). The 003 peak shifts to lower angles gradually because of the migration of Na^+ to the surface while the 104 peak becomes weak and vanishes after 48 h air exposure (**Figure 9f**). According to the XRD patterns in **Figure 9g**, impurities' peaks such as NiO and Na_2CO_3 are observed, indicating the surface reaction when $NaNi_{0.7}Mn_{0.15}Co_{0.15}O_2$ contacts to CO_2 and H_2O. Since the CO_2 and H_2O are absorbed and reacted with $NaNi_{0.7}Mn_{0.15}Co_{0.15}O_2$, the air-exposed sample loses more weight than the fresh sample (**Figure 9h**). All the results above can prove hat $NaNi_{0.7}Mn_{0.15}Co_{0.15}O_2$ can react with the water and carbon dioxide in the air and the impurities of $NaNi^+$, NiO, $NaC_2O_2^-$, $C_3H_2^-$, Na_2F^+ and F^- are generated on the surface.

AIR-STABLE NA_XTMO_2 COMPOUNDS

As mentioned above, $NaTMO_2$ compounds can react with water and CO_2 in air, which lead to: (i) the formation of impure phase on the surface; (ii) the insertion of H_2O and CO_3^{2-} into interlayer spacing and TM layers, respectively. On one side, the formed NaOH and Na_2CO_3 impure phase are electrochemical inactive and have low conductivity hence the rate capability of Na_xTMO_2 suffer serious decrease. On the other side, the water molecules can bring side reaction with electrolyte while the insertion of CO_3^{2-}

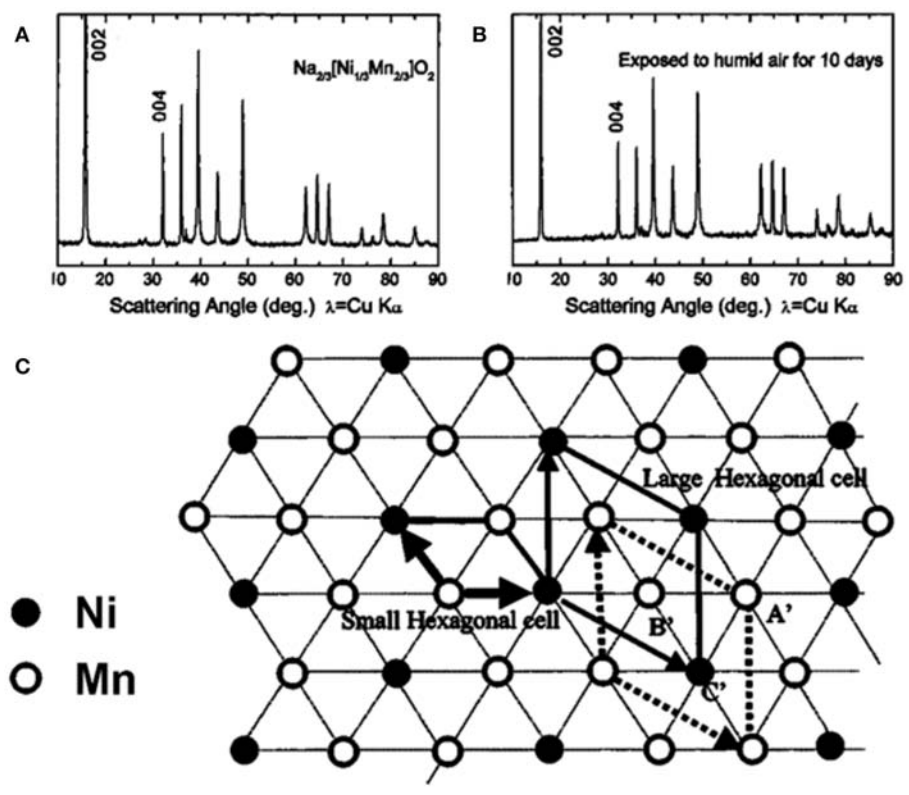

FIGURE 10 | (A) XRD pattern of pristine $Na_{2/3}Ni_{1/3}Mn_{2/3}O_2$, **(B)** XRD pattern of $Na_{2/3}Ni_{1/3}Mn_{2/3}O_2$ after 10 days air-exposure, **(C)** the Ni/Mn cationic ordering arrangement. Reproduced with permission (Lu and Dahn, 2001b). Copyright 2001, American Chemical Society.

affects the valence state of TM ions, leading to severe capacity decay. Therefore, more and more researchers are focusing on strategies to address this air-instable problems.

One strategy is to prevent the materials from contacting moisture. During the materials preparation process, once the high-temperature treatment is done, the Na_xTMO_2 products are transferred to drying room (Wang et al., 2016a) or argon-filled glove box (Yabuuchi et al., 2012a; Vassilaras et al., 2014) immediately for the cooling process and subsequent cell assembling. However, this strategy may not be suitable for the large-scale application because huge cost will rise for materials' storage. Another strategy is to design air-stable Na_xTMO_2 material. Recently, several P2 and O3 type Na_xTMO_2 materials with high stability against moisture have been reported (Lu and Dahn, 2001b; Li Y. et al., 2015; Mu et al., 2015; Guo et al., 2017; Yao et al., 2017; Zheng L. et al., 2017; Chen et al., 2018; Deng et al., 2018). Under the treatment of air exposure and water soaking, these air-stable cathodes can maintain their original crystal structure and electrochemical performance. In this part, several effective strategies for air-stable Na_xTMO_2 designing are summarized.

Constructing TM Cationic Ordering Arrangement

Lu et al. first reported an air-stable P2-$Na_{2/3}Ni_{1/3}Mn_{2/3}O_2$ with high stability under moisture condition (Lu and Dahn, 2001b). For the P2-$Na_{2/3}Ni_{1/3}Mn_{2/3}O_2$ sample, after undergoing a 10 days air-exposure treatment, no peaks shift or new peaks formation were observed in the XRD pattern, indicating that water could not be inserted into the interlayer spacing (**Figures 10A,B**). According to neutron diffraction analysis, the Ni^{2+} and Mn^{4+} ions formed an honeycomb structure with an $\sqrt{3}a \times \sqrt{3}a$ ordering arrangement in the TM layers (**Figure 10C**) (Lu et al., 2000). This Ni/Mn ordering arrangement in TM

layers was supposed to induce a strong interlayer interaction to prevent the water insertion. When this ordering arrangement was suppressed by the substitution of Co or Fe for Ni, water molecules could be inserted into the interlayer spacing (**Figures 5A,B,F**). However, this "interlayer interaction" between adjacent ordering TM layer has not been confirmed yet.

Coating Protective Layer

Coating a protective layer on the surface of Na_xTMO_2 is an effective method to prevent the Na_xTMO_2 from air contacting. The most common way is to coat high-voltage metal oxides with high stability against moisture. In 2017, Zhou and co-workers (Guo et al., 2017). designed an efficient

TABLE 2 | A summary of current air-stable Na_xTMO_2 cathode.

Air stable materials	Design strategies	Test conditions	Rate performance			Cycling performance			References

$Na_{0.6}Mn_{0.9}Cu_{0.1}O_2$	Cu substitution	Air-exposure and water soaking	8	85	50.4%	4	250	70.4%	Chen et al., 2018

spinel-like titanium (III) oxides protective interface to improve the structure/electrochemical stability of $NaMnTi_{0.1}Ni_{0.1}O_2$. The sample surface was covered by a high Ti concentration layer with thickness of 2 nm, as shown in the electron energy-loss spectroscopy image (**Figure 11a**). Two distinct phases could be observed from the high-angle annular dark field scanning transmission electron microscopy (HAADF-STEM) image (**Figure 11b**). The bulk phase was a typical layered structure (**Figure 11c**) while the surface phase was spinel-like structure (**Figures 11d,e**). After exposing the naked bulk phase in humid air, two new peaks appeared around 12° and 25° (**Figure 11f**), indicating the insertion of water molecules. Compared to the naked bulk phase, the XRD pattern of $NaMnTi_{0.1}Ni_{0.1}O_2$ sample showed no peak change since the spinel-like titanium (III) oxides interface can act as shield to protected the bulk phase from water attacking and the electrochemical performance of bulk phase can be maintained. In half cell system, the naked bulk phase showed a dramatic decrease after 50 cycles whereas NMTN sample only showed a slight decay after 100 cycles (**Figure 11g**).

You et al. (2018) coated the surface of $NaNi_{0.7}Mn_{0.15}Co_{0.15}O_2$ with a ZrO_2 protective layer. This protective layer notably maintains the rate capability of $NaNi_{0.7}Mn_{0.15}Co_{0.15}O_2$ against moisture atmosphere. After 7 days air exposure, the ZrO_2@$NaNi_{0.7}Mn_{0.15}Co_{0.15}O_2$ sample still delivers a capacity of 96 mAh/g while $NaNi_{0.7}Mn_{0.15}Co_{0.15}O_2$ shows abnormal charge profile. The surface charge-transfer kinetics are also improved by this protective layer.

Except for Ti and Zr oxides, we suppose that other metal oxides such as MgO, ZnO, and Al_2O_3 also have the ability to work as protective layer because these high-voltage metal oxides all have high tolerance for moisture.

Cu^{2+} Substitution

The Cu^{2+} substitution is the simplest way to obtain air-stable Na_xTMO_2 compounds. The success of Cu^{2+} substitution to achieve high stability against moisture has been proven by many reports (Li Y. et al., 2015; Mu et al., 2015; Yao et al., 2017; Zheng L. et al., 2017; Chen et al., 2018; Deng et al., 2018), few references give the working mechanisms of Cu^{2+} in these air-stable Na_xTMO_2 compounds.

In, 2017, Yao et al. designed an air-stable O3-$NaNi_{0.45}Cu_{0.05}Mn_{0.4}Ti_{0.1}O_2$ (NaNCMT) cathode though cosubstitution of Cu^{2+} and Ti^{4+} in O3-$NaNi_{0.5}Mn_{0.5}O_2$ (NaNM) compound. This strategy could decrease the Na^+ interlayer distance and increase the valence state of TM ions. According to the refined crystal structure of NaNM and NaNCMT, the interlayer distance was reduced from 3.45 Å to 3.37 Å, respectively (**Figure 12A**), which was in favor of preventing the insertion of water molecules. DFT calculation revealed that Cu/Ti cosubstitution facilitated the increasing in valence state of Ni (**Figure 12B**). Compared with NaNM compound (**Figure 6B**), the XRD pattern of NaNCMT sample showed no obvious peaks change after air-exposure or water soaking (**Figure 12C**). During charge/discharge process, only slight capacity decay was observed after aging experiments (**Figure 12D**). (Yao et al., 2017) However, the explanation

about the relationship between valence state of TM ions and air-stability was not mentioned.

Zheng et al. investigated the structure stability of $Na_{2/3}Cu_xNi_{1/3-x}Mn_{2/3}O_2$ compounds ($0 \leq x \leq 1/4$) by air-exposure treatment. Compared to the XRD patterns of pristine samples, neither peaks position change nor new peaks formation were observed after exposing $Na_{2/3}Cu_xNi_{1/3-x}Mn_{2/3}O_2$ in air condition for 21 days (**Figure 13A**). According to charge/discharge profiles, all exposed electrodes had a little higher open circuit voltage than the un-exposed electrodes, but the average voltage and reversible capacity of the exposed electrodes showed no change or decay, indicating the air stability of these electrodes (**Figure 13B**). Since the radii of Cu^{2+} (0.73 Å) and Ni^{2+} (0.69 Å) were similar, replacing Ni^{2+} in $Na_{2/3}Ni_{1/3}Mn_{2/3}O_2$ by Cu^{2+} had no influence on the Ni/Mn cationic ordering arrangement. Therefore, the existence of Cu/Ni/Mn ordering arrangement could prevent the insertion of water molecules into the $Na_{2/3}Cu_xNi_{1/3-x}Mn_{2/3}O_2$ interlayer spacing because of the interlayer interaction between the adjacent Cu/Ni/Mn layer. However, no evidence was provided to prove the Cu/Ni/Mn ordering arrangement.

Other compounds such as O3-$Na_{0.9}Cu_{0.22}Fe_{0.30}Mn_{0.48}O_2$, P2-$Na_{7/9}Cu_{2/9}Fe_{1/9}Mn_{2/3}O_2$, O3-$NaLi_{0.05}Mn_{0.5}Ni_{0.3}Cu_{0.1}Mg_{0.05}O_2$, and P2-$Na_{0.6}Mn_{0.9}Cu_{0.1}O_2$ have been proved to be air-stable because all of their XRD patterns remained unchanged after air-exposure and water soaking treatment (Li Y. et al., 2015; Mu et al., 2015; Chen et al., 2018; Deng et al., 2018).

It seems that the Cu^{2+} plays an important role in maintaining the structure stability of these compounds under moisture. The reported Cu^{2+} substituted Na_xTMO_2 compounds, such as O3-$NaNi_{0.45}Cu_{0.05}Mn_{0.4}Ti_{0.1}O_2$, P2-$Na_{2/3}Cu_xNi_{1/3-x}Mn_{2/3}O_2$, O3-$Na_{0.9}Cu_{0.22}Fe_{0.30}Mn_{0.48}O_2$, O3-$NaLi_{0.05}Mn_{0.5}Ni_{0.3}Cu_{0.1}Mg_{0.05}O_2$, P2-$Na_{7/9}Cu_{2/9}Fe_{1/9}Mn_{2/3}O_2$, and P2-$Na_{0.6}Mn_{0.9}Cu_{0.1}O_2$, all show excellent structure stability under moisture condition. However, few investigations explain the working mechanism of Cu^{2+} substitution in these air-stable compounds. In O3-$NaNi_{0.45}Cu_{0.05}Mn_{0.4}Ti_{0.1}O_2$ compound system, the working mechanism of Cu^{2+} is attributed to the increase of the Ni valence state by DFT calculation, but the relationship between valence state of Ni and air-stability is not clear so far. In addition, how to explain the Ni free compound systems for their air stability after Cu^{2+} substitution still remains problems.

Table 2 lists most of the air-stable Na_xTMO_2 compounds published to date, including the design strategies and the corresponding electrochemical performance.

SUMMARY AND PROSPECTS

Air-stability is one of the key issues for practical application of Na_xTMO_2 SIB cathode materials. In recent years, with understanding the structure of Na_xTMO_2, several strategies have been developed to obtain air-stable Na_xTMO_2 compounds, including constructing TM ordering arrangement, coating protective layer and Cu^{2+} substitution. However, there still remain some challenges. For example, the reaction mechanism of the "strong interlayer interaction" for TM ordering arrangement as well as the substitution of Cu^{2+} and other cations should be further understood. In any case, we believe that the air-stable Na_xTMO_2 materials with low cost and high theoretical capacity are highly competitive as SIB cathode materials in the large-scale energy storage application.

Hunan Province Cooperative Innovation Center for Molecular Target New Drug Study, Department of Biochemistry and Molecular Biology, University of South China, Hengyang, China

Persistent luminescence is a phenomenon in which luminescence is maintained for minutes to hours without an excitation source. Owing to their unique optical properties, various kinds of persistent luminescence materials (PLMs) have been developed and widely employed in numerous areas, such as bioimaging, phototherapy, data-storage, and security technologies. Due to the complete separation of two processes, —excitation and emission—, minimal tissue absorption, and negligible autofluorescence can be obtained during biomedical fluorescence imaging using PLMs. Rechargeable PLMs with super long afterglow life provide novel approaches for long-term phototherapy. Moreover, owing to the exclusion of external excitation and the optical rechargeable features, multicolor PLMs, which have higher decoding signal-to-noise ratios and high storage capability, exhibited an enormous application potential in information technology. Therefore, PLMs have significantly promoted the application of optics in the fields of multimodal bioimaging, theranostics, and information technology. In this review, we focus on the recently developed PLMs, including inorganic, organic and inorganic-organic hybrid PLMs to demonstrate their superior applications potential in biomedicine and information technology.

INTRODUCTION

Persistent luminescence (PL) is an optical phenomenon, in which luminescence is maintained for an appreciable time after the termination of the excitation (Hölsä, 2009). Although the origins of the PL emission are still in debate, the research, and applications of persistent luminescence materials (PLMs) have rapidly grown since the PL emission was first observed from a mineral barite (Bologna stone) in the 17th century (Lastusaari et al., 2012).

Following the enhancement in intensity, stability, and duration of PL, inorganic PLMs covering various emission colors have been fully studied and commercially applied. Since the first $SrAl_2O_4:Eu^{2+},Dy^{3+}$ green emission PLM was discovered by Matsuzawa et al. (1996), persistent luminescence phosphors (PLPs) have been rapidly developed in the last decade (Matsuzawa et al., 1996). Recently, several PLPs emitting in visual spectra have been commercialized as important night-vision materials for various innovations, owing to their sufficiently strong, and ultra-long

(>10 h) PL excited by sunlight or room light (Matsuzawa et al., 1996; Yamamoto and Matsuzawa, 1997; Wang et al., 2003). In the last few decades, visible light emitting PLPs have been widely utilized in critical applications including interior decorations, displays, signals and even certain newly-emerged technologies of anti-counterfeiting, optical recording, or biochemistry (Hölsä, 2009; Pan et al., 2012).

For biomedical applications, the PLMs can be ideal alternatives for traditional fluorescent materials, especially in bioimaging, due to the following two reasons (Lécuyer et al., 2016; Liu et al., 2018a). First, the entire fluorescence signal emitted from the PLMs *in vivo* because the tissue autofluorescence is eliminated owing to the termination of the excitation. Second, the delayed luminescence of PLMs facilitates long-time *in vitro* and *in vivo* bioimaging. In addition, the excitation and emission spectra of PLMs can be tuned conveniently to satisfy diverse demands. A typical example is near-infrared (NIR) luminescence, which is the most widely used excitation or emission wavelength in living imaging to achieve penetrability in deeper tissues (Wang et al., 2017a). However, a major limitation is the biocompatible size of PLMs. In 2007, PLM was synthesized in nanoscale in a pioneering study, initiating the research on persistent luminescence nanoparticles (PLNPs) (le Masne de Chermont et al., 2007). In addition to the above advantages, it has been verified by subsequent research in biomedical theranostics, that PLNPs have excellent dispersibility, biocompatibility and modifiability (Wang et al., 2017a; Sun et al., 2018; Xia et al., 2018).

Meanwhile, the novel generation of organic carbon-based PLMs ranging from small molecules to polymers has attracted significant attention. Compared with inorganic PLMs, the production of organic PLMs is more facile and controllable with reduced costs (Dimitrakopoulos and Malenfant, 2002; Kabe et al., 2016). The functionalization of organic PLMs with organic groups and biological ligands is more achievable. Moreover, their second level lifetime and environmental dependent feature is more suitable for demanding applications including display (Kabe et al., 2016), anti-counterfeiting (Zhou et al., 2015), bioimaging (Mikael et al., 2015), and sensors (Yang and Yan, 2016b).

With deeper understanding of the PL emission mechanism and the rapid development of synthesis technologies, more advanced applications based on PLMs have been explored. In this study, we review the crucial breakthroughs and the latest developments of research on PLMs with and without rare-element doping, to demonstrate their superior applications in biomedicine and information technology.

CLASSIFICATIONS

Inorganic PLMs

Phosphors

Since the first $SrAl_2O_4:Eu^{2+},Dy^{3+}$ PLM of green emission was discovered by Matsuzawa et al. (1996), PLPs have been rapidly developed in the last decade (Matsuzawa et al., 1996). Currently, several PL phosphors emitted in the visual spectrum, such as $CaAl_2O_4:Eu^{2+}$, Nd^{3+} (blue emission), (Yamamoto and Matsuzawa, 1997) $SrAl_2O_4:Eu^{2+},Dy^{3+}$ (green emission), (Matsuzawa et al., 1996), and $Y_2O_2S:Eu^{3+},Mg^{2+},Ti^{2+}$ (red emission) (Wang et al., 2003), have been widely commercialized as important night-vision materials. Recently, researches have mainly focused on extending the emission and excitation spectrum and prolonging the PL duration.

To achieve an unchanged white afterglow color, an effective strategy is to combine different color emission from an identical luminescence center (Liu et al., 2005; Kuang et al., 2006). For example, by doping Tb^{3+} into $Y_3\ Al_2\ Ga_3\ O_{12}$ host, three kinds of cross-relaxation energy transfer proceed: $^5D_3 \rightarrow\ ^5D_4$ and $^7F_6 \rightarrow\ ^7F_0$, $^7D_J \rightarrow\ ^5D_{1,2,3}$ and $^7F_6 \rightarrow\ ^5D_4$, and $^5D_4 \rightarrow\ ^7F_4$ and $^5D_4 \rightarrow\ ^7F_3$ in Tb^{3+}, which are blue, green and red emissions respectively. By tuning the doping concentration of Tb^{3+}, an unchanged white PL was obtained and maintained for more than 2 h (Zhang et al., 2017). In 2015, Pan and co-workers extended the PL into the ultraviolet (UV) spectral region. Using Pb^{2+} as luminescence center, the obtained $Sr_2MgGe_2\ O_7:Pb^{2+}$ phosphors exhibited strong PL emission at 370 nm for more than 12 h (**Figure 1A**) (Liang et al., 2015).

Due to the high penetration depth and low autofluorescence, NIR-emission PLMs have attracted significant interest in biomedicine applications. For the NIR emission, Cr^{3+} is the main luminescent center with a narrow-band emission (700 nm) due to the spin-forbidden $^2E \rightarrow\ ^4A_2$ transition, and a broadband emission (650–1,000 nm) due to the spin-allowed $^4T_2 \rightarrow\ ^4A_2$ transition (Struve and Huber, 1985; Forster, 1990). In 2012, Pan and co-workers developed the $Zn_3Ga_2Ge_2O_{10}:Cr^{3+}$ phosphors for the first time, which achieved an ultra-long NIR PL duration of 360 h (**Figure 1B**) (Pan et al., 2012). This breakthrough established Cr^{3+}-doped gallates, such as $ZnGa_2O_4:Cr^{3+}$ phosphors (Li et al., 2015b), $LiGa_5O_8:Cr^{3+}$ phosphors (Liu et al., 2013), and $Ca_3Ga_2Ge_3O_{12}:Nd^{3+},Cr^{3+}$ phosphors (Lin et al., 2016) as the preferred materials to obtain NIR PLMs. Meanwhile, Cr^{3+}-doped non-gallate NIR PLMs (Zn_2-xAl_2xSn_1-x$O_4:Cr^{3+}$), emitting with a strong 650–750 nm PL for more than 120s, have also been developed (Zhang et al., 2018)

To overcome the short-wavelength excitation limitation in deep tissues application, NIR-recharged PLMs were developed by introducing the upconversion concept (Chen et al., 2018). We fabricated NIR-rechargeable upconverting PL (UCPL) phosphors by combining UV-rechargeable PLPs with typical UV/blue emission upconversion materials (NaYF4:25%Yb, 0.5%Tm) (**Figure 1C**). It should be noted, that multicolor emission can also be realized by using different emission PL components. Compared with the UV excitation, no noticeable difference was found on the persistent phosphorescence properties under the NIR (980 nm) excitation (Hu et al., 2017, 2018).

Nanoparticles

While PLPs have been synthesized and maturely used for more than 20 years, their advanced development for biological application started in 2007, when Scherman et al. introduced nanoscale PLMs in their pioneering work (le Masne de Chermont et al., 2007). The conventional strategies for the preparation of PLPs typically involved high-temperature

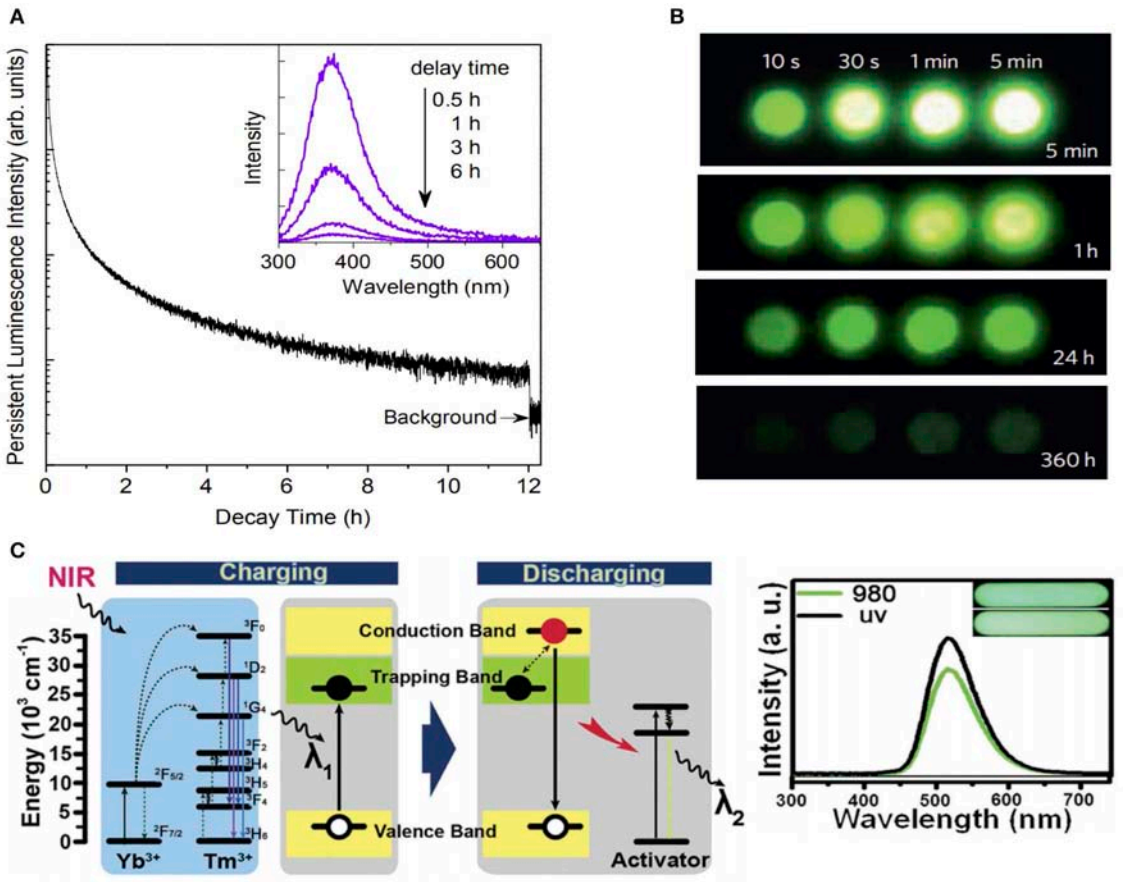

FIGURE 1 | (A) PL decay curve monitored at 370 nm after irradiation by 254-nm UV for 15 min (Liang et al., 2015). **(B)** NIR images of four $Zn_3Ga_2Ge_2O10$: 0.5%Cr^{3+} phosphor discs taken at different afterglow times after irradiation by a 365-nm lamp for durations ranging from 10 s to 5 min (Pan et al., 2012). **(C)** Energy transfer mechanism of UCPL materials (left), and the PL spectra of green emission UCPL materials taken 30 s after the excitation under 980-nm and UV lights for 15 s (right) (Hu et al., 2017). calcination for the formation of lattice defects and trap centers, which were crucial for the afterglow property of phosphors. The inevitable costs were the large irregular size and poor dispersibility of the synthesized PLPs, which limited their biological and medical applications. To overcome the solid-state barrier, Scherman and co-workers developed a sol-gel synthesis approach for the production of the first biocompatible PLNPs ($Ca_{0.2}Zn_{0.9}Mg_{0.9}Si_2O_6$ doped with Eu^{2+}, Dy^{3+}, and Mn^{2+}) and application for *in vivo* imaging. Moreover, those nanoparticles exhibited strong persistent NIR luminescence *in vivo* for more than 1 h after being excited by UV light before injection.

In recent years, motivated by this, an increasing number of synthetic routes have been reported and summarized (Li et al., 2016). In 2017, Wang et al. outlined established techniques for PLNP preparation and classified them into two groups: the top-down and bottom-up approaches (Wang et al., 2017a). In the top-down approach, the PL of PLPs is formed in solid or sol-gel state via high-temperature combustion. From large to small, or top to down, the PLPs with large size are processed into PLNPs by certain physical methods such as grinding and pulsed laser ablation.

To achieve size- and shape-controlled building-up processes, the bottom to top methods, including hydrothermal synthesis and the template method, introduced new approaches for PLNP construction. To obtain PLNPs with diverse morphology, the synthetic processes are highly controllable by adjusting the reaction conditions. In 2015, Han et al. used a hydrothermal method for PLNP production for the first time (Li et al., 2015a). An 8-nm nanoparticle $ZnGa_2O_4Cr_{0.004}$ PLNP was synthesized in solution, which possessed renewable NIR PL and exhibited excellent monodispersity under different aqueous conditions. Yang et al. synthesized $ZnGa_2O_4$:Cr^{3+} PLNPs with specific kiwifruit-like structures using silica as templates (Lin et al., 2017). The designed morphology could be conveniently controlled by changing the size and thickness of the silica templates, which ensured the NIR PL performance during high-temperature calcination. In addition to the size and shape, the superficial geography of PLNPs, which is critical for biomedical applications,

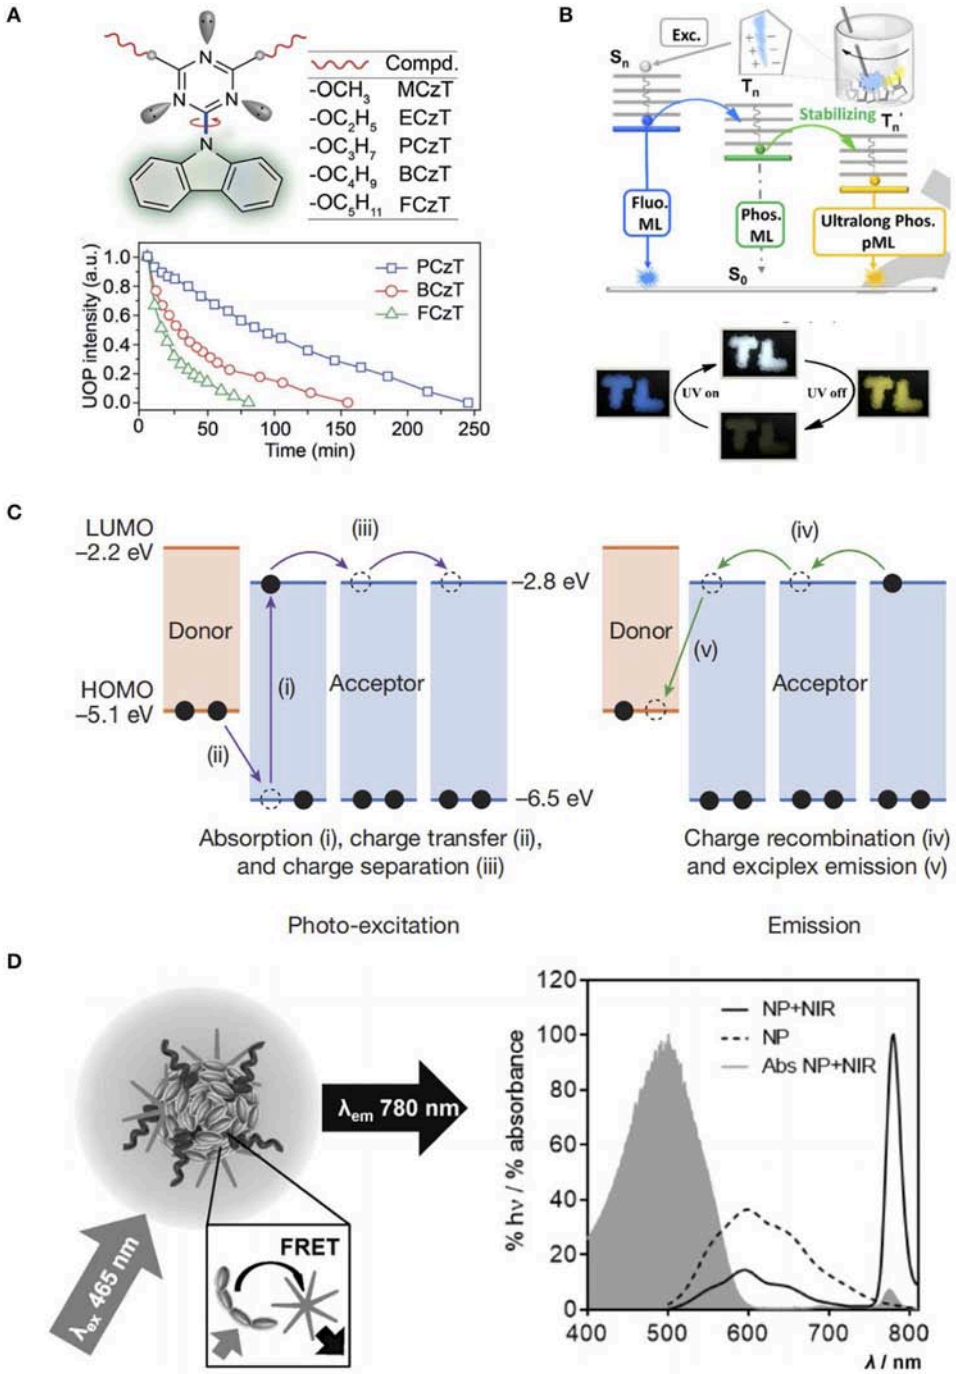

FIGURE 2 | (A) Rational design of molecular rotors (top) and ultra-long organic phosphorescence deactivation process by monitoring the emission intensities at 530 nm under ambient conditions (bottom) (Gu et al., 2018). **(B)** Energy transfer processes for transient and persistent ML of ImBr (top) and tricolor emission switching of ImB (bottom) (Li et al., 2018). **(C)** Emission mechanism of organic PL (Kabe and Adachi, 2017). **(D)** Schematic of the FRET from the MEH-PPV polymer to the NIR775 dye (left), and fluorescence spectra of the NPs with and without NIR775 dye, and absorbance spectrum of the NPs with NIR775 (right) (Mikael et al., 2015). can be easily modified in the bottom-up approach. Yan et al. reported dual-modal PLNPs, functionalized with hyaluronic acid (HA) modified Gd_2O_3 via hydrothermal and biomineralization synthesis (Wang et al., 2017c). The possible application of these versatile nanoprobes can be in PL and magnetic resonance (MR) imaging, as $ZnGa_2O_4:Cr_{0.001}$ provides the NIR PL, Gd_2O_3 enhances the MR signals, and the HA can target tumor cells *in vitro* and *in vivo*.

Organic PLMs

Inorganic PLMs doped with rare-earth elements exhibit excellent optical performance with high durability and long emission. However, these systems have low dispersibility and biocompatibility, and require complex fabrication process, which limit its future applications. To overcome these limitations, several types of organic PLMs have been investigated.

Owing to the short-lived singlet exciton for fluorescence, it is a great challenge to achieve PL in purely small organic molecules, especially in single-component PL. In 2015, Huang et al. proposed that triplet excited states could be stabilized by strong coupling in H-aggregated structures. Based on this principle, a diverse array of purely organic-molecule PLMs was found with ultra-long second level luminescence lifetimes. By tailoring the molecule structures, the emission color can be tuned from green to red (An et al., 2015). In their subsequent research, a series of organic PLMs with a triazine core, carbazole unit, and alkoxy chains were designed (**Figure 2A**). The PL lifetimes were increased from ms to s by exploiting the rotor unit of carbazole and triazine, which could stabilize excited triplet excitons via the manipulation of intermolecular interactions (Gu et al., 2018). In 2018, Chi and co-workers presented a purely organic aggregation-induced emission (AIE) for the first time that exhibited transient, persistent photoluminescence, and persistent mechanoluminescence (ML) at room temperature (Li et al., 2018). As a key functional unit, N-(4-trifluoromethylphenyl)phthalimide was introduced, which was favorable to form crystals and to prevent non-radiative transitions by immobilizing the molecular conformations. Owing to its capability of promoting spin-forbidden transitions, a bromine substituent was used to enhance the intersystem crossing efficiency of the singlet-to-triplet excited state. The tricolor emission switching between blue, white, and yellow could be obtained by simply switching on and off the UV lamp (**Figure 2B**).

To achieve multi-component PL, a commonly used strategy is the host-guests system, which consists of phosphorescent guests and efficient non-radiative vibration- limiting hosts (Hirata et al., 2013). However, the practical preparation is rather complex owing to the requirement of the elaborate selection of host and guest molecules for good compatibility and the careful tuning of doping concentration to obtain the best PL performance. In 2017, Kabe and Adachi proposed a novel strategy to obtain multi-component PLMs, which only required a simple mixture of a strong electron donor N,N,N',N'-tetramethylbenzidine (TMB) with a strong electron acceptor 2,8-bis(diphenylphosphoryl)dibenzo[b,d]thiophene (PPT) (Kabe and Adachi, 2017). The gradual recombination of these two radical anions and cations provided a stable radical cation and high triplet energy, as well as a non-radiative suppressible rigid amorphous environment to generate exciplex emission (**Figure 2C**). More importantly, a breakthrough was achieved in the PL lifetime of the obtained PLMs, which was upgraded to the 1-h level. In their subsequent research, color-tuning emission from greenish-blue to red and even warm white was achieved by simply doping the organic PLMs matrix with a wide variety of emitter molecules. Due to the doped emitters, the exciplexes could generate energy via Förster resonance energy transfer (FRET), as well as prolong the emission by acting as electron trapping sites, which resulted in improved brightness and emission duration (Jinnai et al., 2018).

As important organic macromolecules, polymers were found to be suitable as PL emitters. In 2015, Rao et al. reported a certain type of fluorescent semiconducting poly[2-methoxy-5-(2-ethylhexyloxy)-1,4-phenylenevinylene] (MEH-PPV) nanoparticles, which generated NIR PL for 1-h after being excited by white light (Mikael et al., 2015). Owing to the long π-conjugation conducting bands of MEH-PPV, energy can be stored in the semiconducting layer. In the presence of NIR775, the released energy was transferred to the NIR dye encapsulated in the polymer nanoparticles and resulted in NIR PL (**Figure 2D**).

In addition to single component polymer PLMs, polymers of polylactic acid (PLA), poly-arylene ether phosphine oxide (PBPO), poly-methyl methacrylate (PMMA), poly-vinyl alcohol (PVA) and poly -vinyl-pyrrolidone (PVP) were also suitable as host materials to obtained multi-component PL by minimizing the non-radiative decay of the long-lived triplet excitons (Zhang et al., 2007; Al-Attar and Monkman, 2012; DeRosa et al., 2015; Gu et al., 2018). For example, a flexible organic PLMs system based on the engineering plastic PBPO was developed, and the PL of this system can be articles a for more than 7 min after low-power excitation. This polymer-based system exhibited excellent mechanical flexibility required for future applications such as curved products, fibers, and films (Yang and Yan, 2016b).

Inorganic-Organic Hybrid PLMs

As kind of inorganic-organic hybrids, metal–organic frameworks (MOFs) possess rigid inorganic porous structure, which can capture and stabilize emitter molecules. Therefore, the coordination of organic fluorescent units with common metal ions is effective in achieving PL in MOFs. Recently, Yan and co-workers have devoted significant efforts to explore MOFs-based PLMs. By coordinating terephthalic acid and Zn^{2+}, they developed Zn-isophthalic acid (Zn-IPA) MOFs for the first time, which exhibited green PL with a lifetime of 1.3 s (Yang and Yan, 2016b). To achieve color-tuning emission, N,N'-dimethylformamide (DMF) was introduced into the MOF nanochannels and formed a novel MOFs system [Zn(TPA)(DMF)], which exhibited tunable PL colors from green to red and cyan to yellow (Yang and Yan, 2016a). To increase the lifetime of PL emission, deuterated coronene was introduced into the zeolitic imidazolate framework (ZIF). After being encapsulated within this coronene@ZIF, the non-radiative deactivation of the emitter was proven to be significantly reduced and finally enabled a long lifetime of up to 22.4 s (Mieno et al., 2016).

In addition, metal coordination polymer (CP) materials with conveniently tunable photoactive units and photo-emissive properties were also designed for PLMs. Yan et al. developed a series of Cd-based CPs by coordinating Cd^{2+} with 1,3-benzenedicarboxylic acid (BDC), which exhibited a noticeable

ultra-long afterglow of 0.70 s (Yang et al., 2016a). To achieve color-tunable PL in CPs, a lanthanide cations doping approach was developed (Yang and Yan, 2017; Yang et al., 2017). The doped Eu^{3+} and Tb^{3+}, which have a sufficiently broad absorption band, can capture energy from CPs and show an obvious red and green PL with lifetimes of 10.54 and 57.66 ms, respectively.

APPLICATIONS

Biomedicine

Bioimaging

As mentioned in the previous section, PLNPs, especially those with NIR emission, are ideal probes in bioimaging for ultra-long PL without tissue autofluorescence background, compared

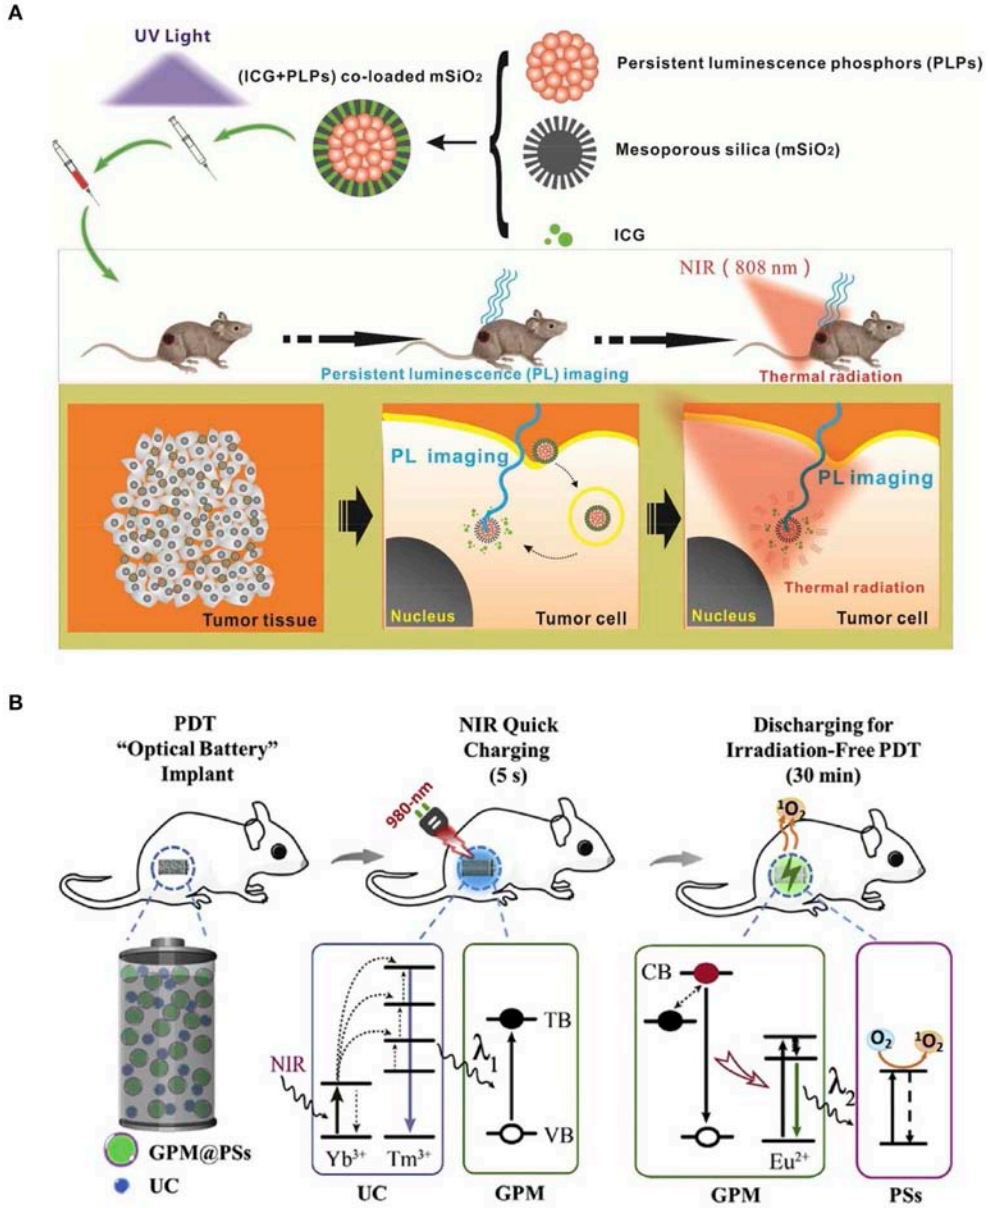

FIGURE 4 | (A) Photothermal therapy using ICG-PLPs@mSiO$_2$ (Zheng et al., 2016). **(B)** Photodynamic therapy using NIR light rechargeable UC-PLNPs (Hu et al., 2018). Reproduced with permission from ACS Applied Materials and Interfaces and Biomaterials, respectively.

with the conventional fluorescent probes such as quantum dots (Liu et al., 2018a). The first generation of PLNPs employed in *in vivo* imaging required pre-excitation by UV before being injected into the body (**Figure 3A**) (le Masne de Chermont et al., 2007). Instead of using short wavelength exciting light resources, the second generation of bioimaging PLNPs can be charged by visible lights, which enable their direct *in vivo* stimulation. Scherman et al. improved their results on living imaging by the synthesis of visible light stimulated $ZnGa_{1.995}Cr_{0.005}O_4$ PLNPs (ZGO) (Thomas et al., 2014a). The ZGO exhibited long-last NIR luminescence excited by orange/red light-emission diode (LED). Following the injection of RAW 264.7 cells with intracellular ZGO, based on the PL signals activated by LED the cells could be traced real-time *in situ* for more than 24 h. To fully exploit the tissue transparency widows in the NIR region, hybrids designs of upconversion materials and PLNPs became widely used. In 2017, Zeng and coworkers reported a combination of upconversion and PL based on the construction of upconversion-PLNPs ($Zn_3Ga_2GeO_8$:Yb/Er/Cr) (**Figure 3Bi**) (Zeng et al., 2017). Due to the upconversion effect, the nanocomposites can be excited by a 980-nm laser and emit 700 nm light, which can be absorbed and stored by PLNPs to produce NIR emission signals.

Furthermore, studies demonstrated rechargeable *in vivo* PL for a duration of more than 10 h, which can achieve actual NIR-to-NIR bioimaging (**Figures 3B**ii,iii).

Therapy

By exploiting the PLMs irreplaceable optical nature, the PL-based theranostic applications typically combined with other therapeutic materials, can be implemented in imaging-guided chemotherapy, photothermal therapy (PTT), and photodynamic therapy (PDT) (Liu et al., 2018a; Sun et al., 2018). In 2014, Richard et al. proposed a hybrid nanostructure containing $ZnGa_{1.995}Cr_{0.005}O_4$ PLNPs and mesoporous silica as an anticancer drug delivery system (Thomas et al., 2014b). The doxorubicin-loaded ZGO@SiO_2 potently inhibited the growth of U87MG cells than the empty vectors *in vitro*. The *in vivo* transportation process was monitored in real-time. As the only FDA-approved water-soluble photothermal agent, indocyanine green (ICG) is often used in PTT systems. Chang et al. presented a novel design combining ICG and PLPs@mSiO_2 (Zheng et al., 2016). Composite materials, exhibiting both PL and photothermal conversion properties, are suitable for imaging-guided PTT (**Figure 4A**). The PL-based PDTs use a combination of PLMs and photosensitizers, which can generate cytotoxic singlet oxygen to damage the targeted cells. Zhang et al. developed a PLMs-based irradiation-free photodynamic therapeutic method by integrating the advantages of PLMs, upconversion materials, and photosensitizer (**Figure 4B**) (Hu et al., 2018). The combination of $NaYF_4$:25%Yb, 0.5%Tm upconversion materials and $SrAl_2O_4:Eu^{2+},Dy^{3+}$ PLMs enabled green PL excited by NIR. By absorbing these persistent green lights, the attached rose bengal (RB) photosensitizers were able to continuously produce singlet oxygen. Owing to the high transparency of NIR and the renewability of inner PL, the implanted material, such as an optical battery, can implement effective PDT for *in vivo* tumor suppression.

Biosensing

In 2011, Yan et al. introduced a PLNP system for biosensing (Wu et al., 2011). They combined PLNPs (Eu^{2+}- and Dy^{3+}-doped $Ca_{1.86}Mg_{0.14}ZnSi_2O_7$) and gold nanoparticles (Ab-AuNPs) modified by α-fetoprotein (AFP) antibody for the detection of AFP in tumor cells (**Figure 5A**i). The AFP is a serum glycoprotein secreted by hepatic cells in newborn period only. The abnormal increase of AFP in the serum can strongly indicate several types of cancerization. The conjugation of PLNPs and Ab-AuNPs results in an FRET attributed to the overlap of PL emission and the AuNP absorption spectra. In this process, the excited energy is captured in the FRET system, which annihilates the emitted light of the nanocomposites. While introduced to AFPs, the competing antibody-antigen bonds released the PLNPs from the AuNPs, which produces long-lasting luminescence. By avoiding the *in situ* excitation, the PLNPs-based nanosystem exhibits high signal-to-noise ratio (SNR) and excellent sensitivity for the quantitative detection of AFP in serum samples and cancer cells with a minimum detectable concentration of 0.41 μg/L (**Figure 5A**ii). Yuan et al. developed a controllable hydrothermal synthesis method to obtain PL nanorods (PLNRs) functionalized for serum lysozyme analysis (**Figure 5B**i) (Wang et al., 2017b). The further functionalization of PLNRs comprised two important parts: lysozyme-binding aptamers and a special

FIGURE 6 | (A) Pattern designed with different phosphors and demonstration of multilevel anti-counterfeiting using MCzT, PCzT, BCzT, and FCzT crystals (Gu et al., 2018). **(B)** Photographs of handwritten characters on a cigarette case under a UV lamp (254 nm) and after the lamp is switched off (Gao et al., 2017). **(C)** Typical objects stamped with orthogonal multicolor UCPL materials and the luminescence images when the 980-nm excitation is switched on and off (Hu et al., 2017). DNA segment for luminescence quenching. The detachment of the DNA quencher together with the specific binding of lysozyme and the aptamer recovered the PL of PLNRs. The accuracy of lysozyme detection was comparable to that of ELISA in three clinical cancer samples with minimum a detectable concentration of 0.31 μM in a normal donor (**Figure 5Bii**).

Information Technology

Anti-counterfeiting

With the rapid development of science and technology, innovative anti-counterfeiting technologies are highly pursued under the situation of increasing counterfeiting activities. In recent years, anti-counterfeiting technologies based on PLMs have received significant attention owing to their properties of high emission intensities and long recognizable time.

Their direct coverage capability on various substrates enables the application of the great potential of organic PLMs in anti-counterfeiting technologies (Deng et al., 2013; An et al., 2015; Jiang et al., 2016; Yang et al., 2016b; Xue et al., 2017). In 2018, Huang and co-workers prepared a series of organic PLMs with controllable tuning of PL photoactivation and deactivation times by customizing the alkoxy chains (Gu et al., 2018). The PL of these molecular compounds can be activated by prolonged photo irradiation, and can be deactivated by thermal treatment

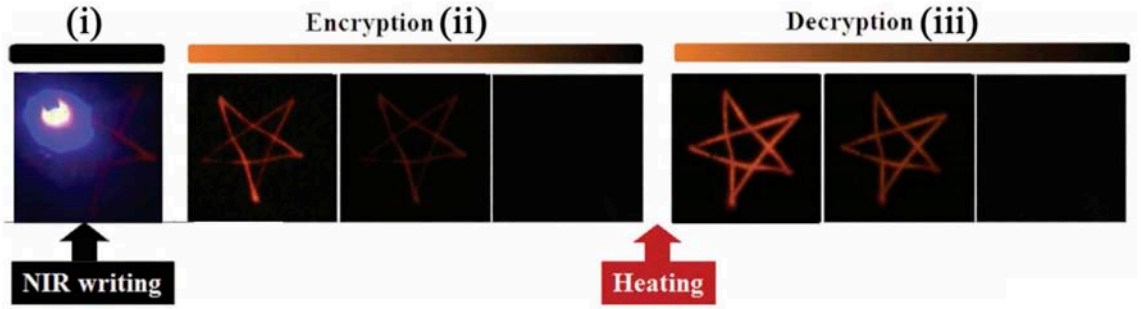

FIGURE 7 | NIR-writing encryption process and heat-induced decryption process (Hu et al., 2017). Reproduced with permission from Advanced Optical Materials.

or UV irradiation for 3 h. Considering the unique dynamic PL features of these materials, the pattern "8," which was built by different crystalline molecular compounds, could be converted into various digital numbers or letters of "8," "11," "I," "H," "E," and "C" under different irradiation or stoppage irradiation conditions (**Figure 6A**). Gao et al. developed a layered double hydroxides based polymer (PMA/LDH@PAA) thin film with a tunable PL color for anti-counterfeiting applications (Gao et al., 2017). The transparent PMA/LDH@PAA was written on a cigarette case and the writing became invisible after thorough drying (**Figure 6B**). Upon UV irradiation, the bright blue word appeared. However, the PMA/LDH@PAA anti-counterfeiting mark was still apparent after the termination of UV irradiation, whereas the proprietary markers disappeared immediately.

Compared with organic PLMs, inorganic PLMs with longer PL time and higher emission intensity are more suitable to realize anti-counterfeiting recognizable with the naked eyes. In 2018, Liu et al. synthesized a series of $NaBaScSi_2O_7$-based phosphor with photoluminescence (PhL), PL, and photostimulated luminescence (PsL) properties using co-doped $Eu^{2+}/Nd^{3+}/Pr^{3+}$ ions (Liu et al., 2018b). Under different light excitation conditions (the excited UV or 980-nm light was switched on or off), a difference in the emission colors of PhL, PL, and, PsL was represented by the different release processes of the carriers. Therefore, multiplex anti-counterfeiting was achieved by simply changing the doping of rare-earth ions in a single matrix. With the introduction of a novel NIR rechargeable orthogonal multicolor UCPL, an orthogonal anti-counterfeiting technique was developed by our research group (Hu et al., 2017). Using a simple method of stamp or modified inkjet printing, these composites enable high-speed patterned deposition on various mediums such as plastic, paper, or ceramics (**Figure 6C**). Each anti-counterfeiting letter formed has two sets of independent orthogonal emission colors recognizable with the naked eye: a multicolor upconversion luminescence when 980-nm NIR is switched on or a multicolor PL when it is switched off, which can be easily detected by a smartphone.

Optical Data Recording

Due to the energy storing capability of the deep traps, a part of the excitation energy is stored for a long time after being exposed to the light. Then, this portion of the energy can be stimulated released by optical, thermal, or mechanical force, which results in emissions and long PL. Therefore, the special phenomenon of thermo-luminescence, photostimulated luminescence, and mechanoluminescence can be applied in information write-in and read-out processes. Our research group has constructed a data-recording device based on the NIR-rechargeable upconversion PLMs (Zhuang et al., 2018). This device was fabricated by simply dispersing PLMs into polydimethylsiloxane to form a film. A 980-nm laser was used as a "pen" to encode date on the device. Following the stopping of writing, this information faded gradually and disappeared completely. However, a portion of energy obtained from the pen was stored in deep electron traps and did not discharge under normal environment for a long time. Then, under heat treatment, the recorded information could be decrypted and appeared instantly with bright PL for a duration of 1 min, due to the thermo-luminescence properties (**Figure 7**). Light-luminescence properties were also used to developed data storage devices. Recently, Xie et al. fabricated flexible phosphor films by encapsulating a series of deep-trap PLMs with multicolor emissions into silica gel (Zhuang et al., 2018). The information was conveniently encoded to the film using a 405-nm laser and the decoding process was conducted by scanning with a 980-nm laser.

CONCLUSIONS AND PROSPECTS

As promising luminescent agents, PLMs have drawn wide attentions owing to their ultra-long afterglow. In this review, we discussed the crucial breakthroughs and latest developments of different PLMs for diverse biomedical and informational applications. Inorganic PLMs with stable, potent and super-long PL were formed via effective traps and strong emitters. To overcome the low dispersibility and biocompatibility and the complexity of production, organic PLMs, consisting of purely small molecules and polymers PLMs, have been investigated.

Considering the advantages of eliminating the *in situ* excitation, PLMs exhibit enormous potential for bioimaging with super-long decay time and high SNR. Moreover, with appropriate functionalization, PLMs are ideal platforms to establish multifunctional systems in imaging-guided delivery and theranostics. Nevertheless, owing to the long reading window

provided by the PL property, PLMs also possess great potential in informational technologies, such as data storage and anti-counterfeiting.

However, for the more convenient applications of PLMs, there are still several problems need to be solved. Firstly, achieving long and strong PL synchronously poses a major challenge, because strong PL requires high radioactive decay rate at the cost of a short PL. To address this problem, the radioactive decay rate needs to be moderate and the excitation transformation needs to be sufficiently efficient. However, neither of these can be realized experimentally. Secondly, for the more efficient application in bioimaging, the stable PL of inorganic or organic PLNPs in aqueous solution is essential. In addition, the color range needs to be broadened, because various visible lights are beneficial in informational applications, and efficient excitation and emission wavelengths in NIR are favorable in biomedical applications.

In conclusion, a thorough interdisciplinary understanding of chemistry, materials science, biomedicine, and information technology is required for the breakthroughs and improvements of PLMs. This emerging and promising interdisciplinary understanding of these disciplines further promotes the application of PLMs in all fields of human society.

Dynamic materials have been given an increased amount of attention in recent years with an expectation that they may exhibit properties on demand. Especially, the combination of fluorescent quantum dots (QDs) and light-responsive organic switches can generate novel photo-switchable materials for diverse applications. In this work, a highly reversible dynamic hybrid system is established by mixing dual-color emitting Mn-doped CdS-ZnS quantum dots (QDs) with photo-switchable diarylethene molecules. We show that the diarylethene 1,2-bis(5-(3,5-bis(trifluoromethyl)phenyl)-2-methylthiophen-3-yl)cyclopent-1-ene (switch molecule **1**) performs fabulous photo-switching property (between its open, **1o** and closed, **1c** forms), and high fatigue resistance in this hybrid system. The emission color switching between blue and pink of the system can be induced mainly by selective quenching/recovering of the Mn- photoluminescence (PL) of the QDs due to the switchable absorbance of the molecule **1**. Mechanistic studies show that quenching of QD emission following UV illumination was caused by both Förster resonance energy transfer (FRET) and reabsorption by surrounding **1c** molecules in the case of the Mn-PL, and solely by reabsorption in the case of badngap- (BG-)PL. This photo-switchable system could be potentially used in applications ranging from self-erasing paper to super-resolution fluorescence imaging.

Keywords: reversible photo-switching, dual-color, Mn-doped CdS-ZnS quantum dots, diarylethene switches, förster resonance energy transfer (FRET), photon reabsorption

INTRODUCTION

Dynamic materials have attracted attention of chemists in the past two decades owing to their potentials to be used for generating responsive materials for various applications (Kay et al., 2007; Grinthal and Aizenberg, 2013; Klajn, 2014). Meanwhile, there is comprehensive development in the syntheses of nanocrystals with controlled size, shape, structure and compositions in various material systems (Gilroy et al., 2016; Pietryga et al., 2016; Talapin and Shevchenko, 2016; Wu et al., 2016). Combining organic molecular switches with inorganic nanocrystals can therefore afford dynamic hybrid systems with switchable properties (Klajn et al., 2010; Qu et al., 2015; Bai et al., 2016; Li et al., 2017). Compared to static counterparts, dynamic materials exhibit intriguing advantages including selectively reversible properties with external stimuli, and thus potential

applications in various fields including self-erasing paper (Kundu et al., 2015), self-healing coating (Roy et al., 2015) bio-imaging etc. (Zhang et al., 2012). Among diverse stimuli, light has been favored as an external input to tune the state of materials on account of its non-chemical contaminations, convenient delivery and specificity of desired wavelengths. As a result, a variety of photo-switchable molecules such as azobenzenes (Bandara and Burdette, 2012), spiropyrans (Minkin, 2004), dithienylethenes (Irie, 2000; Irie et al., 2014), stilbene (Momotake and Arai, 2004) etc. have been employed to functionalize different nanomaterials (Yildiz et al., 2009; Klajn et al., 2010; Wang and Li, 2018) to construct light-responsive systems spanning from metal nanocrystals (Kundu et al., 2015; Manna et al., 2015; Zhao et al., 2015), metal oxide nanocrystals (Mikami et al., 2004; Min Yeo et al., 2008), to quantum dots (QDs) (Zhu et al., 2005, 2006; Díaz et al., 2011, 2015) and metal-organic frameworks (MOFs) (Dolgopolova et al., 2018).

In materials science, doping is a process that intentionally introduces impurity atoms as dopants to host lattices, thus providing unique properties inaccessible to conventional materials (Bryan and Gamelin, 2005). In this regard, doping in QDs may exhibit improved optical, magnetic and electronic properties as compared to their undoped counterparts (Yang et al., 2006; Pradhan and Peng, 2007; Bussian et al., 2008; Norris et al., 2008; Zheng and Strouse, 2011; Cai et al., 2018; Kroupa et al., 2018; Li et al., 2018). For example, when introducing transition metals or rare earth elements to the QDs, a new emission band may emerge, resulting a dual-color emission property with two tunable non-overlapping photoluminescence (PL) peaks (Wu and Yan, 2013). To this extent, Mn-doped CdS-ZnS QDs have been extensively studied as a model system for both fundamental understanding of host-to-dopant energy transfer processes and practical applications that are utilizing their dual-color emission properties (Yang et al., 2006, 2008; Chen O. et al., 2010; Chen et al., 2012; Hofman et al., 2017; Pradhan et al., 2017).

Taking advantages of the dynamic switchable absorbance of diarylethene molecules and the dual-color emission property of Mn-doped CdS-ZnS QDs, in this work, we demonstrate a photo-switchable hybrid system by selectively quenching/recovering the Mn dopant emission. The quenching process is shown to include Förster resonance energy transfer (FRET) from Mn-PL to closed isomer of diarylethenes as well as reabsorption processes. Three diarylethene switches with different electron-withdrawing groups were exploited to examine the performances of the photo-switching process. We demonstrate that the switch diarylethene molecule with substituent of 3,5-bis(trifluoromethyl)phenyl (switch **1**) afford the best fatigue-resistant performance. PL color switching between blue and pink can be obtained by sequential illumination of UV (365 nm) and visible (590 nm) light. This switchable dual-color dynamic system could be potentially useful in a broad range of applications.

MATERIALS AND METHODS

Materials

All chemicals were used without further purification. 2-Chloro-5-methylthiophene (> 96.0%) was purchased from TCI Chemicals. Tributyl borate (98%) was purchased from Strem Chemicals. 1-Bromo-3,5-bis(trifluoromethyl)benzene (99%), *n*-butyllithium (1.6 M solution in hexanes, AcroSeal), zinc dust (98+%), and tetrahydrofuran (THF, 99.9%, extra dry, stabilized, anhydrous, SC, AcroSeal) were purchased from Acros Organics. Tetrakis(triphenylphosphine) palladium(0) ($Pd(PPh_3)_4$, 99%), glutaryl chloride (97%), $TiCl_4$ (99.9% trace metals basis), sulfur powder (99.999%), 1-octadecence (ODE, tech. 90%), and oleylamine (OAm, tech. 70%) were purchased from Aldrich. Manganese acetate tetrahydrate (99%), sodium carbonate (99.8%), and all the solvents were purchased from Fisher Scientific Company. Ethyl 4-bromobenzoate (98+%), $AlCl_3$ (anhydrous, 99.985%), cadmium acetate hydrate (99.999%), cadmium oxide (99.998%), zinc stearate (count as ZnO ≈ 14%), oleic acid (OLA, 90%) and selenium (200 mesh, 99.999%) were purchased from Alfa Aesar. Nitric acid (≥69.5%, TraceSELECT) was purchased from Fluka. 4-bromo-pyridine hydrochloride (98%) was purchased from Matrix Scientific. Cadmium myristate was self-made according to the literature method (Chen et al., 2008).

Synthesis of Diarylethene Molecules

Diarylethenes were synthesized using a previous established route with minor modifications (see **Supplementary Material**) (Tam et al., 2011). The reactions were carried out using Schlenk line under dry N_2 flow. *n*-Butyllithium (1.6 M in hexane, 1.3 mL) was added to a solution of 1,2-bis(5-chloro-2-methyl-3-thienyl)cyclopentene (see **Supplementary Material** for the synthesis, 1.0 mmol) in THF (15 mL) at room temperature. After stirring for 15 min, tributyl borate (3.0 mmol) was added and followed by stirring for another 1 hr. In another flask, DMSO (25 mL) was added and degassed, then 1-bromo-3,5-bis(trifluoromethyl)benzene (2.2 mmol) and $Pd(PPh_3)_4$ (0.02 mmol) were added. After stirring for 15 min, aqueous Na_2CO_3 (2 M, 5 mL) and ethylene glycol (0.5 mL) were added. The mixture was heated up to 60°C after stirring for 15 min, then was added the above prepared solution. The resulting mixture was stirred at 80°C overnight. After cooling to room temperature, 50 mL of water was added and the mixture was extracted with 20 mL of ethyl acetate three times. The combined organic phases were washed with brine, dried over Na_2SO_4 and evaporated. Purification by flash column chromatography afforded compound 1,2-bis(5-(3,5-bis(trifluoromethyl)phenyl)-2-methylthiophen-3-yl)cyclopent-1-ene (**1o**) (32%) as a pale white solid (Herder et al., 2015). **^{1}H-NMR (400 MHz, $CDCl_3$):** δ (ppm) = 7.86 (br s, 4 H, CH_{ar}), 7.71 (br s, 2 H, CH_{ar}), 7.14 (s, 2 H, CH_{th}), 2.88 (t, $J_{H,H}$ = 7.4 Hz, 4 H, CH_2), 2.14 (p, $J_{H,H}$= 7.2 Hz, 2 H, CH_2), 2.06 (s, 6 H, CH_3). Compound 1,2-bis(2-methyl-5-(pyridin-4-yl)thiophen-3-yl)cyclopent-1-ene (**2o**, in **Supplementary Material**) was prepared by exchanging 1-bromo-3,5-bis(trifluoromethyl)benzene with 4-bromo-pyridine hydrochloride (Tam et al., 2011). ^{1}H-NMR (400 MHz, $CDCl_3$): δ (ppm) = 8.53 (d, $J_{H,H}$ = 6.0 Hz, 4H, CH_{ar}), 7.39 (d, $J_{H,H}$ = 6.4 Hz, 4H, CH_{ar}), 7.25 (s, 2H, CH_{th}), 2.86 (t, $J_{H,H}$ = 7.4 Hz, 4H, CH_2), 2.12 (m, 2H, CH_2), 2.03 (s, 6H, CH_3). Compound 4,4′-(cyclopent-1-ene-1,2-diylbis(5-methylthiophene-4,2-diyl))dibenzoic acid (**3o**, in

Supplementary Material) was obtained by switching 1-bromo-3,5-bis(trifluoromethyl)benzene to ethyl 4-bromobenzoate to perform the Suzuki reaction and followed by hydrolysis with 4 M NaOH aqueous solution in dioxane (Mulder et al., 2004; Herder et al., 2015). **^{1}H-NMR (400 MHz, $CDCl_3$):** δ (ppm) = 7.99 (d, $J_{H,H}$ = 8.8 Hz, 4 H, CH_{ar}), 7.53 (d, $J_{H,H}$ = 8.8 Hz, 4 H, CH_{ar}), 7.14 (s, 2 H, CH_{th}), 4.37 (q, $J_{H,H}$ = 7.2 Hz, 4 H, CH_3CH_2O), 2.85 (t, $J_{H,H}$ = 7.4 Hz, 4 H, CH_2), 2.10 (p, $J_{H,H}$ = 7.4 Hz, 2 H, CH_2), 2.01 (s, 6 H, CH_3), 1.39 (t, $J_{H,H}$ = 7.2 Hz, 6 H, CH_3CH_2O). **^{1}H NMR (400 MHz, DMSO-d^6):** δ (ppm) = 12.86 (s, 2H), 7.92 (d, $J_{H,H}$ = 8.0 Hz, 4 H, CH_{ar}), 7.67 (d, $J_{H,H}$ = 8.0 Hz, 4 H, CH_{ar}), 7.48 (s, 2H, CH_{th}), 2.84 (t, $J_{H,H}$ = 7.6 Hz, 4 H, CH_2), 2.07 (m, 2H), 1.92 (s, 6H).

Synthesis of Mn-Doped CdS-ZnS Core-Shell QDs

Mn-doped CdS-ZnS core-shell QDs were prepared following the reported method with minor modifications (Yang et al., 2008). First, CdS core QDs were prepared using a direct heating-up method. In a typical synthesis, cadmium myristate (1.0 mmol), sulfur (0.5 mmol), and ODE (50 mL) were added to a 100 mL-flask. The resulting mixture was degassed at room temperature for 10 min, and then was heated to 240°C under N_2 flow. The reaction was stopped by removing heating mantle and cooling to room temperature. The resulting CdS QDs were precipitated with addition of acetone, following by centrifugation and then were redispersed in hexane. A small amount of OLA can be added to assist QDs to disperse in hexane. The CdS QDs were dispersed in hexane as a stock after purified for three times. Second, ZnS shells were grown on the CdS cores using a layer by layer injection method. Typically, CdS cores (100 nmol) were mixed with ODE (3 mL) and OAm (1 mL), and the resulting mixture was degassed for 1 h at room temperature and then heat up to 220°C under N_2 flow for ZnS growth. Zinc-stearate in ODE (0.1 M) and sulfur in ODE (0.1 M) were injected simultaneously for each monolayer growth of ZnS shell. The reaction time was 10 min after each injection. The growth for first two monolayers ZnS shells was at 220°C and then was at 280°C for later growth. Third, dopant growth was performed in the same pot with ZnS shells growth. Freshly made $Mn(OAc)_2$ solution (5 mM) was injected after five monolayers of ZnS shells growth, accompanying the injection of sulfur precursor for the six monolayer. Dopant growth was allowed for 20 min and was followed by the growth of two more ZnS shells. Finally, zinc-stearate solution for the last monolayer ZnS shell growth (0.1 M, 2 mL) was injected and then the QDs were annealed at 240°C for 30 min. The resulting Mn-doped QDs were purified by three precipitation-redispersion cycles using acetone and hexane.

RESULTS AND DISCUSSIONS

We have synthesized diarylethene switch molecule featuring with electron withdrawing group of 3,5-bis(trifluoromethyl)benzene (**1**) as shown in **Figure 1A**. The ring-open isomer (**1o**) and ring-closed isomer (**1c**) can be interconverted by illumination with UV and visible light showing drastically different absorption feature. Specifically, compared to the open form (**1o**), whose π-conjugation is restricted to each half of the molecule, the

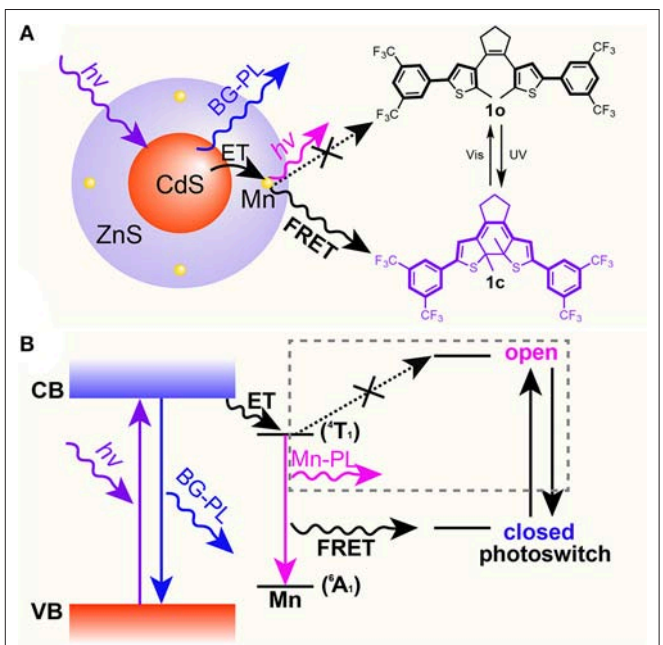

FIGURE 2 | Scheme **(A)** and energy diagram **(B)** of proposed mechanism for the selective Mn-PL quenching between Mn-doped CdS-ZnS core-shell QDs and diarylethene **1** molecules.

closed form (**1c**) possesses extended π-conjugation across the entire molecule. This extended conjugation places the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) of the molecule closer, thus allowing the absorption profile red-shift correspondingly (Kuhn, 1949). UV-visible absorption spectra of the open and closed isomers (**1o** and **1c**) of diarylethene **1** are shown in **Figure 1B**. The open form (**1o**) as prepared only shows absorbance at wavelengths shorter than 380 nm. After illumination with UV light, the molecule turns into the closed isomer (**1c**) and a pronounced absorption peak appears in the visible range (420–650 nm). It should be noted that there is minimal absorbance from both isomers (**Figure 1B**), indicating a nearly transparent window in the range of 400–420 nm. This photo-switchable absorption feature motivated us that a dynamic emitting architectural construct can be achieved when modulated with appropriate dual-color emitting fluorophores.

As mentioned above, high-quality dual-color emitters can be obtained by doping transition metals or rare earth elements in QD lattices. Among them, Mn-doped CdS-ZnS QDs have been robustly synthesized and extensively studied (Yang et al., 2006, 2008, 2009; Chen O. et al., 2010; Chen et al., 2012). When excited with high energy photons, an electron-hole pair (an "exciton") is created and confined inside the Mn-doped QD. This exciton can be radiatively deactivated through either recombination at the CdS-ZnS core-shell QD band edge to give a corresponding blue BG emission, or energy transfer to Mn dopants and subsequently emit a lower energy photon from the $^4T_1$ to $^6A_1$ states of the Mn ions (**Figure 2**) (Yang et al., 2009; Chen H.Y. et al., 2010). Most importantly, their dual-color emission bands can be adjusted to match the dynamic absorption windows of the diarylethene **1** (**Figure 1**) (Ithurria et al., 2007; Chen O. et al., 2010; Chen et al., 2012). Therefore, we hypothesize that when mixing the well-designed Mn-doped CdS-ZnS core-shell QDs and the photo-switchable diarylethene molecules together, FRET from the excited state (i.e., $^4T_1$) of Mn to the switches can be turned on and off in the closed (**1c**) and open (**1o**) forms, respectively (**Figure 2**). Thus, the system would show a combined color of both BG- and Mn-PL of the QDs while the diarylethene **1** stays at the open form (**1o**) and show the emission color mostly from BG-PL when the diarylethene **1** turns into the closed form (**1c**) (**Figure 2**). This color switching process could be simply modulated by illuminating with UV or visible light.

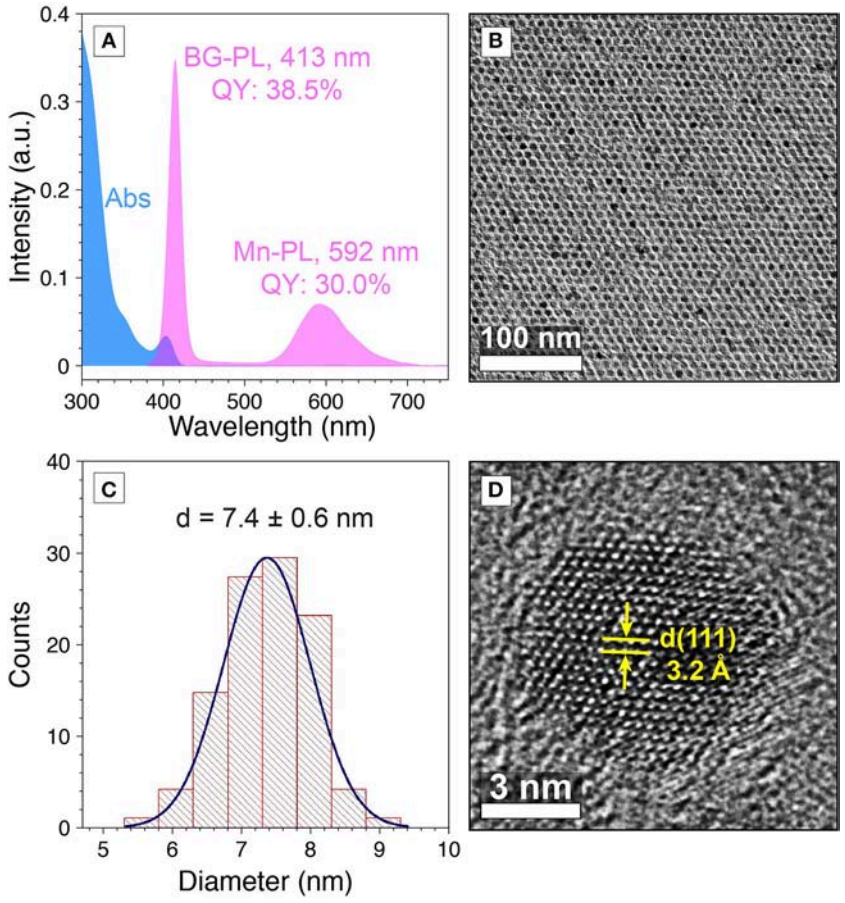

FIGURE 3 | (A) Absorption (blue) PL (pink) spectra, and **(B)** TEM image of Mn-doped CdS-ZnS core-shell QDs. **(C)** Size distribution histogram of Mn-doped CdS-ZnS core-shell QDs. **(D)** HR-TEM image for a Mn-doped CdS-ZnS core-shell QD.

To test our hypothesis, we designed and synthesized Mn-doped CdS-ZnS core-shell QDs with desired emission bands to match with the absorption profiles of the diarylethene **1**. In particular, the BG-PL centered at 413 nm with a full width at half maximum (FWHM) of 16 nm (PL QY of 38.5%) was achieved by controlling the CdS core size and ZnS shell thickness (see materials and methods for details) (**Figure 3A**). This BG-PL lays in the transmission window of the switch molecule disregarding to the open or closed form (**Figure 1B**). Meanwhile, in order to achieve a large spectral overlap between the Mn-PL and absorption feature of the **1c**, Mn-PL centered at 592 nm (PL QY of 30.0%) was accessed by doping Mn ions closer to the surface of the QDs, thus minimizing the local strain of Mn impurities (**Figure 3A**) (Ithurria et al., 2007). The Mn-to-BG PL intensity ratio was determined to be 0.24 (**Figure 3A**). Transmission electron microscopy (TEM) measurements showed the resultant QDs exhibited a spherical shape and a high morphological uniformity with an average

Inset: photograph for the mixture solution under UV light after UV (right) and visible (left) light illumination. **(C)** The ratio of Mn/BG-PL intensity during repetitive switching cycles with sequential UV (blue open circle) and visible (pink open circle) light illumination. **(D)** The PL intensity (solid lines) and integrated Mn-PL intensity (dotted lines) and **(E)** the corresponding Mn-PL lifetime changes during one switching cycle. **(F)** BG-PL lifetime decays after UV (blue) and visible (pink) light illumination.

diameter of 7.4 ± 0.6 nm (**Figures 3B, C**). High-resolution TEM (HR-TEM) image showed (111) plane with *d*-spacing of 3.2 Å (**Figure 3D**).

The prepared Mn-doped CdS-ZnS QDs and diarylethene **1** were employed to test the photo-switching property. It is shown that while both the BG- and Mn-PL are disjoint from the absorbance of **1o**, the BG-PL locates at the absorbance depression area and most of the Mn-PL overlaps with visible-range absorbance of **1c** (**Figure 4A**). We first tested the Mn-doped CdS-ZnS QDs under illumination of either UV or visible light without mixing with diarylethene **1** switches. Both BG- and Mn-PL intensities remained without any variation, indicating the robustness of the QD samples under light illumination. However, when mixing the same QDs with **1o** at a molar ratio of 1:500 in THF, the QD solution showed a pink color from the intact emission due to a minimal spectral overlap between the QD emission and the **1o** absorbance (**Figures 4A, B**). When illuminated with UV light (365 nm) for 90 s, a strong absorption feature arose in the visible range (420–650 nm, **Supplementary Figure 2a**), accompanying the decrease of the ratio of Mn/BG PL intensities from 0.24 to 0.02, corresponding to a change of the emission color from pink to blue (**Figure 4B** and **Supplementary Figure 2b**). The change of the PL intensity ratio is largely due to the dynamic Mn-PL quenching and recovering effect when the switch molecule alternates between closed (**1c**, quenching) and open (**1o**, recovering) forms (**Figure 4B**). Importantly, this observed photo-switching process is highly reversible. Ten photo-switching cycles were carried out to test the fatigue resistance of the switch molecule (i.e., diarylethene **1**), and the stability of the entire system. During these cycles, both the absorption spectra and the intensity ratios of the Mn/BG PL peaks showed excellent reversibility (**Figure 4C** and **Supplementary Figures 3, 4**), indicating a reliable photo-switching property of our designed system.

Two possible Mn-PL quenching/recovering mechanisms are attributable to the observed photo-switching property: 1) FRET from the excited state (i.e., $^4T_1$) of Mn dopant ions to the **1c** non-radiatively; 2) radiated photons of Mn-PL can be reabsorbed by the surrounding **1c**. To explore the origin of the observed Mn-PL quenching effect and their contributions, time-resolved PL lifetime measurements were carried out at different stage of the photo-switching process. When the integrated intensity of the Mn-PL decreased 60.1% of its initial value, the Mn-PL lifetime decreased from 5.99 to 5.16 ms, indicating that a 13.9% of the Mn-PL quenching can be attributed to FRET for the Mn-PL to the switch **1c** molecule in the measuring conditions (**Figures 3**, **4D,E**, see **Supplementary Material** for detailed calculation) (Medintz et al., 2003; Gu et al., 2008; Niebling et al., 2009; Tu et al., 2011; Krivenkov et al., 2019). Consequently, the rest 46.2% of Mn-PL quenching can be explained by the radiative photon reabsorption by surrounding **1c** molecule. A 31.0% of BG-PL integrated intensity decrease was also observed which again was contributed to the photon reabsorption due to the slight increase of the absorbance from the switch molecule (from **1o** to **1c**). No variance in PL lifetime (∼21 ns) of the BG-PL further confirmed the reabsorption process (**Figure 4F** and **Supplementary Figure 5**) without influencing the radiative photon recombination dynamics (Medintz et al., 2003). It is known that the efficiency of FRET process is strongly sensitive to the distance between donors and acceptors (inverse sixth power of the distance between donor and acceptor, typically within 1–10 nm) (Selvin, 2000). FRET process can happen only when the **1c** molecules reach to a close proximity (<10 nm) of the QD surface, which is in line with our experimental observation that only a small portion (13.9% of the total quenching) of the Mn-PL quenching is caused by FRET. Moreover, given the size of the QDs (i.e., 7.4 nm) and the doping radial location of the Mn dopants inside the QDs (at the interface between the 5th

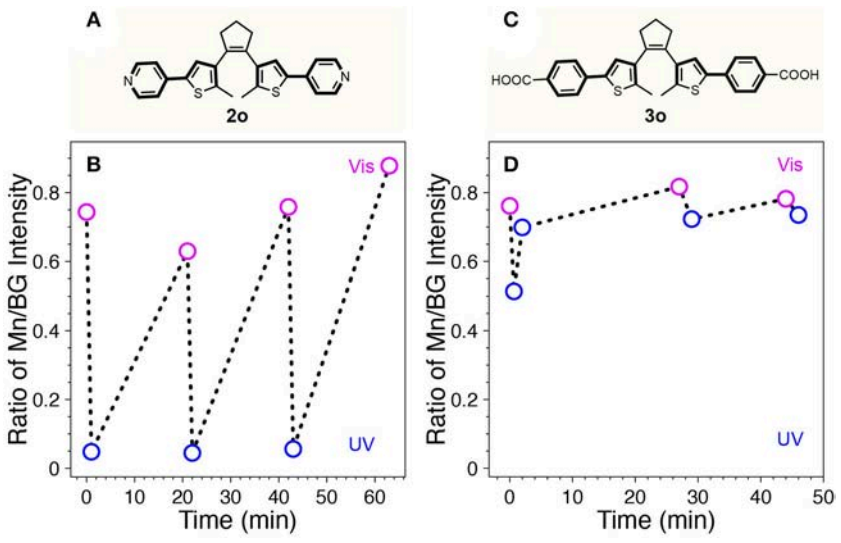

FIGURE 5 | Chemical structures of **2o (A)** and **3o (C)**. The ratio of Mn/BG-PL intensity of the mixture of Mn-doped CdS-ZnS QDs with **2o (B)** or **3o (D)** during repetitive switching cycles with sequential UV (blue open circle) and visible (pink open circle) light illumination.

and the 6th monolayer of the ZnS shell), the distances between the photo-generated exciton (electron-hole pair) center and the **1c** is 3.2 nm larger than that between the Mn ion and the **1c** the exciton center is determined at the center of core-shell QDs, (Yang et al., 2009). This larger distance will dramatically decrease the FRET efficiency between the exciton and **1c** as compared to that from Mn ion to **1c**. This again agrees well with the fact that the decrease of BG-PL is mostly attributable to the photon reabsorption process.

Recently, it was reported that a series of diarylethene switch molecules with electron withdrawing substituents on the adjacent phenyl rings could provide fatigue resistance due to minimized formation of annulated isomers (Herder et al., 2015). According to the study, two other diarylethene-based switches terminated with electron withdrawing groups of pyridine (diarylethene **2**) and 4-benzoic acid (diarylethene **3**) were synthesized and tested in our system (**Figure 5**). Diarylethene **2** was mixed with Mn-doped CdS-ZnS core-shell QDs possessing BG- and Mn-PL peaks at 414 and 600 nm, respectively. The absorption spectral evolution clearly indicated fatigue effect over only 3 cycles (**Supplementary Figure 6**). Accordingly, the BG- and Mn-PL were quenched after visible light illumination whereas the quenching effect was reduced after UV irradiation after cycles (**Supplementary Figure 7**). Since the BG-PL was more affected by the fatigue of diarylethene **2**, the ratio of Mn/BG intensity increased with 3 cycles (**Figure 5B**). Diarylethene photo-switch **3**, which possesses carboxylic groups at the para position of the phenyl rings, was expected to attach on the surface of QDs covalently. This direct attachment of the switch **3** molecules would significantly reduce the mean distance between QDs donor and switch acceptor, thus facilitate the FRET from QD to the **3** molecules. However, our result showed that while **3o** itself can be isomerized to the closed form (**3c**) under UV illumination, it irreversibly stays at its open form (**3o**) mostly after mixing with Mn-doped CdS-ZnS QDs (**Supplementary Figure 8**). It is shown that while the Mn/BG PL intensity ratio decreased with 40 s of UV illumination, it increased back with further UV illumination (**Figure 5D**). This phenomenon can be ascribed to the direct attachment of switch **3** to the surface of the QDs through the carboxylate functional group, thus leading to a close proximity of switch **3** to the QD surface constantly rather than a dynamic on-and-off process as for switches **1** and **2** cases. In this case, the visible Mn-PL of the QDs can trap the switch molecule **3** in its open form (**3o**), preventing them from turning into the closed form (**3c**). Consequently, no reversible photo-switching phenomenon can be observed as shown in **Figure 5D**, in good agreement with our experimental observations.

CONCLUSIONS

To conclude, we demonstrate a photo-switchable hybrid system with a reliable dual-color performance. This system combines photo-switchable diarylethene **1** molecule functionalized with strong electron withdrawing group of 3,5-bis(trifluoromethyl)benzene, and Mn-doped CdS-ZnS QDs with dual-emission band. Selective quenching/recovering of Mn-PL was achieved effectively, resulting in a pink and blue dual-color switching behavior under UV and visible light illumination. This photo-switching process is highly reversible and shows superior fatigue-resistance for at least 10 switching cycles. The mechanism studies using both steady-state and time-resolved PL spectroscopy reveal the PL quenching contributions from both FRET and photo-reabsorption processes. Moreover, we show that the involvements of other electron withdrawing functional groups (i.e., pyridine and carboxylate groups) limit the photo-switching property by significant molecular fatigue or irreversible optical effects. Our study sheds light on the fabrications of highly dynamic and photo-switchable hybrid systems that hold the potential in a broad range of applications spanning from self-erasing paper, biological-imaging to single molecule sensing/tracking and super-resolution imaging/localization microscopy.

Therapeutic proteins are widely used in clinic for numerous therapies such as cancer therapy, immune therapy, diabetes management and infectious diseases control. The low stability and large size of proteins generally compromise their therapeutic effects. Thus, it is a big challenge to deliver active forms of proteins into targeted place in a controlled manner. Nanoparticle based delivery systems offer a promising method to address the challenges. In particular, mesoporous silica nanoparticles (MSNs) are of special interest for protein delivery due to their excellent biocompatibility, high stability, rigid framework, well-defined pore structure, easily controllable morphology and tuneable surface chemistry. Therefore, enhanced stability, improved activity, responsive release, and intracellular delivery of proteins have been achieved using MSNs as delivery vehicles. Here, we systematically review the effects of various structural parameters of MSNs on protein loading, protection, and delivery performance. We also highlight the status of the most recent progress using MSNs for intracellular delivery, extracellular delivery, antibacterial proteins delivery, enzyme mobilization, and catalysis.

INTRODUCTION OF PROTEIN THERAPEUTICS AND MSNs

In 1922 the pancreatic insulin was successfully purified and applied for Leonard Thompson, a 14 years old boy suffering type 1 diabetes, which ushered in the era of protein therapeutics (Banting et al., 1991). Since then numerous protein drugs have been developed and used in various clinical applications. By 2008, 130 protein based therapeutics had been approved by the US Food and Drug Administration (FDA) and the number of approved protein drugs soared to 239 in 2017 (Leader et al., 2008; Usmani et al., 2017). In 2018, 7 of top 10 best-selling human drugs are proteins based ones (Urquhart, 2018). Those protein therapeutics comprise enzymes, monoclonal antibodies, vaccines, hormones, growth factors, tumor necrosis factors, etc., (Usmani et al., 2017). Protein based drugs are receiving growing interest due to their specific functions, less side effects, which are also considered safer than gene therapy as no genetic change happens (Gu et al., 2011). However, the wide applications of protein drugs are hindered due to their intrinsic drawbacks especially low stability. The folded characteristic 3 dimensional structures of proteins are essential for their biological functions, but the conformation is only slightly more stable than unfolded one. From an entropic point of view proteins are easy to be denatured (Villegas et al., 2018). In addition, some therapeutic proteins need to act inside cells, thus intracellular delivery of active forms of proteins into specific cells remains the main challenge of such proteins drugs (Ghosh et al., 2010; Gu et al., 2011).

The rapid development of nanotechnology provides a revolutionary way in the design of nanoparticle based drug delivery systems to protect proteins and deliver them to desired places. New formulations based on nanoparticles or nanostructures have already been used in the clinical setting (Peer et al., 2007; Davis et al., 2008) and have demonstrated enhanced efficacy and reduced side effects, due to the properties brought on by nanoscale effects (Muller et al., 2002; Torchilin, 2005; Naseri et al., 2015). Nowadays, the clinically available delivery systems are mainly organic materials such as liposomes and other lipid formulations and polymers (Gradishar et al., 2005; Sparreboom et al., 2005; Duncan, 2006; Greco and Vicent, 2009). However, the intrinsic instability and limited drug-loading capacity inhibit their applications for protein delivery (Elsabahy and Wooley, 2012; Chen et al., 2013).

Recently, the development of inorganic materials such as MSNs, quantum dots (Gao et al., 2004; Michalet et al., 2005), carbon-based nanomaterials (Liu et al., 2011; Robinson et al., 2011), layered double hydroxides (Bao et al., 2011; Yan et al., 2013; Kura et al., 2014) and magnetic nanoparticles (Arruebo et al., 2007; Sun et al., 2008) have attracted great attention due to their remarkably high chemical stability. Among this group of carriers, MSNs are of special interest because of their excellent biocompatibility, high drug loading capacity, rigid framework, well-defined pore structure, easily controllable morphology, and tuneable surface chemistry (Lind et al., 2003; Meng et al., 2011; Chen et al., 2013; Xu et al., 2014). The delivery of proteins using traditional MSNs is usually limited by the small pores. Recent development of MSNs with large pores and novel pore structures greatly expand their applications for protein therapeutics delivery (Shen et al., 2014; Knezevic and Durand, 2015; Xiong et al., 2015; Xu et al., 2015; Yang J. P. et al., 2015). In addition, with abundant surface modification, various responsive release systems based on MSNs have been developed with numerous advantages such as improved efficacy and reduced toxicity (Zhu et al., 2017). In this review, how to design MSNs for achieving effective protein loading, protection and delivery will be comprehensively reviewed. The progress of MSNs based protein therapy for various applications including intracellular delivery, extracellular delivery, antibacterial proteins delivery, enzyme mobilization and catalysis will be highlighted.

ENGINEERING MSNs FOR PROTEIN LOADING, PROTECTION, AND DELIVERY

Encapsulation of proteins within nanocarriers can overcome the shortcomings of proteins such as poor solubility, poor stability, difficulty in crossing the cell membranes and lack of specificity. In addition, nanocarriers enable the delivery of unique drug combinations which are important for personalized medicine (Mura and Couvreur, 2012; Kim et al., 2013). Compared to current clinically used organic nanocarriers such as liposomes, MSNs can achieve higher protein loading capacity due to their large pore size, high surface area and large pore volume. In addition, it is reported that the solid frame of MSNs would protect the proteins from denaturation (Kao et al., 2014). A large number of MSNs with different structures, morphology, and surface functionalization have already been designed and applied for drug delivery (Carino et al., 2007; Vallet-Regi et al., 2007; Angelos et al., 2008; Wang, 2009; Manzano and Vallet-Regi, 2010; Yang et al., 2012; Chen et al., 2013; Shen et al., 2013; Siefker et al., 2014; Dai et al., 2017). In the following part, the effects of pore size, surface functionalization, pore structure, pore volume and surface area on the protein loading and protection ability are reviewed.

Pore Size

In order to load proteins into the mesopores, the pore sizes of MSNs usually need to be larger than the protein molecule dimensions. MSNs with larger pore sizes usually have higher drug loading amounts and faster release rates compared to the ones with small pores, which may be due to a steric hindrance effect (Vallet-Regi et al., 2008; Cirujano et al., 2017). In one study when the pore sizes of SBA-15 were varied from 8.2 to 11.4 nm, the bovine serum albumin loading ability was increased from 15 to 27% (Vallet-Regi et al., 2008). Zhang et al. (2014) prepared a series of hydrophobic silica vesicles with different entrance sizes ranging from <3.9 to 34 nm (<3.9, 6, 8, 13, 16, 24, 33, 34 nm) and tested the loading capacity of RNase A (with dimension of 2.2*2.8*3.8 nm). Silica vesicles with pore size of 6 nm exhibited the highest RNase loading amount (563 mg/g), which was almost double of that achieved by silica vesicles with small pores (<3.9 nm) or large pores (>13 nm). This effect was also observed in other mesoporous structures such as MCM-48 with a 3D cubic pore structure. MCM-48 with a pore size of 5.7 nm exhibited a higher loading capacity of ibuprofen (IBU) compared to the one with 3.6 nm pores, and a faster release rate (Izquierdo-Barba et al., 2005).

The enhanced activity and stability of proteins, once loaded inside the pores of MSNs, have been well-documented. Kao et al. (2014) studied the activity and stability of lysozyme immobilized in MSNs of various pore sizes by testing the proteins' secondary and tertiary structures with methods such as circular dichroism and activity assay. The activity of the lysozyme when immobilized in the pores of MSNs (pore size close to protein dimensions) was higher than that of native one. In addition, the enzymatic activity was also improved by MSNs from thermal denaturation (**Figure 1**, Kao et al., 2014). Kalantari also reported the immobilization of another enzyme, lipase, into MSNs with tunable pore size (from 1.6 to 13 nm). They concluded that suitable pore size (slightly larger than the size of lipase) is responsible for the loading and the performance of lipase. The MSNs with optimized pore size exhibited a high loading capacity of 711 mg g^{-1}, and an 5.23 times specific activity higher than that of the native enzyme (Kalantari et al., 2017).

Since the pore size of MSNs plays a critical role for the loading and release of protein, methods to control the pore size distribution should be briefly reviewed. Traditionally two ways have been developed to expand the pore size, utilizing polymers/surfactants with longer carbon chains/co-surfactants as template or adding suitable organic agents (swelling agents) to increase the sizes of surfactant templates (Knezevic and Durand,

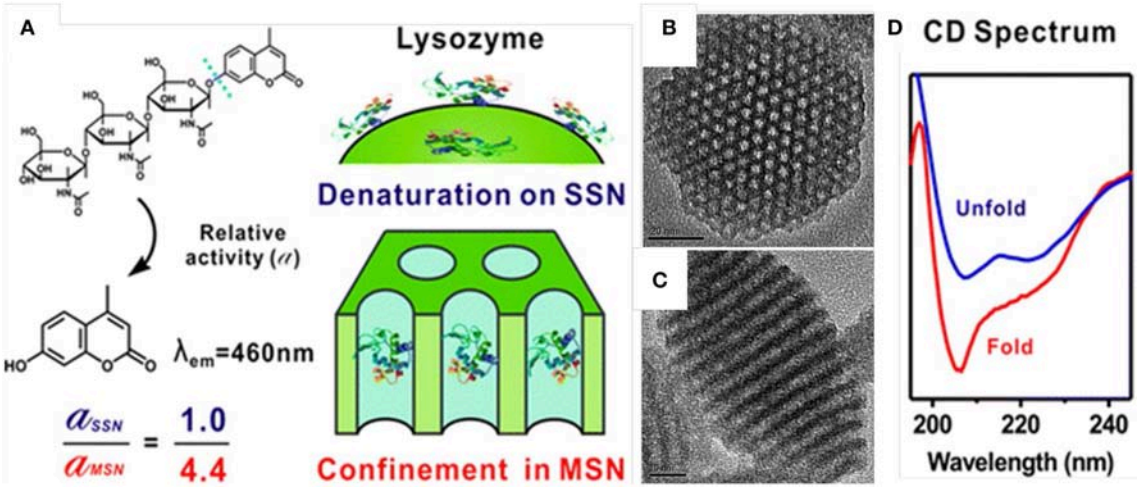

FIGURE 1 | Enhanced stability and activity of lysozyme after loaded inside the mesopores of MSNs. 2015). For the first strategy, the most typical example is the synthesis of SBA-15 using amphiphilic block copolymers as templates, and the pore size can achieve up to 10 nm (Zhao et al., 1998). For the second strategy, 1,3,5-trimethylbenzene (TMB) is the most common pore-expanding agent (Huo et al., 1996; Feng et al., 2000) and the pore size of MSNs can be enlarged in a large range with addition of TMB. It is noted that excessive addition of swelling agents may result in the loss of structure (Knezevic and Durand, 2015). Very recently, MSNs with radial pore structures (Polshettiwar et al., 2010; Shen et al., 2014; Du and Qiao, 2015; Wang et al., 2019) provide another strategy in the synthesis of MSNs with large pores. The pore size can be expanded to 50 nm or even larger (Xu et al., 2015; Wang et al., 2019).

Surface Functionalization

The loading of drug into MSNs are usually achieved by the interaction between the protein molecules and surface of pore channels through non-covalent bindings such as

electrostatic interaction, hydrogen bonding, pi-pi stacking etc, (Yang et al., 2012). Chemical modification of MSNs with appropriate functional groups can provide specific interactions with proteins thus provide effective control over protein loading and release. The high density of silanol groups on the surfaces of MSNs and the large library of available organic silanes make the functionalization of MSNs quite easy through a simple post-grafting or co-condensation method (Manzano et al., 2008; Yang et al., 2008; Chang et al., 2010; Li et al., 2013; Bouchoucha et al., 2014; Jambhrunkar et al., 2014). With suitable surface functionalization, strong interaction between proteins and the pore channels by electrostatic force can be achieved, and protein loading amount can be increased while release rates are slowed. In pioneering studies, positively charged amino modified MCM-41 and SBA-15 showed a much higher loading capacity to IBU (a drug with carboxy groups, negative charged) compared to unmodified negative charged ones (Vallet-Regi, 2006). A slower release rate of IBU was also observed from the amino modified MSNs (Babonneau et al., 2003, 2004; Ramila et al., 2003; Song et al., 2005; Vallet-Regi, 2006). Tu et al. (2016) tested the encapsulation ability of negatively and positively charged MSNs with big pores (10 nm) toward a series of proteins with different molecular weights (from 12 to 250 kDa) and surface charges. It is concluded that the surface chemistry within the channels plays a dominant role in the loading of proteins. It is also notable that the protein loading process was quick, MSNs achieved 95% of maximum proteins loading ability within 20 min (Tu et al., 2016).

Another strategy of surface functionalization to control the protein loading and delivery behaviors is modification of MSNs with hydrophobic groups. Proteins are composed of many amino acids with different hydrophobic properties, a hydrophobic surface modification usually increases the protein loading and enhance the stability. Doadrio et al. (2006) modified SBA-15 with octyl (-C8) and octadecyl (-C18) groups and tested the drug release behaviors after loading with an antibiotic drug erythromycin. They found the MSNs modified with hydrophobic groups showed a slower release rate, the octadecyl-modified SBA-15 exhibited a one order of magnitude lower release rate compared to unmodified SBA-15. The observation was explained as the hydrophobic groups impeded the penetration of aqueous solution and prevented the fast release of the loaded drugs (Vallet-Regi et al., 2007). Bale et al. (2010) utilized n-octadecyltrimethoxysilane modified silica nanoparticles to deliver green fluorescent protein and RNase A into mammal cells. Results indicated that hydrophobic modification helped to preserve the biological activity of proteins and, more importantly, to achieve endosomal escape. Niu et al. (2016) studied the effects of hydrophobic modification (octadecyl-group) as well as surface roughness of silica nanoparticles on the loading capacity, release profile, cellular uptake and endosomal escape of RNase A. They concluded that the hydrophobic modification enhanced the protein loading capacity, achieved sustained release and improved the cellular uptake performance. Octadecyl-functionalized silica nanoparticles with rough surface showed the best performance in RNase A delivery which caused significant cancer cell inhibition. In addition, Zhang et al. (2018) reported that hydrophobic modification of silica vesicles (-C8 and -C18 groups) enhanced the insulin enrichment ability from PBS or artificial urine. They also found that the insulin which loaded inside alkyl modified silica vesicles showed less secondary structure's conformation change than that of hydrophilic ones.

Pore Structure

Various pore structures, in terms of pore geometry, are also reported to affect the protein loading and release properties. Xu et al. (2015) synthesized MSNs with cone shaped pores (MSN-CC, **Figures 2A–D**), which has a large pore size (45 nm) and a high pore volume (2.59 $cm^3\ g^{-1}$). They demonstrated that MSN-CC can achieve a high loading capacity of large proteins and successfully deliver active beta-galactosidase (β-Gal, 8*13*18 nm) into cells. Based on this work, Meka et al. (2016) designed an amine-functionalized hollow MSNs with cone shaped pores using one step synthesis. With the cationic groups, this hollow MSNs (**Figures 2E–H**) showed higher loading capacity toward negative proteins such as β-Gal and better cellular uptake performance by up to 40-fold and 5-fold compared to free protein or protein loaded in unmodified MSNs. In addition, β-Gal delivered by amine-modified MSNs retains its activity and catalytic functions. Andersson et al. (2004) also showed MSNs with cage-like pores provided a higher drug loading amount compared to those with cylindrical pores. The pore structure also influences the drug release behavior. Vallet-Regi et al. (2007) found that MCM-48 with a 3D cubic pore structure released loaded IBU faster than MCM-41 with 2D hexagonal pores (Izquierdo-Barba et al., 2009).

Surface Area

Usually the drug loading process was carried out by immersing MSNs in drug solutions with high concentration followed with separation. Vallet-Regi et al. (2007) compared the maximum loading amount of alendronate in MSNs with similar structure but different surface area. Results showed that under the same loading condition MCM-41 with surface area of 1,157 $m^2\ g^{-1}$ had a higher loading amount than SBA-15 with surface area of 719 $m^2\ g^{-1}$ (139 vs. 83 mg g^{-1}) (Vallet-Regi et al., 2007; Izquierdo-Barba et al., 2009). The pore surface provides the sites for the physical or chemical adsorption of the drugs, thus is an important factor for evaluating the drug loading capacity of MSNs. This conclusion is based on the studies of small molecular drugs. For proteins, large pore negative charged MSNs with different structures (with a core inside vs. hollow) but similar surface area have similar proteins loading capacity (Xu et al., 2015; Meka et al., 2016). More studies with rationale design are suggested to further test the effects the surface area on protein loading. It is noted that the contribution of different (e.g., micropore) surface area need to be considered corresponding influence on protein loading and release.

Pore Volume

Though the drug loading process is considered to be mainly happened on the surface of mesopores, the drug-drug interactions can happen under some conditions such as very high drug loading concentration, which could fulfill the pores. In those cases the pore volume is an important factor which affects the drug loading capacity. For example mesocellular

silica foams with a pore volume of 1.9 cm^3 g^{-1} showed a higher bovine serum albumin loading amount than SBA-15 with a pore volume of 1.1 cm^3 g^{-1} (Schmidt-Winkel et al., 1999). Yang and co-authors coated mesoporous silica foam (pore size > 10 nm) on the outside of solid magnetic oxide composites for protein adsorption. With the addition of several mesoporous silica layers, the pore volume increased to ∼0.49 cm^3 g^{-1} and high loading capacity toward BSA (113 mg g^{-1}) and cytochrome C (142–175 mg g^{-1}) were achieved without compromising the magnetic property (Yang et al., 2014). Xu et al. (2015) synthesized MSNs with cone shaped pores and the pore volume reached as high as 2.69 cm^3 g^{-1}, a ultra-high loading capacity toward large proteins (560 mg g^{-1} toward IgG and 190 mg g^{-1} toward β-Gal) was achieved (Xu et al., 2015; Meka et al., 2016). In general, MSNs with high pore volume can load more amount of proteins under the condition that the pore size is larger than the dimension of proteins. The effect of pore volume toward protein release has not been reported yet to our knowledge.

APPLICATION MSNs FOR INTRACELLULAR PROTEINS DELIVERY

Protein therapeutics are promising drugs to intervene cell functions more precisely due to their high target specificity. They are also considered to be safer compared to gene therapies as no genetic alteration happens. In many applications such as cancer therapy and immune therapy, protein therapeutics need to work inside the cells however bare protein cannot cross the cell membranes by themselves. In 2007, Slowing et al. (2007) first demonstrated the intracellular delivery of a small protein, native cytochrome c (with a size of 2.6*3.2*3.3 nm), into human cervical cancer cells (Hela cells) by MCM-41 type MSNs with 5.4 nm pore size. In this pioneer work, though the intracellular delivery of cytochrome c was proved, the function of the protein after deliver into cells was not tested. Later, Davis et al. (2008) employed PEI modified MSNs to delivery cytochrome c and induced programmed cell death of Hela cells (Huang et al., 2013). In addition to cytochrome c, ribonuclease A (RNase A, with the size of 2.2* 2.8*3.8 nm) is also widely used as a protein drug model to test the delivery efficacy and the intracellular functions. RNase A degraded RNA in the cytosol, after loaded into MSNs and delivered into cancer cells, they can inhabit protein production and cause cell death. Zhang et al. (2014) reported hollow silica vesicles for the intracellular delivery of RNase A. Results show a high protein loading capacity and high potency for cancer cell inhibition. Niu et al. (2016) demonstrated hydrophobic modification (C18-functionalization) of MSNs is an effective strategy for the intracellular delivery of RNase A. Benzene-bridged MSNs (with hydrophobic groups in the framework or silica) were also fabricated and applied for RNase A delivery (Yang Y. N. et al., 2015). In addition to small proteins, protein therapeutics with large molecular weight are also delivered into cells benefiting from the development of MSNs with large pores (Xu et al., 2015; Meka et al., 2016).

In addition to just delivery of proteins into cells, there were more designs on MSNs to achieve "on-demand" responsive intracellular release. For example, organic MSNs with disulfide bond can achieve glutathione (GSH) responsive release to selectively release proteins in cancer cells. Yang et al. (2016) designed disulfidebond-bridged and large-pored MSNs for intracellular RNase A delivery. This disulfide bond-bridged MSNs demonstrated a GSH responsive degradation behavior, which showed a higher degradation rate in cancer cells but a low rate in normal cells. Very recently, oxidative and redox dual-responsiveness organosilica nanoparticles were further developed to selectively deliver and release RNase A in cancer cells and the anticancer performance was evaluated *in vivo* (**Figure 3**, Shao et al., 2018). These diselenide-bridged MSNs with 10 nm pores can load RNase A inside the pore channels with electrostatic interaction and degrade upon exposure to redox or oxidative conditions to release the payload. The anti-cancer performance was also evaluated on nude mice bearing tumors. With surface medication with fragments from the cancer cell membrane, those MSNs showed longer blood circulation time, low toxicity and enhanced tumor inhabitation ability, suggesting dual responsive degradable MSNs with proper surface modification provides a promising strategy for the delivery of protein therapeutics into tumors (Shao et al., 2018).

MSNs are also widely used for immune therapy and to deliver vaccine into antigen presenting cells (Mody et al., 2013). Yang and collaborators reported the delivery of protein antigens using multi-shell dendritic mesoporous organosilica nanoparticles for cancer immunotherapy. The organosilica nanoparticles successfully loaded ovalbumin (OVA) and mediated endo/lysosome escape to macrophages. They evaluated the *in vivo* antitumor performance of organosilica nanoparticles to deliver B16F10 tumor cell fragments in a therapeutic vaccination model, showing better immunity for cancer therapy than pure silica nanoparticles. Their work provided us new insights for the design of MSNs for adjuvants delivery and vaccine developments (Yang Y. et al., 2017). MSNs are also used for oral vaccine delivery. Wang et al. (2012) loaded bovine serum albumin into MSNs with different particle size (130 nm, 450 nm, and 1–2 μm) and administrated orally to mice. They observed the immune response and found MSNs with small size triggered higher IgG antibody concentration in plasma (Wang et al., 2012).

In addition to cancer and immune therapy, MSNs are also used to for other protein therapies such as deliver proteasomes for the treatment of Azhamen's syndrome. Han et al. (2014) utilized MSNs to load and deliver therapeutic proteasomes to degrade tau aggregates for the management of Alzheimer's disease. MSNs were internalized and distributed in the cytosol after endosomes escaping. *In vitro* tests showed proteasomes loaded MSNs degraded the overexpressed tau in the cells more efficiently compared to the native proteasomes, and decreased the levels of the truncated tau which is considered as pathological hallmark of this disease (**Figure 4**).

APPLICATION OF MSNs FOR EXTRACELLULAR PROTEIN DELIVERY

For those protein therapeutics that works outside of cells, MSNs also provide a platform to protect their activity and achieve

responsive release. For example, insulin is widely used for the management of diabetes. However, the daily multiple insulin injections are quite painful, this discomfort can become a barrier to the use the insulin injections for many patients (Hunt et al., 1997; Zambanini et al., 1999). In addition, direct injection manner may cause hypoglycemia and result in serious problems such as unconsciousness or even death (Veiseh et al., 2015). Glucose responsive systems that release insulin automatically in a way that mimics physiological insulin secretion provide a better way and have the potential to change the way in which type 1 diabetes is managed.

Various MSN-based glucose responsive insulin release systems have been developed which take advantage of the high drug loading capacity, good biocompatibility and easy surface modification offered by MSNs (He and Shi, 2011; Zhao et al., 2011; Chen et al., 2013; Xu et al., 2017). In 2009, Zhao et al. (2009) reported boronic acid (one type of phenylboronic acid, PBA, which can form reversible covalent complexes with diol units of glucose) functionalized MSNs for glucose-responsive controlled release of insulin and cyclic adenosine monophosphate. The gluconic acid-modified insulin was immobilized on the exterior surface of MSNs, which also served as caps to encapsulate cAMP

molecules inside the mesopores. The release of both insulin and cAMP was triggered by the introduction of glucose, which competitively bounds to boronic-acid on the surface of MSNs, resulting in the loosening of insulin and the release of cAMP. However, in this work the insulin was modified by gluconic acid which may affect the biological function of this component. Sun et al. (2013) introduced another two PBA derivatives, 3-acrylamidophenylboronic acid and N-isopropylacrylamide for use as capping agents for insulin loaded MSNs. These PBA derivatives formed a dense layer which prevented the release of insulin and underwent swelling upon exposure to glucose to trigger insulin release. In this design unmodified insulin was used which eliminated the concern of denaturation of insulin.

Another design based on GOD mechanism was reported in 2011. Zhao et al. (2011) used MSNs with large pores (approx. 20 nm) for insulin loading, while the pore capping was achieved via a coating of GOD and catalase (CAT), an enzyme capable of catalyzing H_2O_2 into H_2O and oxygen to prevent the accumulation of H_2O_2, using layer-by-layer (LbL) method to control the insulin release. Up to 377 mg/g loading capacity of insulin was achieved using this method. The glucose responsive layers (enzyme layers) were coated onto the insulin loaded MSNs by Schiff base bond formation and functioned as "gates" to preventing insulin release in the absence of glucose. The enzymes (GOD and CAT) converted glucose into gluconic acid with oxygen and the production of gluconic acid decreased the local pH value. In the presence of glucose, the Schiff base bond was partially protonated and the enzyme layers were "loosened" which increased the permeability and triggered insulin release (Qi et al., 2009; Chen et al., 2011, 2012). With this design the insulin was released in response to glucose spontaneously and could achieve repeated on/off releases of insulin under the condition with/without glucose (Zhao et al., 2011).

It is noted that most of current glucose responsive insulin release systems (primarily GOD based systems) release more than half their loaded insulin at a glucose concentration either below 7 mM (De Geest et al., 2006; Ding et al., 2009; Qi et al., 2009; Wang et al., 2009; Zhao et al., 2009, 2011, 2012, 2013; Chen et al., 2011, 2012; Sato et al., 2011; Sun et al., 2013; Chou et al., 2015) or above 20 mM (Gu et al., 2013; Yu et al., 2015). However, the blood glucose levels are adjusted in the range of 3.9 ∼ 6.1 mM under normal physiological conditions, which means most of the glucose responsive systems are too sensitive, releasing more than half the loaded insulin content even under normal blood glucose concentrations. Recently, Xu et al. (2017) reported a glucose-responsive insulin release system based silica vesicles loaded with insulin with a layer-by-layer enzyme polymer coating (**Figure 5**). The insulin-release threshold can be adjusted by changing the polymer amount in the coating layers and the insulin release was switched "ON" in response to hyperglycemia and "OFF" to normal glucose levels. *In vivo* experiments in type I diabetes mice showed this MSNs based system regulated the glycemia levels in a normal range up to 84 h with a single administration while not affected the blood glucose concentration of normal mice. Those MSNs based systems have the potential to be developed as convenient and safe insulin delivery carriers for diabetes management.

For monoclonal antibodies generally working on the surface of cells, loading inside MSNs also enhanced their activity by providing protein and controlling release. For example, cytotoxic T-lymphocyte associated antigen 4 antibody (CTLA-4 Ab) can inhibit checkpoint receptor and has been used in patients with melanoma. Functionalized silica foam with a pore size of 30 nm was used to loaded CTLA-4 Ab and showed an ultra-high loading capacity (up to 800 mg g^{-1}). *In vivo* tests with tumor bearing mice (melanomas) model showed that CTLA-4 Ab loaded silica foam significantly enhanced antitumor activity compared to free

antibodies, attributed to the prolonged release and protection of antibodies at tumor sites (Lei et al., 2010).

APPLICATION OF MSNs FOR ANTIBACTERIAL PROTEINS DELIVERY

The use of nanoparticles as delivery vehicles for antimicrobial proteins shows great potential for the treatment of bacterial infections. For example, lysozyme, a nature protein than can catalyze the hydrolysis of bacterial wall, was coated on the surface of MSN-41 which enhanced the interact with *Escherichia coli* (*E. coli*, one typical Gram-negative bacterium) and raised the local concentrations of lysozyme. The minimal inhibition concentration was 5-folds lower after conjugated with MSNs compared to free lysozyme (Li and Wang, 2013). To tackle the problem of exposure of lysozyme on the external surface, Song et al. (2016) prepared MSNs with large pores which had ability to load lysozyme inside, and demonstrated the enhanced the ability for the treatment of *E. coli in vitro* and in an *ex vivo* small intestine infection model. Wang et al. (2019) prepared dendritic mesoporous silica nanoparticles with pore sizes ranging from 2.7 to 22.4 nm for lysozyme loading. They found MSNs with large pores had a high lysozyme loading ability (244.5 mg g^{-1}) and showed a sustained release profile. Lysozyme loaded inside MSNs showed better antibacterial effect toward *E. coli,* reducing the minimum inhibitory concentration (MIC) from 2,500 mg mL^{-1} of free lysozyme to 500 μg mL^{-1}. Very recently, Xu et al. (2018) reported that MSNs could penetrate inside the biofilms (Biofilms are groups of microbial cells embedded in extracellular polymeric substances and bacteria in biofilms had higher resistance to antimicrobial drugs) and deliver lysozyme into biofilm to kill deeper bacteria (**Figure 6A**). Those hollow mesoporous silica nanoparticles with large cone-shaped pores (**Figure 6B**) had ability to loaded lysozyme inside and penetrated into biofilms (**Figure 6C**). Enhanced therapeutic activity toward E. coli biofilms was demonstrated with rational design of MSNs (**Figure 6D**).

APPLICATION OF MSNs FOR ENZYME MOBILIZATION AND CATALYSIS

MSNs are also of great significance for enzyme immobilization and catalysis by addressing the intrinsic issues of the native enzymes (Wang and Caruso, 2005; Popat et al., 2011; Yang T. et al., 2017). Wang and Caruso (2005) used a series of MSNs with pore sizes from 2 to 40 nm for the immobilization of various enzymes including lysozyme, peroxidase, catalase and cytochrome C. After loading inside MSNs, the enzymatic activity was retained in a wide range of pH and even after exposure to enzyme-degrading substances such as proteases. It is noted that MSNs-enzyme kept 70% of the initial activity after 25 batch of successive reactions. Very recently, Kalantari et al. (2018) also reported the application of dendritic mesoporous organosilica nanoparticles with benzene groups in the framework for an enzyme, lipase, and immobilization. It is interesting to note that after loaded into organosilica nanoparticles, lipase showed enhanced pH and thermal stability and also higher activity than free lipase. In addition, after 5 cycles lipase loaded in MSNs retained 94% catalytic activity, showing the advantage for reusability (Kalantari et al., 2018).

SUMMARY AND OUTLOOK

In conclusion, MSNs demonstrated high loading capacity and protective effects toward proteins, provided advantages in the intracellular, extracellular, antibacterial delivery, immobilization of various proteins with enhanced therapeutic/catalytic efficacy. With the rigid framework and well-defined pores, MSNs provide protection toward protein and preserve their activity. In addition, the fast development of novel MSNs especially those with radial pore structure and large pores promotes the application for protein delivery. We envision that significant progress will be made and new MSNs with rational design and tailored functionalization will be developed in the near future for better protein delivery.

For the future directions, targeted protein delivery and controlled protein release would be emerging technological

strategies to further improve the therapeutic effects. The recent works such as cloaked MSNs with red blood cell membranes or other targeting agents have shown longer circulation time and accumulation in target areas such as tumor (Xuan et al., 2018). The design of various responsive release system based MSNs are also receiving more attention. Many new studies have clearly demonstrated the feasibility and advantage of remote-controlled proteins release systems (Yang et al., 2013).

It is noted that the *in vivo* effects of MSNs based proteins delivery systems are less studied. More intensive preclinical explorations such as animal studies are needed to realize their potential in clinical applications. Currently the investigation of MSNs for the *in vivo* delivery of therapeutic proteins has not kept pace with advances in MSNs fabrication. More studies are expected to evaluated the biocompatibility, stability, efficacy and biological interactions of MSNs based protein delivery system. The close collaborations between materials scientists, biologist, pharmacist, and clinician would fasten this process.

AUTHOR CONTRIBUTIONS

CX, CL, and CY designed this study. CX and CL wrote the manuscript. CX and CY revised the manuscript.

Polymer Chemistry

Junwei Wu

Dr Junwei Wu obtained his BE and ME from University of Science & Technology Beijing (China) and PhD from West Virginia University. He is now an Associate Professor at the Harbin Institute of Technology, Shenzhen. His research concerns novel materials development for energy storage and conversion, such as Li/Na-ion batteries, full solid cell, and solid oxide fuel cell, etc. He also serves as the deputy secretary general of the Shenzhen Association for Vacuum Technology Industries. He has published more than 50 journal papers, and an invited reviewer of Advanced Materials, Energy Storage Materials, Advanced Functional Materials, etc.

Marianna Pannico

Marianna Pannico obtained her PhD in Materials and Structures Engineering at the University of Napoli Federico II in 2010, supervised by Professor C. Carfagna. In January 2011 she joined the laboratory of molecular spectroscopy as part of Professor P. Musto's research group at the ICTP-CNR, later becoming a Researcher there in 2013. Notably, from November 2014 to January 2015 she collaborated with Prof. Maria de Fátima V. Marques on the VAIKUTUS project at the Instituto de Macromoléculas (IMA-UFRJ), Brazil. Dr Pannico's research focuses primarily on polymer nanocomposites, additives diffusion phenomena in polymer matrices, infrared spectroscopy, Raman Spectroscopy, and Surface Enhanced Raman Spectroscopy (SERS).

Romina Rega

Dr Romina Rega graduated in Physics in 2009 at the University of Naples Federico II with the highest honors, with a focus on Organic Electronics. Later, she continued to deepen this field at the National Agency for New Technologies, Energy and Sustainable Economic Development. During her PhD activity in "Innovative Technologies for Materials, Sensors and Imaging", she studied the stability of the organic thin film transistors. In 2014, she joined CNR-ISASI (Institute of Applied Sciences and Intelligent Systems) where she deals with the manipulation of polymeric materials using the pyro-electro-hydrodynamic effect induced by pyroelectric crystals and the realization of polymeric microstructures for biological applications.

Zhanhua Wang

Zhanhua Wang obtained his PhD degree in 2011in Polymer Chemistry and Physics from Jilin University under the supervision of Prof. Bai Yang. After that, he worked as a postdoctoral fellow with Prof. Marek Urban at the University of Southern Mississippi and Clemson University. He then moved to Wageningen University as a postdoctoral researcher and worked with Prof. Han Zuilhof until 2016. Presently, he is an Associate Professor at the Polymer Research Institute of Sichuan University. His current scientific interests are focused on stimuli-responsive polymer materials, self-healing and anti-fouling materials, and 3D printing polymer or polymer composite materials.

Michele Galizia

Michele Galizia is an Assistant Professor of Chemical Engineering at the University of Oklahoma since August 2017. In 2006, when he was an undergraduate student at the University of Bologna, Italy, he was awarded a Graduate Fellowship from the Italian Ministry of Education. After obtaining his PhD in Chemical Engineering, he joined the University of Naples Federico II as a Post-Doc Researcher. Finally, in 2013, he joined the Benny Freeman-Don Paul Research Group at the University of Texas at Austin as a Research Associate. Prof. Galizia's research focuses on membrane science, with emphasis on gas separation and organic solvent nanofiltration.

Alberto Fina

Alberto Fina is active in the field of polymer nanocomposites (nanoclays, POSS, carbon nanotubes, graphene) mainly aiming at enhancing thermal conductivity and flame retardancy. His recent research focuses on the fundamental aspects behind thermal conductivity in polymer nanocomposites, including the study of heat transfer on individual nanoparticles and their networks, as well as on the design and manufacturing of interfaces between nanoparticles, *via* the covalent or non-covalent chemical functionalization of graphene and related materials. A. Fina is a full Professor of Chemistry at Politecnico di Torino (I) and, currently, co-author of 74 papers in peer-reviewed journals with an H-index of 26.

Orietta Monticelli

Orietta Monticelli obtained her Laurea degree with honors in Industrial Chemistry from the University of Genoa in 1992. In 1996, Orietta Monticelli obtained her PhD in Chemistry, working at Genoa University and at the Department of Chemical Engineering (Boulder, Colorado, USA). Between January 1997 and June 1998, she won two scholarships from the European Union (Marie Curie Research Training Grant) and worked at the Centrum voor Oppervlatechemie en Katalise of Leuven University (Leuven Belgium). Since 2014, Orietta Monticelli has been an Associate Professor at Genoa University. Her scientific activity is documented in more than 90 publications in international scientific journals (H-30 index, over 2000 citations, Scopus May 2019). Her recent scientific interest include the development of novel formulations based on bio-polymers, in particular on polylactic acid.

Lithium-ion batteries have dominated the high performance and mobile market for last decade. Despite their dominance in many areas, the development of current commercial lithium-ion batteries is experiencing bottlenecks, limited by safety risks such as: leakage, burning, and even explosions due to the low-boiling point organic liquid electrolytes. Solid electrolyte is a promising option to solve or mitigate those issues. Among all solid electrolytes, polymer based solid electrolytes have the advantages of low flammability, good flexibility, excellent thermal stability, and high safety. Numerous researchers have focused on implementing solid polymer based Li-ion batteries with high performance. Nevertheless, low Li-ion conductivity and poor mechanical properties are still the main challenges in its commercial development. In order to tackle the issues and improve the overall performance, composites with external particles are widely investigated to form a polymer-based composite electrolyte. In light of their work, this review discusses the progress of polymer-based composite lithium ion's solid electrolytes. In particular, the structures, ionic conductivities, electrochemical/chemical stabilities, and fabrications of solid polymer electrolytes are introduced in the text and summarized at the end. On the basis of previous work, the perspectives of solid polymer electrolytes are provided especially toward the future of lithium ion batteries.

Keywords: polymer solid electrolytes, polymer, lithium-ion batteries, Li-ion conductivity, composite

INTRODUCTION

From the moment in 1991 when the SONY corporation launched the commercialization of lithium-ion batteries, lithium-ion batteries have thrived significantly and dominated in many different applications, such as electric vehicles, portable devices (Scrosati and Garche, 2010; Verma et al., 2010; Manthiram et al., 2017). Although lithium-ion batteries have many advantages such as high energy density and long cycle life, the potential safety issues and saturated high energy density have become bottlenecks which impedes further development.

Current commercial lithium-ion batteries use liquid organic electrolytes, which have significant advantages of high conductivity and excellent wettability on electrode surfaces. However, the obvious and inevitable drawbacks of liquid electrolytes are electrochemical instabilities and potential risks, plus low ion selectivity. Compared with liquid electrolytes, solid electrolytes have higher safety and thermal stability, since it can provide a physical barrier layer to separate positive

and negative electrodes and prevent thermal runaway under high temperature or impact. In addition, solid electrolyte makes it possible to use a lithium metal anode, due to its effective suppression of Li dendrite formation. Despite the significant advantages, some weaknesses still remain to be improved, such as low ionic conductivity and insufficient interface contact. Plenty of research is being conducted to conquer the weakness and develop new generation of solid lithium batteries (Tang et al., 2007; Zhao et al., 2012; Liu et al., 2013; Zhang Q. Q. et al., 2017). To meet the commercial requirements, high ionic conductivity, favorable mechanical properties, and outstanding interfacial stability with the electrodes are the most fundamental requirements for solid electrolytes (Fergus, 2010).

Inorganic solid electrolyte (ISE), solid polymer electrolyte (SPE), and composite electrolyte (CSE) are widely studied in lithium-ion batteries. Oxide group and sulfide group are two types widely used in ISE. Some of them [such as sulfide-based $Li_{10}GeP_2S_{12}$ (Kamaya et al., 2011)] exhibit high conductivity equivalent to that of organic liquid electrolytes, but the issues of high processing difficulty, high cost, and large interface impedance restricts its wide application (Knauth, 2009; Fergus, 2010). SPEs not only have excellent electrochemical performance and high safety, but are also good in flexibility and process ability, which has high possibilities for use in next-generation high-energy batteries (Dias et al., 2000; Stephan and Nahm, 2006; Yarmolenko et al., 2018). In the meantime, it avoids the danger of Li metal dendrite growth (Meyer, 1998; Agrawal and Pandey, 2008; Tikekar et al., 2016). SPEs, including polyethylene oxide (PEO) (Farrington and Briant, 1979; Watanabe et al., 1999; Siqueira and Ribeiro, 2006), polycarbonate (Forsyth et al., 1997; Sun et al., 2014; Liu et al., 2015), and polysiloxane (Sun et al., 1996; Fonseca and Neves, 2002) have been extensively investigated. However, the ionic conductivity and mechanical strength of SPEs are still not ideal, which is the major obstacle to hamper their wide applications (Chen et al., 2016).

Different methods are adopted for improving the polymer electrolyte system. Typically, they can be categorized into two approaches: (1) Polymer/polymer coordination and (2) Composite polymer electrolyte.

Copolymerization, crosslinking, interpenetration, and blending are widely used as polymer/polymer coordination; however, it does not significantly increase the mechanical properties of the electrolyte. Various composites had been mixed into polymers, as shown in **Figure 1**, including inert ceramic fillers (Agrawal and Pandey, 2008; Lin et al., 2016), fast-ion conductive ceramics (Aliahmad et al., 2016; Keller et al., 2017; Ling et al., 2018), lithium salts (Do et al., 1996), ionic liquid (Subianto et al., 2009), etc. With the synergistic effect of polymer and inorganic filler, the room temperature conductivity and mechanical strength of composite polymer electrolyte can be greatly improved, as well as the interface stability with the electrode. In my group, similar synergistic effects on composite electrolyte had been reported in inorganic fillers composite with Nafion membrane for direct methanol fuel cell applications (Cui et al., 2015, 2018), the corresponding mechanism is similar with the composite electrolyte with organic fillers. The used polymer matrices and properties for SPE are summarized in **Table 1**.

Solid polymer electrolytes (SPEs) currently have great application prospects in lithium batteries fabrication, numerous researchers also take great efforts to develop innovative SPEs and the successful applications will play a key role in developing lithium battery with excellent performance. **Figure 2** shows that the number of published sci-tech articles in the polymer-based solid electrolyte over a period of 19 years from 2000 to 2018. The trend shows the steady increase from about 750 in 2000 to the largest point around 2,400 in 2017. From the year of 2010, the number of essays in this field keep steady over 2000, which is the fact that polymer-based solid electrolyte will have excellent application prospects. A large number of reviews have summarized the research and development history of polymer electrolytes (Qiu et al., 2004; Dong and Wang, 2005; Srivastava and Tiwari, 2009; Fergus, 2010; Liu et al., 2013; Osada et al., 2016; Zhang Q. Q. et al., 2017). However, there is relatively few reviews on polymer-based solid electrolytes.

This review article highlights recent researches on SPEs for solid state lithium-ion batteries, in particular about the effects of composition with various filler materials. In this review, polymer based composite electrolytes, including polymer/inert ceramics, polymer/fast-ion conductive, polymer/ionic liquid, polymer/MOFs, and polymer/cellulose composite electrolytes. Furthermore, a perspective on the future research direction for developing safety, stable, and high energy density composite polymer electrolytes for solid-state batteries will be provided.

IONIC CONDUCTIVITY AND INTERFACE

Ionic Conductivity Mechanism

In order to develop SPEs with high lithium ion conductivity, the polymer should not only dissolve lithium salt, but also be able to couple with lithium ions. The polar groups in the polymer (—O—, —S—, etc.) are effective building blocks for dissolving lithium salts. Most of the research on all-SPEs is focused on polyethylene oxide (PEO) and its derivatives. The lone pair of oxygens on the PEO segment is coordinated to the lithium ion by Coulombic interaction, causing the anion and cation of the lithium salt to dissociate. In the process, PEO acts as solvent, and the lithium salt dissolves into the PEO matrix. In addition to the oxygen atom (—O—) on the PEO chain, other atoms such as the nitrogen in the imide (—NH—) and the sulfur in the thiol (—S—) also play a similar role. Under the electric field, the migration movement of Li^+ cations are from one coordination point to another along the polymer segment, or jump from one segment to another. The ion transport mechanism of polymer electrolytes such as PEO is shown in **Figure 3** (Xu, 2004).

In the polymer-lithium salt composite system, the ions are not free to move due to the huge size of the polymer chain plus the boundary effect of crystalline domains. The factors affecting the ionic conductivity are the number of lithium ions and the mobility of the polymer chain. The amount of ions that can be migrated depends on the ability of the polymer to dissociate the lithium salt, and thus the lithium salt of low lattice energy and the polymer of high dielectric constant can promote this dissociation (Young et al., 2014). Under steady state conditions, the ionic conductivity can be expressed by the

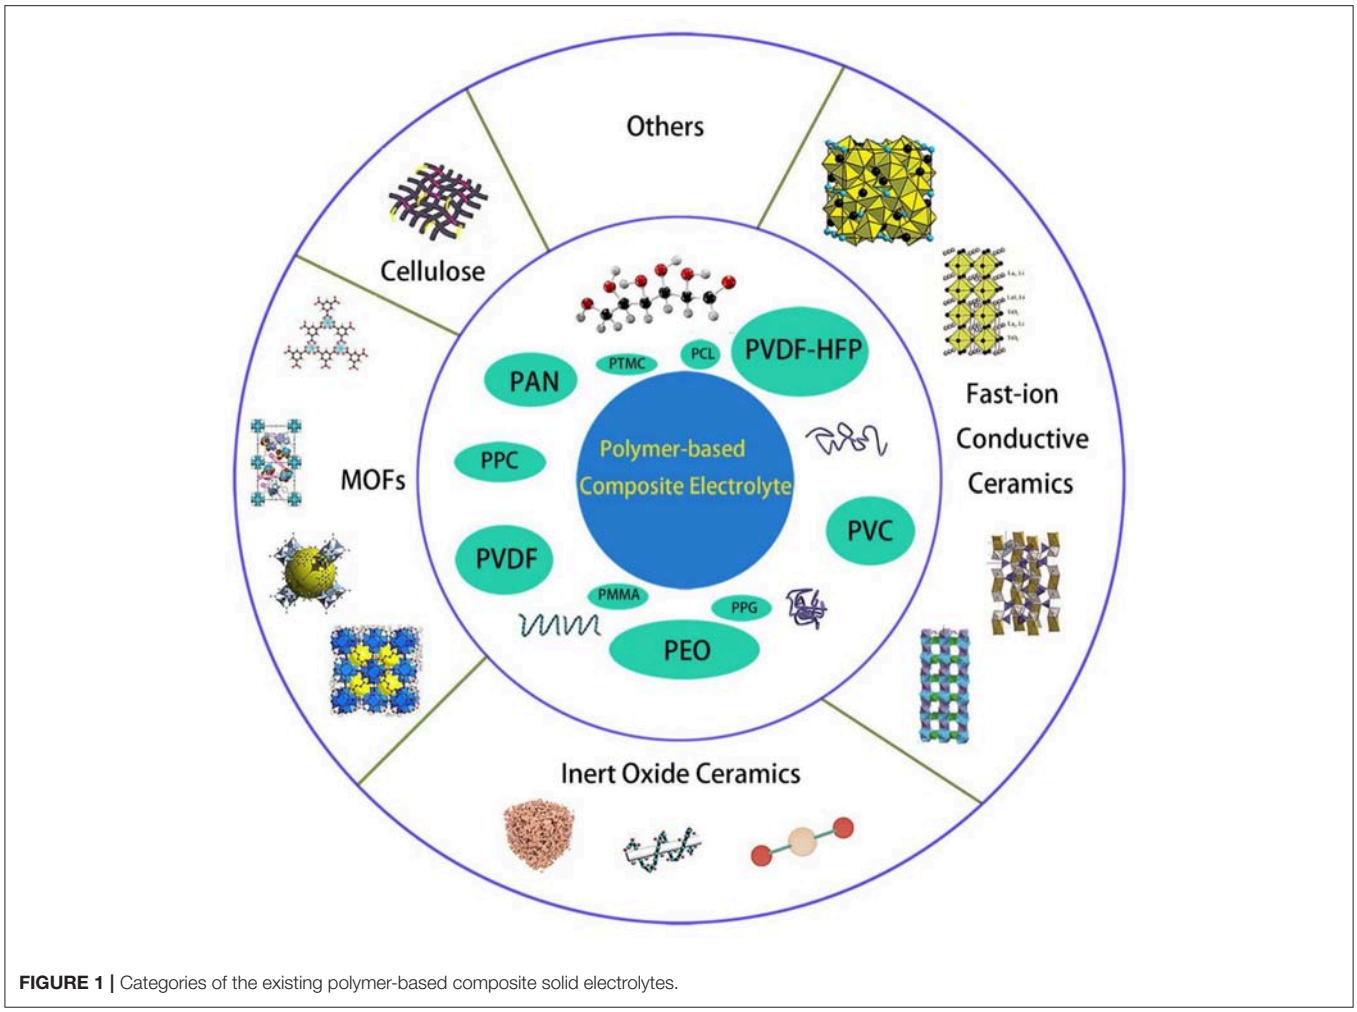

FIGURE 1 | Categories of the existing polymer-based composite solid electrolytes.

following equation (Wei-Min, 2012):

$$\sigma = \mathrm{F} \sum n_i q_i \mu_i \tag{1}$$

Here, F is the Faraday constant; n_i represents the number of free ions; q_i represents the number of charges, and μ_i is the mobility. Therefore, it can be seen that in the polymer electrolyte, the increasement of the concentration of the movable ions and the migration speed of the ions can increase the conductivity of the ions.

In SPEs, the most commonly used theory to explain the migration of ions in polymers includes Arrhenius theory, Vogel-Tammann-Fulcher (VTF) theory, William-Landel-Ferry (WLF) theory, and the combinations of above theories (Ratner et al., 2000; Quartarone and Mustarelli, 2011).

The classical Arrhenius theory explains the temperature relationship of ion migration caused by polymer segment motion, expressed as (Zhang Q. Q. et al., 2017):

$$\sigma = \sigma_0 \exp(\frac{-E_a}{KT}) \tag{2}$$

Here, E_a represents the activation energy for single molecules or groups of ions to migrate, σ_0 represents the pre-exponential factor, while T represents thermodynamic temperature.

Generally, ion jump motion and polymer chain relaxation and/or segmental motion together affect conductivity, so the vs. 1/T curve is generally non-linear (Agrawal and Pandey, 2008). The typical lg-1/T in polymers is usually based on the T_g-based equation, so VTF mainly describes the relationship between polymer electrolyte conductivity and temperature (Zhang Q. Q. et al., 2017):

$$\sigma = \sigma_0 T^{-\frac{1}{2}} \exp(-\frac{B}{T - T_0}) \tag{3}$$

Here, σ_0 is a pre-exponential factor, B is an action factor with dimension as the energy dimension, and T_0 is the reference temperature, which can be expressed in T_g, normally 10–50 K below the experimental glass transition temperature. At room temperature, if only the effect of the polymer segment on conductivity is considered, low glass transition temperature can play a positive role in the improvement of the conductivity.

Based on the study of PEO and PPO salt complexes, the ionic conductivity can be related to frequency and temperature

TABLE 1 | Common polymer matrix.

Polymer matrix	Molecular formula	Glass transition temperature T_g/°C	Melting point T_m/°C
PEO		−64	65
PVC		80	220
PAN		125	317
PMMA		105	Amorphous
PVDF		−40	171
PVDF-HFP		−90	135
PPG		−60	Amorphous
PDMS		−127	−40
PEC		5	Amorphous
PPC		35	Amorphous
PCL		−60	Amorphous
PTMC		−15	Amorphous

by using the William-Landel-Ferry (WLF) equation, considering the relaxation process of polymer molecular chain motion in an amorphous system. The expression is:

$$\lg \frac{\sigma(\mathrm{T})}{\sigma(\mathrm{T_g})} = \frac{C_1(T - T_g)}{C_2 + (T - T_g)} \tag{4}$$

Here, $\sigma(T_g)$ is the conductivity of the relevant ions at glass transition temperature T_g, and C_1 and C_2 are the WLF parameters in the free volume equation of ion migration, respectively.

T_g is one of the most critical parameter of polymer electrolyte. The conductivity is very low as the temperature below T_g, and it

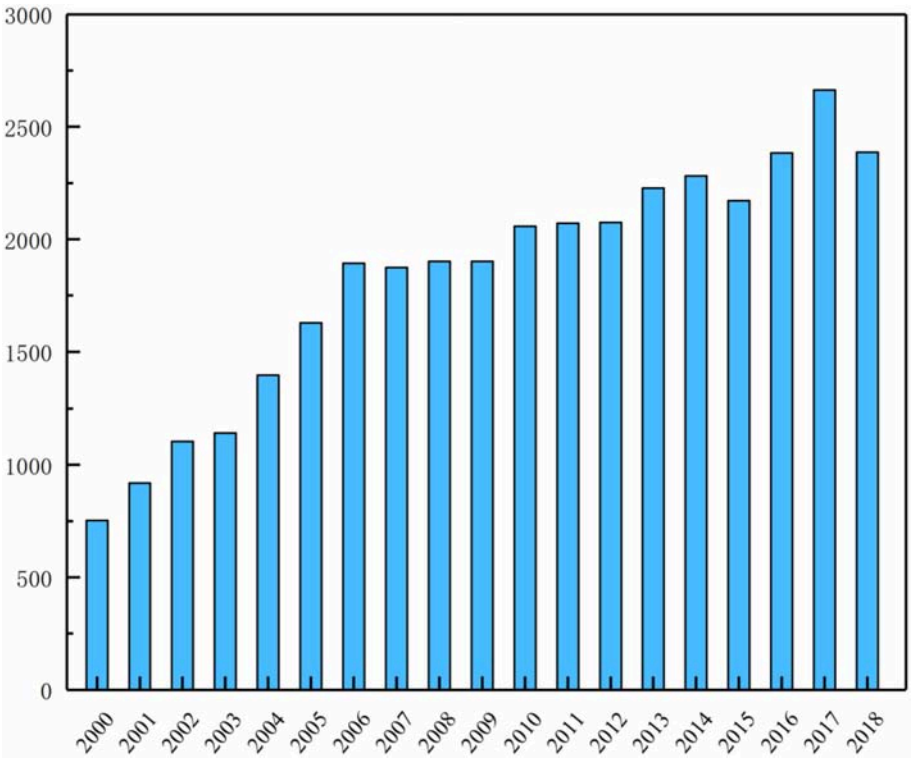

FIGURE 2 | The number of published sci-hech articles in the polymer-based solid electrolyte over a period of 19 years from 2000 to 2019.

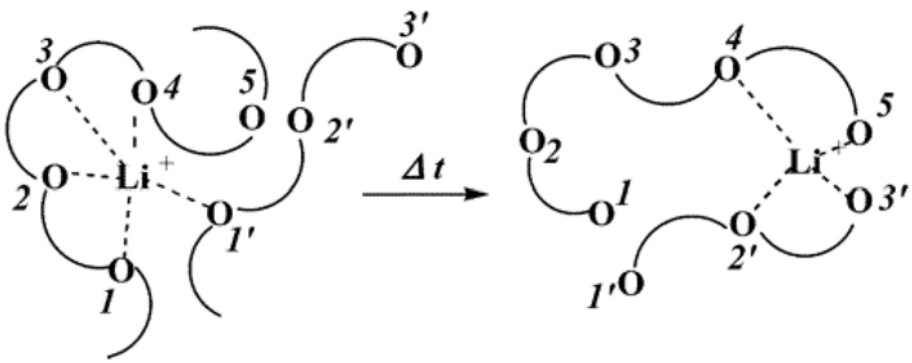

FIGURE 3 | Schematic diagram of lithium ion conduction mechanism of PEO-based polymer electrolyte. [Reproduction with permission from Xu (2004), Copyright 2004, American Chemical Society].

will be obviously improved above T_g. Therefore, to reduce T_g is beneficial to the improvement of conductivity.

The above three theories well-explain the conductive mechanism of the PEO-based electrolyte. The amorphous phase of the polymer is mainly effective for the migration of ions. The theory can also be applied to other polymer electrolytes.

Interface

In the solid lithium-metal battery, the cathode is typically $LiFePO_4$ or $LiCoO_2$. Metallic lithium is used as a negative electrode. The cathode/electrolyte interface requires a solid electrolyte with excellent flexibility to ensure low interface resistance, while the anode/electrolyte interface requires a strong solid electrolyte to withstand the puncture of the metal lithium dendrites (Camacho-Forero and Balbuena, 2018; Wang L. P. et al., 2018; Zhang et al., 2018). The good flexibility of the SPE makes the lower interface resistance possible, but the low mechanical properties are difficult to withstand the puncture of the metal lithium dendrites. In contrast, a rigid inorganic ceramic electrolyte can withstand the metallic lithium dendrites, but has a large interfacial resistance due to insufficient contact with the electrodes (Xu et al., 2018). Therefore, the flexible polymer

electrolyte or the rigid inorganic ceramic electrolyte has difficulty used in solid metal lithium battery separately. In order to take full advantage of polymer and inorganic ceramic electrolyte, polymer composite inorganic ceramic electrolyte offers an option. It is expected that the obtained solid metal lithium battery has both low interface resistance and the ability to inhibit lithium dendrite formation. In addition, the electrochemical instability of the interface easily leads to the occurrence of side reactions and thus the cover of the electrodes form a solid electrolyte interface (SEI), which may lead to a shortened cycle life of the cell (Xu et al., 2018).

SOLID POLYMER ELECTROLYTES WITH INERT OXIDE CERAMICS

In recent years, many studies have been addressed to incorporate inert oxide ceramics particles into polymer electrolyte, in order to improve the mechanical properties, reduce polymer crystallinity, and thus solve the problem of low ionic conductivity of SPE. Different types of inert ceramics had been incorporated into the polymer, such as SiO_2 (Nan et al., 2003; Ketabi and Lian, 2013), Al_2O_3 (Weston and Steele, 1982; Capuano et al., 1991; Tambelli et al., 2002; Liang et al., 2015), TiO_2 (Pal and Ghosh, 2018), zeolite, etc. The ionic conductivities of solid polymer composite electrolyte containing inert ceramic filler are showed in **Table 2**. In 1982, Weston and Steele (1982) mixed PEO with Al_2O_3 to form a composite. It was firstly proved that PEO doped with inert material particles exhibited an improvement of mechanical properties and ionic conductivity. Subsequently, Capuano et al. (1991) explored the contribution of the doping amount and particle size of $LiAlO_2$ powder on the conductivity of solid electrolyte. It was found that the conductivity reached the highest as the doping amount of $LiAlO_2$ was around 10 wt.%. It is also worth noting that particle size of the inert ceramic material affected the conductivity of the SPE, which increases with particle sizes as the size is $<10\,\mu m$. Tambelli et al. (2002) reported that Al_2O_3 can effectively reduce the crystallinity and glass transition temperature of PEO. This confirms that the decrease of polymer crystallinity promotes the improvement of ionic conductivity. The decrease in crystallinity can enlarge the number of free segments of the polymer and accelerate the movement of the segments, which can effectively promote the migration of lithium ions. Similar results were reported on PEO-PMMA-LiTFSI-Al_2O_3 composite electrolytes. They were prepared based on PEO-PMMA as a host matrix and nano Al_2O_3 as filler by solution casting technique (Liang et al., 2015). The composite electrolytes doped with Al_2O_3 exhibited an improvement of the ionic conductivity from 6.71×10^{-7} to 9.39×10^{-7} S/cm.

SiO_2 is also a common inert ceramic filler material used in the preparation of SPE. Lee et al. reported a composite of a PEO matrix and SiO_2 fillers containing ethylene carbonate (EC)/propylene carbonate (PC). The composite had an ionic conductivity of 2×10^{-4} S/cm at ambient temperature (Nan et al., 2003) with 2.5 wt.% filler loadings. In addition to powder, SiO_2 is also designed as a three-dimensional framework doped into the polymer. Lin et al. (2018) prepared a composite of PEO-Silica aerogel which exhibited high ionic conductivity 6×10^{-4} S/cm and high modulus 0.43 GPa. This study effectively solves the issue of poor mechanical properties and ionic conductivity of composite by controlling powder dispersion. SiO_2 aerogel skeleton has a good acidic surface. It can interact with lithium cations extensively and form a continuous channel in the composite material, beneficial to salt dissociation and improvement of ionic conductivity. Ion pairs are difficult to form because of the strong Lewis acid-base interaction of doped TiO_2 and the anion of lithium salt, resulting in more mobile charge carriers (Pal and Ghosh, 2018). Croce et al. (1998) studied a solid polymer electrode consisting of a nanosized TiO_2 particles, PEO, and $LiClO_4$. This hybrid exhibits a higher ionic conductivity of 10^{-5} S/cm. Pal and co-workers fabricated SPEs comprising of PMMA, $LiClO_4$, and TiO_2, by standard solution cast technique (Pal and Ghosh, 2018). The results showed that by composite nanosized-TiO_2 to the polymer electrolytes, the thermal stability can be improved as well. The conductivity reached 3×10^{-4} S/cm at 303 K. Moreover, specific capacity of such polymer electrolyte-based $LiCoO_2$/graphite at 30°C exhibited 30 mAh/g at room temperature in twelfth cycle. In addition, some studies have incorporated a variety of inorganic ceramics into the polymer, and the ionic conductivity has also been improved. For example, nanosized SiO_2, and nanoporous Al_2O_3 were combined with PVDF-HFP to obtain composite electrolytes that delivered moderate conductivity of 10^{-3} S/cm with 2.5 wt.% of fillers (Aravindan and Vickraman, 2008).

Liu et al. (2016) has the designed and fabricated a SPE comprising Y_2O_3 nanoparticle, ZrO_2 nanowire fillers, and PAN by electrospinning (**Figure 4A**). Y_2O_3-stabilized ZrO_2(YSZ) nanowire in PAN have a lot of positively charged oxygen vacancies with Lewis acid character, which may attract the anion of lithium salt and thus promote the dissociation of salts. The addition of YSZ nanoparticles or YSZ nanowires has a different degree of improvement in ionic conductivity compared to the absence of YSZ. The improvement effect of YSZ nanowires is better, and 7YSZ (7 mol% of Y_2O_3-doped ZrO_2 nanowires) had a high room-temperature ionic conductivity of 1.07×10^{-5} S/cm at 30°C with an enhancement of two orders of magnitude compared with pristine PAN electrolyte (**Figure 4B**). Recently, Tao et al. (Sheng et al., 2018) incorporated $Mg_2B_2O_5$ nanowires into PEO-LiTFSI-based solid electrolyte. The composite electrolytes exhibit good mechanical properties, outstanding electrochemical stability, and ionic conductivity, because of the fast ion motion on the surfaces of $Mg_2B_2O_5$ and interactions between the $Mg_2B_2O_5$ and $TFSI^-$ (**Figure 4C**). In addition, other inert oxide ceramics have also been reported to improve the SPE performance, such as $LiAlO_2$ (Gang et al., 1992; Hu et al., 2007), ZnO (Xiong et al., 2006), Fe_3O_4 (Reddy et al., 2006), and $BaTiO_3$ (Itoh et al., 2003a,b).

SOLID POLYMER ELECTROLYTES WITH FAST-ION CONDUCTIVE CERAMICS

Fast ion conductor ceramics, also known as active inorganic electrolytes, exhibit a high ionic conductivity of up to 10^{-2} S/cm

at 25°C. Four structures of fast ion conductors are displayed in **Figure 5**.

However, the poor interfacial contact restricts their direct use as solid electrolytes. Thus, composite of fast ion conductor ceramics with polymer can take full advantages of both parts. Fast ionic conductors commonly have garnet-type, NASICON-type and LISICON-type ceramics etc. **Table 3** gives a summary of fast-ion conductive ceramics/polymer solid electrolytes.

Garnet-Type Composite Polymer Electrolytes

From the moment in 2007 when $Li_7La_3Zr_2O_{12}$ (LLZO) was first found, garnet-type Li solid-state electrolyte generates great interest in recent years. $Li_7La_3Zr_2O_{12}$ (LLZO), garnet-type Li solid-state electrolyte, has attracted much attention since it was first reported in 2007 (Xie H. et al., 2018). $Li_5La_3M_2O_{12}$ (M = Nb, Ta) is the first reported lithium ion conductor with a garnet structure (**Figure 5A**; Thangadurai et al., 2003; O'Callaghan et al., 2008). The traditional garnet chemical formula is $A_3B_2(XO_4)_3$ (A = Ca, Mg, Y, La or rare-earth elements; B = Al, Fe, Ga, Ge, Mn, Ni, or V). Garnet-type Li solid-state electrolyte has high ionic conductivity and wide electrochemical window (Wu et al., 2017). At room temperature, the ionic conductivity of $Li_5La_3M_2O_{12}$ (M = Nb, Ta) reached 10^{-3} S/cm and exhibits outstanding chemical stability over a wide temperature range. However, when the all-solid-state battery is assembled using garnet-type ceramics, the electrode/electrolyte interface always shows poor conductivity, resulting in deteriorated battery performance, as well as increased interface resistance and decreased ionic conductivity (Chen et al., 2018). Polymer/Garnet composite electrolytes offer an option of improving the overall electrochemical performances.

With a large specific surface area, nanoscale garnet ceramic fillers improve the transition rate of ions (Kumar and Scanlon, 2000). A composite electrolyte composed of PEO containing 52.5 wt.% $Li_7La_3Zr_2O_{12}$(LLZO) particles displays a conductivity

which reaches 4.42×10^{-4} S/cm at 55°C (Thokchom et al., 2008). $Li_{6.75}La_3Zr_{1.75}Ta_{0.25}O_{12}$ (LLZTO) is selected as an active filler and dispersed into PVDF matrix to fabricate PVDF/LLZTO hybrid electrolytes (Zhang X. et al., 2017). The hybrid electrolyte with 10 wt.% LLZTO loadings exhibited the highest ionic conductivity (5×10^{-4} S/cm), about seven times more than none LLZTO. It is attributed to that LLZTO particles react with Li^+ via acid-base interaction. Dissociation of the lithium salt will raise the carrier density for conduction. Furthermore, the garnet ceramic filler contributes to reduce the crystallinity of polymer and so to increase the ionic conductivity. Instead of simply mixing active ceramic particles into polymers, Goodenough et al. (Chen et al., 2018) introduced a novel approach of composite polymer into ceramic.

As a consequence, high ionic conductivity (10^{-4} S/cm at 55°C) were gained and the electrochemical window of 0–5.0 V. As used in the all-solid-state Li/$LiFePO_4$ cells, both "ceramic-in-polymer" and "polymer-in-ceramic" with a LiTFSI salt display remarkable cycling stability. The systems, "polymer-in-ceramic" provide higher mechanical strength and safety than "ceramic-in-polymer."

Morphologies of ceramics fillers such as particles, distribution of nanowire and 3D framework may affect the ionic conductivity of polymer composite electrolytes. Unlike particles and random nanowires, aligned nanowires combined with polymers can provide continuous transport pathways for Li^+ (**Figure 6**). Cui et al. (Liu et al., 2017) compares the different morphologies of LLZO to evaluate their benefits for ionic transport. They found that a composite polymer electrolyte with well-aligned inorganic nanowires (LLZO) shows an ionic conductivity of 6.05×10^{-5} S/cm at 30°C, which was increased by almost one order of magnitude than the composite with randomly aligned nanowires or nanoparticles. The appreciable conductivity

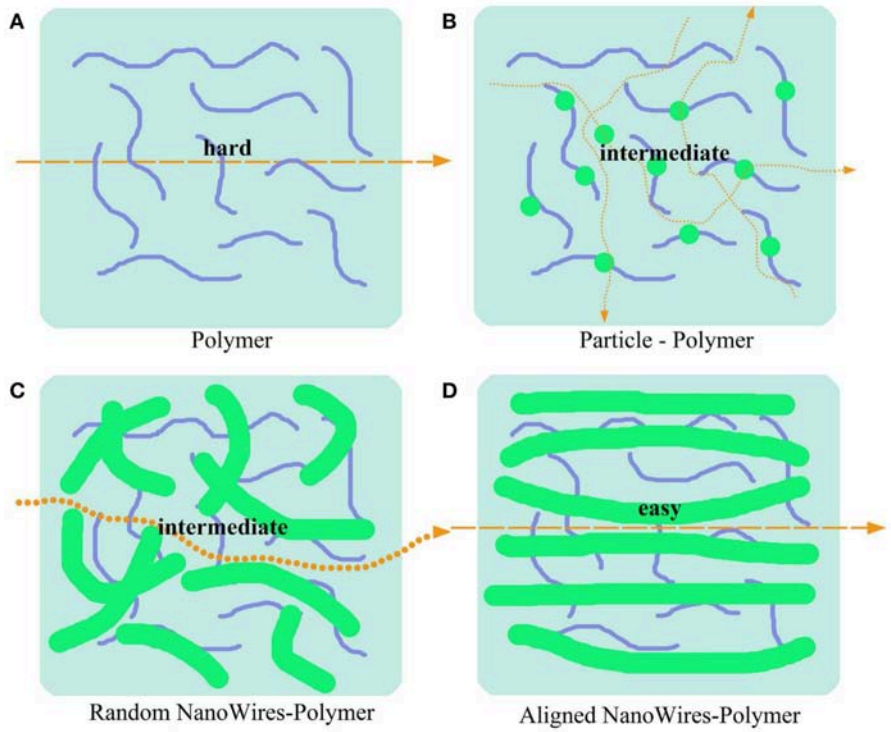

FIGURE 6 | Schematic of conduction mechanism in three kinds of morphologies solid polymer electrolytes. **(A)** Ionic transport path in pure polymer electrolytes. **(B–D)** Ionic transport path in polymer-based composite electrolytes with nanoparticles **(B)**, random nanowires **(C)** and aligned nanowires **(D)**.

improvement is due to Li^+ migration without crossing junctions on the nanowire surfaces.

In addition to 1D nanowires (Bae et al., 2018), prepared 3D ceramic $Li_{6.28}La_3Zr_2Al_{0.24}O_{12}$ networks by using hydrogel and mixed it into polymer solution to attain solid electrolyte. The designed structure is believed to have high conductivity (8.5×10^{-5} S/cm at 25°C) and good interfacial compatibility with electrodes. The integrated structure of 3D LLZO structure provides continuous 3D network of conduction pathways leading to highly improved ionic conductivity and mechanical properties. Similarly, 3D garnet nanofiber networks-polymer composite was also prepared (Fu et al., 2016). In this approach, the LLZO porous structure, composed of casually distributed and interconnected nanofibers, forms a continuous transport network for Li^+. The LiTFSI-PEO polymer is then filled into the porous 3D LLZO ceramic networks, forming the 3D garnet-polymer composite films. Then LiTFSI-PEO polymer and porous 3D Inorganic structure are combined to synthesize a 3D LLZO-polymer composite membrane which exhibited a high ionic conductivity of 2.5×10^{-4} S/cm at 25°C. The three-dimensional ion transport network offers a new option of designing composite electrolytes.

Perovskite-Type Composite Polymer Electrolytes

Perovskite-type solid electrolytes $Li_{3x}La_{2/3-x}TiO_3$ (LLTO) has a cubic structure with space group of P4/mmm and C-mmm (**Figure 5B**; Stramare et al., 2003). LLTO is well-known for its stable at high voltages. However, its preparation conditions are very strict and the ionic conductivity is also low. Recently, a polymer–ceramic composite electrolyte PEO/$LiClO_4$ has been studied by composite PEO with $Li_{0.33}La_{0.557}TiO_3$ nanowires. It exhibited extreme lithium-ion conductivity of 2.4×10^{-4} S/cm at 25°C (Zhu et al., 2018). Cui et al. (Liu et al., 2015) studied the effect of two different morphological LLTO materials on the ionic conductivity of polymer electrolytes, which are nanoscale particles and nanowire LLTO, respectively (**Figure 7**). The introduction of LLTO nanowire into PAN achieved higher ionic conductivity 2.4×10^{-4} S/cm at room temperature as compared to pristine PAN film. The composite electrolyte offers a 3D long distance Lithium-ion transmission network, which reduce the negative effect of agglomeration of inorganic ceramics in polymers relative to nanoparticles. This work opened a new way to develop one-dimensional fast ion conductive ceramic materials in solid electrolytes for lithium batteries.

The ionic conductivity has a strong relationship with the ceramic component loadings in the composite electrolyte. Generally, the higher the content, the lower the ionic conductivity will be, because nano-sized ceramic fillers are agglomerated and may block the percolation network around the phase interface. Meanwhile, in order to achieve high security of the composite electrolyte, it is necessary to reduce the proportion of combustible organic polymer content and increase the flame-retardant inorganic ceramic portion. Goodenough et al. (Bae et al., 2018) constructed a 3D-LLTO/PEO composite electrolyte using a hydrogel-derived method. The LLTO was incorporated into the hydrogel template, then it was cast with

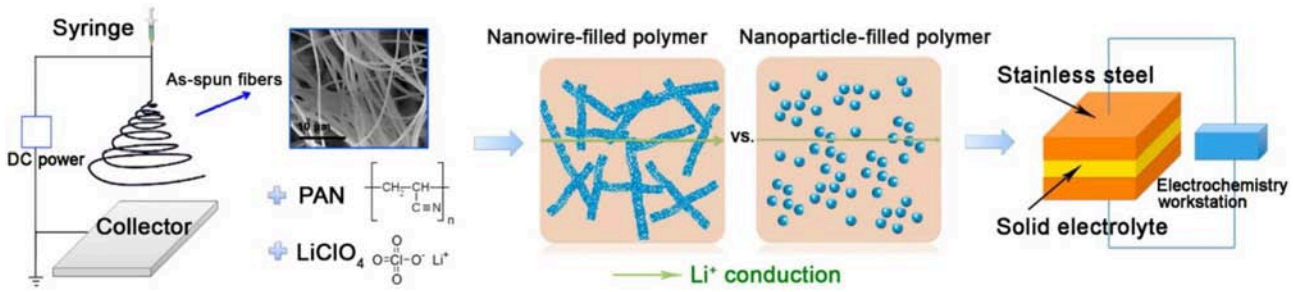

FIGURE 7 | Schematic illustration for the synthesis of ceramic nanowire-filled polymer-based composite electrolytes. [Reproduction with permission from Liu et al. (2015) Copyright© 2009, American Chemical Society].

PEO after removing the template. This artificial 3D infiltration network naturally avoids the agglomeration of nanofillers compared to the traditional simple dispersion process, and its ultra-high specific surface area provides a continuous phase interface network as lithium ion transport channel. Therefore, this composite electrolyte displayed a high ionic conductivity of 8.8×10^{-5} S cm^{-1} at room temperature.

NASICON-Type Composite Polymer Electrolytes

NASICON-type ceramics (aka "sodium super ion conductor") were firstly discovered in 1968 with composition of $NaM_2(PO_4)_3$ (M = Ge, Ti, Zr) (Epp et al., 2015). Surdrean et al. firstly reported NASICON-type solid electrolyte $LiZr_2(PO_4)_3$ at 1989. For formula $LiM_2(XO_4)_3$, $[M_2(XO_4)_3]$ constitutes the basic structure of NASICON. The MO_6 octahedron and the XO_4 tetrahedron are connected in a common angle to form Li-ion transmission channel. Aono et al. (1990) first reported doped trivalent ions into $LiTi_2(PO_4)_3$ and found that the ionic conductivity was improved. In 2014, Perez-Estebanez et al. (2014) achieved high conductivity in the $Li_{1+x}Al_xTi_{2-x}(PO_4)_3$ (LATP) of 6.76×10^{-4} S/cm at 60°C (**Figure 5C**). After that, research on NASICON-type electrolyte experienced fast growth because of its high ionic conductivity (over 10^{-3} S/cm) at ambient temperature and stable in the ambient atmosphere.

Pan group (Yang et al., 2017) fabricated $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$-PEO polymer electrolyte. The discharge specific capacity of $LiFePO_4$/Li using this polymer electrolyte was 158.2 and 94.2 mAh/g at 0.1 and 2 C, respectively. LATP can not only form pathways for lithium transportation in the interphase, leading to improved ionic conductivity, but also physically resist lithium dendrite growth. Lithium aluminum germanium phosphate (LAGP) is also a kind of NASICON-type fast ion conductor ceramic with relative high ionic conductivity ($>10^{-4}$ S/cm). Zhao et al. (2016a) similarly incorporated NASICON-type $Li_{1.5}Al_{0.5}Ge_{1.5}(PO_4)_3$ (LAGP) as Li^+ conductors into PEO matrix. The resultant polymer electrolyte displayed a wide electrochemical window of 0–5.3 V and an ion-conductivity of 6.76×10^{-4} S/cm at 60°C. More intriguingly, such polymer electrolyte based $LiFePO_4$/Li battery showed prominent cycling stability (90% after 50 cycles). Jung et al. (2015) designed a stretchable ceramic-polymer composite electrolyte membrane where NASICON-type LAGP were incorporated into a polymer-Li salt $LiCLO_4$ matrix, to synthesize a polyethylene oxide solid electrolyte membrane (**Figure 8A**). The PEO-$LiCLO_4$-LAGP composite electrolyte with 60–80 wt.% LAGP is still capable of providing enough mechanical modulus and good electrochemical performance. Li/$LiFePO_4$ cells initial discharge capacities reach 138.5 mAh/g and deliver good capacity retention.

Sulfide-Type Polymer Electrolytes

Sulfide-type electrolytes show supreme ion-conductivities in the magnitude of 10^{-2} S/cm at room temperature (Kamaya et al., 2011). However, they demonstrate instability due to reaction with water vapor in air. Sulfide-type ceramics can be divided into three categories: glasses, glass-ceramic, and ceramic. The entire types ion-conductivity can near or exceed liquid electrolyte. Glass/glass-ceramic Li_2S-P_2S_5 and ceramic thio-LISICON $Li_{4-x}Ge_{1-x}P_xS_4$ ($0 < x < 1$) are the most promising ones. $Li_{10}GeP_2S_{12}$ and PEO has been composited to prepare solid electrolyte membrane (Zhao et al., 2016b). The conductivity at room temperature reaches 10^{-5} S/cm, which is higher than other conventional PEO electrolyte at least one order of magnitude, and the electrochemical window spans between 0 and 5.7 V. It greatly expands the selection range of positive electrode materials and presents improved stability to lithium metal. The solid polymer batteries show capacity retentions approaching 92.5% after 50 cycles. Villaluenga et al. (2016) prepared a non-flammable composite electrolytes by fully mechanochemical reaction between hydroxy-terminated perfluoropolyether (PFPE-diol), LiTFSI and $75Li_2S{\cdot}25P_2S_5$ by ball milling for 2 h. The electrolyte containing 77 wt.% ($75Li_2S{\cdot}25P_2S_5$) and 23 wt.% PFPE-diol/LiTFSI displays a conductivity of 10^{-4} S/cm at room temperature (**Figure 8B**).

Solid Polymer Electrolytes With Ionic Liquid

An ionic liquid (IL) is a molten salt at low temperatures and generally consist of organic cations and inorganic anions (Zhao et al., 2016b). Due to the special state, ionic liquids have the characteristics of vapor pressure free, high electrochemical stability, and good thermal stability (Armand et al., 2009).

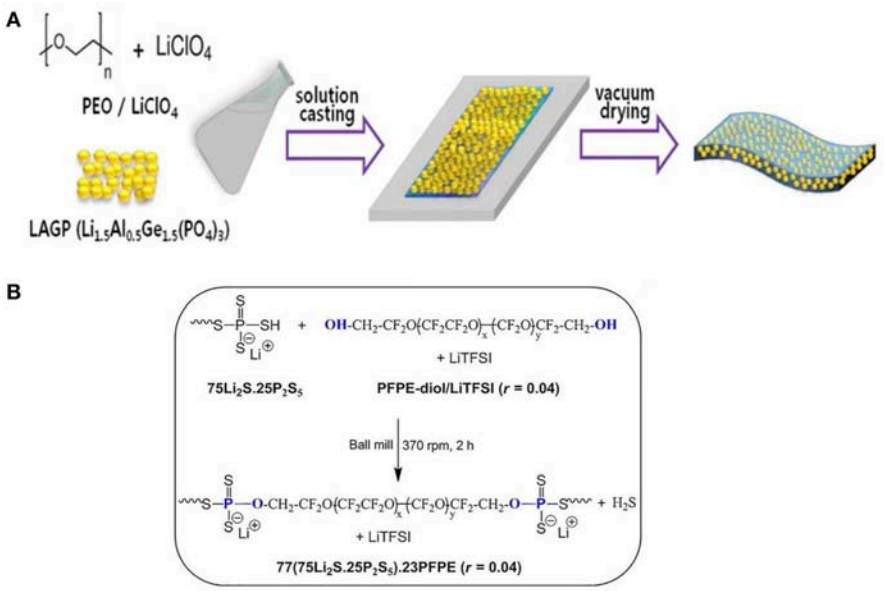

FIGURE 8 | (A) Schematic presentation of preparation for PEO-LiClO4-LAGP hybrid solid electrolyte. [Reproduction with permission from Jung et al. (2015) Copyright 2017, The Electrochemical Society.] **(B)** Synthesis of the hybrid electrolyte $77(75Li_2S.25P_2S_5).23PFPE$ ($r = 0.04$) by mechanochemical reaction. Although ionic liquids have high ionic conductivity, they are not suitable for direct use as electrolytes because of low viscosity. The combination of ionic liquid and polymer offers an option as solid electrolyte for lithium ion batteries.

The introduction of IL into the polymer results in higher ionic conductivity, but it is usually accompanied by a decrease in mechanical strength, especially at high temperature. Lower IL concentration leads to higher mechanical strength, and a smoother continuous electrolyte surface, which is more favorable for ion transport. Therefore, the amount of IL plays an important influence on the ionic conductivity and mechanical properties. Moreover, battery cycling at high temperatures usually causes decomposition of IL components, resulting in degraded performances. It added one more requirement of the polymer components to retain high IL contents.

IL-based polymer electrolytes are mainly classified into three categories. (1) polymer doped IL; (2) ILs/polymerizable monomers crosslinks; (3) polymeric ionic liquids (PILs). The first one is just IL added to the polymer solution or infused in the polymer film directly. For example, Subianto et al. (2009) prepared an electrolyte consisting of IL, silica nano-particles, and Nafion by using sulfonated polyhedral oligomeric silsesquioxane (S-POSS) modified Nafion membranes soaking with 1-butyl-3-methylimidazolium bis-(trifluoromethylsulfonyl)imide (BMI-BTSI) (**Figure 9**). The thermal stability of Nafion films was improved after ionic liquid infiltration. More importantly, the conductivity of the infiltrated films is increased by one to two orders of magnitude than that of the unmodified one. ILs/polymer monomer cross-linking is the mixing of ILs and polymerizable monomers to obtain electrolytes by means of thermal or photo polymerization. Polymeric ionic liquids (PILs) can be designed by the direct polymerization of polymerizable IL-based monomer or polymerizing a modified polymer and an IL monomer. By taking full advantages of the specific properties of ionic liquids and polymers, PIL membrane has generated great interest in recent years. By adopting solution cast technique, Karuppasamy et al. (2016) designed PIL synthesized solid electrolytes by preparing ionic liquids of lithium N, N-bis(trifluoromethanesulfonyl)imide (LiTFSI) in N-ethyl-N-methylimidazolium–bis(trifluoromethanesulfonyl) imide (EMImTFSI) IL with incorporated organic solvent and nanoparticle into PEO. The prepared PIL electrolyte exhibits high ionic conductivity of 10^{-2} S/cm and high electrochemical stability. Yang et al. (Li et al., 2011) designed a solid electrolyte by combining PIL with different anions such as BF_4^-, PF_6^-, ClO_4^-, and $N(CF_3\ SO_2)_2^-$. PILs electrolyte with 1g2-MA-BF_4/$LiBF_4$ exhibited ionic conductivity as high as 1.35×10^{-4} S/cm at 30°C. Starting from PEO, modified sepiolite (TPGS-S), LiTFSI, and 1-Butyl-1-methylpyrrolidinium bis(trifluoromethanesulfonyl)imide (PYR14TFSI) ionic liquid, electrolytes was synthesized via solvent free extrusion method (Gonzalez et al., 2018). The resultant polymer electrolyte displayed wide electrochemical window of 4.2 V and ion-conductivity of 5×10^{-4} S/cm at 60°C.

SOLID POLYMER ELECTROLYTES WITH MOFs

Metal–organic frameworks (MOFs) are a new kind of porous material, which are composed of metal ions and bridging organic ligands (Stavila et al., 2014; Indra et al., 2018; Xie X. C. et al.,

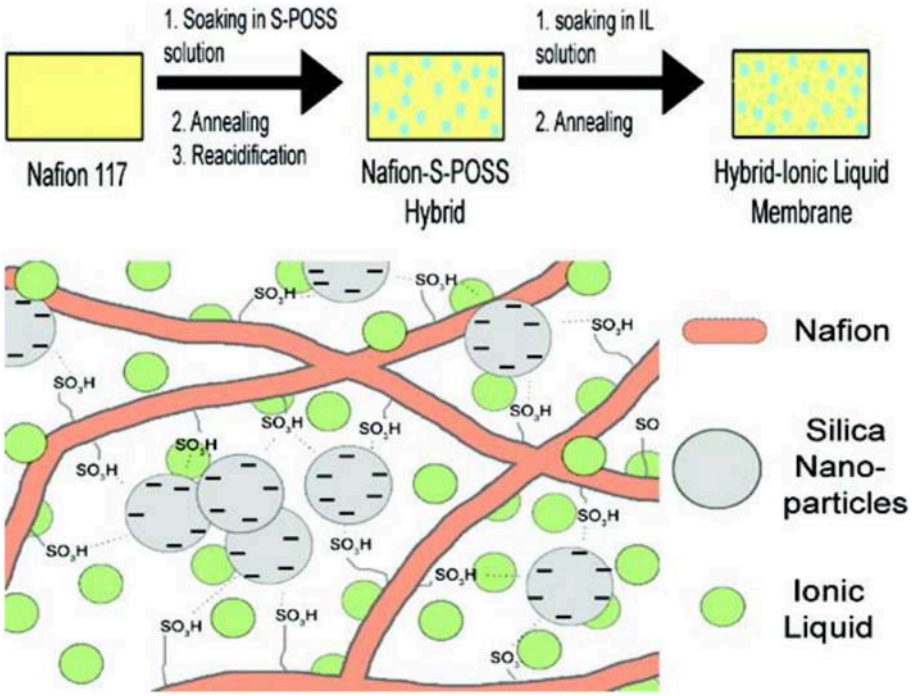

FIGURE 9 | Schematic illustration of the overall procedure for the preparation of Hybrid-Ionic liquid electrolyte. [Reproduction with permission from Subianto et al. (2009). Copyright© 2009, American Chemical Society].

2018). MOFs have many properties such as porosity, large specific surface area, and polymetallic sites (Yuan et al., 2013), so they are widely used in many fields including gas adsorption, molecular separation, drug delivery (Mueller et al., 2006; Kuppler et al., 2009; Li et al., 2009). Many investigations have indicated that MOFs also has positive effect on increased ionic conductivity due to high specific surface and the good adsorption property. Yuan et al. (2013) prepared a new SPE by the addition of Zn-based MOF-5 into PEO polymer electrolyte. The combination of MOFs and polymer showed positive effect on the mechanical and electrochemical properties as solid electrolyte. The ionic conductivity of these membrane can reach 3.16×10^{-5} S/cm at ambient temperature, which is attributed to two parts. Firstly, the interaction of the Lewis acidic sites on the MOF-5 with the PEO chain and the lithium salt hinder the crystallization of the PEO, and facilitate the formation of Li^+ conductive channels. Secondly, the isotropic open MOF-5 can adsorb solvent to accelerate the transport of ions. Gerbaldi et al. (2014) proposed a new filler material (aluminum-based MOF) (**Figure 10A**), which was successfully prepared and incorporated in a PEO-based polymer matrix. Ionic conductivity of the composite membrane is two orders of magnitude greater than that without mixed MOFs. lithium batteries ($Li/LiFePO_4$) with the electrolyte showed distinguished charge-discharge performance and high specific capacity. At 1 C rate, the battery can still cycle stably at 50°C, and the decay of specific capacity is not obvious when restored to 70°C. After 500 cycles, the capacity is almost maintained as the initial, and the Coulombic efficiency is only slightly decreased. This shows an excellent capacity retention capability and good cycle stability (**Figure 10B**). Recently, Wang Z. et al. (2018) synthesized a new chemically linked composite MOF-polymer electrolyte. The film was prepared by photopolymerization with post-synthetic modification of the MOF (M-UiO-66-NH_2), poly(ethylene glycol) diacrylate and LITFSI (**Figure 11**). The interface between MOF and polymer provides a fast channel for lithium-ion transport, accordingly the conductivity of the composite electrolyte (HSPE-1-8) is 4.31×10^{-5} S/cm at 30°C that is up to five times more than that of no composite MOF. The solid $Li/LiFePO_4$ cells assembled with these SPEs cycled at 60°C demonstrated excellent coulombic efficiencies.

SOLID POLYMER ELECTROLYTES WITH CELLULOSE

Cellulose is a non-toxic harmless, inexpensive, and natural eco-friendly materials with high mechanical strength and a large specific surface area (Baxter et al., 2009; Sheng et al., 2017) Due to the unique properties, cellulose can not only enhance the mechanical properties of polymers in electrolytes, but hinder the growth of lithium dendrites effectively acting as a physical barrier. The interface between cellulose and polymer behaves as a channel for ion transport, facilitating ion transport. In addition, polar groups in cellulose can improve salt dissociation (Shi et al., 2017). Nair et al. (2009) reported a polymer composite electrolyte with cellulose reinforcement. The reinforced electrolyte exhibited a high ionic conductivity (2.0×10^{-4} S/cm at 25°C) and

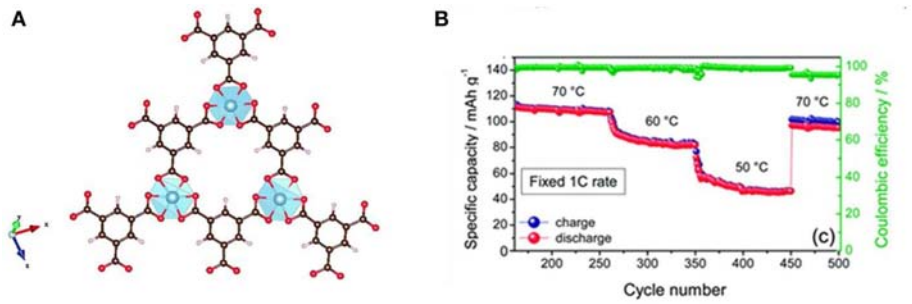

FIGURE 10 | (A) Schematic diagram of the ideal network structure of an aluminum(III)-1,3,5-benzenetricarboxylate (Al-BTC) metal organic framework. **(B)** Electrochemical characteristics of the $LiFePO_4$/S4-NCPE/Li cell at different temperatures and current regimes. an exceptional mechanical property, which is expected for flexible electronic devices applications. Furthermore, ionic liquid compounded with cellulose can solve the issues of IL leakage in the composite electrolyte. Shi et al. (2017) designed a new type of 3D self-assembled polymeric ionic liquid (PIL)-nano-cellulose to form polymer electrolyte. The structure not only enhances the mechanical properties of the SPE, but also forms strong lithium coordination to promote lithium salt dissolution. The dissolved lithium salt can combine with IL to form an ion-conducting domain, thereby promoting ion transport. Asghar et al. (2012) adequately utilizes the characteristics of networked cellulose (NC), with mechanical strength and adopted it to design quasi-solid PEG-LiClO4-NC polymer electrolyte. The resultant composite electrolyte with a 12.8 wt.% NC resulted in the highest ion conductivity (10^{-4} S/cm at 25°C) and is electrochemically stable up to 4.7 V. Similarly, Zhang et al. (2014) combined cellulose non-woven with PCA-PEO to fabricate a rigid-flexible coupling SPE, upgrading their comprehensive properties of the composite electrolyte significantly.

SUMMARY AND OUTLOOK

Although lithium-ion batteries have long been commercialized, the use of liquid electrolytes has some disadvantages such as poor safety and unstable electrochemical performance, which greatly limits its further development and wider applications. Solid composite polymer electrolyte in lithium-ion batteries has received a lot of attention lately because of its low flammability, good flexibility, excellent thermal stability, and high safety. In this review, we have provided fundamental understandings of the ionic conductivity mechanisms and interfaces for solid composite electrolytes, in the meantime, recent progresses on polymer-based composite electrolytes were summarized, including polymer/inert ceramics, polymer/fast-ion conductive, polymer/ionic liquid, polymer/MOFs, and polymer/cellulose composite electrolytes.

Although substantial researches have been dedicated to the polymer-based composite electrolytes, some fundamental issues still need to be solved urgently before commercialization. For

example, ionic conductivity of the composite solid electrolyte still differs by several orders of magnitude from the liquid counterpart; many polymer-based solid electrolytes exhibit high ionic conductivity at high temperatures, while it drops dramatically at lower temperatures; the conductivity mechanism and interfacial interaction need to be further clarified not accelerate further studies.

At present, the polymer/ionic liquid solid electrolyte inevitably causes a decrease in mechanical properties when obtaining high ionic conductivity, which has great safety hazards. The difficulty in polymer/inert ceramic solid electrolytes is how to construct a good dispersion and strengthen the interaction between the filler and the polymer, which restricts the further improvement of ionic conductivity. In comparison, polymer/fast ion conductors composite electrolytes have both high ionic conductivity at room temperature and good mechanical properties. The future development direction of polymer-based solid electrolytes is likely to be the combination of fast ion conductors and polymers, which can combine the advantages of high ion conductivity of fast ion conductors and solve the problem of poor interface contact. Of all the types of polymer-based composite solid electrolytes, SPEs with fast ion conductors have gained all the advantages and are the direction of development of commercial solid electrolytes.

The following aspects were recommended of focusing on solid electrolyte in future developments. Firstly, using materials genome database to analyze, guide, and design composite material can promote efficiency and cost savings. Material calculations facilitate an in-depth understanding of the material. The corresponding ionic mechanism can be simulated and interpreted by material calculations. Secondly, most of battery materials, such as electrodes, electrolytes, and SEI films, are sensitive to electron beams and difficult to observe under conventional transmission electron microscopy (TEM). Advanced characterization techniques can facilitate analysis of material mechanisms. For example, using cryo-electron microscopy, Zachman et al. (2018) reveals atomic structure of sensitive battery materials and interfaces. Similarly, Meng et al. (Wang et al., 2017) studied the interface of solid electrolytes via Cryogenic TEM, which has greatly promoted further research on the interface. Finally, struggling to find suitable composite electrolytes with high conductivities at low temperature always deserves more study. Commercial solid electrolytes require high ionic conductivity at room temperature, safety and easy processing to compete with the liquid counterpart.

AUTHOR CONTRIBUTIONS

PY, JW, and HY collected the data, performed the statistical analysis, interpretation of the results, and wrote the manuscript. ZD, YL, and JL carried out the bibliographical research and performed the inferential analyses together with other authors. ML and XL offered Suggestions and revisions in English for the article.

Sorption of Water Vapor in Poly(L-Lactic Acid): A *Time-Resolved* FTIR Spectroscopy Investigation

Marianna Pannico and Pietro La Manna*

Institute of Polymers, Composites and Biomaterials, National Research Council of Italy, Pozzuoli, Italy

In this contribution the sorption of water vapor in Poly(L-lactic acid) (PLLA) was studied by time-resolved FTIR spectroscopy. The collected FTIR data were analyzed by complementary approaches such as difference spectroscopy, two-dimensional correlation spectroscopy (2D-COS), and least-squares curve-fitting analysis which provided information about the overall diffusivity, the nature of the molecular interactions among the polymer and the penetrant and the dynamics of the various molecular species. The diffusion coefficient were evaluated as a function of vapor activity and were found in good agreement with previously reported values. The system showed a Fickian behavior with diffusivity increasing with penetrant concentration. Two distinct water species (first-shell and second-shell layers) were detected and quantified by coupling FTIR and gravimetric measurements.

Keywords: water vapor, diffusion, FTIR spectroscopy, PLLA, molecular interaction

INTRODUCTION

Over the past decade, the use of polymeric biodegradable materials has increased substantially because of their versatility in a variety of applications as well as for the increasing environmental concern. They are widely used in the pharmaceutical, medical, and packaging fields due to their unique properties such as biocompatibility, biodegradability, eco-friendliness, and processability (Ikada and Tsuji, 2000; Temenoff and Mikos, 2000; Chen et al., 2002; Noda and Ozaki, 2004; Nair and Laurencin, 2007; Siracusa et al., 2008; Sabir et al., 2009; Armentano et al., 2010; Leja and Lewandowicz, 2010). Among the wide family of biopolymers, Poly(lactic acid) (PLA), and, in particular, its L-isomer, PLLA, has gained prominence owing to its excellent biocompatibility and good mechanical properties. Commercially, PLLA has been introduced in food packaging applications including oriented and flexible films, extruded and/or thermoformed packages for food and beverage containers, cups, overwrap, and blister packages (Tullo, 2000; Auras et al., 2004; Sagar et al., 2007; Tawakkal et al., 2014). In the realm of biomaterials, Dürselen et al. (2001) demonstrated that PLLA fibers are ideally suited for ligament and tendon reconstruction as well as stents for vascular and urological surgery. PLLA based microspheres were also used as injectable material in facial reconstructive surgery and in drug delivery systems (DDS) for the administration of a wide variety of medical agents (Imola and Schramm, 2002; Eppley et al., 2004; Tyler et al., 2016). PLLA contains flexible ester bonds whose hydrolytic degradation is caused by water diffusing into the bulk material. The hydrolytic products are non-harmful and non-toxic monomers/oligomers because they are metabolized via the citric acid (Krebs) cycle. For both medical and packaging applications, hydrolysis would be one of the most important degradation mechanism to account for. The PLLA hydrolysis behavior in biomedical devices such as implants and carriers in DDS, has

been widely investigated in different media at various temperatures (Göpferich, 1996; Li, 1999; Liu et al., 2000; Tsuji et al., 2000, 2003, 2011; Tsuji and Miyauchi, 2001; Fukuda et al., 2002; Kikkawa et al., 2002; Yuan et al., 2002). Literature data are mainly concerned with the effects of water in the liquid state. Only few studies have been reported on the PLLA hydrolysis carried out by water vapor (Ho et al., 1999; Copinet et al., 2004; Holm et al., 2006). Water sorption in PLA significantly affects the physico-chemical properties of the polymer matrix. Rocca-Smith et al. (2017) clearly showed that the stability of PLA was also influenced by the water physical state. It is evident that, in all the above applications, the diffusion of water in the bulk material represent one of the major issue to be considered. In this contribution, a molecular level description of water vapor diffusion in a fully amorphous PLLA matrix is reported. Among the different spectroscopic techniques employed for the investigation of water–polymer systems (Rothwell et al., 1984; Taylor et al., 2001) (Solid-state NMR, Raman, neutron scattering, light scattering) FTIR spectroscopy has been demonstrated to be very powerful because of its sensitivity toward H-bonding detection and its sampling flexibility (Cotugno et al., 2001; Scherillo et al., 2013).

We report on a *time-resolved* FTIR study performed at different relative pressures of water vapor. The spectral data have been analyzed by different and complementary approaches, namely, difference spectroscopy (DS), least-squares curve fitting (LSCF), and 2-D correlation spectroscopy (2DCOS) which allowed us to isolate the spectrum of the penetrant and to improve the resolution of its complex band profile in the ν(OH) frequency range. The above techniques, taken together, provided information on the nature, number, and dynamic behavior of the water species present in the investigated system. By coupling the spectroscopic data with gravimetric measurements, carried out in the same conditions of temperature and vapor pressure, we were able to quantify the water species population.

EXPERIMENTAL

Materials

PLLA was a commercial grade product (Ingeo Biopolymer 2003D) kindly provided by Nature Works (Minnetonka, MN, USA). It had $\overline{M}_n = (79.4+1.1)\,kDa$, $\overline{M}_w = (121.3+0.5)\,kDa$ and a polydispersity of 1.53 ± 0.02. The present PLLA resin, in the form of pellets, contains, according to the supplier, 4% D-lactic acid isomer; it has a density of 1.240 g/cm^3, a melting temperature of 145–170°C, a glass transition temperature (T_g) of 55–58°C, and a crystallinity (maximum attainable) of 35%. Chloroform, 99.8% purity, was purchased from Sigma-Aldrich (Milan, Italy) and used with no further purification.

Film Preparation

A 20 wt% solution of PLLA in chloroform was spread onto a glass plate with a Gardner knife to obtain a film thickness of 46 ± 5 μm. The PLLA film was kept overnight at room temperature to remove most of the solvent. Final drying was accomplished in a vacuum oven at 40°C for 10 days. No residual solvent was detected by spectroscopic (FTIR) and gravimetric (TGA) measurement.

FTIR Sorption Measurements

Time-resolved spectra were collected in transmission mode during sorption/desorption cycles of water vapor in the samples. The experiments were performed using a vacuum-tight FTIR sorption cell in which a free standing PLLA film is exposed from both sides to water vapor at constant temperature (35°C) and selectable relative pressures (p/p_0 = 0–0.5) of the penetrant. The sorption cell was accommodated in the sample compartment of a suitably modified FTIR spectrometer [Spectrum 100 from Perkin-Elmer (Norwalk, CT)], equipped with a Ge/KBr beam splitter and a wide-band DTGS detector. The cell was directly connected through service lines to a water reservoir, a turbo-molecular vacuum pump, a pressure transducer [MKS Baratron 121 (Andover, MA); full scale, 100 Torr; resolution, 0.01 Torr; accuracy, ± 0.5% of the reading] and a Pirani vacuometer. Full details of the experimental apparatus are reported in Cotugno et al. (2001). Before each sorption measurement, the sample was dried under vacuum, overnight, at 35°C in the same apparatus used for the test. The instrumental parameters for data collection were set as follows: resolution = 2 cm^{-1}; optical path difference (OPD) velocity = 0.2 cm/s; spectral range, 4,000–600 cm^{-1}. Spectra were acquired in the single-beam mode for subsequent data processing. Automated data acquisition was controlled by a dedicated software package for *time-resolved* spectroscopy (Timebase, from Perkin-Elmer).

Gravimetric Measurements

For calibration purposes, gravimetric measurements were performed using a microbalance Q5000 SA apparatus (produced by TA Instruments, New Castle, DE, USA) that is a fully automated gravimetric water vapor sorption analyzer, operating in the 5–85°C temperature range. The sample was exposed to

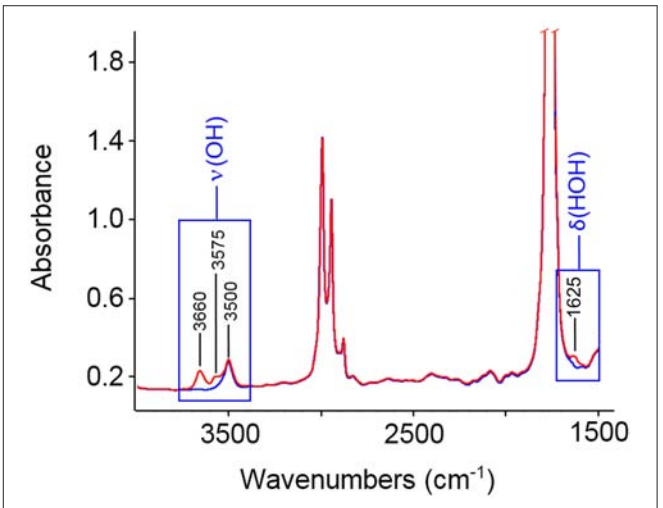

FIGURE 1 | FTIR spectra of: fully dried PLLA film (blue trace); the same film equilibrated at p/p_0 = 0.5 (red trace).

a series of humidity step changes at a constant temperature of 35°C. The relative humidity in the sample chamber is dynamically controlled in the 0–98% RH range, with an accuracy of ±1% RH, by mixing, in due proportion, a dry and a gaseous nitrogen stream saturated with water vapor by means of electronic mass flow controllers. Integral sorption runs were performed at four selected values of relative pressure, p/p_0, i.e., 0.202, 0.396, 0.582, and 0.764. Prior to each sorption test, the sample was dried in the microbalance under dry nitrogen steam until a constant weight was attained. Further details on the experimental apparatus and data treatment are reported in Scherillo et al. (2012b).

FTIR Data Analysis

Full absorbance spectra (i.e., sample plus absorbed water) were obtained using a background collected on the empty cell at the same relative pressure of water vapor used for the sorption measurement. The spectra representative of absorbed water were obtained by using the difference spectroscopy (DS) technique, i.e., by subtracting the spectrum of the dry sample from that of the sample equilibrated at different p/p_0 values:

$$A_d(\nu) = A_s(\nu) - k \cdot A_r(\nu) \quad (1)$$

where $A(\nu)$ is the absorbance at frequency ν and the subscripts d, s, and r denote, respectively, the difference spectrum, the sample spectrum (*wet* specimen), and the reference spectrum (*dry* specimen). k is an adjustable parameter which allows to compensate for thickness differences (if any) between the sample and the reference spectra. It was experimentally verified that negligible thickness changes take place during sorption; therefore, the k values were consistently taken as unity. The DS procedure allowed us to eliminate the interference of the polymer spectrum in the analytical ranges of interest [3,800–3,400 cm^{-1}, ν(OH), and 1,660–1,550 cm^{-1}, δ(HOH)]. Separation of multicomponent bands into individual peaks was achieved by a least-squares curve fitting (LSCF) algorithm based on the Levenberg–Marquardt method (Marquardt, 1963). The peak function was a mixed Gauss–Lorentz line-shape of the form:

$$f(x) = (1 - Lr)H \exp - \left[\left(\frac{x - x_0}{FWHH} \right)^2 (4 \ln 2) \right] + Lr \frac{H}{4\left(\frac{x - x_0}{FWHH}\right)^2 + 1} \quad (2)$$

where x_0 is the peak position; H the peak height; $FWHH$ the full-width at half height and Lr is the fraction of Lorentz character. In order to keep the number of adjustable parameters to a minimum, the baseline, the number of components and the band-shape (Lr parameter) were fixed, allowing the curve-fitting algorithm to optimize $FWHH$, H, and x_0 for the individual components.

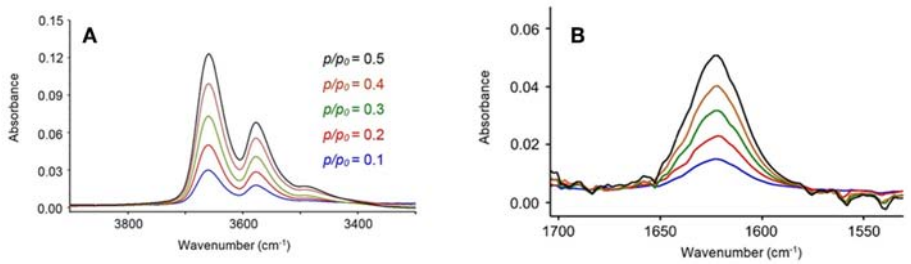

FIGURE 2 | Difference spectra in the 3,900–3,300 cm^{-1} range **(A)** and in the 1,700–1,540 cm^{-1} range **(B)** for the PLLA film equilibrated at different relative pressures of water vapor.

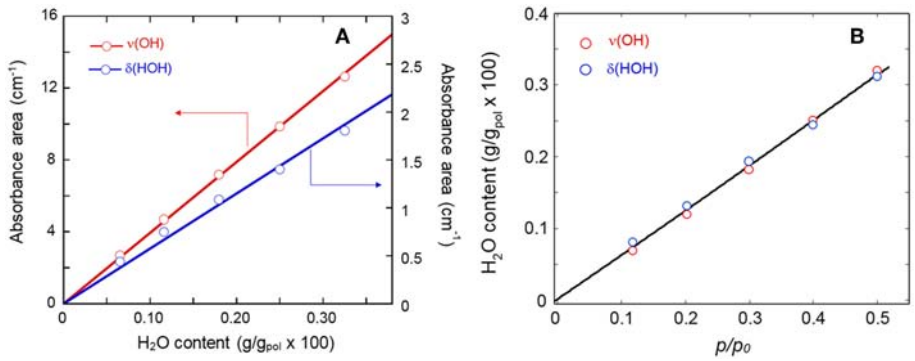

FIGURE 3 | (A) Calibration curves (Absorbance vs. gravimetric concentration) for the ν(OH) and the δ(HOH) bands of sorbed H_2O. **(B)** Sorption isotherm as evaluated from the two analytical signals.

Two-Dimensional Correlation Spectroscopy (2D-COS) Analysis

The experimental spectra for 2D-COS analysis were pre-processed to avoid the occurrence of artifacts due to baseline instabilities and other non-selective effects. The frequency region of interest (3,900–3,300 cm^{-1}) was isolated and offset to zero absorbance. Generalized 2D-IR analysis was performed by a script written in house with the MATLAB programming language (Mathworks, Natick, MA). The MATLAB environment also provided the tools for the graphical representation of the correlation spectra (contour plots, 3D images). The algorithm proposed by Noda relying on the Hilbert transform (Noda, 2000) was used for the numerical evaluation of the correlation intensities. The 2D correlation analysis was performed on an evenly spaced sequence of 100 spectra collected at a constant sampling interval of 0.98 s. The analyzed time-span (98 s) was sufficient to attain sorption equilibrium (vide infra). The notation adopted to identify the peaks appearing in the correlation spectra is that described in Musto et al. (2007).

RESULTS AND DISCUSSION

FTIR SPECTROSCOPY

In **Figure 1** are reported the FTIR spectra of the fully dried PLLA film (blue trace) and of the same film equilibrated at a relative pressure of water vapor, p/p_0, equal to 0.5 (red trace). Sorbed water displays characteristic bands around 3,660 cm^{-1} [ν(OH)] and 1,625 cm^{-1} [δ(HOH)]. Difference spectroscopy (DS) allows us to suppress the interference of the substrate and to isolate the spectrum of the penetrant. This is represented in **Figures 2A,B** in the 3,900–3,200 cm^{-1} range and in the 1,700–1,500 cm^{-1} range, respectively. The spectra were collected at the indicated relative pressures of water vapor. Both ν(OH) and δ(HOH) bands increase with relative pressure and the bandshapes are very reproducible, which suggests that, in the explored p/p_0 range the molecular interactions formed between the probe and the polymer substrate (and, eventually, the probe self-association) do not depend on H_2O concentration. The featureless and symmetrical profile of the δ(HOH) band reflects the very low sensitivity of the δ-mode to H-bonding (Murthy and Rao, 1968). This characteristic makes the bending peak suitable for analytical purposes. The stretching band is more complex, owing to the high sensitivity of these modes to the molecular environment.

Two well-defined maxima are observed at 3,660 and 3,578 cm^{-1}, suggesting the presence of multiple water species involved in different types of H-bonding interactions. These results confirm that in-depth analysis of the ν(OH) profile will provide molecular level information on the system under scrutiny. Preliminary attempts at curve resolution of the traces in **Figure 2A** by LSCF analysis using only two components were unsuccessful, regardless of the adopted bandshape.

This suggests a more complex structure of the experimental profile, which had to be explored by resolution-enhancement approaches.

In **Figure 3A** is represented the correlation between the absorbance area of the ν(OH) and the δ(HOH) bands with the amount of sorbed water measured gravimetrically. The linear trend through the origin confirms the validity of the Beer-Lambert relationship and allows us to use the photometric data for the quantitative monitoring of the diffusion kinetics and for measuring solubility vs. relative-pressure isotherms.

The sorption isotherm at 35°C in the p/p_0 range 0.1–0.5 is reported in **Figure 3B**, while **Figure 4** shows the sorption kinetics at $p/p_0 = 0.5$. As expected, data taken from the two analytical signals are essentially coincident; the isotherm is linear in the explored pressure range and the maximum mass uptake is 0.33 wt%. This value is low and only slightly higher than those for other semicrytalline polyesters of similar molecular structure

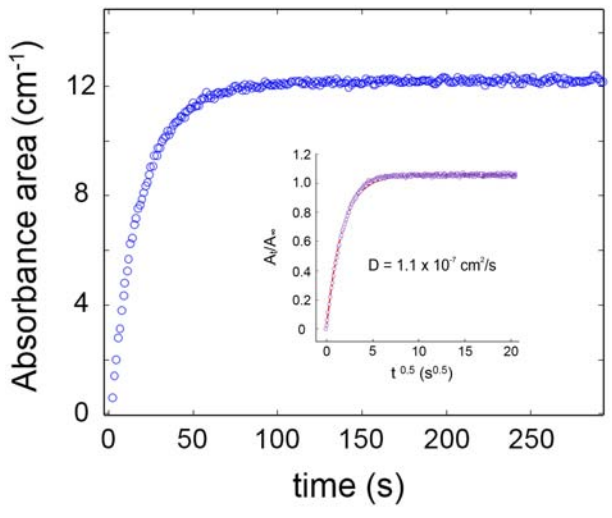

FIGURE 4 | Absorbance of the ν(OH) band of water as a function of time for a sorption experiment at $p/p_0 = 0.5$. The inset displays the Fick's diagram obtained therefrom. Open circles refer to experimental data points; the continuous line is the least-squares regression with model Equation (3).

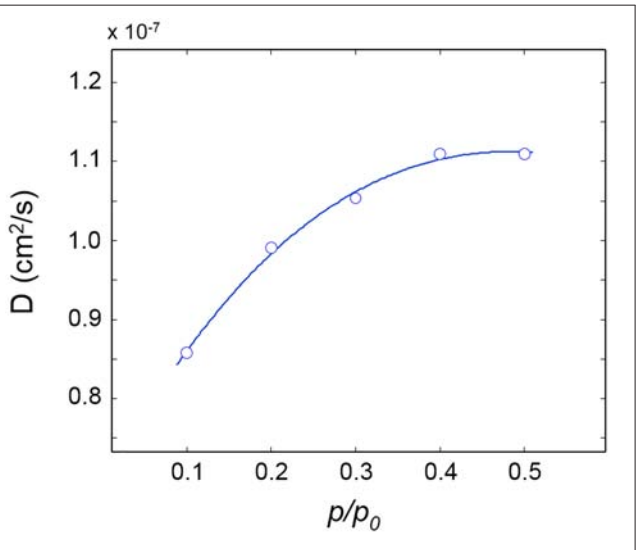

FIGURE 5 | Diffusivity of H_2O in PLLA as a function of relative pressure of water vapor. The connecting line is for eye guidance.

[PCL, poly(propylene sebacate)], on account of the hydrophobic character of these polymers. More on this later. The kinetic behavior was modeled by the Fick's second law of diffusion expressed in terms of absorbance, which, for the case of a plane sheet exposed to an equal penetrant activity on both sides, can be written as (Crank, 1975):

$$\frac{A(t)}{A_\infty} = \frac{M(t)}{M_\infty} = 1 - \frac{8}{\pi^2}\sum_{m=0}^{\infty}\frac{1}{(2m+1)^2}\,exp\left[\frac{-D\,(2m+1)^2\,\pi^2 t}{L^2}\right] \quad (3)$$

In Equation (3) $A(t)$ and A_∞ represent the integrated absorbance of the ν(OH) band at time t and at equilibrium, L is the film thickness and D is the mutual diffusivity.

The model consistently simulates the experimental data in the whole time range (see inset of **Figure 4**), and the $A(t)/A_\infty$ vs. $t^{0.5}$ curve is linear up to an ordinate value of 0.6, which demonstrates the Fickian behavior of the system. This result is in line with earlier literature reports on polyesters belonging to the same family (Musto et al., 2014; Scherillo et al., 2016).

Sorption kinetics were monitored at five p/p_0 values from 0.1 to 0.5 and the diffusion coefficients, D, evaluated therefrom are plotted as a function of p/p_0 in **Figure 5**.

The D-value reported in the literature (0.7×10^{-7} cm^2/s by gravimetry) (De Santis et al., 2015) is found in good agreement

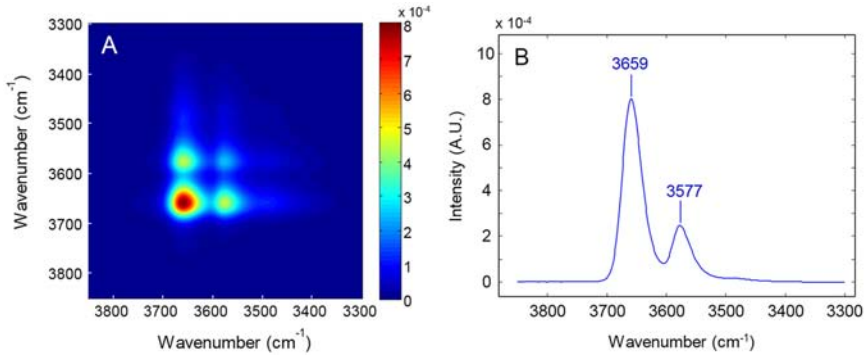

FIGURE 6 | (A) 2D-COS synchronous color-map obtained from the *time-resolved* spectra collected during the sorption experiment at $p/p_0 = 0.5$. **(B)** Power spectrum calculated therefrom.

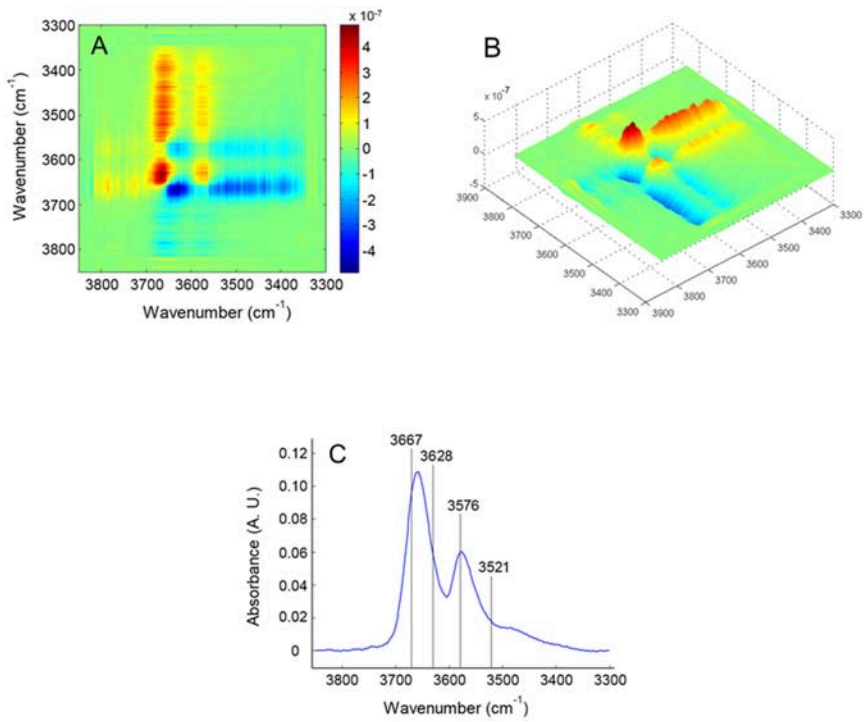

FIGURE 7 | 2D-COS asynchronous map obtained from the *time-resolved* spectra collected during the sorption experiment at $p/p0 = 0.5$. with the present spectroscopic determinations; an increasing trend of D with the water vapor pressure is also noted in **Figure 5**, which indicates that the mutual diffusivity coefficient is a growing function of the penetrant concentration.

This behavior is generally associated to a swelling effect of the penetrant, which increases the available free volume, with the consequence of enhancing the mobility of the diffusing molecules. In the present case, no direct spectroscopic evidence is found for the swelling of the sample upon sorption. However, a possibility exists that, while the swelling is so small to remain below the limits of detection, it is still sufficient to produce a sizeable effect at the molecular level. The present diffusivity data only allow us a tentative interpretation; a deeper analysis supported by thermodynamic and/or MD modeling is currently underway.

2D-COS Analysis

The 2D-COS technique was shown to be a powerful method for studying molecular interactions that produce broad, poorly resolved features (Noda and Ozaki, 2004; Galizia et al., 2014). It is a perturbative technique by which a system initially at equilibrium is subjected to an external stimulus: a correlation analysis is performed on the spectral response (absorbance, in the present case) as a function of a third common variable related to the perturbing function (time, in the present case).

In **Figures 6A,B** are represented, respectively, the synchronous spectrum in the 3,800–3,300 cm^{-1} range, obtained from the time-resolved spectra collected during the sorption experiment performed at $p/p_0 = 0.5$ and the power spectrum, i.e., the autocorrelation profile taken across the main diagonal. The synchronous map displays the autopeaks (and the corresponding cross-peaks) already identified in the frequency profile; in the power-spectrum the two components are fully resolved and there is no evidence of further spectral features, in contrast with the results of the LSCF analysis.

TABLE 1 | Position, sign, and type of the correlation peaks appearing in the synchronous and asynchronous spectra.

ν_1 (cm^{-1})	ν_2 (cm^{-1})	Sign[a]	Type[b]	Trend[c]
SYNCHRONOUS				
3,659	3,659	+	A	> >
3,577	3,577	+	A	> >
3,659	3,577	+	C	> >
ν_1 (cm^{-1})	ν_2 (cm^{-1})	Sign[a]	Type[b]	Rate of change
ASYNCHRONOUS				
3,628	3,667	−	C	3,628 < 3,667
3,576	3,628	+	C	3,576 > 3,628
3,521	3,667	−	C	3,521 < 3,667
3,521	3,576	−	C	3,521 < 3,576

[a] *The sign refers to the cross-peaks in the lower side of the spectrum, with respect to the main diagonal. The sign of the cross-peaks in the upper side can be deduced on the basis of the symmetry properties of the respective matrices (synchronous, symmetric; asynchronous, antisymmetric).*

[b] *A, autopeak (along the main diagonal); C, cross-peak (off-diagonal).*

[c] *>, increasing peak; <, decreasing peak.*

In **Figure 7** is displayed the asynchronous spectrum in the form of a contour-map (**Figure 7A**) and as a 3D iso-intensity surface (**Figure 7B**) which highlights finer details on the shape of the correlation bands. The components identified in the asynchronous map are indicated in the frequency spectrum of **Figure 7C**. The results of the analysis are summarized in **Table 1**. The specificity and the resolution enhancement brought by asynchronous correlation allows us to identify two components in the main frequency peak at 3,659 cm^{-1}, located, respectively, at 3,667 and 3,628 cm^{-1}. These are readily recognized in the form of two well-developed cross-peaks (in the lower side of the map with respect to the main diagonal) at [3,628–3667 (–)], [3,576–3,628 (+)]. The shape of these two cross-peaks is typical of a correlation between two sharp signals. Two more correlation bands occur at [3,521–3,667 (–)] and [3,521–3,576 (–)]. These are less defined and display the elongated shape characteristic of a correlation between a sharp signal and a much broader band. In particular, the band at [3,521–3576 (–)] is only slightly above the noise level (see **Figures 7A,B**), reflecting the low intensity of the signal at 3,521 cm^{-1}. The two above features clearly identify the presence of a broad component approximately centered at 3,521 cm^{-1}, already suggested by the preliminary LSCF analysis. The asynchronous map displays a more detailed pattern and is richer of information than the synchronous.

This effect is related to the fact that in the former case resolution enhancement occurs via two distinct mechanisms, i.e., the spreading of the spectral data over a second frequency axis, and the vanishing of the asynchronous correlation intensity for signals evolving at the same rate. A detailed discussion of the latter effect is reported in Musto et al. (2018). In the synchronous spectrum only the first mechanism is operative.

To summarize, 2D-COS identified four components in the ν(OH) range: three are sharp and are located at 3,667, 3,628, and 3,576 cm^{-1}, the fourth is much broader and is so weak to be barely detectable in the frequency spectrum. Taking into account the correlation relationships from the 2D-COS maps, the following interpretation can be advanced: the four components are arranged pair-wise, the two signals centered at 3,667 and 3,576 cm^{-1} evolve synchronously and at a different rate with respect to the couple at 3,628–3,521 cm^{-1} that is also synchronously correlated. Applying the Noda correlation rules (Noda and Ozaki, 2004) the sign of the cross-peaks reveals that, in the sorption experiment the doublet at 3,655–3,562 cm^{-1} grows faster than the doublet at 3,611–3,486 cm^{-1}.

The above findings can be interpreted considering that a single water molecule produces two OH-stretching modes (in-phase at lower frequency and out-of-phase at higher frequency). Thus, the two couples of signals suggest the presence of two distinct water species. The doublet at 3,667–3,576 cm^{-1} is assigned, respectively, to the ν_{as} and the ν_s modes of isolated water molecules interacting with the PLLA carbonyls, while the second couple at 3,628–3,521 cm^{-1} originates from a self-associated water species. It has been demonstrated that, when aggregates of the type C=O....H–O–H (Iwamoto et al., 2003) are formed, the "free" O–H bonds in the complex produces a characteristic signature at 3,690 cm^{-1}. The absence of this feature, coupled with the 2D-COS results which detected only two H_2O species,

provides support for the conclusion that in the present system the amount of H_2O molecules forming an H-bonding interaction with a single carbonyl group is negligible. The stoichiometry of the carbonyl-to-water interaction is thus 2:1, i.e., of the type:

–C=O....H–O–H....O=C–.

Of the two components belonging to the self-associated species, the one at 3,628 cm^{-1} originates (predominantly) from a "free" O–H bond, while that at 3,521 cm^{-1} is due to the O–H bond forming the self-interaction. In fact, the breadth of the latter band, around four times larger than the other three signals (see the forthcoming paragraph on LSCF analysis), is characteristic of water-to-water H-bonding, with the associated distribution of bond-lengths and geometries. The two water species identified spectroscopically with the signals they produce are schematically represented in **Figure 8**.

LSCF Analysis

The 2D-COS results were used as a benchmark to guide the LSCF analysis. Thus, a Gaussian component at 3,520 cm^{-1} was added to the model; the high-frequency peak was maintained as single component because no evidence of a fine structure was discernible. The regression of the spectrum representative of water sorbed at equilibrium in PLLA at $p/p_0 = 0.5$ is reported in **Figure 9**.

The adopted model afforded a satisfactory and consistent simulation of all the experimental profiles collected at the different p/p_0 values. The intensity of the resolved components can be converted into absolute concentration of the two water species provided that the values of the relative molar absorptivities, ε_i, are known or can be estimated. In the present case, a method based on coupling the Beer-Lambert expression for the total concentration of sorbed water with the mass-balance relationship (Musto et al., 2014) was adopted. In brief,

$$C_{tot} = \frac{A_{bc}}{\varepsilon_{bc} L} + \frac{A_{sa}}{\varepsilon_{sa} L} \quad (4)$$

$$C_{tot} = C_{bc} + C_{sa} \quad (5)$$

$$\frac{A_{bc}}{C_{tot}} = \varepsilon_{bc} L - \frac{\varepsilon_{bc}}{\varepsilon_{sa}} \cdot \frac{A_{sa}}{C_{tot}} \quad (6)$$

In Equations (4–6) A is the integrated absorbance, C the volumetric concentration and L the sample thickness. The subscripts *bc* and *sa* refer, respectively, to the H_2O molecules bound to carbonyls and to those self-associated (see **Figure 8**); *tot*

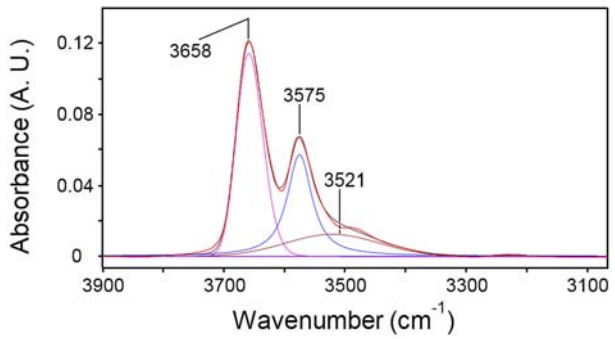

FIGURE 9 | Curve fitting analysis of the spectrum representative of H_2O sorbed in PLLA ($p/p_0 = 0.5$). The figure displays the experimental profile (red trace), the best-fitting curve (black trace) and the resolved components.

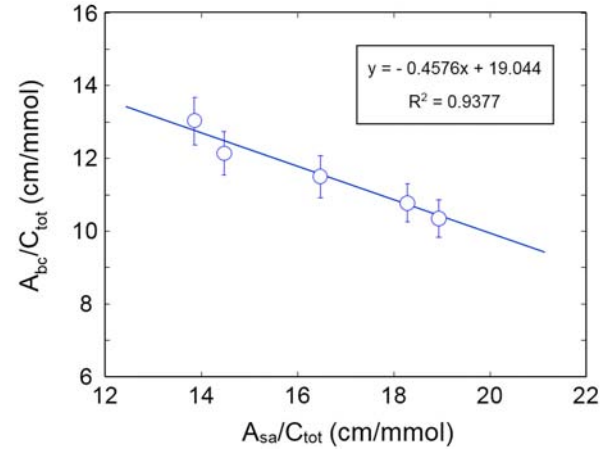

FIGURE 10 | Plot of $\frac{A_{bc}}{C_{tot}}$ as a function of $\frac{A_{sa}}{C_{tot}}$.

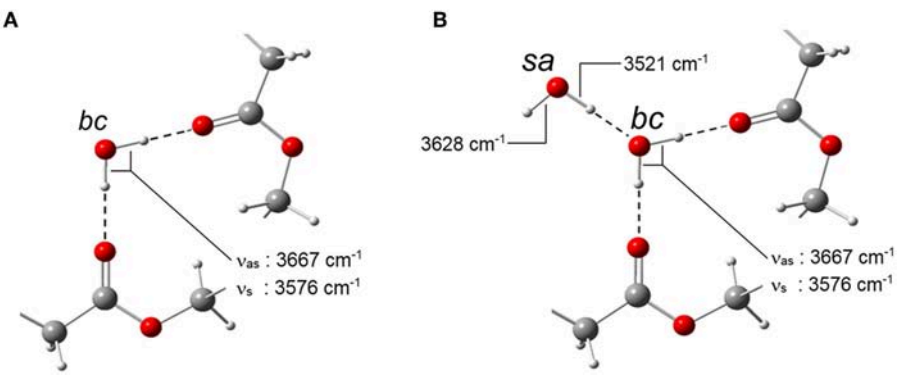

FIGURE 8 | Schematic representation of the two water species identified in the H_2O/PLLA system. **(A)** *bc* stands for *bound to carbonyls;* **(B)** *sa* stands for *self-associated*.

stands for total. The C_{tot} values were taken from the gravimetric measurements as a function of p/p_0. The density of PLLA (1.240 g/cm^3), assumed invariant with H_2O sorption, was employed to convert gravimetric weight ratios into volumetric concentration values. The components at 3,575 and 3,521 cm^{-1} were selected as analytical peaks for the *bc* and the *sa* species, respectively, because of the unresolved, two-component structure of the 3,658 cm^{-1} peak.

The plot of $\frac{A_{bc}}{C_{tot}}$ vs. $\frac{A_{sa}}{C_{tot}}$ is displayed in **Figure 10**: the data exhibit the expected behavior. The absorptivity values calculated from the slope and the intercept of regression line are: $\varepsilon_{bc} = 41.3$ km/mol and $\varepsilon_{sa} = 90.2$ km/mol. These values compare favorably with those obtained for the system H_2O/PCL ($\varepsilon_{bc} = 72.2$ km/mol and $\varepsilon_{sa} = 98.2$ km/mol) (Musto et al., 2014) and the system H_2O/polyetherimide ($\varepsilon_{bc} = 34.5$ km/mol and $\varepsilon_{sa} = 89.7$ km/mol) (Musto et al., 2014; de Nicola et al., 2017).

In **Figure 11** are reported the absolute concentrations (mmol/cm^3) of the two water species (calculated from the respective Lambert-Beer relationships) as a function of relative pressure of water vapor. In the same plot, for comparison, are also reported the total concentration of sorbed water (C_{tot}) and the excess C_{bc} values, i.e., $C_m = C_{bc} - C_{sa}$.

In the light of the proposed structures of the H_2O/PLLA molecular aggregates, C_{sa} corresponds to the concentration of H_2O dimers and C_m to the concentration of isolated (monomeric) species in the system. The change of monomer concentration is modest, with a slight decreasing trend at high p/p_0 values. In the whole pressure range the dimers represent the prevailing species. The C_{sa} curve displays an upward concavity not observed in the C_{bc} curve, which suggests an intersection of the two curves just above 0.6. At the intersection the isolated species are no longer present ($C_m = 0$) and all the H_2O molecules bound to carbonyls are self-associated. If the C_{sa} offsets the C_{bc}, aggregates of more than two water molecules are being formed in the system, which indicates the onset of the clustering process. In the present system this point lies above $p/p_0 = 0.5$ and has not been reached (Musto et al., 2012; Scherillo et al., 2012a, 2014; Galizia et al., 2014).

It is informative to compare the sorption behavior of the H_2O/PLLA and H_2O/PCL systems (Musto et al., 2014) (see **Figure 11B**). Both substrates are aliphatic polyesters with a very close molecular structure (the only difference being in the aliphatic chain, comprising five CH_2 groups for PCL and one –C(CH_3)– unit for PLLA). PCL is semicrystalline with a crystallinity degree of 58% (DSC); the PLLA sample used in the present investigation is fully amorphous. The amount of water sorbed at equilibrium is significantly higher in PLLA than in PCL in the whole p/p_0 range. This can be partially attributed to the higher interactive character of PLLA (higher density of C=O groups). The main effect is however related to the absence, in PLLA, of a crystalline phase impervious to the penetrant.

In PCL the analysis of the two-species population indicated that up to 0.6 p/p_0 values only dimers are formed, while at higher relative pressures of H_2O vapor, clustering takes place (Musto et al., 2014). In PLLA, dimers are still the prevailing species, but monomeric water is present up to $p/p_0 = 0.5$ and beyond. This result is again to be related to the higher number of proton acceptors (C=O) per unit volume in PLLA compared to PCL, which increases the probability for the penetrant of finding two close carbonyls in the right configuration for forming the aggregate represented in **Figure 8A**. The increased relevance of

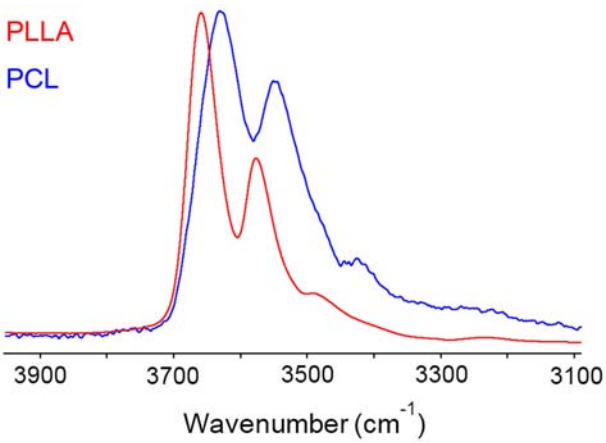

FIGURE 12 | Spectra representative of water sorbed in PLLA (red trace) and in PCL (blue trace) in the ν(OH) region (3,900–3,100 cm^{-1}).

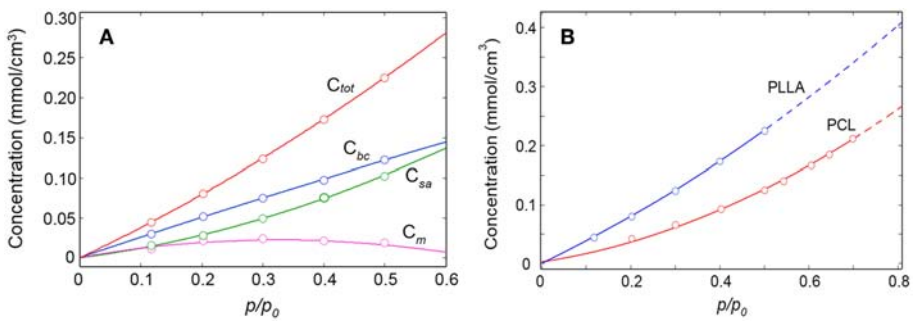

FIGURE 11 | C_{tot}, C_{bc}, C_{sa}, and C_m as a function of the relative pressure of water vapor **(A)**; comparison between the sorption isotherms of the H_2O/PLLA and H_2O/PCL systems **(B)**.

self-association in PCL is clearly reflected in the appearance of the penetrant spectrum (see **Figure 12**) where the broad component at lower frequency (self-associated O–H bond) is significantly larger than in PLLA.

CONCLUSIONS

In the present contribution the sorption of water vapor in PLLA has been studied by FTIR spectroscopy. Data gathered at sorption equilibrium and during the diffusion process have been analyzed by different techniques, namely, difference spectroscopy, two-dimensional correlation spectroscopy and least-squares curve fitting, which provided complementary information. Two distinct molecular species were detected in the system: single H_2O molecules bound to the PLLA carbonyls via a –C=O....H–O–H....O=C– stoichiometry and self-associated H_2O molecules forming second- shell layers. No evidence was found of the presence of C=O....H–O–H species.

Coupling the spectroscopic data with gravimetric measurements, it was possible to evaluate the population of the two water species. It was found that, in the explored p/p_0 range (0–0.5) dimers represent the prevailing species, but monomeric water remains well-detectable. In the present system the onset of the clustering process (i.e., when aggregates of more than two water molecules are formed) lies above $p/p_0 = 0.5$ and has not been reached. The diffusion coefficient were measured as a function of water activity and is in good agreement with literature values. The diffusivity was found to increase with water concentration possibly due to a swelling effect.

Localized electric fields have become, in recent years, a source of inspiration to researchers and laboratories thanks to a huge amount of applications derived from it, including positioning of microparticles as building blocks for electrical, optical, and magnetic devices. The possibility of producing polymeric materials with surface charge thus opens new perspectives for applications where process simplicity and cost-effectiveness of flexible electronics are of fundamental importance. In particular, the influence of surface charges is widely studied and is a critical issue especially when new materials and functional technologies are introduced. Here, we report a voltage-free pyro-electrification (PE) process able to induce a permanent dipole orientation into polymer sheets under both mono- and bipolar distribution. The technique makes use of the pyroelectric effect for generating electric potentials on the order of kilovolts by an easy-to-accomplish thermal treatment of ferroelectric lithium niobate (LN) crystals. The PE allows us to avoid the expensive and time-consuming fabrication of high-power electrical circuits, as occurs in traditional generator-based techniques. Since the technique is fully compatible with spin-coating-based procedures, the pyro-electrified polymer sheets are easily peeled off the surface of the LN crystal after PE completion, thus providing highly stable and freestanding charged sheets. We show the reliability of the technique for different polymers and for different applications ranging from live cell patterning to biofilm formation tests for bacteria linked to food-processing environments.

Keywords: dipoles orientation, pyro-electrification, pyroelectric effect, lithium niobate, cell patterning and manipulation, bacteria biofilm

INTRODUCTION

The possibility of tailoring the material surface properties has allowed an increasingly active field for a wide variety of researches and applications ranging from materials science, nanotechnology, and electronics to biological and medical systems (Stuart et al., 2010). One possibility for functionalizing surfaces and thus tuning interfacial properties is to use specific chemical treatment or to design and induce the electrostatic charges in specific locations. In particular, materials that show net electrostatic charges have been the key issue for fruitful applications in electronics, mechanics, and

biological systems. Supports with localized charges are widely used to control the behavior of thin-film electronic devices (Jacobs and Whitesides, 2001). Moreover, obtaining templates with a pattern of electrostatic charges becomes very useful in applications including sorting and self-assembling of micro- and nano-particles (Palleau et al., 2011; Zhao et al., 2011), macromolecules (Seemann et al., 2007; Zhao et al., 2011; Xi et al., 2012), or other building blocks (Cole et al., 2010). Recently, the programming and patterning of electric charges have been widely demonstrated by simple and effective processes in ferroelectric substrates (Grilli et al., 2008b; Esseling et al., 2013; Gennari et al., 2013; Carrascosa et al., 2015; Chen et al., 2016) devoting much attention to the possibility of using polymeric materials thanks to their ability to be economically produced on a large scale and with the further advantage of flexible thin-film technology. The techniques for charging polymeric surfaces are numerous and are quite well-established. The most common approaches require an external voltage source as in the case of contact poling (Hill et al., 1994) or corona poling (Rychkov et al., 2011). However, these techniques present severe limitations. In the case of contact poling, a large charge injection could produce a detrimental dielectric breakdown of the films (Hill et al., 1994; DeRose et al., 2006), while in the case of corona poling, the good homogeneity of the polarization is not guaranteed due to the difficult control of the high field intensity required. In addition, the poled films present often several surface damages due to various reactive and energy species, such as ozone or nitrogen oxides, that are produced by the corona discharge (Sprave et al., 1996).

Here, we propose a simple and voltage-free process based on pyro-electrification (PE), capable of producing polar orientation and 2D polar patterning in freestanding polymer sheets. Compared to conventional electrification techniques, the PE is electrode-free and is able to produce high voltages by a simple thermal treatment in ferroelectric crystals of lithium niobate (LN), thus simplifying the whole process significantly. Moreover, we can produce both homogeneous and bipolar charge distributions simply by using one-domain or homemade periodically poled LN crystals obtaining pyro-electrified polymer sheets with a net surface charge. Recently, we investigated the presence of such charge by analyzing the second harmonic signal and by observing the adhesion and spreading of eukaryotic cells on PE polymers that would be otherwise cytophobic surfaces (Rega et al., 2016a,b; Lettieri et al., 2017). Moreover, we evaluated *in vitro* the ability of bacteria to form biofilms very rapidly (Gennari et al., 2018).

It is recognized that the adhesion and proliferation of different types of cells on polymeric materials depend on surface characteristics and can be significantly influenced by the surface charge on that material (Robertus et al., 2010; Li et al., 2018; Liu et al., 2018; Ma et al., 2019).

Polystyrene (PS) and poly (methyl methacrylate) (PMMA) are materials typically used in labware equipment. They are cytophobic and require a chemical or physical treatment to promote cell adhesion. The most common treatments make use of sulfuric acid, or chromic acid, which can produce different kinds of functional groups on the surface, such as sulfonate, hydroxyl, or carboxyl. Another family of techniques makes use of protein adsorption, such as fibronectin, laniline, and Arginylglycylaspartic acid (RGD) peptide that chemically mimic the extracellular microenvironment and alter the structure of the surface. On the other hand, physical treatments able to activate the surface of traditional cytophobic surfaces by mild oxidation involve ultraviolet light or corona discharge stimulation. Regardless of the method, the cell adhesion promotion requires an electrostatically charged surface. All of these treatments are well-established but are laborious and expensive with additional drawbacks related to potentially polluting materials.

Here, we show the possibility of obtaining charged polymeric surfaces capable of interacting electrostatically with cell cultures under safe conditions by an easy and economical procedure, tracing the route as an alternative tool for all those applications in which the use of chemical agents or complicated physical treatments can be detrimental for both environment and cell cultures.

MATERIALS AND METHODS

The ferroelectric LN is a rhombohedral crystal belonging to the point group 3 m that exhibits pyroelectricity at room temperature. The spontaneous polarization P_s changes according to $\Delta P_i \alpha p_i \Delta T$, where P_i is the coefficient of the polarization vector, p_i is the pyroelectric coefficient, and ΔT is the temperature variation. At room temperature, the equilibrium condition makes the charge of the spontaneous polarization P_s to be balanced fully by the environmental screening charges, and no electric field exists (Grilli et al., 2008a). The temperature variation changes the polarization magnitude and perturbs this equilibrium, causing a lack or excess of surface screening charge (Bhowmick et al., 2017). As a consequence, an electrostatic state appears and generates a high-intensity electric field at the crystal surface (Bhowmick et al., 2017) with mono- or bipolar properties depending on the nature of the LN crystal, mono-domain in the first case and periodically poled (PPLN) in the second one. The PPLN crystals were homemade by standard electric field poling onto photoresist patterned samples (Detrait et al., 1998; Huang et al., 2012; Pagliarulo et al., 2018) and consisted of an array of ferroelectric domains with opposite polarization. The pyroelectric effect generates an array of surface charges with opposite sign, following the pattern of the reversed domains. Recently, we demonstrated for the first time the possibility of using the pyroelectric effect for a wide variety of applications ranging from biological to soft matter manipulation application (Ferraro et al., 2010; Mecozzi et al., 2016, 2017; Rega et al., 2019).

The PE exploits this electric field during an appropriate thermal treatment. The PE induces a permanent orientation of the dipoles when exceeding the glass transition temperature of the polymer, namely, when the dipole molecules can be easily oriented. This technique guarantees simplicity and cost-effectiveness since only a polymeric solution is needed, spin coated on an LN crystal and thermal treated on conventional hotplates. The fundamental role is played by the LN crystal since it supports, heats, and polarizes the polymer layer, which, at the

end of the process, is easily removed, obtaining a freestanding charged sheet.

THE PYRO-ELECTRIFICATION

Figure 1 shows the schematic view of the procedure.

The LN crystal sample is spin coated with a polymer solution at room temperature and then heated by a digitally controlled hotplate according to a thermal treatment based on three steps identified here by the following labels: slow heating (Stuart et al., 2010), holding (Jacobs and Whitesides, 2001), and fast cooling (Palleau et al., 2011). The slow heating induces a temperature rise from room temperature (T_i) up to the glass transition temperature of the polymer (T_f) at a rate of 1°C/min. The holding step keeps the sample at the final temperature T_f for 10 min. In the fast cooling step, the polymer-coated crystal is moved to a second hotplate set at a lower temperature T_l ∼50°C. The slow rate of temperature increase in the first step and the holding state are of crucial importance for keeping the electrostatic equilibrium between the slight polarization change of the LN and the screening charges on the surface, prior to reaching the glass transition of the polymer. Once this state is reached, the polymer becomes very amorphous and the dipole molecules can orient easily under the action of the strong electric field generated onto the surface of the crystal by the pyroelectric effect. The monotonic cooling step is necessary to provide large ΔT that generates a steady and strong electric field capable of poling the polymer and, simultaneously, freezing the poled state into the polymer itself. The poled polymer layer can be peeled off from the surface of the crystal proving a freestanding sheet with the same polarization orientation of the LN crystal that drove the PE process.

The technique can be performed under two different configurations and with different polymer solutions. The single-domain PE (SD-PE) uses a single domain crystal, while the multi-domain PE (MD-PE) makes use of a periodically poled crystal PPLN with different geometries. In the case of the SD-PE configuration, the polymer layer exhibits a polarization charge with single orientation, while in the case of the MD-PE configuration, the polymer shows the pattern of domains with reversed polarization according to the ferroelectric domain pattern of the driving PPLN crystal. The driving crystal can be re-used indefinitely after appropriate solvent cleaning.

THE POLYMER SOLUTIONS

Solid-state polymers were used as received, without further purification (Sigma-Aldrich, Milan, Italy). Polysulfone (PSU) transparent pellets (M_w 35,000) were dissolved at 80% w/w in anisole and stirred at 70°C for 3 h. PS powder (M_w 350,000)

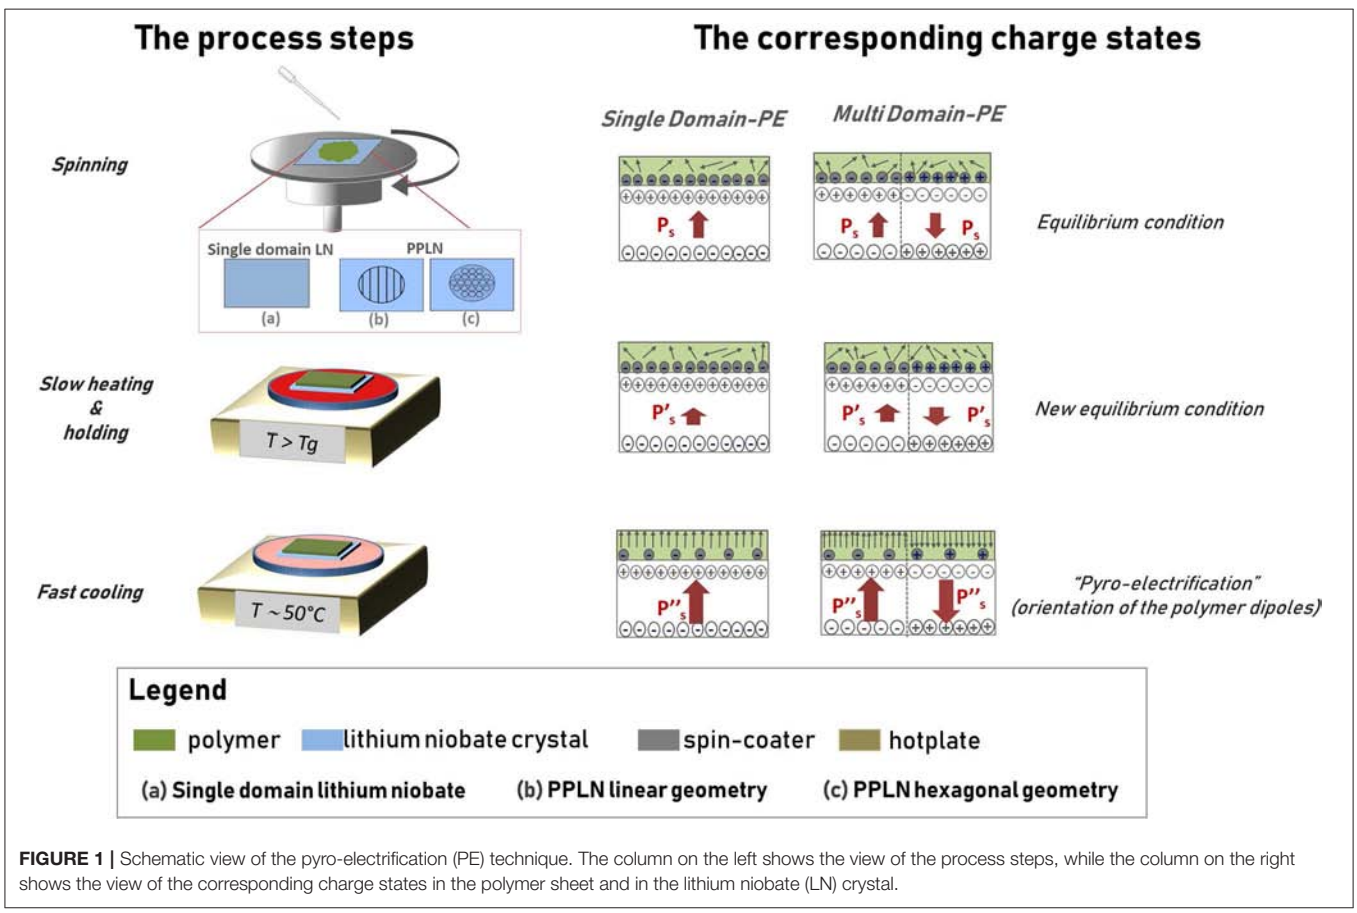

FIGURE 1 | Schematic view of the pyro-electrification (PE) technique. The column on the left shows the view of the process steps, while the column on the right shows the view of the corresponding charge states in the polymer sheet and in the lithium niobate (LN) crystal.

was dissolved at 60% w/w in anisole and stirred at 70°C for 6 h. PMMA (M_w 996,000) was dissolved at 15% w/w in anisole and stirred at 70°C for 3 h. The resulting polymer solutions of PSU, PS, and PMMA were stored at 4°C.

THE PERIODICALLY POLED LN CRYSTALS

The LN crystals were bought from Crystal Technology Inc., Palo Alto, California, in the form of both sides polished into 500 μm-thick c-cut 3-inch. wafers and were cut into square samples (2 × 2 cm^2) by a standard diamond saw. The PPLNs were obtained by standard electric field poling onto photoresist-patterned samples (Huang et al., 2012; Bhowmick et al., 2017; Pagliarulo et al., 2018). Two geometries were considered: linear (period, 200 μm) and square array of hexagons (period, 200 μm).

THE BARE SHEETS (CONTROL)

The freestanding PSU, PS, and PMMA bare sheets were obtained by spin coating a 2 × 2 cm^2 sized glass coverslip at 4,000 RPM for 2 min with the polymer solution and by peeling off the slide accurately just after solvent evaporation.

THE SH-SY5Y HUMAN NEUROBLASTOMA AND THE NIH-3T3 MOUSE EMBRYONIC FIBROBLAST CELLS

The SH-SY5Y and NIH-3T3, cells lines were purchased from European Collection of Authenticated Cell Cultures (ECACC) (Sigma-Aldrich, Milan, Italy). They were routinely grown in Dulbecco's modified Eagle's medium (DMEM) containing 4.5 g/L D-glucose and supplemented with 2 mM L-glutamine, penicillin (100 units/ml), and streptomycin (100 μg/ml), and containing 20% (v/v) fetal bovine serum (FBS) (GIBCO, Gaithersburg, MD, USA). For the cell culture experiments, the SH-SY5Y and NIH-3T3 were detached by means of Trypsin/Ethylenediaminetetraacetic acid dipotassium salt dihydrate (EDTA) solution (Sigma, Milan, Italy), resuspended in DMEM−20% FBS, seeded at a concentration of 1.0 × 10^5 cells/ml on the MD-PE sheets (immersed in DMEM medium at 37°C for 1 h prior to use), and then incubated into conventional 30 mm-diameter Petri dishes at 37°C and in a saturated humidity atmosphere containing 95% air and 5% CO_2. Cells were allowed to grow in DMEM−20% FBS on different substrates for 24 h. Cell adhesion and spreading were observed over 24 h under a standard inverted optical microscope (AxioVert, Carl Zeiss, Jena, Germany).

IMMUNOFLUORESCENCE

The cells were cultured 24 h on the surface of interest and then fixed by standard procedures. The cells were then stained by Alexa Fluor 488 phalloidin and by blue fluorescent Hoechst 33,342 dye and trihydrochloride trihydrate (Molecular Probes Invitrogen) for visualizing nuclei and actin filaments.

BACTERIAL STRAIN AND CULTURE CONDITIONS

In the present study, we used the Gram-positive Listeria innocua (strain DSMZ 20649) provided by the Deutsche Sammlung von Mikroorganismen und Zellkulturen, Braunschweig, Germany. The bacteria strains were plated and incubated on Luria-Bertani (LB) agar plates (10 g/l NaCl, 10 g/l tryptone, 5 g/l yeast extract, and 15 g/l agar, Thermo Fisher Scientific). One day before the experiments, a single bacterial colony was picked up and cultured in LB broth medium at 37°C in a shaker incubator at 225 RPM for 16–18 h to achieve saturation conditions. A 1:5 volumetric dilution of the cell culture was then grown in LB until reaching the log phase. Then, the growth was stopped and bacteria were harvested by centrifugation at 7.200 g (Beckman Coulter tj-25 centrifuge, California, USA) for 10 min in order to separate the cells from the medium. Sterilized LB broth was measured (3 ml) into sterile tubes. The bacteria concentration was evaluated by the spectrophotometric measurement (Bio-Rad SmartSpecTM Plus Spectrophotometer, California, USA) of the suspension absorbance at 600 nm (optical density at 600 nm, i.e., OD_{600}), considering that 8 × 10^8 cells/ml have an $OD_{600} = 1$.

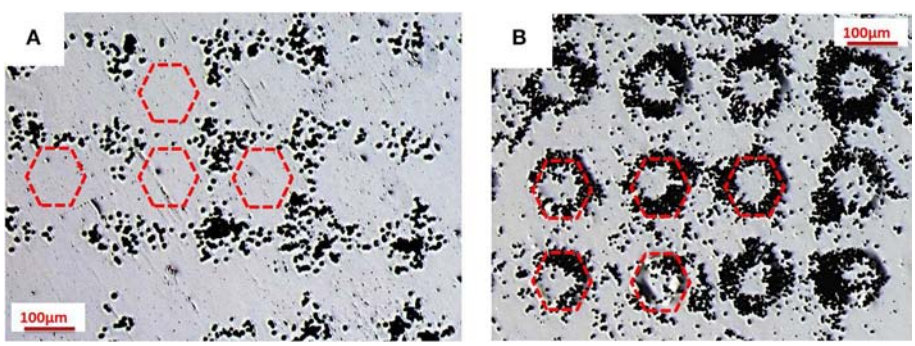

FIGURE 2 | Optical microscope images of decoration technique: toner distribution on two polystyrene (PS) sheets after pyro-electrification (PE) by a periodically poled lithium niobate (PPLN) crystal, where the hexagons exhibit **(A)** positive and **(B)** negative charge polarity. The hexagons are indicated by the schematic drawings with the red dotted line.

MICROTITER-PLATE TEST

In order to quantify the biofilm formation, we use the crystal violet assay (Stepanović et al., 2000). This technique involves fixing the bacterial film with methanol, staining with crystal violet, releasing the bound dye with 33% glacial acetic acid, and measuring the optical density (OD) of the solution at 600 nm by spectrophotometric measurement (Bio-Rad SmartSpecTM Plus Spectrophotometer, CA, USA).

The dashed lines correspond to the boundaries between regions with opposite polarities.

THE VIABILITY TEST

The viability of the bacterial strain (*L. innocua*) was tested through the live/dead viability/cytotoxicity assay kit (Live/Dead *Bac*Light bacterial viability kit, Thermo Fisher Scientific, Waltham, MA, USA). The easy-to-use live/dead kit is utilized for monitoring the viability of the bacterial populations as a function of the sheet integrity of the cell. The live/dead BacLight Bacterial Viability Kits utilize mixtures of our SYTO® 9 green-fluorescent nucleic acid stain and the red fluorescent nucleic acid stain, propidium iodide. These stains differ both in their spectral characteristics and in their ability to penetrate healthy bacterial cells. Cells with a compromised sheet that are considered to be dead or dying will stain red, whereas cells with an intact sheet will stain green. The cells were incubated on each substrate for 24 h. After incubation, each substrate was immersed in 8 μl of 1,000-fold diluted live/dead kit solution and was incubated for 15 min in the dark. The fluorescence micrographs were acquired by an inverted laser scanning confocal microscope (Zeiss LSM 700, Germany), equipped with a 20× objective.

RESULTS AND DISCUSSION

Two PMMA sheets were subjected to PE by using a PPLN crystal (see **Figure 1** for the multi-domain procedure). A faster test to verify the presence of the charges on the PE sheet is the decoration technique. The polymer solution was spun on one face of the crystal and, in the second experiment, on the other face of the PPLN. As a consequence, we produced two freestanding PS sheets with a bipolar polarization pattern following the pattern of reversed domains of the PPLN. The hexagonal regions of the PS sheets exhibited positive and negative polarity, respectively. **Figures 2A,B** shows the typical optical microscope images of these two PS sheets after gentle sprinkling of toner dust on the surface.

These images show clearly that the particles of toner, bringing a negative charge, are attracted electrostatically by the hexagonal regions (positive charge) in the first case (see **Figure 2A**) and by the surrounding regions (positive charge) in the second case (see **Figure 2B**), thus demonstrating the non-negligible electric field generated on the surface of the pyro-electrified PS sheets.

We demonstrate here the possibility of using the permanent electric field on the PE sheet for guiding live cell adhesion *in vitro*. PS and PMMA labware equipment have been used for cell culture since about 1965. Many cell types adhere to and move on the surfaces of such materials and present a morphology that is very similar to that seen when the cells are grown on glass. However, it has long been known that these materials must be subjected to a surface treatment to render their surface suitable for cell attachment. Bare PS and PMMA are unsuitable for cell attachment, meaning that cells seeded and incubated onto surfaces made of such polymers cannot find adhesion cues and remain suspended. This has been attributed to the surface chemistry of the materials, and many different specific surface treatments have been made to change the chemistry involved in the non-adhesive nature of these polymers (Klemperer and Knox, 1977; Maroudas, 1977; Grinnell, 1978; Lee et al., 1994; Buttiglione et al., 2007).

Here, we demonstrate the cytophilic capability of PE polymer for cultured NIH-3T3 cells (see Materials and Methods for details) on PS and PMMA sheets pyro-electrified on a single domain crystal. **Figure 3** shows the optical microscope images of the sheets after 24 h incubation with NIH-3T3 cells. In particular, the image in **Figures 3a,b** show the cytophobic behavior of bare PS and PMMA polymer spotted on a glass coverslip where it is clearly seen that the cells are not able to adhere and spread. These materials are often treated in a chemical or physical way in order to permit cell adhesion and spreading. **Figures 3c–e** show the adhesion of NIH-3T3 cells on a conventional PS Petri dish (generally treated with UV light), PS coated with fibronectin protein, and PMMA coated with fibronectin protein, respectively. **Figures 3f,g** show

the NIH-3T3 cells grown on the pyro-electrified PS and PMMA, respectively.

On substrates treated with fibronectin, the cellular conformation and their spatial distribution are characterized by a more compact organization and a more spread cellular shape, indicating a stronger cell–cell interaction than the interaction with the adhesion surface. The cellular distribution on the pyro-electrified sheets shows, on the other hand, an elongated shape of the nuclei and cellular filopodes, typical of cells polarized along one preferential direction. This characteristic is an indication of a strong interaction with the contact surface, which is predominant with respect to the cell–cell interaction.

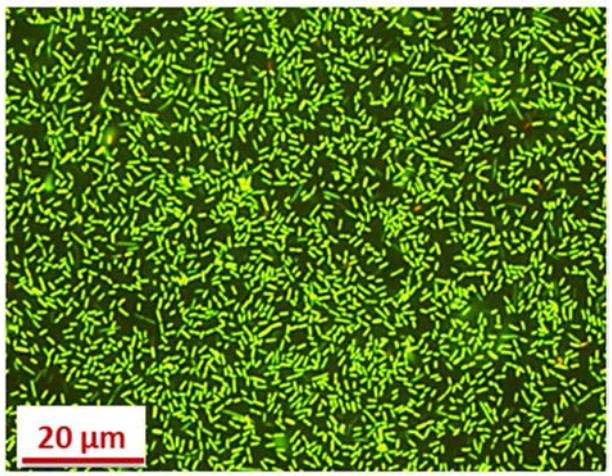

FIGURE 6 | Fluorescence microscopy images of *L. innocua* forming biofilms onto the PSU-PE sheet after 24 h incubation and live/dead staining.

Moreover, as already shown in our previous paper (Rega et al., 2016a,b), it is possible to have a cell pattern configuration when seeded on sheets pyro-electrified by a multi-domain crystal with a bipolar configuration of the charge distribution on the sheet surface. Here, we demonstrate the reliability of the technique with other periods and different concentrations of the polymer.

Figure 4A shows that SH-SY5Y cells adhered selectively on the positive region of PS sheet with bipolar domains having linear geometry with a 200 µm period, while **Figure 4B** corresponds to a PMMA (15% in anisole w/w) sheet, with bipolar domains having two-dimensional distributions at a 200 µm period. Moreover, in order to better elucidate the material–cytoskeleton cross-talk during adhesion, we fixed the cells after 24 h incubation on PS sheets pyro-electrified by PPLN crystals with hexagonal domains, and we performed immunofluorescence reactions (**Figure 4C**) (see Materials and Methods for details). The cells appear clearly to adhere selectively on the regions with positive polarity in the case of linear domains as well as in the case of two-dimensional domains. In fact, the cells bring a negative net charge on the external sheet (Ohgaki et al., 2001) and, as a consequence,

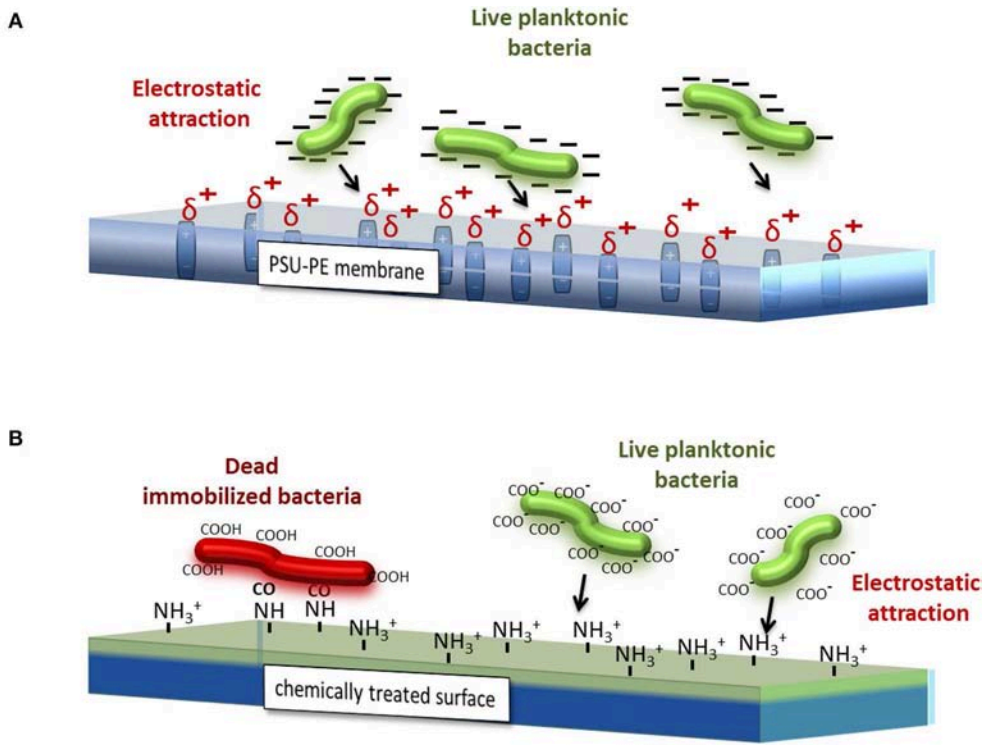

FIGURE 7 | Simplified schematic views of the different interaction mechanisms between bacteria, the cytomembrane, and **(A)** the PSU-PE sheet and **(B)** a generic chemical-coated sheet.

are attracted electrostatically by the regions of the sheet exposing a net positive polarization charge.

The PE allows us to achieve cell patterning results through a cation-free method, avoiding time-consuming and expensive lithographic-based procedures and moreover directly onto freestanding, and cheap polymer sheets. The relatively easy-to-accomplish procedure, which makes use simply of LN crystals and conventional hotplates, would be easily implementable in biology laboratories for routine cell biology experiments where selective cell adhesion configurations are of crucial importance. For example, in the case of electric-field-sensitive cells, we envisage the possibility of using PE for developing pre-defined neuronal networks for deep studies on their physiology and morphology behavior.

Recently, we demonstrated the possibility of using pyro-electrified sheets and fibers for rapid and reliable "biofilm electrostatic test" (Gennari et al., 2018) of *Escherichia coli* and *Staphylococcus epidermidis*, with potential applications in the field of biomedicine. In fact, the rapid biofilm formation promoted by our sheets would have a significant impact on health service when a fast response to an antibiogram test can save lives. Here, we show how the pyro-electrified sheets promote a rapid biofilm formation also in the case of *L. innocua*, a non-pathogenic species closely related to *L. monocytogenes* (Scifò et al., 2009; Tajkarimi et al., 2016; Jeon et al., 2018; Sheng et al., 2018). We use an SD-PE sheet as a tool for simple, rapid, and cost-effective evaluation of biofilm formation, through the electrostatic interaction of planktonic bacteria with a pyro-electrified carrier (Asadishad et al., 2011; Gennari et al., 2018). The fact that biofilms have a multidisciplinary impact that includes environmental, industrial, and clinical characteristics, and that over 60% of all human bacterial infections and up to 80% of all chronic infections are related to bacterial biofilms, is of fundamental importance in assessing how different environmental factors may affect the bacterial vitality. The cellular mechanisms underlying microbial biofilm formation and behavior are beginning to be understood and are targets for novel specific intervention strategies to control bacteria colonies formation in different fields and in particular for the food-processing environment (Dickson and Koohmaraie, 1989; Sahm et al., 1994; Linke and Goldman, 2011; Bianco et al., 2017; Bruslind, 2017; Mandracchia et al., 2019).

Here, we demonstrate that SD-PE carrier provides a polarization field able to immobilize the *L. innocua* bacteria and test their ability to form live biofilms within 2 h, avoiding time-consuming and laborious incubations and/or intermediate chemical treatments. PSU sheets (about 100 μm thickness and 2 × 2 cm^2 sized) were produced: (Stuart et al., 2010) a bare sheet that represents the control and (Jacobs and Whitesides, 2001) polysulfone pyro-electrified (PSU-PE), where the positive side was in contact with the bacterial suspension. These sheets were incubated at different times (2 and 4 h) at 37°C in two different Petri dishes (35 mm) covered with 1 ml of *L. innocua* bacterial suspension (Gram-positive) and 2 ml of phosphate-buffered saline (PBS). The control and the SD-PE sheets were observed under an optical microscope, and **Figure 5** shows the corresponding typical images.

These microscope images show the immobilized and biofilm forming bacteria on the control and PSU-PE sheet at different time intervals. The number of adhesion bacteria on the PSU-PE sheet appeared clearly higher than that on the control at each observation time. These results are confirmed by the quantitative evaluation of biofilm formation obtained by the microtiter-plate test (see Materials and Methods for details). The diagram in **Figure 5e** shows results averaged over five measures of biofilm OD (optical density) formation and shows evidence of the larger population of bacteria on the PE sheet.

To verify the viability of the biofilms, the PSU-PE sheet was mounted onto a glass slide in a well after 24 h incubation with planktonic bacteria in order to perform the reaction with the live/dead staining kit (see Material and Methods for details). After 24 h incubation, we found that the viability of the high-density biofilms formed onto the PSU-PE sheet was clearly evident (**Figure 6**). The PSU-PE sheet immobilized planktonic bacteria more rapidly than the control and favored biofilm formation without damaging the bacterial cytomembrane even after 24 h incubation, thus demonstrating biocompatiblity.

On the contrary, chemical coatings could immobilize planktonic bacteria, but could even destroy the bacterial cytomembrane causing their death. Cationic surfaces are obtained usually by the covalent attachment of different chemical compounds, such as quaternary ammonium organo-silanes (Isquith et al., 1972; Gottenbos et al., 2002; Li et al., 2006), antimicrobial peptides (Gabriel et al., 2006; Gao et al., 2011), polyethylenimines (PEI) (Lin et al., 2003), and many others. The mechanism of interaction, as already explained in Gennari et al. (2018), is schematized in **Figure 7**. The PE process provides a sheet (in this case, the PSU-PE sheet) with δ^+ charge due to the permanent dipole generated during the process. Those charges attract the negative net charge onto the bacterial cytomembrane (COO^- groups), thus leading to bacteria immobilization and promoting the biofilm formation. In contrast, the cationic groups $NH3^+$, generally formed on the chemically treated surface, form an electrostatic bond with the COO^- groups onto the cytomembrane of bacteria adhered, thus displacing the divalent cations forming the lipopolysaccharide network. This causes the disruption of the cytomembrane and then microorganism death.

The PE of freestanding polymer sheets could find applications in the food processing field as a quality check tool. The ultimate goal is the development of a rapid and easy PE assay for a quantitative analysis of a food sample, enabling food technologists to detect the contaminant agents in fresh products that represent a serious risk for all the consumers. In fact, it would be desirable having a compact and efficient system that could be used, for example, in an industry outside the laboratory. However, to develop and to design industrial applications for food processing, more data on the interaction between the process and the target organism are required. PE assay approaches will help to close this gap in the future, because they have the potential to be used as a method to control bacteria contamination and to ensure fresh food safety.

CONCLUSION

Here, we show an innovative PE technique capable of inducing a permanent dipole charge into freestanding polymer sheets by exploiting the pyroelectric properties of LN crystals, under both single- and multi-domain configurations. The resulting sheets can correspondingly have a mono- and bipolar charge with a magnitude able to selectively promote the adhesion of both eukaryotic and prokaryotic cells. The innovative use of the pyroelectric effect allows us to avoid expensive and time-consuming fabrication of electrodes and high-voltage circuits, since the appropriate thermal treatment of LN generates electrical potentials on the order of kilovolts. The same LN crystal can be used indefinitely for different PE cycles. The technique is free from lithography-based procedures and free from the use of cation-based chemicals, eventually detrimental for specific cell sheet structures. We show how these sheets can be used for cell patterning as well as for rapid biofilm formation. The relatively easy implementation makes PE implementable in a biology laboratory, opening the route to a novel generation of platforms for manipulating cell adhesion *in vitro* through non-invasive polarization charges, with the additional advantage of being flexible, freestanding, and cheap.

AUTHOR CONTRIBUTIONS

RR planned, conducted experiments and wrote the manuscript. OG, MM, FN and EO prepared the biological cultures. VP made the PPNL samples. PF and SG supervised the project. All authors discussed the results and contributed to the manuscript.

FUNDING

Ultrasound Reversible Response Nanocarrier Based on Sodium Alginate Modified Mesoporous Silica Nanoparticles

Xiaochong Li, Zhanhua Wang and Hesheng Xia*

State Key Laboratory of Polymer Materials Engineering, Polymer Research Institute, Sichuan University, Chengdu, China

Mesoporous silica nanoparticles (MSN) covered by polymer coatings, cross-linked by weak coordination bonds were expected to present a reversible responsiveness under on-off ultrasound stimuli. Herein, we prepared a sodium alginate (SA) modified MSN with carboxyl-calcium (COO^{-}-Ca^{2+}) coordination bonds in the modified layer, which could block the mesopores of MSN and effectively prevent the cargo from pre-releasing before stimulation. The coordination bonds would be destroyed under the stimulation of low intensity ultrasound (20 kHz) or high intensity focused ultrasound (HIFU, 1.1 MHz), leading to a rapid and significant cargo release, and then they could be reformed when ultrasound was turned off, resulting in an instant cargo release stopping. The reversible cleavage and reformation of this coordination bonds under on-off ultrasound stimulus were confirmed by the gel-sol transition behaviors of the SA-$CaCl_2$ gels. An excellent real-time control of rhodamine B (RhB) release performance was obtained under the ultrasound stimuli. Obviously, the cargo release ratio could reach to nearly 40% when HIFU (80 W) was turned on for 5 min, and remained basically constant when ultrasound was turned off, which would finally reach to nearly 100% within 30 min under this on-off pulsatile status. These hybrid MSN based nanoparticles with excellent reversible ultrasound on-off responsiveness were of great interest in on-demand drug delivery applications in the future.

INTRODUCTION

During recent decades, with the development of nanotechnology, nanoparticles have been widely applied and well-developed in the field of biomedicine for drug delivery. The most important reason behind this revolution is that nanomaterials as drug carriers can overcome the shortcomings of the conventional small molecule drugs, such as the short half-life, the fast metabolism, and concentration reduction, which consequently decrease the therapeutic effects and increase the toxic side effects on the human body (Hubbell and Chilkoti, 2012). In fact, nanomaterials can make drugs accumulated at the tumor site and reduce the drug concentration in the normal tissue cell sites, thereby improving the anticancer effect as well as reducing the side effects (Panyam and Labhasetwar, 2003; Allen and Cullis, 2004; Farokhzad and Langer, 2009). Moreover, traditional anticancer drugs are usually very small in size and are quickly cleared in the blood so that the

effective concentration at the site of the tumor will be reduced. By loading these small anticancer drugs into the appropriate nanocarriers, the circulation time of the drug molecules in the blood can be extended (Bae et al., 2011; Bogart et al., 2014).

Among various nanomaterials employed for drug delivery applications, the fast-growing attention to mesoporous silica nanoparticles (MSN) has been vastly highlighted due to their outstanding properties, such as large specific surface areas, uniform pores with adjustable structures, excellent biocompatibility, and thermal stability, as well as a facile modification on surface (Trewyn et al., 2007; Chang et al., 2013; Argyo et al., 2014; Paris et al., 2015). However, conventional bare MSN cannot effectively prevent the drugs from being pre-released because of their open mesopores, therefore they cannot achieve an accurate controlled therapeutic efficacy. One alternative that has been proposed to date is the study of the smart drug delivery system, which allows the elaborate surface modifications based on MSN and endows one or more stimuli responsiveness onto them (Chen et al., 2010; Li Z. et al., 2012; Mura et al., 2013; Argyo et al., 2014; Baeza et al., 2015; Wen et al., 2017). Smart drug delivery systems can make mesoporous entrance open or close under exposure to various single internal stimulus [i.e., pH (Li et al., 2014; Cheng et al., 2017; Zeng et al., 2017], redox substances Zhao et al., 2009; Sauer et al., 2010, and enzymes Bernardos et al., 2010; Sun et al., 2013), single external stimulus [i.e., light (Ferris et al., 2009; Martínez-Carmona et al., 2015), temperature (Chung et al., 2008; Schlossbauer et al., 2010), magnetic field (Chen et al., 2011; Xuan et al., 2018), and ultrasound (Chen Y. et al., 2014; Paris et al., 2015; Anirudhan and Nair, 2018)] or a combination of multiple stimuli (Chen X. et al., 2014; Li et al., 2015, 2018). Among all of the studied stimuli, ultrasound attracts great attention due to its robust and unique advantages, especially for the high intensity focused ultrasound (HIFU). Generally, ultrasound has two kinds of categories according to the frequency: low intensity ultrasound (20–200 kHz) and HIFU (>200 kHz). Both types of ultrasound can easily realize a spatiotemporal control of drug release at the targeted location and can easily regulate the penetrate depth by tuning the frequency, power density, and duration (Mura et al., 2013; Boissenot et al., 2016). Additionally, ultrasounds are also appealing because of their non-invasiveness, non-ionizing and cost effectiveness, as well as the enhanced cell membrane permeability. More importantly, compared with low intensity ultrasound, HIFU can focus the intense ultrasonic wave in a targeted small spot, while in other areas the intensity of the wave is relatively low and can be accepted by the human body. So HIFU is effective and safe as a promising stimulus, which has been widely used in human drug delivery applications (Schroeder et al., 2009; Xia et al., 2016).

In general, ultrasound has two main effects which are thermal effect and acoustic cavitation effect; both can play a role in triggering the release of drugs from nanocarriers (Sirsi and Borden, 2014; Xia et al., 2016). When acoustic waves are passing through a tissue the attenuation is generated. The attenuation energy will be converted into thermal effect. Acoustic cavitation is a process where plenty of microbubbles form, grow and collapse during a very short period of time when ultrasound is applied. Cavitation threshold is easily realized by low intensity ultrasound while the thermal effect is more significant when high intensity focused ultrasound (HIFU) is used. Indeed, although both thermal effect and acoustic cavitation effect can make polymers unstable or even destroyed, the latter factor is usually considered as the main reason for ultrasound-induced drug release by bond cleavage of hybrid nanocarriers (Tong et al., 2013; Chen X. et al., 2014; Paris et al., 2015; Li et al., 2016; Anirudhan and Nair, 2018). The strong physical forces associated with the collapse of cavitation bubbles can induce some cleavages of mechano-labile bonds and scission of polymer chains, which is termed as mechano-chemistry. Therefore, for those hybrid nanocarriers that are introduced with the mechano-labile bonds, they will have ultrasonic responsiveness and the modified structure will be broken up when ultrasound is on and, eventually, the inner drugs can be released (Li et al., 2017).

Previously, there have been many studies on ultrasound-induced cleavage of some chemical bonds, such as covalent bonds (ester bond, disulfide bond, Diels-Alder linkage) and supramolecular interaction (hydrogen bond, metal coordination, electrostatic interaction, and π-π interaction) in well-designed polymers, which were applied to ultrasound responsive drug delivery (Li et al., 2010, 2018; Xuan et al., 2012; Tong et al., 2013; Liang et al., 2014) and self-healing/shape memory materials (Li G. et al., 2012; Lu et al., 2014). However, most of the covalent bond cleavages in solution are irreversible, which cannot be applied to the drug delivery field in combination with nanocarriers, and cannot effectively reserve residual drugs after ultrasound stopping. On the contrary, metal coordination, one of the supramolecular interactions, can meet the above requirements well due to its reversibility (Beck and Rowan, 2003; Vermonden et al., 2003; Paulusse and Sijbesma, 2004). It has been widely demonstrated that many metal coordination complexes could achieve reversibility under certain stimulation, such as Fe(III)-polyphenols complexes (Ju et al., 2015), Cu(II)–terpyridine complexes (Liang et al., 2014), Pd(II)-phosphane complexes (Paulusse and Sijbesma, 2004), Ca(II)-carboxyl complexes (Huebsch et al., 2014), and borate-PEGylated coordination complexes (Liu et al., 2018). Reversible ultrasonic responsive hybrid nanocarriers based on metal coordination interaction and combined with MSN are expected to be achieved and applied in the field of drug delivery. To this aim, dynamic metal coordination bonds formed between carboxyl groups (COO^-) and calcium ions (Ca^{2+}) come into our view. The labile metal coordination bonds, formed by Ca^{2+} and COO^- of SA, may be cleavable when ultrasound is turned on and also can be reformed after ultrasound is turned off. Porous nanoparticles covered by cross-linked polymer coatings through coordination bonds formed between Ca^{2+} and COO^- could successfully open the pores and release the loaded cargoes by breaking up the cross-linking structure under low intensity ultrasound or HIFU. In order to verify our hypothesis and obtain a novel kind of reversible ultrasound responsive drug carrier, we prepared a novel kind of hybrid MSN by grafting sodium alginate (SA) polymer onto the MSN surface, which was further cross-linked by $CaCl_2$ solution after cargo loading. Preparation and each step surface modification of MSN particles were

fastidiously characterized. The hypothesis that COO^{-}-Ca^{2+} coordination bonds are dynamically reversible was tested by the gel-sol transition of the SA-$CaCl_2$ gels under ultrasound. The responsive cargo release pattern and the possible mechanism behind that were further investigated by using different two kinds of ultrasound (low intensity ultrasound or HIFU). Almost no drug release behavior under heating at 100°C suggested that the acoustic cavitation was the primary reasons of release. This research may provide an effective method to achieve an on-demand drug release pattern by using remote ultrasound stimulation and build up the frame for advancing future therapeutic applications.

EXPERIMENTAL

Materials

Cetyltrimethylammonium bromide (CTAB, 99.9%), tetraethyl orthosilicate (TEOS, 99.99%), sodium alginate (SA), and N-hydroxysuccinimide (NHS) were purchased from Aladdin (China). 3-aminopropyltriethoxysilane (APTES, 98%) was obtained from Adamas Reagent Co. Ltd. The model drug, Rhodamine B, and 1-ethyl-3-(3-(dimethylamino)- propyl) carbodiimide (EDC·HCl) were purchased from Best Reagent Co. Ltd (Chengdu, China). Methanol, ethanol, toluene, sodium hydroxide (NaOH), hydrochloric acid (HCl), ethyl acetate (EtOAc), and anhydrous calcium chloride ($CaCl_2$) were all analytical chemicals supplied by Kelon Chemical Reagent Co. Ltd (Chengdu, China). Toluene was dried by refluxing in the presence of calcium hydride (CaH_2) prior to use. All of the other regents were used as received.

Synthesis of Mesoporous Silica Nanoparticles (MSN)

The preparation procedure was followed on a previously reported method with a little modification (Lee et al., 2010; Chang et al., 2013). Cetyltrimethylammonium bromide (CTAB, 1 g) was absolutely dissolved in 500 mL of deionized water (DI water) in a three-necked flask. Then, 2.0 M NaOH (3.5 mL) as the base catalyzer of the sol-gel reaction was added. Under the heating of water bath, the above mixture was mechanically stirred at 300 rpm for 2 h when the temperature raised to 70°C. Thereafter, tetraethyl orthosilicate (TEOS, 5 mL) and ethyl acetate (5 mL) were added sequentially at intervals of 1 min. The mixture was stirred for another 30 s and immediately stopped to keep at 70°C for 2 h. The solvent was removed by centrifugation and the precipitate was washed with a large amount of DI water and ethanol in turn. Finally dried the product under vacuum at 60°C overnight and collected before using.

In order to make MSN possess internal mesoporous structure, the reflux process with acid methanol solution was applied. The as-prepared particles (1.0 g) were extracted by refluxing in methanol (100 mL) and concentrated hydrochloric acid (1 mL) at 60°C for 6 h. After centrifugation and washing with DI water and ethanol three times, respectively, the template-removed mesoporous silica nanoparticles (MSN) were dried at 60°C in a vacuum overnight.

Synthesis of Amino-Modified MSN (MSN-NH_2)

As-synthesized MSN (1.0 g) and anhydrous toluene (75 mL) were placed into a round bottom flask which had been purged with high pure N_2, and then 3-aminopropyltriethoxysilane (APTES, 4 mL) was added. This mixture was stirred under an inert atmosphere at 85°C for 24 h. The particles were separated by centrifugation and washed with anhydrous toluene and ethanol three times, respectively. The final product was obtained through drying under vacuum at 60°C overnight.

Synthesis of Alginate-Grafted MSN (MSN-SA)

Firstly, a solution of sodium alginate (SA, 0.2%, w/v) at pH 5.0 was prepared, which was adjusted by adding 1 M HCl solution. Next, 1-ethyl-3-(3-(dimethylamino)- propyl) carbodiimide (EDC, 5.8 g) was dissolved in the above SA solution (50 mL) in a round-bottom flask and stirred at room temperature for a while, followed by the addition of MSN-NH_2 particles (0.30 g) and N-hydroxysuccinimide (NHS, 3.5 g). After stirring the reaction mixture for 24 h at room temperature, the solution was centrifuged and washed with an excessive amount of DI water. The alginate-grafted MSN (MSN-SA) was dried in a vacuum oven at 60 °C overnight.

Cargo Loading and Ionic Coordinated Cross-Linking via $CaCl_2$

The model cargo, Rhodamine B (RhB), was loaded into the channels of MSN-SA by soaking the MSN-SA particles (40 mg) in an aqueous solution of RhB (24 mL, 3 mM) at room temperature. After stirring in the dark for 24 h, the saturated $CaCl_2$ solution (50 mL) was added and the reaction solution was continuously stirred for another 24 h, leading to the cross-link reactions between Ca^{2+} and the COO^{-}. The RhB-loaded, Ca^{2+} cross-linked MSN were separated by centrifugation and washed with DI water more than 3 times until the supernatant was nearly colorless to remove the unloaded cargoes, and the supernatant was collected for loading capacity calculation. Finally, the resulting materials (RhB@MSN-SA@Ca^{2+}) were dried in a vacuum oven at 60°C overnight. The loading amount of RhB was quantitatively evaluated by UV-vis spectroscopy and calculated by the following equation with the collected supernatant:

$$\text{Loading Capacity} = \frac{\textit{initial weight of RhB} - \textit{supernatant weight of RhB}}{\textit{total weight of cargo loaded particles}} \times 100\%$$

The Ca^{2+} cross-linked MSN without RhB loaded (MSN-SA@Ca^{2+}) was prepared by the method as same as the previously mentioned.

Cargo Release

The cargo release experiment from RhB@MSN-SA@Ca^{2+} nanocarriers was operated as follows: particles (5 mg) were soaked in 5 mL of Dulbecco's PBS (dPBS, pH 7.4, with an additional 15 mM Ca^{2+}) and transferred into a dialysis bag

(MWCO 3500), which was maintained in 45 mL of dPBS buffer and shaken at 37°C. To measure the concentration of the released cargo, 3 mL external dPBS buffer was withdrawn and tested by UV-vis spectroscopy, with replenishing subsequently the same volume of dPBS buffer to keep a constant release medium.

To study the ultrasound (US) responsiveness of RhB@MSN-SA@Ca^{2+} nanoparticles, the sample dispersion was exposed to low intensity US (20 kHz) or high intensity focused ultrasound (HIFU, 1,1 MHz). Two different types of ultrasound devices are depicted in **Figure S1**. Before applying US irradiation, the RhB@MSN-SA@Ca^{2+} (5 mg) was ultrasonicated widely in dPBS solution (1 mL) for a short time. In the case of HIFU exposure, the suspension was sealed in a dialysis bag (MWCO 3500), which was immersed in a custom-built glassware containing another dPBS solution (10 mL). At every point of studied time, 3 mL of outer releasing medium was withdrawn to test the cargo release amount by UV-vis and replenished with the equal volume of fresh dPBS. As to the low intensity US, the double jacketed beaker was used to hold the nanoparticle suspension and the outer layer is filled with condensed water (<26°C). After a certain irradiation period of US, the suspension was transferred into a dialysis bag and then processed in the same way as before. The release property of hybrid nanoparticles treated with low intensity ultrasound was compared with those treated under HIFU condition.

Pre-experiment of Ultrasonic Reversible Responsiveness

For *in vitro* ultrasound stimulation experiments, the gel was obtained by dropwise adding 50 mM $CaCl_2$ solution to a stirred sodium alginate (SA) solution in a bottle. The intensity and duration of low intensity ultrasound were 9.02 W/cm^2 and 5 min at 20 kHz. Low intensity ultrasound was carried out in an environment with condensed water, whose temperature was kept <26°C. As to HIFU stimulation, the gel was formed in the mouth of a tube and then the tube was placed upside down on the focal of HIFU wave. The power and application time of HIFU was 40 W and 5 min at 1.1 MHz. HIFU irradiation was carried out in a water bath, so the influence of focal thermo effect on the cross-linked structure should be studied. After that, gels were kept under different heating conditions (70, 100, 120°C) for an hour as control experiments, observing whether gel-sol transformation occurred, to exclude the thermo effect of HIFU.

In vitro Cytotoxicity Assay

The cytotoxicity of MSN-SA and MSN-SA@$CaCl_2$ was assessed by the standard MTT assay using HeLa cells. Five replicates were set in each test group. Firstly, Hela cells were seeded into a 96-well plate and the cell density was adjusted to 6×10^3 cells/well. After overnight incubation, the cells were incubated with different concentrations of MSN-SA and MSN-SA@$CaCl_2$ for 48 h, and then 0.5 mg/mL MTT (200 μ L) solution was added to incubate each well for another 4 h at a constant temperature of 37°C and 5% CO_2. Then, the supernatant was removed, and the obtained crystals were dissolved in dimethyl sulfoxide (150 μ L). After gently shaking in the dark for 10 min, the average absorbance was analyzed by a microplate reader (Rayto, Rt2100c) at a wavelength of 492 nm.

Characterizations

Cargo release profiles were obtained by a Cary 60 UV-Vis spectrophotometer (Agilent, USA). Fourier transform infrared (FT-IR) analysis was operated on a Nicolet-560 spectrometer. The morphology and mesoporous structures were visualized using a scanning electron microscopy (SEM) on a Quanta 250 instrument (FEI Co. Ltd, USA) and transmission electron microscopy (TEM) on Tecnai G2 F20 S-TWIN (FEI Co. Ltd, USA), respectively. Zeta-potential was measured by a Zetasizer Nano-ZS (Malvern) at 25°C. N_2 adsorption–desorption isotherms were obtained on an Autosorb-IQ2 Fully Automatic Analyzer. Thermogravimetric analysis (TGA) was carried out on a PerkinElmer TGA4000 from 100 to 800°C (10°C/min) in N_2 atmosphere. Powder small-angle X-ray diffraction (XRD) measurements were implemented using an Empyrean powder diffractometer. X-ray photoelectron spectroscopy (XPS) was carried out with a KRATOS XSAM800 spectrometer.

RESULTS AND DISCUSSION

Preparation and Characterization of Hybrid Mesoporous Silica Nanocomposites

Schematic illustration of our designed hybrid nanoparticles with reversible ultrasonic responsiveness and the preparation route were demonstrated in **Figure 1**. First, 3-aminopropyltriethoxysilane (APTES) was used to modify the MSN surface with -NH_2 groups. Then, sodium alginate (SA) polymers were grafted onto the amino modified MSN (MSN-NH_2), which was then cross-linked by $CaCl_2$ solution to form the COO^--Ca^{2+} coordination bonds. As depicted in **Figure 2**, SEM and TEM images could intuitively confirm the particle morphology and pore structure. The pure MSN had a regular, spherical shape with an average diameter of 134 ± 14 nm, which was manually counted from 110 particles (**Figures 2a,c**). The channel structure of pure MSN could be clearly seen from the TEM image (**Figure 2b**). After a few steps of surface modifications, the average diameter of obtained particles increased to around 147 ± 19 nm (**Figures 2d,f**). The structure of channels became blurred and so did the edge of MSN materials which become less smooth (**Figure 2e**) proving that the polymer was successfully grafted and cross-linked on the surface of MSN.

The successful modifications of SA polymer onto the MSN surface were characterized by various spectroscopy means. Powder small-angle XRD analysis was employed to characterize the 2D hexagonal pore array structure of pure MSN, which was indicated as (100), (110), and (200) characteristic diffraction peaks (**Figure 3A**). After modifications, the three Bragg peaks of MSN-NH_2 and MSN-SA showed a decreased intensity compared to the pure MSN curve, which resulted from the successful introduction of SA polymer on the surface of particles. Fourier transform infrared (FT-IR) spectroscopy was used to characterize each modification step performed on the surface of pure MSN, as displayed in **Figure 3B**. Firstly, the hydrocarbon vibrational peaks of the methyl and methylene groups at 2850 and 2920 cm^{-1} disappeared with the removal of the CTAB template, leaving a Si-O-Si vibration peak near 1100 cm^{-1} and

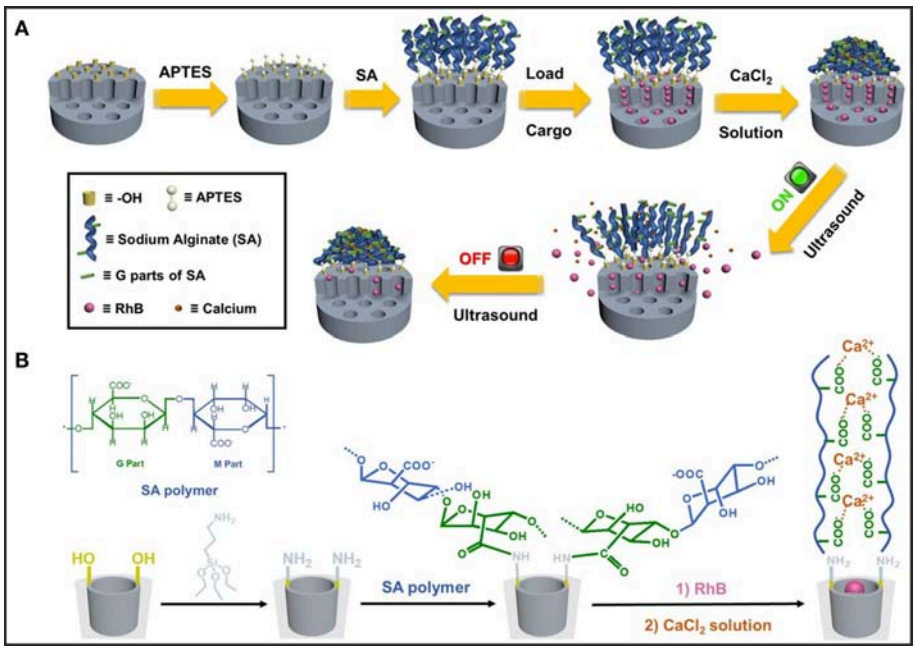

FIGURE 1 | (A) Schematic illustration of the preparation process and ultrasonic reversible responsive behavior of the dynamic cross-linked network on hybrid MSN nanoparticles. **(B)** Molecular structure of sodium alginate (SA) and the synthetic route of calcium ion cross-linked MSN-SA.

a silicon hydroxyl peak near 3400 cm^{-1} which belonged to the neat MSN. A high intensity at 1630 cm^{-1} of MSN was ascribed to absorbed water bending vibration. Next, the amino groups (-NH_2) were immobilized on the surface of MSN in the presence of 3-aminopropyltriethoxysilane (APTES), which was confirmed by the characteristic peak of MN-NH_2 at 1560 cm^{-1}. After the reaction between -NH_2 and SA, two peaks at 1640 and 1370 cm^{-1} of MSN-SA assigned to the amide group (–CONH–) and carboxylic acid group (–COOH), respectively. This observation was proof that SA polymer had been successfully linked to the MSN surface, in line with the previous SEM, TEM, and XRD results (**Figures 2**, **3A**).

To further verify the accomplishment of each step modification, the MSN-based samples were characterized by X-ray photoelectron (XPS) spectroscopy. As displayed in **Figure 3C** and **Table S1**, a new peak appeared at 404 eV

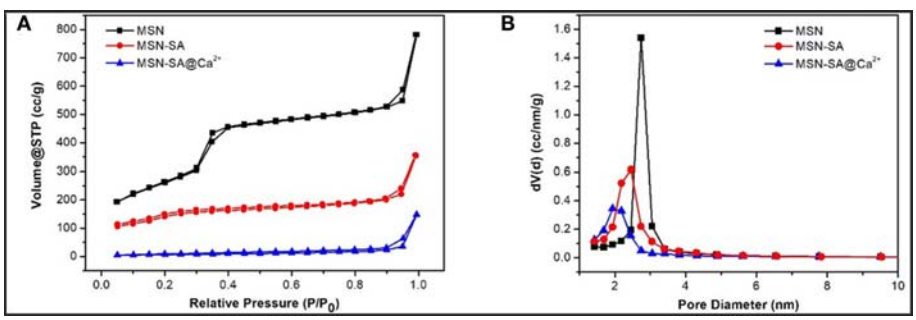

FIGURE 4 | (A) Nitrogen adsorption-desorption isotherms and **(B)** pore size distribution of MSN, MSN-SA, and MSN-SA@Ca^{2+}, respectively.

TABLE 1 | N_2 adsorption-desorption results of MSN and hybrid MSN particles in brief.

Sample	BET surface area (m^2/g)	BJH pore size (nm)
MSN	970.42	2.74
MSN-NH_2	548.96	2.45
MSN-SA@Ca^{2+}	252.36	1.93

ascribed to the N element from MSN-NH_2 result (red curve in **Figure 3C**), which confirmed the successful reaction between silanol groups and APTES. The percentage of N element of MSN-NH_2 was estimated to be 5%, whereas before modification only O, C, Si elements could be detected in the composition of MSN (black curve). Comparing the spectra of MSN-SA (blue curve in **Figure 3C**) with that of MSN-NH_2 (red curve in **Figure 3C**), the intensity of C element increased, while the intensity of Si decreased due to the polymer shielding effect after SA polymer modification. The presence of Ca 2p peak at 347 eV of MSN-SA@Ca^{2+} spectra (green curve in **Figure 3C**), whose percentage of Ca element was calculated to be 2.23%, indicated the successful cross-linking of SA polymer by $CaCl_2$ substance.

The weight loss percentage of various MSN-based samples was characterized by the thermogravimetric analysis (TGA), which were presented in **Figure 3D**. The final weight loss of MSN, MSN-NH_2, MSN-SA, and MSN-SA@Ca^{2+} were 6.2, 13.5, 24.4 and 30%, respectively. Increasing weight losses indicated

the successful immobilizations of APTES, SA polymer and cross-linked agent $CaCl_2$ on MSN particles. There is about 4.56 mmol/g amino on MSN-NH_2 as calculated from an extra 7.3% weight loss after being modified. The percentage of SA and $CaCl_2$ on particles was about 11 and 5.6%, which further demonstrated the reaction of SA polymer and $CaCl_2$. Beyond this, the average surface zeta potentials of all MSN-based materials were detected, and the data were shown in **Figure S2** and **Table S2**. The zeta potential of MSN-NH_2 was +38.09 mV, which indicated the introduction of amino groups compared with −27.56 mV of MSN. The zeta potential of MSN-SA was lowered to −34.10 mV since SA polymer has a large number of carboxyl groups. As to cross-linked nanoparticles, the zeta potential increased mainly due to the introduction of cationic calcium.

In addition, the surface area and pore size distribution of pure MSN and modified MSN nanoparticles were measured by the N_2 adsorption-desorption isotherms (**Figure 4** and **Table 1**). Clearly, the curve of pure MSN analyzed by the Brunauer–Emmett–Teller (BET) method showed a relatively sharp adsorption step at ∼ 0.3 P/P_0, which was classified as a typical IV behavior (Chang et al., 2013). This phenomenon was mainly due to the well-ordered mesoporous structure of MSN. It was worth noting that there were narrow H1-type hysteresis loops in the isotherms, which were mainly attributed to the capillary condensation. A narrow pore size distribution for each nanoparticle could be obtained by the Barrett–Joyner–Halenda (BJH) method. Nevertheless, the isotherms of MSN-SA and cross-linked MSN became flattered after modifications, and the pore diameter also decreased apparently. As summarized in **Table 1**, the surface area and the pore size of MSN was 970.42 m^2/g and 2.74 nm, respectively. As to MSN-SA@Ca^{2+}, these parameters were reduced to 252.36 m^2/g and 1.93 nm, respectively, resulting from the successful surface modification of pure MSN which limited the absorption of N_2.

Exploration of Ultrasound Reversible-Responsiveness

Before investigating whether there was the ultrasonic reversible response of designed hybrid MSN materials, cross-linked SA-$CaCl_2$ gel under ultrasound irradiation was studied first. According to the literature reported (Huebsch et al., 2014), ultrasound could break the complexation of divalent cations (e.g., Ca^{2+}) and SA, while the presence of Ca^{2+} in physiological fluids would allow re-crosslinking after removal of the stimulus, therefore achieving a reversible on-demand response. To emphasize the role of ultrasound in

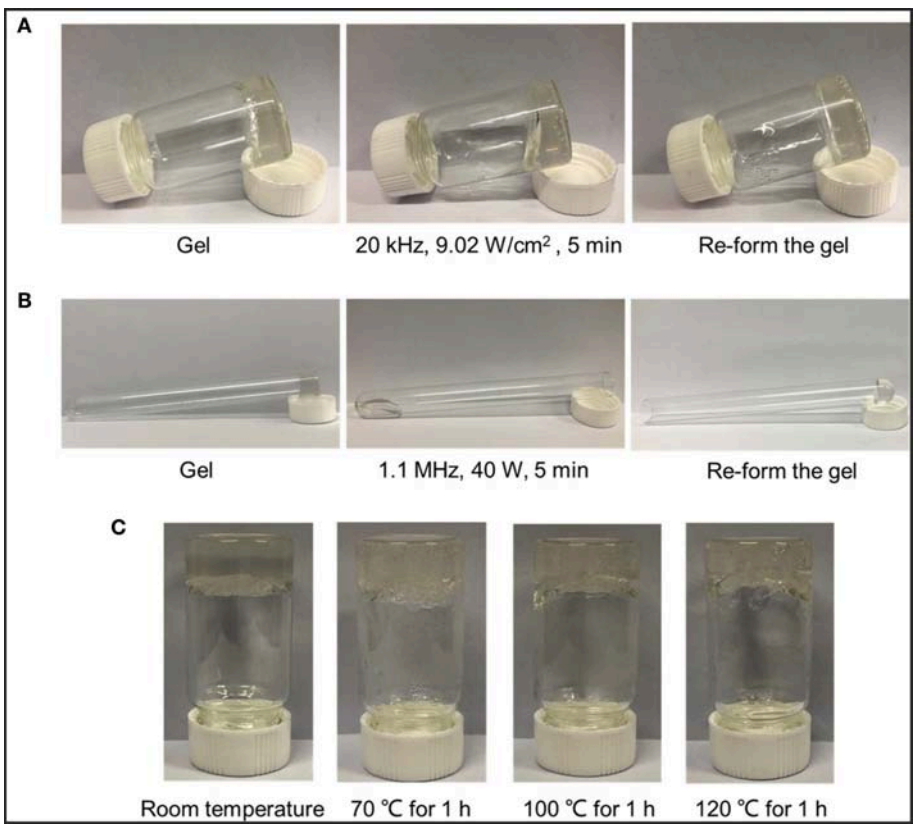

FIGURE 5 | Ultrasound induced disruption and reformation of ionically cross-linked gels. Macroscopic images of the proposed ability of **(A)** low intensity ultrasound and **(B)** HIFU to induce temporary disruption of cross-linked structure by $CaCl_2$ with SA polymer; **(C)** Macroscopic images of gels' status before and after treatment at different heating temperatures.

the cross-linked network, two different intensity ultrasounds were applied and the reversible gel-sol transition behaviors were studied.

As shown in **Figure 5**, ultrasounds and heating conditions were applied to the collected gel, respectively. A series of macroscopic photographs clearly illustrated the reversible nature of the calcium-alginate cross-linking system and its response to the activation effect of ultrasounds. From **Figures 5A,B**, the original gel state would become a flowing liquid state after activating either by low intensity ultrasound or HIFU, which was named as a gel-sol transition. After removal of ultrasound, the sol state could subsequently return to the original gel state. Since the test of cross-linked gel stimulated by low intensity ultrasound was carried out in condensed water which the environmental temperature was maintained lower than 26°C, so the thermal effect could be eliminated and only the acoustic cavitation of low intensity ultrasound had an influence on the cross-linked structure. As to the HIFU, the thermal effect was stronger than that of low intensity ultrasound, so it was necessary to test which of the two effects was the main reason. A control experiment that gels were put into the different heating environment for an hour to test the main ultrasonic effect was designed. **Figure 5C** showed the images of SA-$CaCl_2$ gel before and after thermal treatment. Only the content of water decreased and no gel-sol transition occurred. This phenomenon excluded the thermal effect from influence factors and concluded that the ultrasonic cavitation did play a major role in disrupting the ion-cross-linked structure of the gel (Paulusse and Sijbesma, 2004, 2008; Karthikeyan et al., 2008).

Cargo Loading and Release

The feasibility of applying this ultrasonic reversible response ion-crosslinked structure to the on-demand cargo delivery was investigated by using Rhodamine B (RhB) as a model drug. There was about 14.3% of RhB loaded in the mesopores of MSN-SA, which was determined by a pre-established calibration curve (**Figure S3A**) using UV-vis spectroscopy. To investigate the US responsive release of cross-linked nanoparticles, the low intensity ultrasound and HIFU were both applied. Similarly, the releasing content of RhB was calculated using a standard calibration cure in **Figure S3B**. HIFU-triggered RhB releasing profiles under different power (40, 60, and 80 W) were firstly studied. For the first six hours, the sample was placed in the 37°C environment without irradiation. Immediately after 5 min of HIFU stimulation, the sample was continuously placed in the 37°C constant water bath shaker and the released cargo was collected at the specific time. As shown in **Figure 6A**, without stimulation, the cumulative release percentage was nearly zero for the initial several hours. However, a sudden increase in the release profile could be obtained by stimulating samples with HIFU. Upon exposure to HIFU, the percentage of final release of RhB could reach as high as 25, 48, and 78% at the output power of 40, 60, and 80 W, respectively. It has been demonstrated that the effects of ultrasound, both thermo effect and cavitation, could cause the sonodynamic shear to break the weak bonds, such as covalent bond, non-covalent π-π bond, metal coordination interaction, and hydrogen bond, therefore, damaging the integrity of structure network and discharge the embedded drugs (Li et al., 2010, 2018; Tong et al., 2013; Xia et al.,

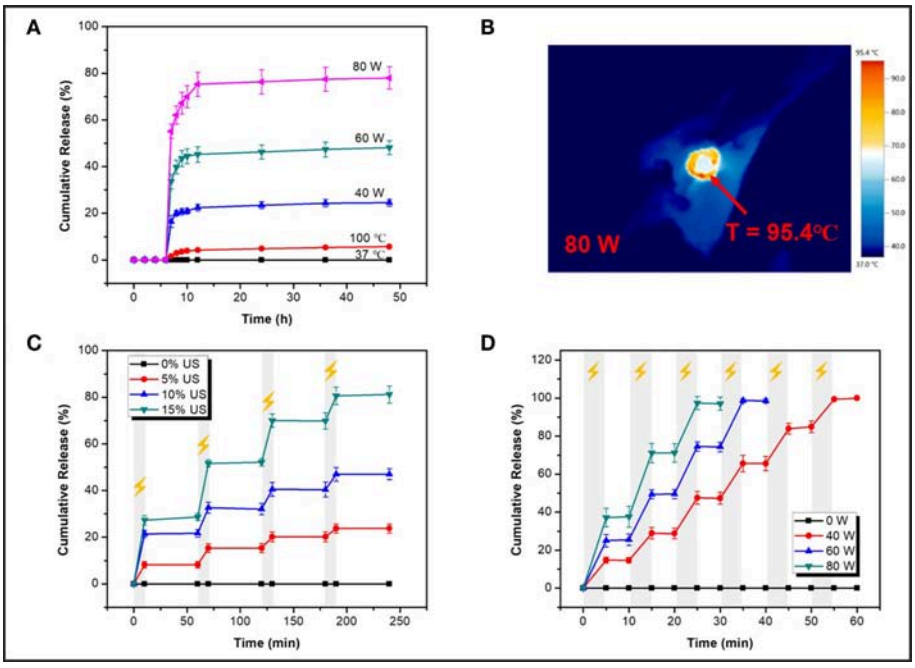

FIGURE 6 | (A) Nature release profiles (release at 37°C) after different treatments for 5 min (40, 60, 80 W of HIFU and heating at 100°C); **(B)** The maximum temperature of latex membrane at the focal of HIFU wave recorded by an Infrared Thermal Imager at 80 W; **(C)** On-off releasing profiles at different outputs of low intensity ultrasound (0, 5, 10, and 15% of power, 10 min irradiation); **(D)** On-off releasing profiles at different power of HIFU (40, 60, 80 W, 5 min irradiation).

2016). In the previous part, thermo effects had been concluded that ould not make a major impact on the gel-sol transition of SA-$CaCl_2$ gel (**Figure 5C**). It still needed to be determined for cross-linked MSN particles whether acoustic cavitation dominates the destruction of SA-Ca^{2+} cross-linked structure and the promotion of cargo release. The Infrared Thermal Imager was used to record the maximum temperature of latex membrane at the focal of the HIFU wave under different power outputs, the images were presented in **Figure 6B** and **Figure S4**. The temperature could reach to 61.3, 77.8, 95.4°C after irradiation for 5 min at 40, 60, and 80 W, respectively. 100°C, which was higher than the maximum temperature corresponding to the maximum power, was chosen to do the control experiment. After heating at 100°C for 5 min, the RhB releasing process was operated at 37°C, which was the same as the HIFU-triggered releasing experiment condition that was previously mentioned. In the end, the final percentage of RhB release was about 6%, which, although higher than that of untreated samples, was still much lower than that of HIFU exposed samples. These results further confirmed that cavitation effect rather than thermal effect of HIFU broke the SA-Ca^{2+} cross-linked structure and promoted the cargo release.

Figures 6C,D were cargo release profiles under the different power of low intensity ultrasound and HIFU. As depicted in **Figure 6C**, upon exposure to pulsatile ultrasound, cross-linked nanoparticles showed an obvious responsive release compared to non-stimulated samples (0% US). When ultrasound was turned on for 10 min, cargoes' releasing performance was apparent and when ultrasound was turned off, cargoes' releasing behavior stopped as well. Upon this pulsatile ultrasound (10 min-exposure per hour), the total RhB-releasing percentage could reach as high as 24, 47, and 81% at different powers (5%, 10%, 15% of total power) over 240 min. Then, the releasing profile was further studied under HIFU irradiation. A significantly increased release percentage was observed in an on/off pattern at a different output power of HIFU (**Figure 6D**). Ultrasonic stimulation was on for 5 min, then off for next 5 min, and nearly 100% of the RhB could be released in 60 min upon HIFU exposure. As an illustration, within a short duration of 55 min, the RhB-releasing percentage could reach up to 99% at the output power of 40 W. And yet it took only 30 min to obtain nearly 98% RhB-releasing at the output power of 80 W. All RhB cargoes could be released within 60 min upon HIFU exposure. What's important is that from the release pattern, the amount of RhB release was minor, even nil when either low intensity ultrasound or HIFU was off, proving from the side that the previously proposed SA-Ca^{2+} cross-linked structure indeed had the property of reversible self-recovery under ultrasound exposure. Comparing the time of releasing 80% of RhB, HIFU with no doubt had a shorter time (∼22 min for 80 W) and, in other words, higher efficiency than low intensity ultrasound (∼190 min for 15% of power) for the releasing stimulation. On the other hand, the maximum power of the above HIFU (80 W) was definitely safer than that of low intensity ultrasound (15% of total power) in practical human drug delivery because the latter would do harm to other healthy organizations in the body due to its strong cavitation effect. Thus, ultrasound, especially HIFU, could be an ideal external stimulation to realize a fast response releasing behavior with an on/off pattern, and these designed hybrid nanocarriers with reversible open/close responsiveness were intriguing candidates for effective drug delivery.

In vitro Cytotoxicity Assay

The investigation on the cytotoxicity of blank hybrid nanoparticles of MSN-SA and MSN-SA@$CaCl_2$ was also necessary before using them as drug carriers for future therapeutic application. The *in vitro* cytotoxicity experiment against HeLa cells was carried out with a standard MTT assay. As clearly illustrated in **Figure 7**, with the increase concentration of two nanoparticles, the cell viabilities performed a decrease trend. Nevertheless, MSN-SA and MSN-SA@ $CaCl_2$ nanoparticles did not show high cytotoxicity even up to a concentration of 60 μg/mL, indicating these two nanoparticles both had good biocompatibilities and were suitable as drug carriers in therapeutic application.

CONCLUSIONS

In summary, we developed a kind of hybrid organic-inorganic nanoparticles composed of MSN and SA-$CaCl_2$ cross-linked coatings which possess a reversible ultrasonic responsiveness with an apparent on/off release pattern. The sodium alginate (SA) polymer was successfully grafted onto the surface of mesoporous silica nanoparticles (MSN) through an amino terminated silane coupling agent, then $CaCl_2$ was introduced to cross-link the SA polymer layer which acted as a gatekeeper to prevent the RhB from premature releasing. The obtained hybrid nanoparticles presented a reversible-responsiveness to both low intensity ultrasound and high intensity focused ultrasound (HIFU), which was proved by calcium alginate gel-sol transformation experiments under ultrasound. The cargo loaded nanoparticles showed a fast ultrasound-induced release behavior and performed a good on/off release pattern under a pulsatile ultrasonic status. The mechanism of ultrasound-induced disruption was investigated and concluded that it

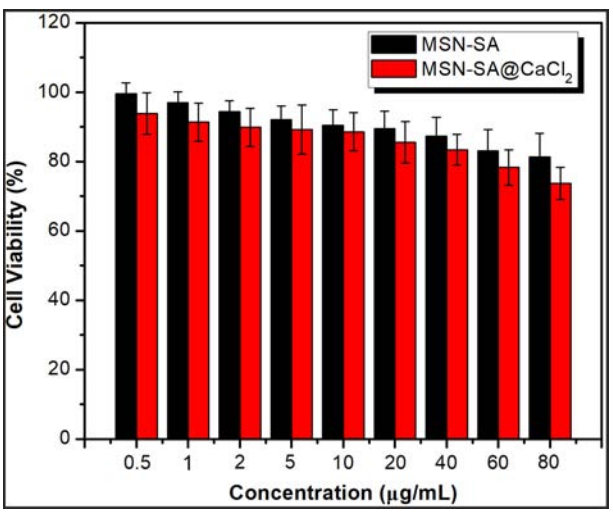

FIGURE 7 | Cell viability of Hela cells in MSN-SA, MSN-SA@$CaCl_2$ dispersion at different concentrations (0.5, 1, 2, 5, 10, 20, 40, 60, 80 μg/mL) by the standard MTT assay ($n = 5$).

was indeed the cavitation effect that dominated the process of breaking the metal coordination interaction. This study envisions that these new ultrasound stimulus reversible responsive organic-inorganic hybrid nanoparticles may possess potential applications in building on-demand drug delivery for timing-specific stimulation.

Advances in Organic Solvent Nanofiltration Rely on Physical Chemistry and Polymer Chemistry

Michele Galizia and Kelly P. Bye*

School of Chemical, Biological and Materials Engineering, The University of Oklahoma, Norman, OK, United States

The vast majority of industrial chemical synthesis occurs in organic solution. Solute concentration and solvent recovery consume ∼50% of the energy required to produce chemicals and pose problems that are as relevant as the synthesis process itself. Separation and purification processes often involve a phase change and, as such, they are highly energy-intensive. However, novel, energy-efficient technologies based on polymer membranes are emerging as a viable alternative to thermal processes. Despite organic solvent nanofiltration (OSN) could revolutionize the chemical, petrochemical, food and pharmaceutical industry, its development is still in its infancy for two reasons: (i) the lack of fundamental knowledge of elemental transport phenomena in OSN membranes, and (ii) the instability of traditional polymer materials in chemically challenging environments. While the latter issue has been partially solved, the former was not addressed at all. Moreover, the few data available about solute and solvent transport in OSN membranes are often interpreted using inappropriate theoretical tools, which contributes to the spread of misleading conclusions in the literature. In this review we provide the state of the art of organic solvent nanofiltration using polymeric membranes. First, theoretical models useful to interpret experimental data are discussed and some misleading conclusions commonly reported in the literature are highlighted. Then, currently available materials are reviewed. Finally, materials that could revolutionize OSN in the future are identified. Among the possible applications of OSN, isomers separation could open a new era in chemical engineering and polymer science in the years to come.

INTRODUCTION

Polymer technology is of paramount importance in several fields. Petrochemical, materials, food and tissue engineering, as well as medicine, optics and microelectronics are some of the areas were polymers endowed with specific structural or functional properties are sought (Haupt and Mosbach, 2000; Ma et al., 2002; Ulbricht, 2006). In this review we discuss the use of functional polymers to achieve molecular separations in liquid phase.

The vast majority of industrial organic synthesis occurs in solution. Downstream processes, such as solute concentration and solvent recovery, play a crucial role in the chemical industry and pose problems that are as relevant as the synthesis process itself (Marchetti et al., 2014). Often, especially in the food or pharmaceutical industry, traditional thermal separation processes, such as

distillation, cannot be exploited, since exposure to high temperatures would permanently damage thermally labile molecules, such as drugs, active principles and aromas (Kim et al., 2016; Priske et al., 2016). Liquid chromatography may represent, especially on small scales, an alternative to distillation, however it requires large volumes of solvent to be processed (Liang et al., 2008).

Nowadays, separations consume 15% of the energy produced in the world. Specifically, 80% of the energy demanded to separate chemicals is used for distillation (Lively and Sholl, 2017). Membrane separations operate at relatively mild conditions and do not require a phase change, which makes them less energy demanding relative to thermal processes (Galizia et al., 2017a). Moreover, while distillation requires very large equipment and huge investment costs, membrane modules are compact and much easier to assemble and operate. As a case study, let us consider one cubic meter of acetone solution containing a generic solute. Concentrating by a factor 10 this solution by distillation would require an amount of energy equal to 850 MJ. If the same separation is performed at room temperature and 25 bar using a membrane module, the energy consumption would be 2.2 MJ.

The separations mentioned above are generally classified as organic solvent nanofiltration (OSN) and organic solvent reverse osmosis (OSRO) (Koh et al., 2016; Koros and Zhang, 2017). OSN refers to situations in which a bulky solute, whose molecular mass is in the range 200–1000 g/mol, has to be separated from a solvent. OSN membranes generally operate based on the size sieving mechanism (Marchetti et al., 2014). First, the mixture to be separated is compressed to 30–40 atm and fed to the membrane: bulky solute molecules diffuse slowly through the membrane and, for entropic reasons, tend to be sorbed to a small extent by the membrane materials so, based on the solution-diffusion model (cf. section Solution-Diffusion model), they are rejected by the membrane and concentrated in the retentate side. Conversely, small solvent molecules preferentially permeate through the membrane (Marchetti et al., 2014). During the process, the downstream side of the membrane is kept at atmospheric pressure, so the pressure difference across the membrane drives the selective permeation of the solvent over the solute. OSRO refers to membrane separation of two or more liquids of like size. Since the currently available polymer materials cannot accomplish the latter separation, OSRO research efforts are being directed toward inorganic membranes based on carbon molecular sieves (Koros and Zhang, 2017; Lively and Sholl, 2017). Such materials separate molecules of like size based on the so-called entropic selectivity (Singh and Koros, 1996; Koros and Zhang, 2017).

There are several incentives for using OSN in the industrial practice. First, membrane filtration can be used either alone or in combination with traditional processes, such as distillation or liquid chromatography, giving rise to the so-called process intensification. As demonstrated by several techno-economic studies, such practice would reduce significantly the energy consumption of traditional processes, while ensuring high separation efficiency (White, 2006; Van der Bruggen, 2013; Marchetti et al., 2014; Szekely et al., 2014). Another advantage for using membrane filtration is its flexibility. Indeed, three operating modes are possible for OSN membranes, namely concentration, purification, and solvent exchange. Concentration processes involve the separation of a single solute from a solvent. As mentioned above, solute is concentrated in the retentate side, and solvent is recovered in the permeate side. Purification processes consist in separating two or more solutes, for example the main product of a chemical reaction from the byproduct. Finally, solvent exchange is used to enrich a solution in the solvent B by removing the solvent A.

Although ceramic materials have been also explored, polymers appear more suitable for OSN applications. The large amount of energy required to fabricate defect-free ceramic membranes, as well their intrinsic brittleness, represent the most relevant drawbacks for using ceramics in membrane manufacturing (Li, 2007).

Although OSN membranes are supposed to work based on the size exclusion mechanism, several factors, such as chemical-physical properties of the solute, solute-membrane interactions, solvent-membrane interactions, and membrane structure influence the membrane performance (Tsarkov et al., 2012; Postel et al., 2013; Volkov et al., 2014, 2015; Ben Soltane et al., 2016; Marchetti et al., 2017). However, little research efforts have been devoted to the analysis of these fundamental aspects.

The first attempt to use polymer membranes for organic liquid separation dates back to 1964, when Sourirajan used cellulose acetate to separate xylene from ethanol (Sourirajan, 1964). For almost 30 years, cellulose acetate was considered the standard material for separations involving organic liquids (Kopecek, 1970; Fang et al., 1992). The lack of materials capable to withstand chemically challenging environments has represented, for a long time, the real roadblock to progress in OSN (Cook et al., 2018). Indeed, organic solvents are sorbed to a significant extent by glassy and rubbery polymers. Such very high sorption, which often exceeds 50% by weight, may prejudice the membrane stability. Sometime, polymers can even dissolve in the presence of organic solvents. Several stable materials were developed in the last two decades, so the issue of membrane stability can be considered partially solved. Among these materials, cross-linked Lenzing P84 polyimide (White, 2001, 2002) has been particularly successful and it made possible small scale industrial applications of OSN in dewaxing of lube oil, homogeneous catalyst recovery, and enrichment of aromatics.

In the last decade, research has been focusing on tough polymers. This class of materials includes glassy polymers made of condensed aromatic rings with superior stability in solvents, such as polybenzimidazoles (Vogel and Marvel, 1961; Valtcheva et al., 2014, 2015; Borjigin et al., 2015) and polymers of intrinsic microporosity (PIMs) (Budd et al., 2004; Fritsch et al., 2012; Gorgojo et al., 2014; Ogieglo et al., 2017). Perfluorinated polymers (Chau et al., 2018), polyether ether ketone (PEEK) (Da Silva Burgal et al., 2015, 2017), and polyarylates (Jimenez-Salomon et al., 2016) also received significant attention for separations in harsh environments. In this review, we provide a detailed discussion of these materials, including synthesis routes, transport properties and property-structure correlations.

New interesting applications of OSN are in the pharmaceutical industry and, more specifically, in the downstream processing

of drugs, peptides and oligonucleotides. Noteworthy, membrane filtration in pharmaceutical industry can be exploited for separations, extractions, drying and also for particles formation (i.e., crystallization) (Buonomenna and Bae, 2015). For example, oligonucleotides and peptides are synthesized in solution and require a thorough purification before use. OSN represents a valid alternative to other processes, such as distillation or solvent extraction, which could potentially damage thermally and chemically labile biomolecules. Membranes based on cross-linked polybenzimidazole were successfully used to purify peptides and oligonucleotides, opening a new avenue in the area of oligo therapeutics (Kim et al., 2016).

Although membrane separation of organics has been indicated as one of the seven molecular separations that could change the world in the next decades (Lively and Sholl, 2017), OSN is currently one of the most poorly understood processes at a fundamental level. Specifically, the lack of fundamental knowledge about molecular factors governing solute and solvent transport in OSN membranes hampers OSN to take off the ground. Fundamental understanding of transport phenomena in OSN membranes would help not only to develop guidelines for the rational design of materials with pre-assigned transport properties, but also to select the optimal operative conditions to maximize the productivity and selectivity of existing membranes. Such aspect constitutes an essential prerequisite to make OSN competitive with traditional processes.

In this review we provide the state of the art of OSN using polymeric membranes. First, theoretical models useful to interpret experimental data are discussed and some misleading conclusions commonly reported in the literature are highlighted. The correct interpretation of OSN data is an essential pre-requisite to identify the key factors affecting solute and solvent transport in OSN membranes. Specifically, the individuation of a general framework to interpret transport data in OSN membranes represents the first step toward the development of structure-property correlations useful for the rational design of OSN membranes. A general theoretical framework for OSN is presented in section Transport Phenomena is OSN Membranes: Mechanism and Challenges. Then, currently available materials are reviewed. Finally, materials that could revolutionize OSN in the future are identified. For each of them, synthesis routes and structure-property correlations are presented and discussed.

TRANSPORT PHENOMENA IS OSN MEMBRANES: MECHANISM AND CHALLENGES

Solution-Diffusion Model

The solution-diffusion model sets the mechanism by which gases, vapors, liquids, and ions diffuse through dense (i.e., non-porous) polymers (Paul, 1973, 2004; Wijmans and Baker, 1995). Leveraging on an elegant series of experiments and a purposely built theory, Paul and coworkers, in the early 70's, demonstrated that the solution-diffusion mechanism rules the pressure driven transport of organic liquids in rubbery polymers (Paul and Ebra-Lima, 1971). The pioneering studies conducted by Paul can be considered the first attempt to understand OSN at a fundamental level, although, at the time, OSN was not recognized as such.

According to the solution-diffusion model, penetrant molecules first partition between the feed and the upstream face of the membrane. Then, sorbed molecules diffuse through the membrane thickness, down a concentration (or chemical potential) gradient. Finally, they desorb from the downstream face of the membrane. When considering the transport of liquids through dense polymer membranes, the permeability coefficient, which is an intrinsic property of the membrane material, is defined as the pressure and thickness normalized flux (Paul, 1973):

$$P_1 = \frac{n_1 l}{\rho_1 \Delta p} \tag{1}$$

where subscripts 1 and 2 stand for the penetrant and the membrane species, respectively. In Equation 1, n_1 is the steady-state penetrant mass flux relative to the fixed frame reference, i.e., the membrane, ρ_1 is the penetrant density, Δp is the pressure difference across the membrane, and $\boldsymbol{l}$ is the membrane thickness. To simplify the matter, let us consider the diffusion of a pure liquid through a polymer. To quantitatively describe this phenomenon, it is necessary to define a frame of reference. Two frames of reference can be used, namely fixed or moving (Paul, 1973; Kamaruddin and Koros, 1997; Galizia et al., 2016). In the moving framework, the diffusional flux is defined with respect to the center of mass of the polymer-penetrant system, which, in turn, moves with its own bulk velocity. Within this framework, the diffusional velocity relative to the bulk velocity causes the penetrant flux through the membrane. In the fixed or stationary frame of reference, the membrane itself is used as the frame of reference. The penetrant mass flux through the membrane, n_1, with respect to the fixed frame is expressed as follows (Paul, 1973; Kamaruddin and Koros, 1997; Galizia et al., 2016):

$$n_1 = n_1^{diff} + n_1^{conv} = j_1 + \omega_1 (n_1 + n_2) \tag{2}$$

where j_1 is the diffusive mass flux, i.e., the mass flux of species 1 relative to the center of mass of the polymer-penetrant system, ω_1 is the penetrant mass fraction in the membrane, and n_2 is the membrane flux (cf. **Figure 1**). This result can be extended to multicomponent permeation, so that, with respect to the fixed frame of reference, the mass flux of each permeating species is given by the convective flux resulting from the bulk motion of the permeating mixture (second term at the right-hand side in Equation 2), plus the diffusive flux (first term at the right-hand side in Equation 2).

In case of Fickian diffusion, j_1 is expressed as follows:

$$j_1 = -\rho D_1 \frac{d\omega_1}{dx} \tag{3}$$

where D_1 is the effective, concentration averaged penetrant diffusion coefficient through the membrane, ρ is the density of polymer-penetrant mixture, and x is the generic abscissa through the membrane thickness. Combining Equations 2, 3 and remembering that at steady state the polymer flux, n_2, is zero,

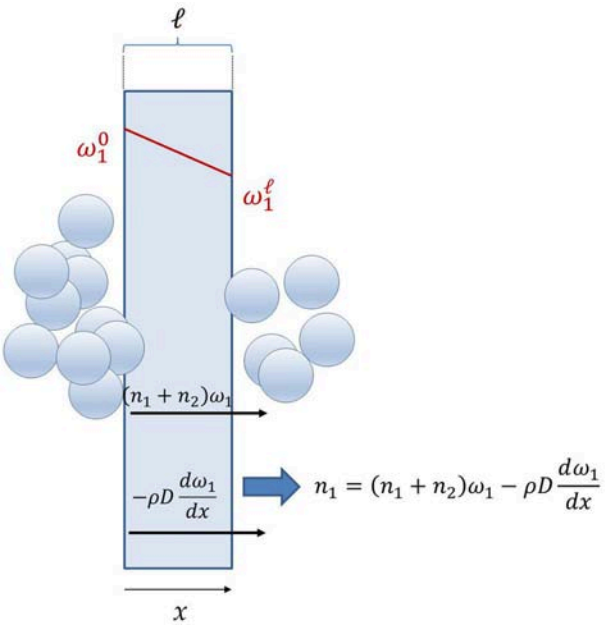

FIGURE 1 | Schematic of small molecule transport through dense polymer membranes.

leads to the following expression for the penetrant mass flux with respect to the fixed frame of reference:

$$n_1 = -\left(\frac{\rho D_1}{1-\omega_1}\right)\frac{d\omega_1}{dx} \tag{4}$$

During a permeation experiment, penetrant flux is measured with respect to the membrane, i.e., the experimentally measured flux is n_1 (Paul, 1973). However, when considering gas and vapor transport in polymers, ω_1 is vanishing, so that $1-\omega_1 \cong 1$. In this situation, the experimentally measured flux, n_1, is essentially equal to the diffusive flux, j_1. In contrast, liquid solvent uptake by polymers may be significant, so $1-\omega_1 \ll 1$, which means that n_1 significantly departs from j_1. In the latter situation, neglecting the factor $1/(1-\omega_1)$ in Equation 4 would cause significant errors in the estimation of the diffusion coefficient (Paul, 1973).

As the approach presented above can be generalized to the diffusion of multicomponent mixtures, Equation 4 should be used to describe solvent and solute transport in OSN membranes. Interestingly, such approach can be further generalized to account for the effects of osmotic pressure and concentration polarization (Peeva et al., 2004). Details about integration of Equation 4 were reported by Dinh (Dinh et al., 1992) and Paul (Paul, 1973). Integration of Equation 4 requires that the penetrant concentration profile in the membrane is known. As reported in previous studies (Paul, 2004; Galizia et al., 2016), the ω_1 profile can be considered linear, so that $\omega_1 = \omega_1^0\left(1-\frac{x}{l}\right)$, where ω_1^0 is the penetrant concentration in the upstream face of the membrane, which can be estimated from liquid sorption experiments.

Correcting the Fick's law for the frame of reference is not sufficient. When considering a membrane separating two solutions with different compositions, the chemical potential gradient across the membrane is the driving force for penetrant diffusion (Bird et al., 1960). However, as concentration is much easier to measure than chemical potential, often the concentration gradient across the membrane is assumed as the actual driving force for penetrant transport. Indeed, in writing Equation 4, we followed the latter approach. When the driving force is expressed in terms of concentration gradient, the diffusion coefficient appearing in Equation 4, D_1, is the product of a purely kinetic quantity, i.e., the mobility coefficient, L_1 , which accounts for the frictional resistance offered by the polymer matrix to penetrant diffusion, and the thermodynamic factor, $\frac{1}{RT}\frac{\partial\mu_1}{\partial ln\omega_1}$, related to polymer-penetrant interactions (Doghieri and Sarti, 1997; Galizia et al., 2011):

$$D_1 = L_1\left(\frac{1}{RT}\frac{d\mu_1}{dln\omega_1}\right) \tag{5}$$

In Equation 5, μ_1 is the penetrant chemical potential in the polymer-penetrant mixture and ω_1 is the penetrant mass fraction in the polymer. When polymer-penetrant mixing is ideal (i.e., no special interactions take place), the factor $\left(\frac{1}{RT}\frac{d\mu_1}{dln\omega_1}\right)$ is equal to one. Conversely, when polymer-penetrant mixing is non-ideal, which happens frequently, the thermodynamic factor deviates from one. Specifically, when the polymer and penetrant exhibit like physical-chemical properties and their mutual interactions are thermodynamically favorable, $\left(\frac{1}{RT}\frac{d\mu_1}{dln\omega_1}\right) > 1$. Conversely, when polymer-penetrant interactions are thermodynamically unfavorable, $\left(\frac{1}{RT}\frac{d\mu_1}{dln\omega_1}\right) < 1$ (Doghieri and Sarti, 1997; Galizia et al., 2011). This aspect complicates significantly the analysis of diffusion coefficients, which need to be corrected also for thermodynamic non-idealities. While the latter issue has been addressed by Paul for rubbery membranes, based on the Flory-Huggins theory (Paul, 1973), no general solution has been proposed so far for glassy membranes. Such aspect represents a potential research topic *per se*, since polymers used for OSN are typically glassy. A very simple method to correct diffusion coefficients in glassy polymer for thermodynamic non-idealities relies on vapor sorption data. Gas and vapor sorption isotherms in glassy polymers can be described using the dual mode sorption model (Koros et al., 1976), which provides the following analytic expression for the thermodynamic factor (Merkel et al., 2000):

$$\frac{1}{RT}\frac{d\mu_1}{dln\omega_1} = \frac{k_D + \frac{C_H' b}{1+bp}}{k_D + \frac{C_H' b}{(1+bp)^2}}\left[1 + \frac{M_w}{22414\rho_p}\left(k_D p + \frac{C_H' bp}{1+bp}\right)\right] \tag{6}$$

where k_D, C_H' and b are the three dual mode parameters, which can be estimated by fitting vapor sorption isotherms, p is the vapor partial pressure, M_w is the penetrant molecular mass and ρ_p is the polymer density. If vapor sorption data are available, the thermodynamic factor can be calculated as a function of activity using Equation 6, and then it can be extrapolated at activity 1, i.e., to the case of liquid sorption. However, such very simple method does not always work. For example, lower alcohols

(e.g., methanol and ethanol) sorption is some glassy polymers, such as polyacetylenes, cannot be described by the dual mode model, due to the occurrence of significant penetrant clustering (Galizia et al., 2011, 2012). For this reason, advanced methods based on more fundamental models are under development. For example, the non-equilibrium lattice fluid model provides a general, analytic expression for the penetrant chemical potential in mixture with a glassy polymer (Doghieri and Sarti, 1996), from which the derivative appearing in Equation 5 can be calculated analytically.

For rubbery polymers, the diffusion coefficient corrected for the frame of reference and thermodynamic non-idealities is given by (Paul, 1973):

$$L_1 = D_1 \left(1-\phi_1\right)^2 \left(1 - 2\chi_1\phi_1\right) \tag{7}$$

where D_1 is the experimentally determined diffusion coefficient, ϕ_1 is the penetrant volume fraction in the membrane, and χ_1 is the polymer-penetrant Flory-Huggins interaction parameter (Flory, 1942).

Paul (1973) successfully used this approach to describe a set of experimental diffusion data presented by White (1960). White measured pure liquid water transport through rubbery polyacrylamide membranes whose water content was about 70% vol. Interestingly, water diffusion coefficient through the membrane, calculated as the ratio of permeability to sorption coefficients, resulted one order of magnitude larger than water self-diffusion coefficient (i.e., 2.8×10^{-5} cm^2/s). To explain this unexpected result, White speculated that, for such highly swollen membrane, water transport occurs by pore flow. Paul demonstrated that the results presented by White could be rationalized using Equations 4 and 7 (Paul, 1973). Indeed, since the polyacrylamide membrane was highly swollen, neglecting the term $1/(1-\omega_1)$ in Equation 4, as well as thermodynamic non-idealities, led White to overestimate the diffusion coefficient by orders of magnitude. After correction for the effect of the frame of reference and thermodynamic non-ideality, water diffusion coefficients in polyacrylamide were far below the liquid water self-diffusion coefficient. So, invoking pore flow to describe water transport in polyacrylamide membranes was inappropriate.

In recent years, similar conclusions were drawn by Volkov et al. (1996) when assessing the suitability of glassy poly(trimethylsilyl propyne) (PTMSP) for OSN application. They observed that liquid ethanol diffusion coefficient in PTMSP (i.e., 1.27×10^{-8} cm^2/s) was larger than ethanol self-diffusion coefficient (i.e., 1.10×10^{-9} cm^2/s) and speculated occurrence of pore flow transport. This conclusion is dramatically altered if the experimental data are analyzed using the Paul's approach. From swelling experiments, ethanol volume fraction in PTMSP at room temperature resulted 0.46. If one assumes, in first approximation, the Flory-Huggins theory to account for thermodynamic non-ideality, the χ parameter can be estimated from liquid ethanol sorption data. Doing so, gives $\chi = 0.813$. Finally, from Equation 7, the ethanol diffusion coefficient in PTMSP corrected for the frame of reference and thermodynamic non-idealities is 9.30×10^{-10} cm^2/s, which is below the ethanol self-diffusion coefficient and fifteen times smaller relative to the value calculated by Volkov. The dual mode approach, although more appropriate for glassy PTMSP, cannot be used to correct ethanol diffusion coefficient for thermodynamic non-idealities, since ethanol sorption is PTMSP is not dual-mode type (Doghieri and Sarti, 1997).

The examples discussed above show how poor has been, so far, the fundamental analysis of transport phenomena in OSN membranes, and how this issue continues to generate misleading interpretations of experimental data.

The solution-diffusion model links penetrant permeability, solubility and diffusion coefficients in the membrane as follows (Wijmans and Baker, 1995):

$$P_1 = D_1 \times S_1 \tag{8}$$

When considering the permeation of a binary mixture through a membrane, the selectivity for the component *i* vs. the component *j* is defined as follows (Wijmans and Baker, 1995):

$$\alpha_{ij} = \frac{P_i}{P_j} = \frac{D_i}{D_j} \times \frac{S_i}{S_j} = \alpha_D \times \alpha_S \tag{9}$$

where α_D and α_S are the diffusivity-selectivity and the solubility-selectivity, respectively. The diffusivity-selectivity is believed to control the selective permeation of solvent over solute through OSN membranes. Indeed, since diffusivity decreases markedly with increasing penetrant size, solute molecules are expected to be rejected by the membrane due to their very slow diffusion in the membrane material. However, deviations from this rule of thumb have been observed. For example, Postel reported that during removal of non-polar hydrocarbon solutes (e.g., alkanes) from polar solvents (e.g., isopropanol) using rubbery PDMS membranes, solute permeability through the membrane largely exceeds solvent permeability (Postel et al., 2013). As a consequence, the solute is enriched in the permeate side relative to the feed side (i.e., the membrane is solute-selective instead of solvent-selective, cf. **Figure 2**). Postel hypothesized that preferential solute sorption in PDMS, caused by its higher thermodynamic affinity with the polymer, is responsible for this phenomenon, even though no direct proof of this hypothesis has been provided (Postel et al., 2013).

As we will see in the forthcoming sections, often commercial membranes are made by a thin active layer, which actually performs the separation, cast onto a porous support. Since the thickness of the active layer cannot be measured accurately, application of Equation 1 to calculate permeability is not straightforward. So, the performance of these composite membranes is expressed in terms of permeance instead permeability. Permeance is the thickness normalized permeability and, as such, it is not an intrinsic property of the membrane, since it depends on its geometry. Likewise, in practical applications, rejection is used instead selectivity. Rejection of species *i* is defined as follows (Marchetti et al., 2014, 2017):

$$R_i = 1 - \frac{C_i^p}{C_i^f} \tag{10}$$

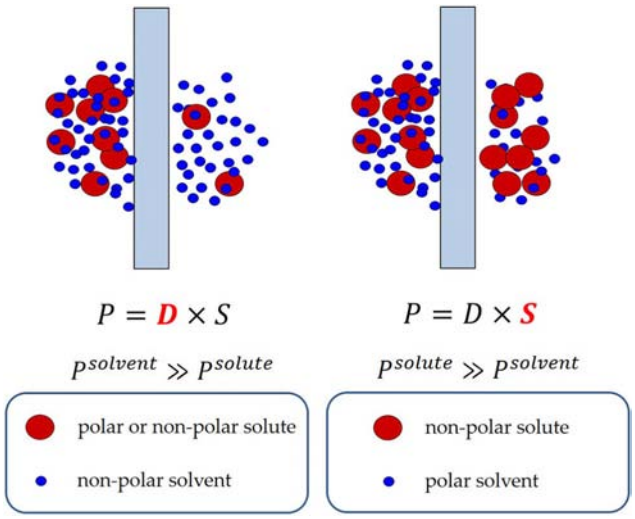

FIGURE 2 | Solvent and solute transport in PDMS-based membranes. On the right is reported the case where solute permeability exceeds solvent permeability. Solute preferential sorption is believed to be the cause of this behavior (Postel et al., 2013).

where C_i^p and C_i^f are the concentrations of species i in the permeate and feed, respectively. Rejection is related to selectivity as follows:

$$\alpha_{ij} = \frac{1 - R_i}{1 - R_j} \tag{11}$$

Plasticization

Membrane plasticization indicates an increase in chain mobility caused by penetrant sorption (Chiou et al., 1985). Such improved chain mobility reduces the energy penalty required to open gaps between polymer chains, thus enhancing penetrant diffusivity and permeability. However, such an increase in permeability is accompanied by a loss in membrane selectivity. OSN membranes must exhibit adequate resistance to plasticization, as they face directly organic liquids during their operation. Methods to mitigate membrane plasticization rely essentially on polymer chemistry: covalent or ionic cross-linking, as well as use of rigid monomers with limited rotation freedom are some relevant examples (Vanherck et al., 2013; Valtcheva et al., 2014, 2015).

Physical Aging

Rigid materials, such as glassy polymers, are sought in OSN applications. Glassy polymers contain an excess free volume trapped in their structure and, as such, they are non-equilibrium materials. Excess free volume is *per se* unstable and tends to be relaxed over time, producing a progressive densification of the polymer matrix. This process is referred to as physical aging (Huang and Paul, 2004, 2006). Loss of free volume significantly affects transport properties of glassy membranes, as it reduces small molecule permeability and enhances selectivity. Paul and co-workers demonstrated that the physical aging rate of glassy polymer films is inversely proportional to their square thickness, which justifies the accelerated aging exhibited by thin films typically used in membrane applications (Huang and Paul, 2004, 2006). Membranes 1 μm thick or less lose 25% of their permeability within a few days after manufacturing. Another 25% of their permeability is lost in the following 15 days (Galizia et al., 2017a). For example, asymmetric membranes based on cross-linked Lenzing P84 polyimide, the current standard material for OSN, exhibit solvent permeance ranging from 1 to 2 L/(m^2 h bar). Thermal annealing at 200°C decreases solvent permeance to zero, due to polymer densification (See See-Toh et al., 2007a). The issue of physical aging becomes dramatic during operation at medium-high temperatures, as polymer chains motion, who is ultimately responsible for physical aging of glassy polymers, becomes faster with increasing temperature.

Strategies to mitigate this issue have been devised, which rely on covalent cross-linking and use of rigid monomers with frustrated rotation freedom. While the former strategy was sometimes successful, the latter did not always guarantee good results, as rigid polymers, such as PIMs (Bernardo et al., 2017) and thermally rearranged (TR) polymers (Wang et al., 2014) also exhibit physical aging when manufactured as thin films.

Recently, Livingston and co-workers reported negligible aging in poly(ether ether ketone) (PEEK) membranes for OSN (Da Silva Burgal et al., 2015, 2017). PEEK is a fully aromatic, semi-crystalline polymer made by hydroquinone and benzophenone segments. Physical aging of bulky membranes (10–50 μm) typically used in the academia is a slow process and its effects do not show up within experimentally accessible timescales (Galizia et al., 2017a). To accelerate physical aging, Da Silva Burgal annealed thick films made by PEEK, Lenzing P84 polyimide and polybenzimidazole at 120°C for 48 h (Da Silva Burgal et al., 2017). Polyimide and PBI samples became very brittle after thermal annealing, due to the accelerated free volume relaxation, which reduced polymer chain mobility. Their Young's modulus could not be measured after annealing. In contrast, PEEK didn't show any brittleness and its Young's modulus increased from 61 MPa to 108 MPa after annealing at 120°C. The unusual stability exhibited by PEEK is likely due to the presence of ultra-rigid crystalline domains, which freeze polymer chains in the amorphous domain in their original position (Da Silva Burgal et al., 2017).

Three dimethylformamide (DMF) filtration experiments were run with PEEK, polyimide P84 and PBI membranes at 30, 85, and 140°C, respectively, followed by a fourth run at 30°C. Permeance of P84 decreased by a factor 6 from 30 to 85°C. At 140°C, cross-linking thermal scission caused the membrane failure. PEEK and PBI permeance increased by a factor 20 and 2.5, respectively, from 30 to 140°C. Interestingly, during the fourth filtration cycle, when temperature was returned to 30°C, PEEK exhibited the same permeance as in the first run, and PBI lost 25% of its original permeance (cf. **Figure 3**). This result was justified by invoking negligible aging in PEEK (Da Silva Burgal et al., 2017).

Permeability-Selectivity Trade-Off

The existence of a trade-off between permeability and selectivity in polymer membranes for gas separation was reported on empirical bases by Robeson (Robeson, 1991, 2008), and it was explained theoretically by Freeman (1999). Generally, highly permeable membranes exhibit poor selectivity, and vice-versa. As a consequence, the performance of polymer membranes is

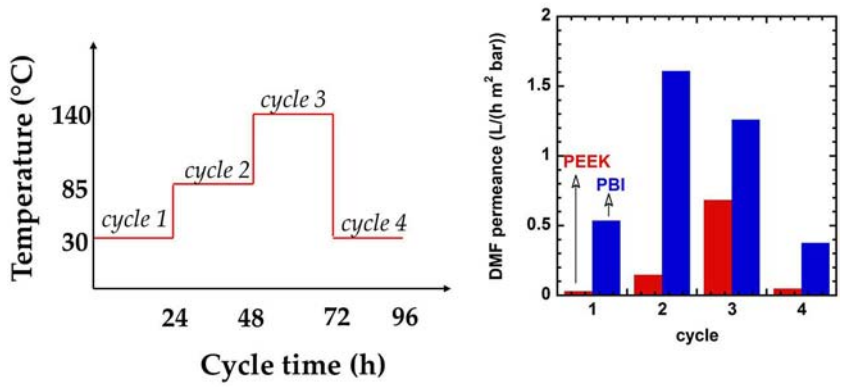

FIGURE 3 | Effect of physical aging on poly (ether ether ketone) and polybenzimidazole membranes. Adapted from Da Silva Burgal et al. (2017), with permission of *Elsevier*.

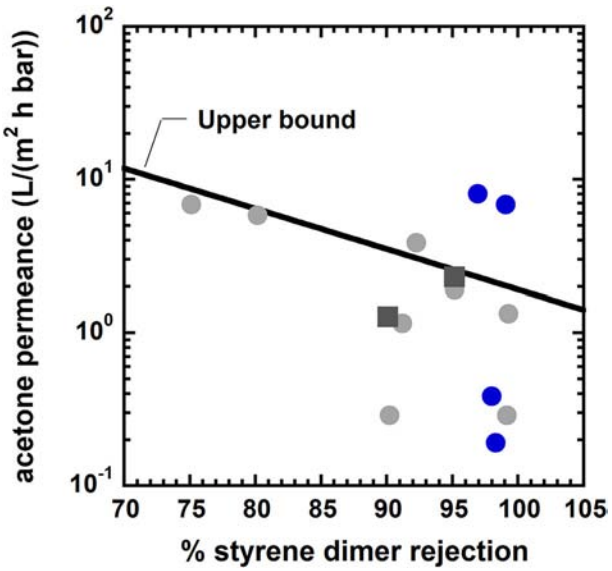

FIGURE 4 | Upper bound diagram for styrene dimers (molecular mass 236 g/mol) separation from acetone at room temperature. Solid gray circles: conventional asymmetric membranes. Solid black square: conventional composite membranes. Solid blue circles: nanoporous polyarylates synthesized by Jimenez-Salomon et al. (2016). Blue circles above the upper bound refer to polyarylates obtained using contorted, non-planar monomers [i.e., 9,9-bis(4-hydroxyphenyl)fluorine]. Blue circles below the upper bound refer to polyarylates obtained using planar, non-contorted monomers (i.e., dihydroxyanthraquinone). Adapted from Jimenez-Salomon et al. (2016), with permission of *NatureResearch*.

limited to stay below the upper bound defined by the best performing materials. Conversely, inorganic materials, such as zeolites, often surpass the upper bound, as they exhibit high levels of permeability and selectivity. Recently, a permeability-selectivity trade-off for OSN membranes was reported by Marchetti (Marchetti et al., 2017). Such finding strongly supports the idea that the solution-diffusion mechanism rules solute and solvent transport in OSN membranes. An example of permeance/rejection upper bound for OSN is reported in **Figure 4**.

Effect of Pressure on Solvent Flux

One of the most controversial aspects in OSN is the dependence of solvent flux on the upstream pressure. Several authors observed that flux is linear with Δp (i.e., the pressure difference across the membrane), and it declines at high pressures. Membrane compaction caused by the upstream pressure has been invoked to explain this behavior (Machado et al., 1999; Grekhov et al., 2012; Ben Soltane et al., 2013). However, while this explanation could be physically sound for soft, rubbery membranes, such as PDMS (elastic modulus < 4 MPa), it seems unrealistic for rigid glassy polymers typically used in OSN (elastic modulus $\cong 4$ GPa), especially if we consider that flux decline often starts at relatively low pressures, such as 10–12 bar. We believe the right explanation of this phenomenon should be found in the pioneering studies from Paul and co-workers (Paul and Ebra-Lima, 1970, 1971; Paul, 1973). Paul demonstrated that the driving force for liquid transport through a swollen membrane is the swelling gradient between the upstream and the downstream face of the membrane, $\phi_1^0 - \phi_1^l$, where ϕ is the liquid volume fraction in the membrane material (Paul, 1973). While ϕ_1^0 (i.e., the liquid volume fraction in the upstream face) is constant, as it does not depend on the applied pressure, ϕ_1^l (i.e., the liquid volume fraction in the downstream face) decreases with increasing upstream pressure. When the upstream pressure is high enough, ϕ_1^l can become zero. In this situation, the maximum driving force is available, which means that flux cannot further increase with increasing pressure (cf. **Figure 5**). Paul derived the following expression for solvent mass flux as a function of applied Δp (Paul, 1976, 2004):

$$n_1 = \frac{C_1^0 D_1}{l\left(1-\omega_1^0\right)}\left[1 - exp\left(-\frac{\tilde{V}_1 \Delta p}{RT}\right)\right] \tag{12}$$

where C_1^0 and ω_1^0 are the solvent concentration and mass fraction at the upstream face of the membrane, respectively, $\tilde{V}_1$ is

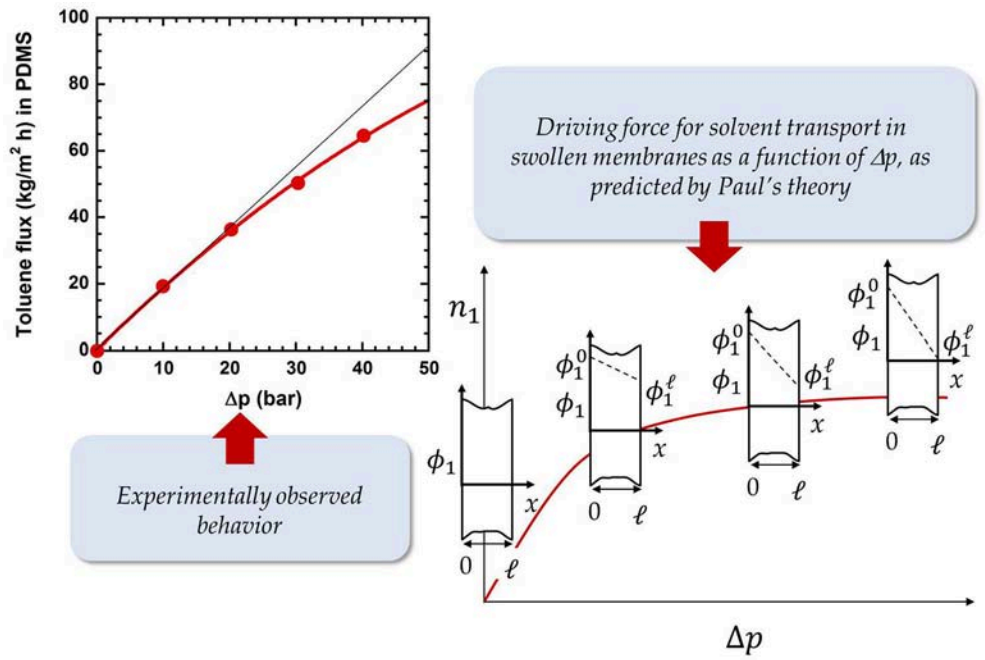

FIGURE 5 | Toluene flux through PDMS as a function of Δp at room temperature. Data were taken from Postel et al. (2013). The evolution of driving force for solvent transport as a function of Δp is reported as well, adapted from Paul (2004), with permission of *Elsevier*.

the solvent molar volume and Δp is the pressure difference across the membrane. Equation 12 states that the ceiling flux is attained more rapidly with increasing permeant molar volume.

Machado and co-workers (Machado et al., 1999) measured the permeability of pure liquid alcohols and hydrocarbons as a function of applied pressure in MPF-50, a commercial membrane made by cross-linked silicon rubber. They observed, especially for higher alcohols (i.e., isopropanol, butanol, and pentanol) and large hydrocarbons (n-pentane), a severe flux decline starting at 15 atm. For methanol such decline was less pronounced. To justify this behavior, Machado and co-workes invoked membrane compaction. However, in doing so, the authors recognized that flux decline at high pressures was significant especially for bulky solvents, i.e., solvent endowed with large molecular size. We believe their conclusions are somehow misleading, since membrane compaction is a purely mechanical effect that should take place regardless of penetrant size. Machado used the following empirical expression to fit flux vs. pressure curves:

$$n_1 = n_1^0 exp\left(-\alpha_p \Delta p\right) \tag{13}$$

where n_1^0 is a pre-exponential factor and α_p is an empirical parameter that measures membrane compaction: the higher the membrane compaction, the higher α_p. So, flux decline becomes faster with increasing α_p (that is, flux decline starts at lower pressures with increasing α_p). Paul's theory can be used to rationalize this behavior, without invoking membrane compaction. Indeed, Equation 12 states that (i) at low Δp flux is linear, as it can be demonstrated by replacing the exponential term with a first order Taylor expansion (i.e., $1 - exp\left(-\frac{\tilde{V}_1 \Delta p}{RT}\right) \cong \frac{\tilde{V}_1 \Delta p}{RT}$ when Δp is small), and (ii) at sufficient high Δp, the downward curvature of the flux-pressure curve becomes more pronounced as the solvent molar volume increases. **Figure 6A** shows the dimensionless flux, n_1^{dim} , (i.e., $n_1^{dim} = \left[1 - exp\left(-\frac{\tilde{V}_1 \Delta p}{RT}\right)\right]$) as a function of Δp, for different values of $\tilde{V}_1$. The downward curvature of the flux-pressure curves becomes more pronounced with increasing permeant molecular size, as observed by Machado.

Interestingly, for any given couple of solvents, i and j, the α_p^i/α_p^j ratio matches very well with the molar volumes ratio, $\tilde{V}^i/\tilde{V}^j$ (cf. **Figure 6B**). This analysis points out that the parameter α_p in the empirical Machado's model does not account for membrane compaction, as the authors state. According to Paul's theory, α_p is a measure of penetrant molecular size. So, occurrence of flux decline is not sign of membrane compaction, as commonly believed in the literature. Flux decline simply indicates that the system is approaching a condition where the driving force for solvent transport is maximum. When this maximum is reached, the flux attains its ceiling value. Moreover, the magnitude of flux decline increases with increasing permeant molecular size. So, the empirical Machado's model, if interpreted correctly, coincides with the rigorous Paul's model.

CURRENT OSN MATERIALS

OSN is a relatively young process, but with enormous potential for growth. Small scale applications of OSN are today in the

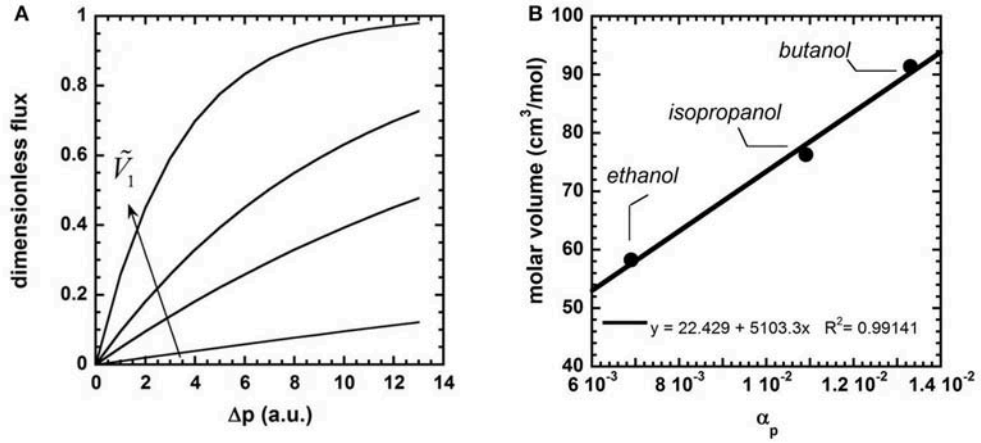

FIGURE 6 | (A) Solvent dimensionless flux vs. Δp at various solvent molar volumes, as predicted by the Paul theory (Paul, 1973). **(B)** Solvent molar volume, $\tilde{V}_1$, vs. α_p in silicone rubber MPF-50 (Machado et al., 1999).

pharmaceutical and cosmetic industry, as well as in refinery (dewaxing of lube oil) (Marchetti et al., 2014, 2017; Buonomenna and Bae, 2015). Composite membranes, consisting of a very thin (<1 μm thick) active layer supported onto a porous backing, are often considered in the academic research and industrial practice (cf., **Figure 7**). The active layer and the backing support are made by different materials and have different structures and properties. They are combined together exploiting interfacial polymerization, as well as well-established spin coating or dip coating techniques. The support is generally made by polysulfone, polypropylene, polyimide or polybenzimidazole, depending on the environment the membrane has to face with. The active layer, which performs the separation, is generally made by cross-linked Lenzing P84 polyimide or cross-linked silicon rubber (PDMS) (Marchetti et al., 2014). The chemical structure of P84 polyimide and PDMS and their relevant chemical-physical properties are reported in **Table 1**. Alternatively, asymmetric membranes can be used (cf., **Figure 7**). Asymmetric membranes exhibit a dense skin, which performs the separation, supported onto a porous medium, made of the same material as the skin itself. They are prepared via phase-inversion, a process originally developed by Loeb and Sourirajan (Loeb and Sourirajan, 1963). A dilute solution of the membrane material in an appropriate solvent is cast onto a fabric backing. Then, the freshly cast membrane is soaked in a non-solvent bath where phase separation occurs. The polymer-rich phase generates the dense active layer, and the polymer-poor phase generates the porous support. Compared to composite membranes, asymmetric membranes exhibit lower resistance to physical aging and less stable properties during operation.

Standard membrane materials for OSN are polyimides (White, 2002) and cross-linked silicone rubber (Postel et al., 2013), even though new materials, such as polybenzimidazole and PIMs, are emerging as promising candidates (Valtcheva et al., 2014, 2015). Unlike gas separation, OSN currently relies on a limited number of membrane materials, since polymers capable to withstand organic environments are rare.

Since the pioneering studies conducted by White in the early 2000's (White, 2001, 2002), Lenzing P84, a polyimide obtained by the condensation of 2,4-diidocyanato-1-methylbenzene and 1,1′-methylenebis(4-isocyanatobenzene) with 5,5′-carbonylbis(1,3-isobenzofurandione), is currently the standard membrane material for OSN (Silva et al., 2005; See-Toh et al., 2007a, 2008). Lenzing P84 films can be fabricated via solution casting from DMF, NMP, DMSO and DMAc solutions. Due to its fully aromatic, rigid structure, Lenzing P84 exhibits long lasting resistance to several solvents, such as hydrocarbons, toluene, alcohols and ketones. White prepared asymmetric membranes based on Lenzing P84 to separate linear from branched alkanes in toluene solutions. He showed that pristane, a saturated hydrocarbon bearing 19 carbon atoms, exhibited lower flux through Lenzing P84 relative to n-docosane, a linear saturated hydrocarbon bearing 22 carbon atom. This behavior is interesting, since pristane has lower molecular weight and molar volume relative to docosane. White attributed this behavior to the larger cross-section area of pristane, which increases the frictional resistance offered by the polymer to molecular diffusion. Based on this picture, pristane is better rejected than docosane due to its slower diffusion through the membrane material (White, 2002).

Afterwards, White used Lenzing P84 to separate aromatic from aliphatic aromas: interestingly, aromatic compounds exhibited higher fluxed than aliphatic ones. This behavior was attributed to the sorption contribution. Indeed, aromatic compounds interact more favorably with the aromatic polymer backbone than aliphatic species do. Such favorable thermodynamic interaction enhances the solubility of aromatic over aliphatic species in the membrane, which, based on the solution-diffusion model, justifies the experimental findings (White, 2002).

To improve the stability in aggressive aprotic solvents (e.g., THF, DMF and NMP), in which polyimides are soluble, Livingston and co-workers crosslinked Lenzing P84 using aliphatic diamines (ethylenediamine, propanediamine,

hexanediamine, and octanediamine) in methanol solution. The cross-linking mechanism was described in detail by Liu et al. (2001). Specifically, the amino groups available on the cross-linker react with the imide groups on the polymer backbone to form amide moieties. The matrix swelling induced by methanol sorption is an essential pre-requisite for the formation of cross-linking. Indeed, if the polymer is not swollen enough, the reaction between the amino and the imide groups can be very slow. The method devised by Livingston produces uniform cross-linking throughout the whole membrane thickness. Other methods based on the radical-initiated cross-linking cannot be exploited, since they would effectively cross-link just the membrane surface, thus causing the membrane failure in aprotic acids. Cross-linked Lenzing P84 exhibited excellent stability in tetrahydrofuran (THF), N-methyl pyrrolidone (NMP), and dimethylformamide (DMF). FTIR analysis demonstrated that no morphological changes occurred in the membrane after soaking in these solvents for 120 h (See-Toh et al., 2007b). Obviously, the gain in stability upon cross-linking is accompanied by a decrease in permeability, caused by the enhanced chain packing.

Cross-linked PDMS has been tested to concentrate dyes from organic solutions and remove solvents from vegetable oils (Subramanian et al., 2001, 2003; Koike et al., 2002; de Morais Coutinho et al., 2009). The main drawback for using PDMS is its poor resistance to aggressive solvents. Indeed, due to the high chain flexibility and weak rigidity, PDMS sorbs a significant amount of solvent (Favre et al., 1994; Whu et al., 2000; Sheth et al., 2003; Vankelecom et al., 2004), which prejudices the membrane stability.

Both Lenzing polyimide and PDMS suffer of several limitations. Lenzing PI exhibits, indeed, modest fluxes but high resistance to aggressive environments. In contrast, PDMS exhibits high fluxes but poor chemical resistance. So, new materials are sought to overcome such limitations.

In recent years, polybenzimidazole (PBI), commercially available under the trade name of Celazole®, emerged as a promising material for OSN. PBI, first synthesized by Vogel and Marvel (Vogel and Marvel, 1961), is prepared from isophthalic acid and 3-3′-diaminobenzidine. It exhibits a rigid, aromatic structure with frustrated chain mobility. Moreover, intermolecular hydrogen bonding acts as a cross-link and contributes to mitigate swelling and plasticization in the presence of organic liquids. PBI exhibits also unusual thermal stability, with a negligible mass loss (< 5%) upon exposure to 570°C. Such

unique combination of rigidity, high glass transition temperature and unprecedented chemical and thermal resistance, makes PBI suitable for separations in chemically challenging environments (Borjigin et al., 2015). However, the lack of solubility in most of organic solvents makes it difficult manufacturing thin membranes based on PBI. This polymer is only soluble in aggressive solvents, such as dimethylacetamide (DMAc). To further improve solubility in DMAc, LiCl is added to the dope solution, which complicates the post-processing treatment of the membranes as, after fabrication, LiCl has to be removed. These issues hamper the use of PBI in the industrial practice.

Livingston and co-workers developed cross-linked asymmetric membranes based on PBI with superior resistance in acid environments (Valtcheva et al., 2014). PBI was cast from a DMAc solution onto a non-woven polypropylene support. The nascent membrane was then soaked in water to generate phase separation and induce the asymmetric structure. Following this protocol, membranes were cross-linked upon immersion in a hot solution of dibromobenzene in acetonitrile (cf., **Figure 8**). Interestingly, the resulting cross-linked membranes exhibited good separation performance for several PEG markers in acetonitrile and dimethylformamide, as well as excellent dimensional stability even in hydrochloric acid solutions.

Since the pioneering work by Sourirajan in the early 60s, cellulose acetate and its derivatives have been, for at least two decades, the most studied materials for OSN applications. However, due to its poor resistance to aggressive solvents, cellulose acetate could only be used to separate a limited number of mixtures, such as water/alcohol. Moreover, due to the presence of crystalline domains, solvent flux through cellulose acetate membranes is relatively low. Recently, Vanherck et al. developed a new strategy to enhance the permeability of cellulose acetate OSN membranes without sacrificing the selectivity (Vanherck et al., 2011). They exploited the principle of photothermal heating by embedding gold nanoparticles (GNPs) into a cellulose acetate membrane. In this way it is possible to increase the local temperature in the membrane during operation by light irradiation, which, in turn, significantly enhances solvent flux. Such increase in solvent transport rate is essentially ascribable to an increase in diffusion coefficient. Indeed, solvent mobility coefficient through the membrane increases exponentially with increasing temperatures, due to the reduction of frictional resistance offered by polymer chains to penetrant diffusion. In contrast, the effect of temperature on the sorption coefficient is much weaker. The same principle was exploited by Nakai to improve by 37% CO_2 permeability through cellulose acetate (Nakai et al., 2002).

The method proposed by Vanherck leverages on the gold nanoparticles ability to absorb light and convert it into heat (Daniel and Astruc, 2004). Such an effect becomes especially efficient at specific wavelengths, where surface plasmon resonance occurs. Golden nanoparticles were generated directly into a pre-made cellulose acetate membrane using the protocol reported by Huang (Huang et al., 2005). The amount of nanoparticles in the membrane was varied between 0 and 2% wt. To run nanofiltration experiments, Vanherck modified a dead-end filtration cell by building a glass window on top of it, to allow an argon-ion laser beam (wavelength = 514 nm) to irradiate the active membrane area (Vanherck et al., 2011).

Interestingly, water and alcohol permeability increased up to 15 and 400%, respectively, upon laser irradiation, with no detectable effects on solute (bromothymol blue) rejection. Moreover, solvent permeability returned to its original value after the laser was turned off, indicating that the observed change in transport properties was only due to the reversible membrane heating and not to permanent structural modifications. The much larger permeability improvement observed for alcohols was attributed to the lower specific heat of alcohols relative to water, which permits a more rapid heating of the swollen membrane. Likewise, alcohols exhibit lower thermal conductivity relative to water, so, while flowing through the membrane, they remove less heat.

MOLECULAR FACTORS AFFECTING SOLUTE AND SOLVENT TRANSPORT IN OSN MEMBRANES

The vast majority of research efforts on OSN focused, so far, on applications: commercially available or newly synthesized materials were used to measure solvent flux and solute rejection and such measurements helped to assess the suitability of those materials for specific applications. However, little information is available about molecular factors affecting solute and solvent transport in OSN membranes. The transport mechanism itself is object of discussion, as some researchers assume a solution-diffusion mechanism, others a pore-flow mechanism (Marchetti and Livingston, 2015; Ben Soltane et al., 2016). However, many factors, above all the existence of a permeability-selectivity trade-off, suggest that OSN membranes work based on the solution-diffusion mechanism. This conclusion was confirmed unequivocally by a series of simple but effective experiments performed by Paul in the early 70s. Specifically, Paul measured solvent permeability through a stack of several membranes. After reaching steady-state, the membranes were rapidly removed from the permeation cell and weighed. The experimental solvent concentration profile in the stack was in excellent agreement with that predicted assuming a solution-diffusion transport mechanism (cf. **Figure 5**, Paul and Ebra-Lima, 1971).

Fundamental structure-property correlations are available for gas separation membranes, which makes it possible to design polymers with pre-assigned transport properties. For example, use of polyethers for CO_2 separation leverages on the high thermodynamic affinity between CO_2 molecules and polar ether groups, which enhances CO_2 sorption and, according to Equation 8, CO_2 selective permeability (Bondar et al., 1999). So, membranes for gas separation are engineered by properly tuning solubility and diffusivity of the target penetrant in the membrane material. This goal is achieved, in turn, by tuning the polymer chemistry, that is, using monomers bearing specific functional groups.

The lack of information about the role of sorption and diffusion coefficients on solvent and solute transport is actually a roadblock toward the rational design of smart OSN membranes.

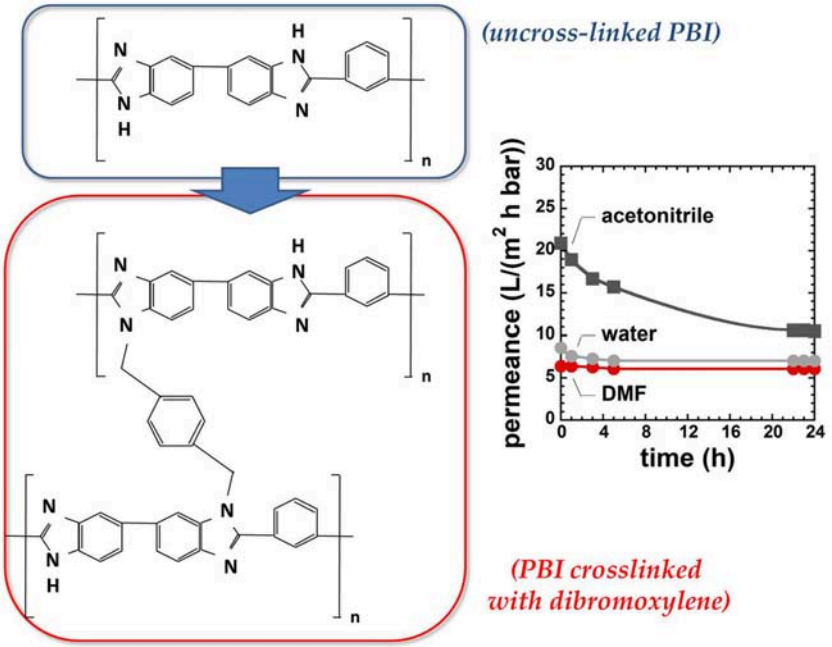

FIGURE 8 | Structure and properties of novel PBI membranes cross-linked with dibromoxylene. Adapted from Valtcheva et al. (2014), with permission of *Elsevier*.

Nevertheless, in this section we identify, based on the few data available, the main molecular factors that influence solute and solvent transport in OSN membranes.

From a theoretical standpoint, small molecule sorption in polymers is a phase equilibrium problem (Galizia et al., 2012). Sorption equilibrium is reached when penetrant chemical potential in the external fluid phase equates that in the polymer mixture. As chemical potential contains, by its definition, an enthalpic (i.e., energetic) and an entropic contribution, small molecules sorption in polymers is influenced by these two effects (Galizia et al., 2012). Enthalpic effects are related to polymer-penetrant interactions and, as a rule of thumb, favorable interactions translate in high penetrant solubility in the membrane material. Entropic effects are related to penetrant size. As general rule, sorption decreases with increasing penetrant size. Indeed, absent specific interactions, it is less and less likely to accommodate bulkier penetrant molecules in the polymer matrix than smaller penetrant molecules.

Vankelecom et al. (1997) and Cocchi et al. (2015a) reported sorption and diffusion coefficients of several liquids in rubbery PDMS. Alkanes solubility in PDMS decreases linearly with the number of carbon atoms, indicating that sorption is affected essentially by entropic factors. In contrast, solubility of polar alcohols in PDMS follows a non-monotonous trend with the number of carbon atoms, as it increases moving from ethanol to 1-butanol, and then decreases linearly going from 1-butanol to higher alcohols, following the same trend observed for alkanes. This phenomenon was justified based on the interplay between enthalpic and entropic effects. Indeed, PDMS exhibits poor thermodynamic affinity with lower polar alcohols. The strong repulsive interactions between –OH polar groups and the non-polar PDMS backbone strongly oppose to alcohol dissolution in the polymer. When the length of the alkyl tail increases, the affinity between alcohols and PDMS increases, which justifies the increase in solubility observed going from methanol to 1-butanol. When the alkyl tail is long enough, the polar –OH group is sterically shielded, so alcohols start to behave as alkanes and their solubility in PDMS decreases with increasing penetrant size. So, the increase in solubility from methanol to 1-butanol is driven by enthalpic (i.e., energetic) effects, and the subsequent decrease is driven by entropic effects.

Vankelecom demonstrated that the solubility of organic liquids in PDMS decreases linearly with increasing the difference between the penetrant and polymer Hildebrandt solubility parameter, $\delta - \delta_{PDMS}$ (Vankelecom et al., 1997). Afterwards, Cocchi showed that a better linear correlation is obtained if penetrant solubility in PDMS is plotted against $M_w^{0.75}(\delta - \delta_{PDMS})^2$, where M_w is the penetrant molecular weight (Cocchi et al., 2015a). Indeed, while the correlation reported by Vankelecom accounts just for energetic factors, that reported by Cocchi accounts for both energetic (through δ) and entropic (through M_w) factors. Doing so, sorption data for hydrocarbons, alcohols and several other organic liquids fall on a master curve. Unfortunately, such analysis is fairly absent in the literature for glassy polymers. Cocchi et al. (2015b) also reported mixed solvent-solute solubility data in PDMS. In mixed conditions, solute solubility in the membrane is greatly enhanced, up to 25 times, compared to pure solute solubility, which indicates that real solvent-to-solute solubility-selectivity is lower than that predicted on the basis of pure component sorption data. The

large enhancement in solute sorption in mixed conditions was justified based of the high degree of membrane swelling induced by the solvent.

Diffusivity-selectivity data for solute-solvent mixtures are virtually absent in the literature. Small molecules diffusion coefficients in polymers generally decrease with increasing penetrant size (Galizia et al., 2017b). The critical volume, as well as the kinetic diameter or squared kinetic diameter have been used as a measure of penetrant size. Interestingly, diffusion coefficients of liquid penetrants in PDMS do not always correlate to penetrant size. For example, as reported by Cocchi et al. (2015a), acetone diffusivity in PDMS is larger than water diffusivity, despite water (kinetic diameter = 0.265 nm) is a smaller molecule than acetone (kinetic diameter = 0.50 nm). This behavior was explained considering that acetone is sorbed to a greater extent than water by PDMS, so acetone diffusion occurs in a much more swollen membrane, which offers a lower frictional resistance to penetrant transport. However, subtle interactional effects influence penetrant diffusion in polymers. As discussed above, penetrants diffusion coefficient in polymers is the product of a purely kinetic quantity, i.e., the mobility coefficient, L_1, which quantifies the frictional resistance offered by the polymer matrix to penetrant diffusion, and a thermodynamic factor, related to polymer-penetrant interactions. The thermodynamic factor is higher than one when polymer-penetrant interactions are thermodynamically favorable, and less than one when such interactions are thermodynamically unfavorable. Due to the strong hydrophobicity of PDMS, acetone-PDMS affinity is much higher than water-PDMS affinity, so the thermodynamic contribution to acetone diffusion in PDMS is expected to largely exceed that of water (Favre et al., 1994; Singh et al., 1998), which would justify the experimental findings reported by Cocchi.

RECENT ADVANCES AND FUTURE DIRECTIONS IN OSN

Polybenzimidazoles

In this section, we identify new generation materials for OSN and outline applications that will likely drive OSN research in the next decades. As mentioned in section Current OSN Materials, polybenzimidazole exhibits unprecedented thermal, mechanical and chemical stability, however, some drawbacks limit its use in the industrial practice. Above all, the poor chain mobility caused by the rigid diaminobenzidine segments, combined with the efficient chain packing produced by intermolecular hydrogen bonds, reduces small molecule permeability in PBI. As a matter of fact, PBI exhibits quite low fluxes (i.e., low productivity), which makes it unappealing for practical applications. To circumvent these issues, Riffle and coworkers synthesized a substituted PBI with improved processability and higher permeability relative to commercial PBI (Borjigin et al., 2015). They replaced the linear, rigid diaminobenzidine monomer with 3,3′, 4,4′ tetraaminodiphenylsulfone (TADPS). Such monomer exhibits higher flexibility relative to diaminobenzidine, due to the presence of the sulfonyl linkage between diaminophenyl groups (cf. **Table 2**). Moreover, the kinked structure of TADPS-PBI induced by sulfonyl groups frustrates chain packing and enhances small molecules sorption and transport. Interestingly, substituted PBI exhibits improved solubility in solvents (DMAc, DMSO, NMP), while maintaining chemical, mechanical and thermal stability comparable to those exhibited by commercial PBI. H_2 and CO_2 permeability coefficients in TADPS-PBI and in commercial PBI were fairly similar, but TADPS-PBI exhibited higher H_2/CO_2 selectivity. This fact is significant, since the improved flexibility induced by sulfonyl groups did not sacrifice the membrane performance. Investigation of substituted PBI for OSN application is underway.

Polymers of Intrinsic Microporosity (PIMs)

The most known member of this family of polymers, PIM-1, first synthesized by Budd and McKeown in 2004, is prepared by the nucleophilic substitution reaction of tetrafluoro-phathalonitrile with 5,5,6,6-tetrahydroxy-3,3,3,3-tetramethyl-1,1′-spirobisindane. The spiro-center of 5,5,6,6-tetrahydroxy-3,3,3,3-tetramethyl-1,1′-spirobisindane is responsible for the contorted structure exhibited by this polymer. PIM-1 exhibits a glass transition temperature above 450°C and a three-dimensional ladder structure, which frustrates chain packing and produces interconnected free volume cavities whose dimension is < 2 nm. Consistently, the BET surface area is very high, up to 800 m^2/g. Due to this ladder-type, rigid structure, PIMs are poorly soluble in solvents, except THF and chloroform (Budd et al., 2004).

A drawback for using PIMs in OSN is their tendency to swell in the presence of solvents (Ogieglo et al., 2017), such as acetone and toluene, which produces very high flux but poor solute rejection. Several attempts have been made to synthesize alternative PIMs, but only a limited number of monomers is able to give polymers with a sufficiently high molecular weight (Sanders et al., 2013). Combining PIM-1 with other polymers could be, in principle, another route to improve its properties, but serious compatibility issues were reported. Gao et al. coated a PVDF support with a thin PIM-1 layer, but the adhesion of the active layer to the substrate was poor (Gao et al., 2017).

Currently, research efforts are underway to improve PIMs resistance to solvents by cross-linking or chemical modification. Fritsch (Fritsch et al., 2012) blended PIM-1 with polyethyleneimine (PEIm) in THF solution. Then, poly(ethylene glycol diglycidyl ether) (PEGDEG) was added to the solution. PEGDEG cross-linked the blend by reacting with the PEIm amino groups. Cross-linked PIM-1-PEIm membranes exhibited much better dimensional stability in solvents. Moreover, blending with rubbery PEIm reduced significantly the PIM-1 brittleness.

Livingston and coworkers developed composite membranes made of a 140 nm thick PIM-1 layer supported on PAN or alumina, which exhibited excellent resistance to physical aging after annealing for several hours at 150°C (Gorgojo et al., 2014). Remarkably, solvent permeability was almost 2 orders of magnitude higher than in commercial membranes based on Lenzing P84 polyimide. Unexpectedly, solvent permeance decreased with decreasing the active layer thickness below 140 nm. Indeed, as demonstrated by light interferometry, chain packing is enhanced in ultrathin films.

TABLE 2 | New materials for OSN application.

Material	Structure
PBI	TADPS-PBI	PIM-1	PIM-8	PTMSP	Teflon® AF	Pebax	Polyarylates	
Very recently, PIMs emerged as promising materials for isomer separation. The latter is among the most challenging separations, as isomers exhibit like size and very similar chemical-physical properties, which makes it difficult developing membranes with adequate levels of selectivity. Such separations are highly demanded in the pharmaceutical industry, where isomers of a given compound often exhibit different therapeutic properties. Intrinsically chiral materials exhibited high selectivity for chiral separations. Weng and coworkers (Weng et al., 2015) synthesized intrinsically chiral PIMs with spectacular selectivity for several isomers of practical deal. Chiral ladder (+)PIM-CN was prepared by condensation reaction between enantiomerically pure 5,5′,6,6′-tetrahydroxy-3,3,3′,3′-tetramethyl-1,1′-spirobisindane and 2,3,5,6-tetrafluorophthalonitrile in DMF, in the presence of K_2CO_3. Selectivities as high as 14 were observed for some chiral separations (e.g., the resolution of R,S mandelic acid and R,S-binol). Interestingly, sorption experiments revealed that solubility-selectivity is equal to one, so the selective permeation of isomers through this material is solely driven by the diffusion contribution. However, the fundamental origin of this behavior is still unknown.

Future research efforts will likely focus on PIMs different than PIM-1. For example, PIM-8 was synthesized by Ghanem et al. by polymerization of 2,3,6,7-tetrahydroxy-9,10-dimethyl-9,10-ethanoanthracene (Ghanem et al., 2008). PIM-8 exhibited a 50% higher selectivity for linear vs. branched alkanes relative to PIM-1. Cook and coworker attributed this behavior to a narrower and much regular size distribution of free volume cavities in PIM-8 (Cook et al., 2018).

Perfluorinated Glassy Polymers

Perfluorinated polymers are soluble in a limited number of fluorinated liquids and exhibit excellent resistance to the vast majority of organic solvents. Recently, Chau reported solvent permeability and solute rejection data for a series of perfluorodioxole copolymers, such as Hyflon® AD and Cytop® (Chau et al., 2018). Solvent (methanol, hydrocarbons, aromatics, THF) sorption in perfluorodioxole copolymers is about 1% wt, which is much lower than in other glassy polymers. Interestingly, n-heptane sorption in perfluorodioxole copolymers is much larger, 2.5% wt, which enhances n-heptane flux far above that of other organic solvents and reduces substantially solute rejection. The molecular origin of this behavior was tentatively attributed to the higher matrix dilation induced by bulky n-heptane molecules. This explanation, however, appears not convincing on the basis of the relatively low n-heptane sorption level. This example demonstrates the urgent need of fundamental transport studies in glassy OSN membranes.

Block Copolymers With Hard and Soft Segments

Poly(ether block amide), commercially available under the trade name Pebax®, is a thermoplastic block copolymer made by rigid polyamide segments, which provide mechanical rigidity, interspaced with highly permeable, rubbery polyether segments.

Pebax® has shown superior performance in gas separation (Bondar et al., 2000), and recently it raised attention in OSN (Aburabie and Peinemann, 2017). The relative amount of glassy and rubbery segments can be tuned, resulting in different Pebax® grades exhibiting different transport and mechanical properties (Bondar et al., 1999, 2000). The role of the glassy segments consists in providing mechanical strength, reducing the swelling of the highly permeable rubbery blocks and maintaining good levels of dimensional stability and selectivity. Pebax® can be cross-linked upon immersion in toluene diisocyanate (TDI) solutions, which promotes the formation of urethane linkages between the hydroxyl groups on the polyether segments and the carbonyl groups of TDI (Aburabie and Peinemann, 2017). The cross-linking mechanism proposed by Aburabie was confirmed via DSC analysis. Compared to the pristine, uncross-linked sample, the endothermic peak attributed to the fusion of polyether blocks in the cross-linked sample shifted from 50 to 80°C, whereas the peak assigned to the polyamide blocks did not show any change. This result confirms that the cross-linking is produced by the reaction of TDI with the polyether blocks, as explained above (Aburabie and Peinemann, 2017).

Aburabie showed that ethanol permeance of composite membranes fabricated by coating a PAN support with Pebax® was 8 times reduced relative to the PAN support alone (Aburabie and Peinemann, 2017). Moreover, the Pebax® active layer was not able to reject brilliant blue in ethanol solution, due to the excessive membrane swelling. A significant enhancement in separation performance was observed after cross-linking. The best results were obtained using a 2% wt cross-linker concentration and a reaction time of 30 min. In this condition, rejection of brilliant blue was about 95% and ethanol permeance was 0.1 L/(m^2 h bar). When the reaction time was larger than 30 min, the membrane assumed a strongly packed structure, likely due to a very high degree of cross-linking. In this condition, ethanol flux was fairly zero even at pressures of 20 bar.

Interestingly, Pebax®/PAN membranes cross-linked with 2% TDI for 30 min exhibit 100% rejection of olive oil from a 10% wt olive oil solution in acetone (Aburabie and Peinemann, 2017). Thus, Pebax® appears suitable for application in the food industry, where organic solvents are often used to extract vegetable oils from seeds. Currently, solvent recovery from edible oils is performed by distillation, which can alter the organoleptic properties of oils.

The main drawback for using Pebax® in OSN is its tendency to swell in water and alcohols, which leads to lower selectivities. Water flux through uncross-linked Pebax® membranes increases by almost 50% after 20 h of soaking in water. In contrast, membranes cross-linked with TDI do not exhibit any increase in water flux after swelling in water for 20 h (Aburabie and Peinemann, 2017). So, cross-linking with TDI appears a viable route to produce stable Pebax® membranes for OSN applications.

High Free Volume Polyacetylenes

Substituted polyacetylenes, such as poly(trimethylsilyl propyne) (PTMSP) and poly(methylpentyne) (PMP), exhibit a rigid, glassy structure and bulky functional groups that produce inefficient chain packing, with fractional free volume levels up to 30% (Tanaka et al., 1985; Merkel et al., 2000; Galizia et al., 2014). Composite PTMSP membranes exhibited ethanol permeances as high as 17 L/(m^2 h bar), which is one of the highest values reported in the literature so far (Grekhov et al., 2012; Volkov et al., 2013). However, freshly cast PTMSP membranes exhibit an accelerated physical aging even when they are fabricated as bulky films (Nagai et al., 2000). This behavior is due to the strong departure of this material from equilibrium conditions, as witnessed by the high free volume level. Recently, Lau and co-workers discovered that physical aging of PTMSP and PMP can be stopped upon addition of microporous PAFs (Porous Aromatic Frameworks) (Lau et al., 2014). Specifically, microporous PAFs exert a chain threading effect by partially sorbing the polymer in their pores, which freezes the polymer structure and keeps the polymer chains in their original position. Such beneficial effect completely stops compaction and densification of high free volume polyacetylenes. This result represents a breakthrough and could bring the scientific community to reconsider application of polyacetylenes in OSN. In principle, to further improve its stability in chemically aggressive environments and delay physical aging, PTMSP can be cross-linked with 3,3′-diazidodiphenylsulfone. However, as noted by Kelman et al., chemical cross-linking reduces gas permeability by 70% relative to uncross-linked PTMSP, which makes this material no longer attractive for industrial applications (Kelman et al., 2007). As a matter of fact, no systematic study about the use of cross-linked PTMSP in OSN is available in the literature.

Isoporous Membranes

Developing isoporous membranes for OSN, i.e., membranes with a very uniform size and distribution of free volume cavities (improperly defined "pores"), will be an important goal over the next years (Yu et al., 2014). While this approach is under investigation for gas separation membranes (Abetz, 2014), a few authors attempted to exploit it for OSN. The actual challenge is that free volume architecture can be disrupted upon exposure to aggressive solvents, thus thwarting the efforts made to synthesize materials with specifically-sized free volume cavities.

Recently, Jimenez-Salomon exploited interfacial polymerization to fabricate highly permeable and selective polyarylate nanofilms, <20 nm thick, onto cross-linked polyimide nanofiltration membranes (Jimenez-Salomon et al., 2016). They used contorted monomers, such as 5,5′,6,6′-tetrahydroxy-3,3,3′,3′-tetramethylspirobisindane (TTSBI) and 9,9-bis(4-hydroxyphenyl)fluorine (BHPS) to prepare polyarylates with controlled and specifically-sized free volume elements. During polymerization, TTSBI units acquire a non-coplanar orientation, which leads to polymers having three-dimensional structures and interconnected free volume elements. This picture was confirmed by molecular simulations. For comparison, they also synthesized polyarylates with planar, non-contorted monomers, such as dihydroxyanthraquinone and 1,3-benzenediol, which exhibited much lower permeance but similar selectivity relative to materials containing contorted

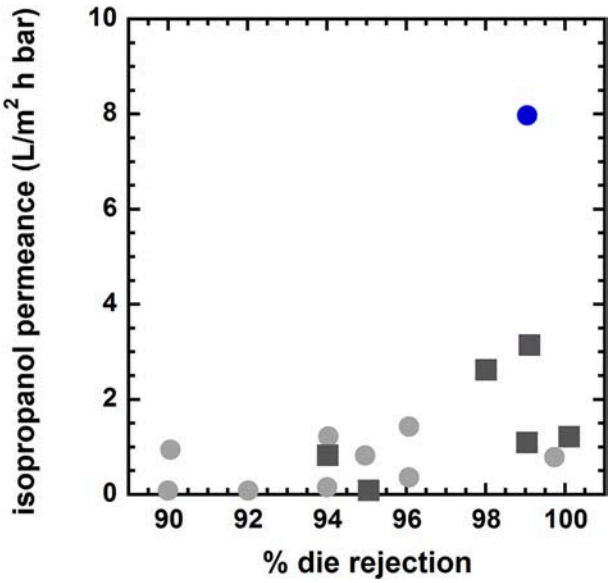

FIGURE 9 | Isopropanol permeance vs. rose Bengal rejection at room temperature and $\Delta p = 30$ bar. Solid gray circles: conventional asymmetric membranes. Solid black squares: conventional composite membranes. Solid blue circle: polyarylate synthesized using non-planar, contorted monomers (Jimenez-Salomon et al., 2016). Adapted from Jimenez-Salomon et al. (2016), with permission of *NatureResearch*.

monomers. Interestingly, isoporous polyarylates surpass abundantly the upper bound in several applications. As shown in **Figure 9**, isopropanol permeance exhibited by polyarylates is twice that of conventional asymmetric and composite membranes for OSN, and dye (rose Bengal) rejection is over 99%.

Another possible approach for the design of polymers with controlled free volume architecture relies on using monomers bearing triptycene moieties. Recently, this approach has been successfully used to design gas separation membranes (Luo et al., 2016, 2018; Weidman and Guo, 2017; Weidman et al., 2017) endowed with unprecedented levels of permeability and selectivity. Triptycenes are three-dimensional, paddlewheel-like structures formed by three aromatic rings arranged at 120° on three different planes. Once incorporated into the polymer backbone, trypticenes disrupt chain packing and introduce an ultra-fine microporosity which enables for superior size-sieving ability. Specifically, the microporosity is provided via the internal free volume associated to each triptycene moiety. Moreover, unlike ordinary glassy polymers, whose free volume is purely conformational, the internal free volume of triptycene units is configurational and, as such, it is not collapsible. According to this physical picture, iptycene-based polymers exhibit uncommon resistance to physical aging (Luo et al., 2016, 2018; Weidman and Guo, 2017; Weidman et al., 2017). Potential use of such materials in OSN is fairly unexplored. The advantages for using iptycene-based polymers in OSN could be twofold. First, the fine and homogeneous internal free volume provided by triptycenes is inaccessible to solute molecules, but it is potentially accessible to solvent molecules whose diameter is <4Å, which should guarantee high solvent flux and high solute rejection. Moreover, tough glassy polymers, such as polybenzoxazoles modified introducing triptycene moieties, would also guarantee outstanding resistance in harsh environments, which is an essential condition for applications in OSN.

Hybrid Materials

The most revolutionary application of OSN in the future will likely be the separation of isomeric solutes from organic solutions. This application is relevant in the pharmaceutical and petrochemical industry. For example, separation of hexane isomers is crucial to enhance gasoline octane number. Mixed matrices formed by selective fillers embedded in polymer membranes could make this application a reality. For example, ZIF-77 has been identified as a good candidate for isomer separations (Dubbeldam et al., 2012; Krishna and van Baten, 2017), but, surprisingly, no publication dealing with mixed matrix membranes containing ZIF-77 is available in the literature.

Recently, a new MOF with hydrophobic quadrilateral channels was synthesized via a solvothermal process from $[Fe_3(\mu_3\text{-}O)(COO)_6]$ and 2,2-bis(4-carboxyphenyl)-hexafluoropropane (6FDA) and tested for separation of hexane isomers (Lv et al., 2018). The successful separation of n-hexane from its branched isomers relies essentially on solubility-selectivity, as linear n-hexane can be selectively sorbed by the $[Fe_3(\mu_3\text{-}O)(COO)_6]$-6FDA MOF, while sorption of branched isomers is sterically hindered. The sorption selectivity exhibited by the $[Fe_3(\mu_3\text{-}O)(COO)_6]$-6FDA MOF is 20 times higher than that of other sorbents, such as ZIF-8, zeolite 5A and zeolite β (Luna-Triguero et al., 2017). Moreover, this smart MOF exhibits very stable sorption capacity and selectivity after several sorption-desorption cycles.

Significant research efforts are being devoted to the fabrication of hybrid materials that surpass the permeability-selectivity upper bound. For example, Wu and coworkers incorporated MXenes nanosheets in hydrophilic poly(ethyleneimine) (PEIm) and hydrophobic silicon rubber (PDMS) (Wu et al., 2016). MXenes, first reported by Naguib et al. in 2014, are 2-D inorganic structures consisting of a thin layer of transition metals (Naguib et al., 2014). The resulting membranes were mechanically robust and exhibited higher alcohol permeability and much higher alcohol selectivity relative to neat polymers, thus surpassing the permeability-selectivity upper bound. Specifically, MXenes nanosheets contain polar -OH groups which enhance alcohol sorption and, based on the solution-diffusion model, alcohol permeability (Wu et al., 2016). For example, isopropanol permeability in PDMS-MXenes membranes is 162% higher than in neat PDMS. Moreover, the MXenes nanosheets block solute (e.g., PEG oligomers whose molecular weight ranged from 200 to 1000 Da) transport through the membrane, by making their diffusional pathway more tortuous, which produces a significant increase in solute rejection.

The isopropanol flux and PEG1000 rejection of the PEim-MXenes membrane at room temperature and 10 bar was tracked for 12 h (cf. **Figure 10**). Isopropanol flux declined by 20% (i.e.,

from 33.5 to 28 L/m^2 h) in the first 4 h and then reached a pseudo-steady state value for the following 8 h. PEG1000 rejection changed from 98.8 to 99.2% within the same time frame. The flux decline was explained invoking membrane compaction and pore blockage by solvent molecules (Wu et al., 2016).

Membranes Based on Preassembled Nanoparticles

The phase separation process leads to membranes exhibiting a relatively broad distribution of free volume size. The possibility of tailoring the membrane microstructure so as to impart a well-defined free volume architecture has been explored is several ways. As discussed above, one possibility consists in using isoporous membranes. An alternative route to control the free volume architecture and create "manipulated" permeation pathways consists in preparing membranes based on preassembled nanoparticles. Several attempts have been made to deposit polymer nanoparticles on porous supports (Siddique et al., 2011). Nanoparticles can assemble in regular arrays, whose geometry influences the final transport properties of the membrane. Interstitial space between nanoparticles provides preferential permeation pathways. The "pore" size of these membranes can be controlled by tuning the nanoparticles size: if the nanoparticles size distribution is very uniform, the size of the interstitial channels is also uniformly distributed, which is an essential prerequisite to fabricate highly selective membranes (Siddique et al., 2011).

Siddique et al. deposited several layers of NIPAM (N-isopropylacrylamide)-HEMA(2-hydroxyethyl methacrylate) nanoparticles, whose diameter was 120 or 300 nm, onto a porous support via spin coating (Siddique et al., 2011). NIPAM-HEMA nanoparticles were first modified with acryloyl chloride to create polymerizable vinyl groups on their surface. The coating was then stabilized by UV cross-linking via radical polymerization. The support was prepared by casting a P84 polyimide solution onto a non-woven polyester backing. Phase separation of P84 was then induced upon immersion in a water bath. Following this step, the polyimide support was cross-linked upon soaking into a 1,6-hexanediamine-isopropanol solution. Finally, spin coating from methanol solutions was exploited to deposit a nanoparticle layer whose thickness ranged from 1 to 23 μm.

TEM micrographs show that moderate nanoparticle deformation takes place after deposition and UV cross-linking. Moreover, nanoparticles partially occupy the pores of the support membrane. Such observations are crucial to explain the results of nanofiltration experiments. Indeed, based on geometrical considerations, the theoretical pore size should be in the range 9–23 nm, so membranes coated with nanoparticles should not be able to separate molecules in the nanofiltration range (Siddique et al., 2011). However, rejection of styrene oligomers from toluene and acetone solutions was close to 100%, indicating that molecular separation in the nanofiltration range took place. The authors speculated that nanoparticle deformation is responsible for this behavior. As mentioned above, TEM analysis confirms

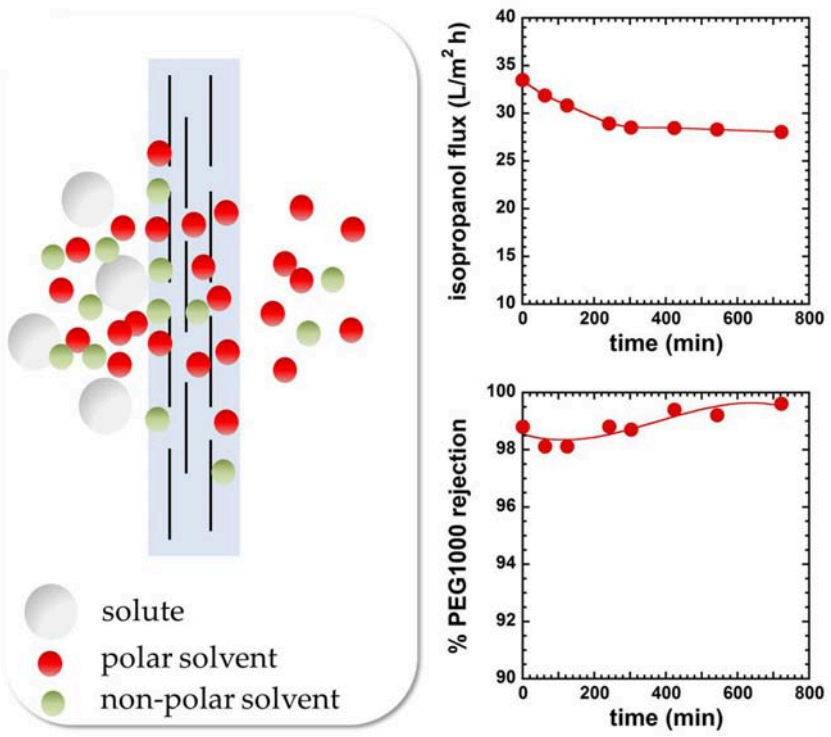

FIGURE 10 | Structure and properties of mixed matrix membranes based on PEIm and MXenes (Wu et al., 2016). OSN experiments were run at room temperature and 10 bar using an isopropanol/PEG1000 solution. Adapted from Wu et al. (2016), with permission of *Elsevier*.

this hypothesis. Interesting, solvent fluxes as high as 55 L/(m^2 h) were measured, which led the authors to hypothesize that polystyrenes transport occurs in the interstitial spaces only, while solvent permeates through both the interstitial spaces and the nanoparticles (Siddique et al., 2011). Such hypothesis is consistent with the typical behavior exhibited by swollen NIPAM nanogels, which are highly permeable to small molecules, and practically impermeable to bulky solutes (Schild, 1992).

Interestingly, polystyrenes rejection increases with increasing the thickness of the nanoparticle layer, due to the narrower pore size distribution, and decreases with increasing nanoparticle diameter, due to the formation of larger interstitial spaces. So, the best membranes are obtained upon deposition of a relatively thick layer of small nanoparticles (Siddique et al., 2011). Deposition of nanoparticles exhibiting different sizes further improves solute rejection. Specifically, the mean pore size can be decreases by coating the support with larger nanoparticles first, and then with smaller nanoparticles.

Nanopapers

Manufacturing of polymer nanofiltration membranes often requires the use of large amounts of toxic solvents and chemicals. Use of membranes made of cellulose or nanocellulose would provide a solution to the above mentioned issue, as these materials can be processed in aqueous solution (Mautner et al., 2014; Sukma and Culfaz-Emecen, 2018). Nanofibrillated cellulose in the paper form, also called nanopaper, exhibits outstanding mechanical properties and thermal stability, other than good barrier properties (Klemm et al., 2011; Mautner et al., 2014). Moreover, nanopapers exhibit nanopores whose size is comparable to that of a single molecule and, for this reason, they would be ideal candidates for OSN applications (Mautner et al., 2014). Recently, Mautner et al. prepared solvent stable OSN membranes from aqueous suspension of (2,2,6,6-tetramethylpiperidin-1-yl)oxy (TEMPO) oxidized nanofibrillated cellulose (Mautner et al., 2014). Addition of trivalent salts, such as $AlCl_3$, to the aqueous suspension induces the flocculation of nanofibrils by changing their surface charge. Specifically, trivalent cations are sorbed on the negatively charged nanofibrils surface, causing a decrease of the ζ-potential (Mautner et al., 2014). Nanofibrils compaction leads to the formation of self-standing membranes that have shown organic solvents permeances up to 100 L/(h m^2 MPa) and retention of polystyrene close to 100%.

Interestingly, organic liquids (n-hexane, tetrahydrofuran) permeance was larger than that of water, irrespective of the hydrophilic behavior of nanocellulose (Mautner et al., 2014). The molecular origin of this behavior is still unknown, since permeability coefficients were not deconvoluted into their elemental sorption and diffusion contributions. Moreover, water permeance decreased from 47 to 5 L/(h m^2 MPa) after 1 h of operation (Mautner et al., 2014). The authors attributed this behavior to membrane compaction under pressure.

Interestingly, the average pore size is equal to the nanofibrils diameter, so the porosity of these membranes can be finely tuned by changing the size of the cellulose nanofibrils (Mautner et al., 2014).

CONCLUSIONS

Organic solvent nanofiltration is a new paradigm in the chemical industry. Despite it is intrinsically safe, energy efficient and scalable, OSN is today one of the most poorly understood processes at a fundamental level. Factors that limit its exploitation in the industry are:

i) The lack of fundamental knowledge about solute and solvent transport mechanism. Moreover, the few elemental transport data available are often interpreted in a too simplistic way, which contributes to the spread of misleading conclusions in the literature.
ii) The lack of materials capable to tolerate chemically challenging environments.

While recent research efforts contributed to address the latter point, fundamental understanding of OSN remains poor and incomplete. For example, diffusion coefficients in solvent swollen membranes have to be estimated carefully, by accounting for the effects of the frame of reference and thermodynamic non-idealities. Not taking into account these effects, hampers the possibility of developing structure-property correlations to be used for the rational design of OSN membranes.

The most important recent advances in OSN are the introduction of polymers and hybrid materials with improved permeability, selectivity, and long term stability. Polybenzimidazoles, PIMs, block copolymers with hard and soft segments, hybrid materials containing MOFs and ZIFs and membranes based on pre-assembled nanoparticles appear as the best candidates for future developments.

The most challenging application in the next decades will likely be the separation of isomers. Solving this problem will open a new era in chemical, petrochemical, food, and pharmaceutical industry. Joined efforts from polymer chemistry (to synthesize and modify materials) and physical chemistry (to understand and define optimal transport properties) are necessary to make such new era a reality.

AUTHOR CONTRIBUTIONS

MG conceived and wrote the manuscript. KB contributed to select the contents, prepared the figures and run calculations.

FUNDING

Financial support from the UROP Program sponsored by the University of Oklahoma is gratefully acknowledged.

ACKNOWLEDGMENTS

MG wishes to dedicate this work to his mentor and friend, Prof. Donald R. Paul, with whom he worked for some years. His brilliant scholar inspired some of the ideas discussed in this paper.

The control of nanostructuration of graphene and graphene related materials (GRM) into self-assembled structures is strictly related to the nanoflakes chemical functionalization, which may be obtained via covalent grafting of non-covalent interactions, mostly exploiting π-stacking. As the non-covalent functionalization does not affect the sp^2 carbon structure, this is often exploited to preserve the thermal and electrical properties of the GRM and it is a well-known route to tailor the interaction between GRM and organic media. In this work, non-covalent functionalization of graphite nanoplatelets (GnP) was carried out with *ad-hoc* synthesized pyrene-terminated oligomers of polylactic acid (PLA), aiming at the modification of GnP nanopapers thermal properties. PLA was selected based on the possibility to self-assemble in crystalline domains via stereocomplexation of complementary poly(L-lactide) (PLLA) and poly(D-lactide) (PDLA) enantiomers. Pyrene-initiated PLLA and PDLA were indeed demonstrated to anchor to the GnP surface. Calorimetric and X-ray diffraction investigations highlighted the enantiomeric PLAs adsorbed on the surface of the nanoplatelets self-organize to produce highly crystalline stereocomplex domains. Most importantly, PLLA/PDLA stereocomplexation delivered a significantly higher efficiency in nanopapers heat transfer, in particular through the thickness of the nanopaper. This is explained by a thermal bridging effect of crystalline domains between overlapped GnP, promoting heat transfer across the nanoparticles contacts. This work demonstrates the possibility to enhance the physical properties of contacts within a percolating network of GRM via the self-assembly of macromolecules and opens a new way for the engineering of GRM-based nanostructures.

Keywords: PLA stereocomplex, graphite nanoplatelets, interfacial thermal resistance, thermal bridging, non-covalent functionalization

INTRODUCTION

Graphene and graphene-related materials (GRM) are one of the most intensively explored nanoparticles family in materials science owing to their superior properties (Geim and Novoselov, 2007; Gómez-Navarro et al., 2007; Lee et al., 2008; Stoller et al., 2008; Balandin and Nika, 2012). In particular, graphene oxide (GO), reduced graphene oxide (RGO), multilayer graphene (MLG), and

graphite nanoplatelets (GnP) attracted a wide research attention in the last decade (Ferrari et al., 2015). Their peculiar mechanical, electrical and thermal properties make GRM ideal platforms for the construction of sophisticated nanostructured systems, which fabrication requires precise control of graphene chemistry, including chemical modifications with specific functional groups (Rodriguez-Perez et al., 2013). In this field, the organic functionalization of GRM has led to the manufacturing of high-performance multifunctional graphene-based materials where covalent and non-covalent bonding provides bridges between adjacent layers (Meng et al., 2013; Wan et al., 2018). However, the covalent attachment of any functional group affects the thermal and electronic properties of GRM because of the perturbation of their aromatic character. Therefore, the supramolecular functionalization is often preferable as it may preserve the structure and properties of non-oxidized GRM, while it simultaneously enables the attachment of specific organic moieties, through π-stacking or hydrophobic and electrostatic interactions (Zhang et al., 2007; Choi et al., 2010; Liu et al., 2010; Cheng et al., 2012; Hsiao et al., 2013; Ji et al., 2015; Georgakilas et al., 2016). In particular, π-π stacking interactions between GRM and polyaromatic hydrocarbons, such as pyrene, perylene, hexabenzocoronene, have been widely investigated and validated for the preparation of GRM-based materials (Björk et al., 2010; Georgakilas et al., 2012; Parviz et al., 2012; Hirsch et al., 2013; Wang et al., 2014). Non-covalent functionalization of GRM may indeed be exploited to tailor interfaces between nanoplatelets and the surrounding organic media or to control interfaces within GRM networks.

Compatibilization between GRM nanoplatelets and organic polymers have been widely studied to promote dispersion in the preparation of nanocomposites as well as to tailor their physical properties (Kuilla et al., 2010; Potts et al., 2011; Mittal, 2014; Papageorgiou et al., 2017). Polyaromatic derivatives, mostly based on pyrene or perylene substituted with a dangling chain able to compatibilize toward the organic polymer have been largely studied, including the functionalization of GRM with polymers bearing pyrene groups (Liu et al., 2010; Liang et al., 2012; Tong et al., 2013; Wang et al., 2015; Fina et al., 2018).

On the other hand, the modification of interfaces between GRM nanoplatelets within their percolating network is currently of high interest to enhance mechanical, electrical, and thermal performance in GRM aerogels, foams and nanopapers. In particular, thermal properties of GRM nanopapers have attracted a significant research interest for the application as flexible heat spreaders (Shen et al., 2014; Song et al., 2014; Xin et al., 2014; Renteria et al., 2015; Bernal et al., 2017, 2018). However, the application of GRM based nanopapers is typically limited by their low mechanical resistance and brittleness. The incorporation of a limited amount of polymers into GRM nanopapers may enhance their toughness and deformability, while decreasing the heat transfer efficiency of the nanopaper, as polymers are well-known for their typically low thermal conductivity. However, as the thermal conductivity of polymers is strongly dependent on chain orientation (Singh et al., 2014; Chen et al., 2016) and crystallinity (Choy et al., 1993; Ronca et al., 2017), the possibility to control local orientation and crystallization of macromolecules at the surface of GRM currently appears as a fascinating route to produce mechanically strong and high thermal conductivity nanostructures.

Several polymers have been shown to effectively nucleate on GRM (Ferreira et al., 2013; Manafi et al., 2014; Bidsorkhi et al., 2017; Colonna et al., 2017b), despite the self-organization of highly ordered crystalline domains onto the surface of GRM remains challenging. An interesting option to self-assemble crystalline domains is via stereocomplexation of complementary polymer enantiomers. For instance, polylactic acid (PLA) has two optically active enantiomers because of the chiral nature of the monomer: poly(L-lactide) (PLLA) and poly(D-lactide) (PDLA). PLLA and PDLA are able to co-crystallize into racemic stereocomplexes (SC), which have been studied mostly for their higher thermal stability and superior physical properties than the homocrystals of the homopolymers (Tsuji et al., 1992; Tsuji, 2005; Hirata and Kimura, 2008). The incorporation of small amounts of GRM and functionalized GRM in PLLA/PDLA blends was also shown to promote the intermolecular coupling between the enantiomers, thus acting as nucleating agents for the stereocomplex (Sun and He, 2012; Wu et al., 2013; Gardella et al., 2015; Xu et al., 2015, 2016; Yang et al., 2016; Zhang et al., 2017).

In this work, we report a facile approach to promote PLA SC formation onto the surface of GnP, exploiting the denser chain packing in the SC structure (Anderson and Hillmyer, 2006; Xu et al., 2006) to modify the physical properties of the contact between graphite nanoplatelets. Pyrene-end functionalized enantiomeric PLAs with low molecular weight were synthesized and used to supramolecularly modify GnP. Then, stereocomplexation of the PLLA and PDLA anchored to the GnP surface was carried out, to produce highly crystalline domains acting as junctions between nanoplatelets. Results obtained demonstrated the promotion of the intermolecular coupling between the enantiomeric PLAs adsorbed on the surface of the nanoplatelets, leading to the efficient stereocomplexation of the systems. More importantly, the presence of highly crystalline domains from PLLA/PDLA stereocomplexation delivered nanopapers with a higher through-plane efficiency in heat transfer, acting as efficient thermal bridges between overlapped GnP.

EXPERIMENTAL SECTION

Materials

L-lactide and D-lactide (purity ≥98%) were purchased from Sigma-Aldrich. Before polymerization, both monomers, L-lactide and D-lactide, were purified by three successive re-crystallizations from 100% (w/v) solution in anhydrous toluene and dried under vacuum at room temperature. 1-Pyrenemethanol (Pyr-OH) (purity 98%) and stannous octanoate, tin(II) 2-ethylhexanoate ($Sn(Oct)_2$, purity ∼95%) were purchased from Sigma-Aldrich and used as received. All solvents, toluene (anhydrous, purity 99.8%), chloroform (purity ≥99.5%), methanol (purity ≥99.8%), N-N-dimethylformamide (DMF) (anhydrous, purity 99.8%) and dimethyl ether (DME) (purity ≥99.0%) were purchased

from Sigma Aldrich and used without further purifications. Graphite nanoplatelets (GnP) were synthesized by Avanzare (Navarrete, La Rioja, Spain) according to a previously reported procedure (Colonna et al., 2017a). In brief, overoxidized-intercalated graphite was prepared starting from natural graphite, followed by rapid thermal expansion of at 1,000°C, to produce a worm-like solid, and then mechanically milled to obtain GnP.

Synthesis of Pyrene-End Functionalized PLLA and PDLA (Figure 1A)

Pyrene-end functionalized poly(L-lactic acid) (Pyr-L) and pyrene-end functionalized poly(D-lactic acid) (Pyr-D) were synthesized by the ring-opening polymerization (ROP) of monomers, L-lactide and D-lactide, initiated with Pyr-OH and catalyzed by $Sn(Oct)_2$ in bulk at 140°C, as previously reported (Eleuteri et al., 2018). In detail, L-lactide or D-lactide (5.5 g, 38 mmol) were charged under argon flow into the reactor (i.e., a 50-ml two-neck round-bottomed flask equipped with a magnetic stirrer). Pyr-OH (220 mg, 0.94 mmol) was introduced under argon flow and the flask was evacuated for 15 min and purged with argon; these vacuum/argon cycles were repeated three times in order to thoroughly dry the reactants. The monomer-to-Pyr-OH molar ratio was calculated to obtain an average theoretical molecular weight (M_{nth}) for Pyr- L or Pyr- D of 7,000 g/mol. Then, the reactor vessel was immersed in an oil bath at 140°C under stirring. Once the reactants were completely melted and homogenized, a freshly prepared solution of $Sn(Oct)_2$ in toluene (271 μL, $[lactide]/[Sn(Oct)_2] = 10^3$) was added under argon and the reaction was allowed to proceed under inert atmosphere for 24 h. After cooling to room temperature, the reaction was quenched in an ice bath and the crude products were dissolved in chloroform and poured into an excess of cold methanol (2°C). The solid residue was filtered and dried in vacuum at 40°C. Then, Pyr-L was dissolved in DMF (15 mg mL^{-1}) at 65°C for 15 min. The solvent was allowed to evaporate at 25°C for 48 h and the residual solvent was removed by drying at 60°C for 3 h.

Preparation of Pyr-L/Pyr-D Stereocomplex

Equivalent amounts of Pyr-L and Pyr-D were separately dissolved in DMF (15 mg mL^{-1}) at 65°C. The solutions were then mixed and stirred at 65°C for 15 min. The mixed solution was casted on a Petri dish. The solvent was allowed to evaporate at 25°C for 48 h and the residual solvent was removed by drying at 60°C for 3 h. The above-described blends were denoted as Pyr-L/Pyr-D SC. It is worth mentioning that both parallel and antiparallel stereocomplex structures may be obtained from the blend of Pyr-L and Pyr-D, as previously reported for similar pyrene-terminated PLA oligomers (Danko et al., 2018). However, the two structures have very limited differences in cell dimensions (Brizzolara et al., 1996) and interaction energies, so that the two cannot be distinguished by XRD data and thermal analyses and, most importantly, are expected to deliver very similar material properties.

Preparation of Functionalized GnP Pyr-L (Figure 2A)

One hundred milligram GnP were added to a 100 mL solution of Pyr-L in DMF (0.5 mg·mL^{-1}) and sonicated in pulsed mode (30 s ON and 30 s OFF) for 15 min with power set at 30% of the full output power (750 W) by using an ultrasonication probe (Sonics Vibracell VCX-750, Sonics & Materials Inc.) with a 13 mm diameter Ti-alloy tip. After that, the suspension was left to stand for 24 h to ensure the adsorption of the stereoisomer on the basal plane of GnP. Then, the suspension was filtered through a Nylon Supported membrane (0.45 μm nominal pore size, diameter 47 mm, Whatman) and the filtrate analyzed by UV-Vis. The filtered cake was re-dispersed in DMF (50 mL), sonicated in an ultrasonication bath for 10 min, filtered and the filtrate analyzed by UV-Vis. The dispersion-filtration cycle was repeated a second time to ensure the completely disappearance of the Pyr-L on the filtrate. Finally, the functionalized GnP were washed with methanol (50 mL) and diethyl ether (50 mL) and dried at 60°C for 24 h.

Preparation of Functionalized GnP Pyr-L/Pyr-D SC (Figures 2B,C)

Functionalized GnP Pyr-L/Pyr-D SC were prepared following two different methods. In the first method (**Figure 2B**), 100 mg GnP was added to a 100 mL DMF solution containing equivalent masses of Pyr-L (25 mg) and Pyr-D (25 mg). The procedure previously described for sonication, filtration and purification of the functionalized GnP Pyr-L was followed and the modified GnP obtained by this method are coded as GnP Pyr-L/Pyr-D SC_A. In the second method (**Figure 2C**), two suspensions of GnP Pyr-L and GnP Pyr-D (25 mg of enantiomer and 50 mg GnP in 50 mL DMF) prepared as described previously for GnP Pyr-L were mixed together to obtain a final solution with the same concentrations of enantiomers and GnP as in GnP Pyr-L/Pyr-D SC_A. The procedure previously described for sonication, filtration and purification was followed and the modified GnP obtained by this method are coded as GnP Pyr-L/Pyr-D SC_B.

Preparation of GnP and Functionalized GnP Nanopapers

GnP nanopapers were prepared by suspension of GnP in DMF at a concentration of 0.2 mg mL^{-1} and the solutions were sonicated as described previously for the preparation of functionalized GnP. Then, GnP nanopapers were prepared by vacuum filtration, dried and mechanically pressed, following the procedure previously reported (Bernal et al., 2017).

GnP nanopapers containing the stereocomplexes were prepared following the method described previously for GnP Pyr-L/Pyr-D SC_A. The total concentrations of Pyr-L and Pyr-D in DMF were 0.1 mg mL^{-1}, while the final concentration of GnP in the solutions was 0.2 mg mL^{-1}. For comparison purposes, two additional nanopapers were prepared for the formation of the stereocomplex, increasing the concentrations of the stereoisomers to 0.2 and 0.4 mg mL^{-1}, denoted as GnP Pyr-L/Pyr-D SC_A′ and GnP Pyr-L/Pyr-D SC_A″, respectively.

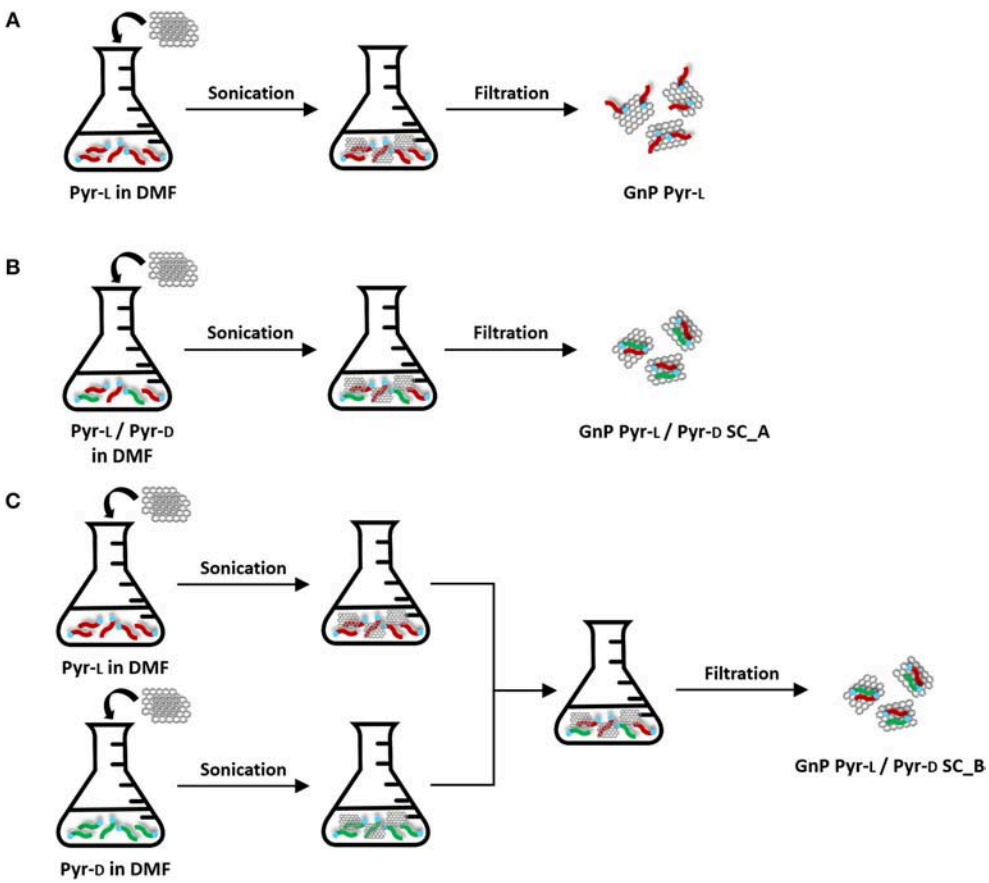

FIGURE 2 | Preparation of functionalized GnP: **(A)** GnP Pyr-L, **(B)** GnP Pyr-L/Pyr-D SC_A, and **(C)** GnP Pyr-L/Pyr-D SC_B.

Characterization Methods

All ^{1}H Nuclear Magnetic Resonance (NMR) spectra were recorded on a NMR Varian Mercury Plus 300 MHz. Samples were dissolved in deuterated chloroform ($CDCl_3$) with TMS as internal reference (chemical shifts δ in ppm).

Differential scanning calorimetry (DSC) measurements were performed on a DSC Q20 (TA Instruments, USA). Approximately 5 mg of sample were placed in the aluminum pans. The samples were heated from 25 to 250°C at a heating rate of 10°C min^{-1} and kept for 1 min to erase the thermal history. Afterwards, the specimens were cooled down to 25°C, and finally reheated to 250°C at 10°C min^{-1} to evaluate the crystallization and melting behavior of the samples. For functionalized GnP, the reference aluminum pan was filled with pristine GnP to facilitate the observation of the thermal transitions arising from the Pyr-L and Pyr-L/Pyr-D SC.

Powder X-ray diffraction (XRD) measurements for the stereoisomers, the SC crystallites and functionalized GnP were carried out using an X-ray diffractometer (PANalytical X'Pert Pro MPD, Philips PW3040/60) with a Cu Kα radiation source with a wavelength of 1.542 Å. The measurements were operated at 40 kV and 40 mA with scan angles from 5 to 25° at a scan step of 0.026°. XRD measurements on nanopapers were carried out also with a 2D detector, exploiting a Gemini R Ultra diffractometer. All data were collected using Cu Kα radiation. Data collection and reduction was carried out with CrysAlisPro software, version 1.171.35.11 (Agilent Technologies UK Ltd. Oxford, UK). 2D images were collected with a time from 10 to 30 s depending on the 2θ. The 2D data were then reduced to intensity vs. 2θ profiles by the same software, to investigate preferential orientations in the nanopapers and well as to obtain averaged XRD profiles over the whole possible orientations.

Thermal gravimetrical analysis (TGA) were performed using a TGA Discovery (TA Instruments, USA) under nitrogen atmosphere from 50 to 800°C at 10°C min^{-1}. The thermal degradation temperatures were defined as the temperatures corresponding to the maximum DTG peaks, obtained from the first derivative curve of the TGA thermogram.

Fourier-transform infrared (FT-IR) spectra were recorded on a Perkin Elmer Perkin Elmer Frontier spectrometer (Waltham, MA, USA) in the range of 400–4,000 cm^{-1} with 16 scans at a resolution of 4 cm^{-1}.

X-ray photoelectron spectroscopy (XPS) were performed on a VersaProbe5000 Physical Electronics X-ray photoelectron spectrometer with a monochromatic Al source and a hemispherical analyzer. Survey scans and high-resolution spectra were recorded with a spot size of 100 μm. The samples were prepared by depositing the GnP powders onto adhesive tape and keeping the samples under vacuum for 15 h prior to the measurement. A Shirley background function was employed to remove the background of the spectra.

The morphology of the graphene papers was characterized by a high resolution Field Emission Scanning Electron Microscope (FESEM, ZEISS MERLIN 4248).

The density (ρ) of the nanopapers was calculated according to the formula $\rho = m/V$, where m is the mass of the nanopaper, weighed at room temperature using the TGA microbalance (Sensitivity: < 0.1 μg) and V is calculated from a well-defined disk film using the average thicknesses measured by FESEM.

The in-plane thermal diffusivity ($\alpha_{\parallel}$) and cross-plane diffusivity ($\alpha_{\perp}$) were measured using the xenon light flash technique (LFT) (Netzsch LFA 467 *Hyperflash*). The samples were cut in disks of 23 mm and the measurement of the $\alpha_{\parallel}$ was carried out in a special in-plane sample holder while the $\alpha_{\perp}$ was measured in the standard cross-plane configuration. Each sample was measured five times at 25°C.

RESULTS AND DISCUSSION

Synthesis of Pyr-L and Pyr-D by ROP and Formation of Pyr-L/Pyr-D SC

The Pyr-L and Pyr-D synthesized by the ring-opening polymerization of L-lactide and D-lactide using Pyr-OH as initiator have been first characterized for their molar masses. The number average molecular weight (M_{nNMR}) of Pyr-L and Pyr-D was estimated based on the ^{1}H-NMR spectra (**Figure S1**), using the integral area of the methine protons signals in the PLA chain and next to the terminal hydroxyl group, at δ = 5.16 ppm and δ = 4.35 ppm, respectively. The M_{nNMR} is *ca.* 7,000 g mol^{-1}, which is in accordance to the theoretical number average molecular weight (M_{nth}) calculated from the monomer-to-Pyr-OH molar ratio, thus confirming the controlled polymerization reaction. Furthermore, the characteristic absorption bands of pyrene (**Figure S2**) confirm the presence of the cromophore group in the enantiomers.

Crystallization of as-synthesized Pyr-L or Pyr-L/Pyr-D SC was obtained after dissolving the product in N,N-dimethylformamide (DMF) and left to crystallize. DMF was chosen in this study, allowing for the formation of stereocomplex crystallites and providing sufficient affinity for the subsequent dispersion of graphene nanoplatelets, as the surface tension of DMF (37.1 mJ m^{-2}) is similar to that of graphene (Hernandez et al., 2008; Coleman et al., 2011). Given the influence of the solvent on the polymorphic crystalline structure of poly(L-lactide) (Marubayashi et al., 2012, 2013) and stereocomplex crystallization of PLA (Tsuji and Yamamoto, 2011; Yang et al., 2017) have been previously reported, for comparison purposes, Pyr-L or Pyr-L/Pyr-D SC crystallizations were also performed in chloroform, being the most common solvent for PLA (result comparison in **Supporting Information**).

The structures of the Pyr-L and Pyr-L/Pyr-D SC after crystallization from DMF were corroborated by FTIR spectroscopy (**Figure 3**). The ν(C=O) band, which is sensitive to the morphology and the conformation of PLA (Kister et al., 1998), changed after the stereocomplexation, showing a downshift of the signal which is related to the weak hydrogen bond formation between the CH_3 groups and the C=O group in the Pyr-L/ Pyr-D SC (Kister et al., 1998; Zhang et al., 2005; Gonçalves et al., 2010). Furthermore, the CH_3 and CH bending region, between 1,250 and 1,400 cm^{-1}, showed asymmetric and broad bands for Pyr-L compared to Pyr-L/Pyr-D SC, being the δ(CH) band high-frequency shift for the stereocomplex (∼10 cm^{-1}), as previously observed by Kister et al. (1998).

The band at 920 cm^{-1}, observed in Pyr-L and assigned to the α-helix of an enantiomeric PLA, disappeared in and Pyr-L/Pyr-D SC and a new band appeared at 909 cm^{-1}, corresponding to β-helix, characteristic of the stereocomplex, accordingly to previous report by Michalski et al. (2018). Finally, after stereocomplexation the ν(C-COO) stretching mode at 872 cm^{-1} is shifted at higher frequency and appears less asymmetric compared to the corresponding band in Pyr-L spectrum, thus further confirming the successful formation of the stereocomplex crystallites.

The stereocomplexation of pyrene-based PLA systems were analyzed by DSC (**Figure 4A**) and XRD (**Figure 4B**). The stereoisomers, Pyr-L and Pyr-D, were confirmed to crystallize in the stereocomplex form as demonstrated by the increase of the melting temperature (T_m), from 152.2°C for Pyr-L to 207.5°C for Pyr-L/Pyr-D SC. Moreover, the formation of the Pyr-L/Pyr-D SC leads to both higher enthalpy of melt crystallization (ΔH_m) and high T_m in DMF compared to the stereocomplex formed in chloroform (see **Figure S3** and **Table S1**), evidencing for the crucial role of the solvent in promoting stereocomplexation. Interestingly, no crystallization peak (T_{cc}) at around 100°C was observed during the formation of Pyr-L/Pyr-D SC in DMF, which is ascribed to the crystallization during the previous cooling scan (Bao et al., 2016). Hence, the π-π interactions between pyrene groups in low molecular weight Pyr-L and Pyr-D did not hinder the stereocomplex crystallization (de Arenaza et al., 2013), as exclusive stereocomplex crystallites are formed in DMF (Yang et al., 2017). The effect of DMF on the crystallization of Pyr-L and the formation of SC crystallites in Pyr-L/Pyr-D SC were also confirmed by XRD (**Figure 4B**). In fact, Pyr-L shows the typical diffraction peaks of the stereoisomer at 2θ 14.8, 16.7, 19.1, and 22.4°, corresponding to the (010), (110)/(200), (203), and (210) planes. Additionally, the crystalline complex ε-form, induced by the formation of complexes in specific solvents with five-membered ring structure such as DMF (Marubayashi et al., 2012, 2013), is evidenced by the peak observed at 2θ ≈ 12.4°. Pyr-L/Pyr-D SC formed in DMF exhibits only the diffraction peaks of SC crystallites at 12.1, 21.1, and 24.0°, thus indicating the exclusive formation of SC crystallites, due to the low vapor pressure of DMF and the dissimilar solubility parameter between solvent and polymer (Tsuji and Yamamoto, 2011; Yang et al., 2017).

Supramolecular Functionalization of GnP With Pyrene-End Functionalized PLAs

The formation of the stereocomplex in the presence of GnP was investigated using two different approaches: (i) sonicating the nanoplatelets in a solution containing both Pyr-L and Pyr-D (**Figure 2B**) and (ii) sonicating separately the GnP with each of the stereoisomers, Pyr-L or Pyr-D, before mixing them to form the stereocomplex (**Figure 2C**). After that, the products were washed thoroughly to remove any DMF-soluble oligomers unbound to GnP (See **Figure S4** in the Supporting Information).

The modification of GnP was investigated by XPS (**Figure S5**), which provides information about the elemental composition

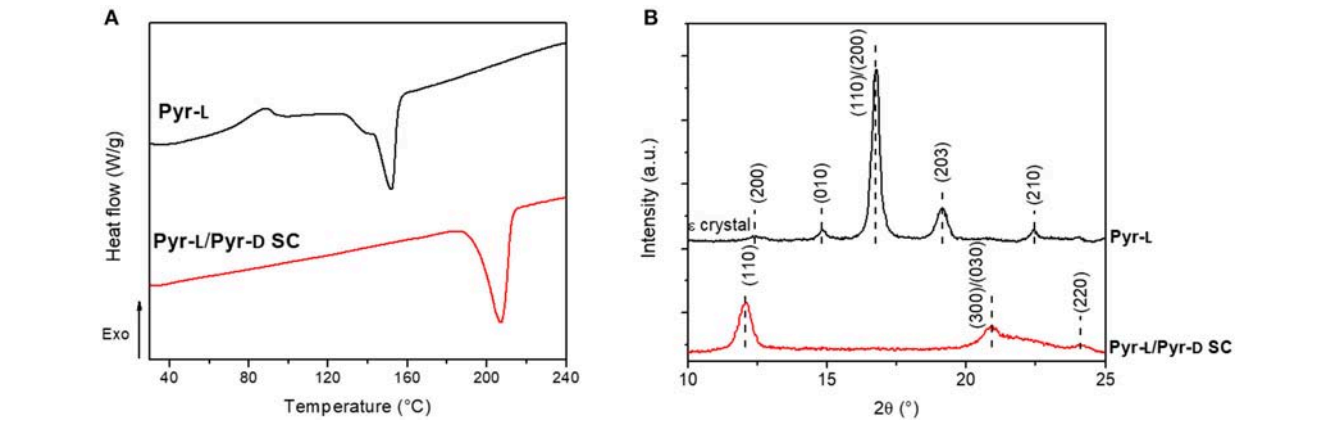

FIGURE 4 | (A) DSC thermograms of Pyr-L and Pyr-L/Pyr-D SC recorded during the second heating (10°C min^{-1}). **(B)** Powder XRD patterns of Pyr-L and Pyr-L/Pyr-D SC.

and chemical binding states of the samples. Pyr-L and Pyr-L/Pyr-D SC were first analyzed, showing signals at ∼284.9 eV attributed to aliphatic carbons (–CH_2, –CH_3), at 285.5 eV (C-OH), the C-O-C peak at 286.8 eV and the 288.9 eV binding energy of the –C=O. The deconvolution of the C_{1s} spectra of the functionalized GnP are dominated by the peak at 284.4 eV, related to the sp^2 C-C bonds and thus the differentiation of the additional aliphatic carbons of the polymer backbone was difficult, suggesting for a limited fraction of PyrL or PyrD onto GnP. However, the O_{1s} spectra (**Figure S5B**) showed the three bands typical of the composition of PLA (O-C=O at 531.5 eV, C-O-C at 533.0 eV and C-OH at 534.2 eV) reflected in GnP Pyr-L and GnP Pyr-L/Pyr-D SC, evidencing significant differences compared to pristine GnP and directly evidencing for grafted PLA chains. The fitting of XPS spectra, with additional comments and atomic ratios for each oxygen functional group are reported in Supporting Info, **Figure S5** and **Table S2**.

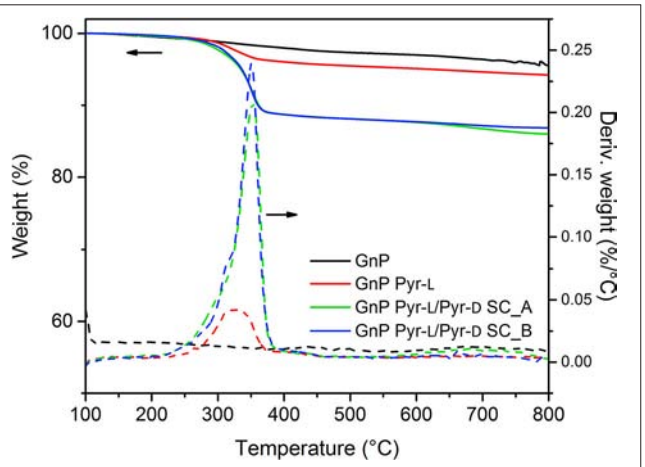

FIGURE 5 | TGA curves of GnP and functionalized GnP.

The functionalization of GnP by the stereoisomers and the formation of the stereocomplex on the basal plane of GnP was also corroborated by thermal analysis (**Figure 5**). Pristine GnP showed a 3.0% weight loss until 600°C under N_2 atmosphere, because of the decomposition of organic impurities and or elimination of the few oxidized groups obtained during the synthesis process of such nanoplatelets (Colonna et al., 2017a). On the other hand, the major weight loss for PLA-functionalized GnP is observed between 200 and 400°C, corresponding to the decomposition of the polymer chains. In this temperature range, GNP Pyr-L showed a small weight loss ∼ 3 wt.% (after subtraction of the weight loss corresponding to the pristine GnP), which corresponds to an adsorption concentration of 0.0535 mmol g^{-1} or adsorption density of ∼1,400 chains μm^{-2}. The adsorption of the stereoisomers in the surface of GnP can be explained by (i) the π-π interactions between pyrene moieties and GnP and (ii) the intermolecular CH-π interactions between the –CH groups of PLLA and GnP (Hu et al., 2009; Arenaza et al., 2015), the former assumed to be more significant. Therefore, the limited adsorption of Pyr-L is mainly ascribed to the low content of pyrene anchoring units, as each oligomeric PLA chain is end capped with a single pyrene group. This observation is consistent with previous studies on the non-covalent functionalization of carbon nanoparticles with pyrene containing polymers, where lower pyrene/polymer ratios showed a weakening of the polymer-carbon nanoparticle interactions (Meuer et al., 2008, 2009).

GnP Pyr-L/Pyr-D SCs, prepared with the two different methodologies, were also investigated for their thermal decomposition. GnP Pyr-L/Pyr-D SCs exhibited a higher thermal stability, as observable from the onset temperature of 353.0°C, compared to 322.3°C for GnP Pyr-L to. Most interestingly, the amount of polymer chains adsorbed on the nanoplatelets is in both cases *ca.* 10 wt.%, (20 wt.% of the total initial amount of polymer) that corresponds to an adsorption concentration and density of 0.190 mmol g^{-1} and ∼12,000 chains μm^{-2},

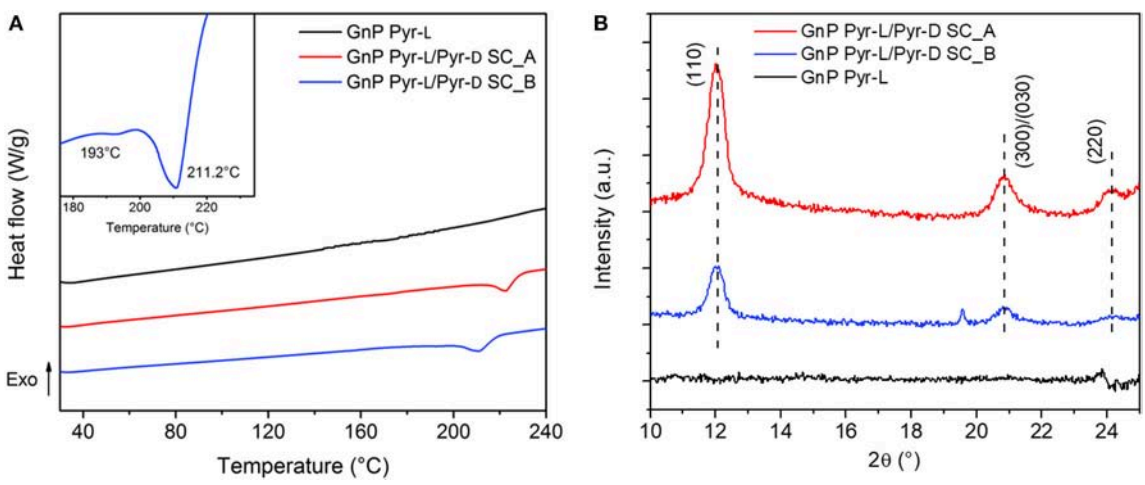

FIGURE 6 | (A) DSC thermograms of GnP Pyr-L and GnP Pyr-L/Pyr-D SC recorded during the second heating (10°C min^{-1}). Inset shows the melting region of GnP Pyr-L/Pyr-D SC_B. **(B)** Powder XRD patterns of GnP Pyr-L and GnP Pyr-L/Pyr-D SC.

respectively. These values are one order of magnitude higher than those calculated for the GnP functionalized with only Pyr-L. The strong ability of carbon-based nanoparticles to induce the stereocomplex crystallization of PLA (Hu et al., 2009; Xu et al., 2010; Yang et al., 2016) together with the formation of SC precursors in the presence of DMF adsorbed on the GnP during the sonication process, favors the supramolecular functionalization of GnP with the SC.

DSC heating curves and XRD patterns of functionalized GnP (**Figure 6**) were further performed to discern the phenomena related to the adsorption of the stereoisomers on the GnP and the formation of the SC crystallites. The DSC thermogram of GnP Pyr-L did not show any clear melting peak of the homocrystals (**Figure 6A**) and no diffraction peaks of Pyr-L could be observed on the XRD pattern (**Figure 6B**). These results confirm the low amount of stereoisomer adsorbed on the basal plane of GnP, as already evidenced from TGA. On the other hand, GnP Pyr-L/Pyr-D SC exhibited clear evidences of PLA stereocomplexation, with significant differences as a function of the preparation method (**Figure 6A** inset). GnP Pyr-L/Pyr-D SC_A, prepared sonicating GnP in a mixed solution of the stereoisomers in DMF, showed a single T_m at 222.8°C, which is 15.3°C higher than the T_m of the SC in the absence of GnP, while showing the typical diffraction peaks (**Figure 6B**) of the SC crystallites at $2\theta = 12.0$, 20.8, and 24.1°, assigned to the (110), (300)/(030), and (220) planes (Tsuji, 2005; Bao et al., 2016). On the other hand, GnP Pyr-L/Pyr-D SC_B, where GnP was separately sonicated in the presence of one of the stereoisomers before mixing them to form the SC, exhibited two partially overlapped melting peaks at about 193 and 211°C (**Figure 6A**, inset), while displaying a XRD signal at the same position but with lower intensities, when compared to GnP Pyr-L/Pyr-D SC_A. The double melting peak has been previously observed in the precipitates of PDLA + PLLA mixtures of the stereoisomers in solution and explained by melting of less perfect crystallites and recrystallization into more stable crystallites (Tsuji et al., 1992). It is worth noting that the main melting point of SCs in GnP Pyr-L/Pyr-D SC_B was found at a temperature (211.2°C) that is significantly lower than the T_m of GnP Pyr-L/Pyr-D SC_A. These differences highlight the role of both GnP and interactions of pyrene-terminated PLA oligomers to its surface. Indeed, in GnP Pyr-L/Pyr-D SC_B, the stereoisomers anchored onto the basal plane of GnP through pyrene terminals clearly affects the nucleation and growth of the SC crystallites. Hence, the probability of the intermolecular contact between the stereoisomers in solution and those on GnP increases, enhancing the stereocomplex crystallization from the surface of the nanoparticles (Hu et al., 2009; Yang et al., 2016). However, the mobility of Pyr-L and Pyr-D chains adsorbed on the GnP is limited, organizing the SC crystallites in a poorly stable state, as observed by the DSC

results. In GnP Pyr-L/Pyr-D SC_A, two competing effects are occurring simultaneously: the anchoring of the polymer chains to the nanoplatelets and the formation of the SC crystallites from enantiomers in solution. Here, the mobility of the polymer chains is promoted by sonication in solution together with the GnP, enhancing the stereocomplexation process, while the pyrene groups favor their adsorption on the basal planes of the GnP. As a direct consequence, more organized and stable crystallites are obtained in GnP Pyr-L/Pyr-D SC_A.

Functionalized GnPs were used to prepare nanopapers, to assess the effect of the modification with Pyr-D/Pyr-L on the thermal transfer properties. In particular, the nanopapers have been prepared following the method described for GnP Pyr-L/Pyr-D SC_A, that has been previously confirmed that this strategy forms better SC crystallites. Furthermore, two nanopapers with increasing concentration of the stereoisomers were prepared to investigate the effect of the SC content on the properties of the nanopapers.

Nanopapers density was significantly decreased by the presence of Pyr-L/Pyr-D SC, in the range of 0.3 ÷ 0.4 g cm^{-3}, compared to 1.0 g cm^{-3} for the pristine GNP nanopaper (**Table 1**). Despite the density is slightly decreasing with increasing the enantiomer concentration, the strong reduction in density is not consistent with the simple presence of the SC phase, based on the organic content, as determined by residue at 600°C in thermogravimetric analyses (**Table 1** and **Figure S6**). Therefore, the nanopaper density appears to be mainly dependent on a different organization of the flakes, driven by the organic functionalization with Pyr-L/Pyr-D.

To investigate the microstructure of the nanopapers, FESEM analyses were carried out; top-view and cross-sectional images of the nanopapers are shown in **Figure 7**. The presence of the organic phase, corresponding to the Pyr-L/Pyr-D SC (**Figures 7b–d**), can be observed on the top-view images as thin coating onto the GnP flakes. The cross-sectional images of the nanopapers (**Figure 7** insets) suggest the presence of the polymer chains, indeed modifies the structural organization of the GnP flakes. To further investigate the self-assembly of GnP flakes in the nanopaper, 2D-XRD measurements were carried out to qualitatively evaluate the degree of in-plane orientation. In **Figure 8**, 2D XRD patterns for the nanopapers of pristine GnP and GnP Pyr-L/Pyr-D SC are reported. As expected for nanopapers prepared by vacuum filtration from suspensions of 2D nanoparticles, a very high degree of in-plane

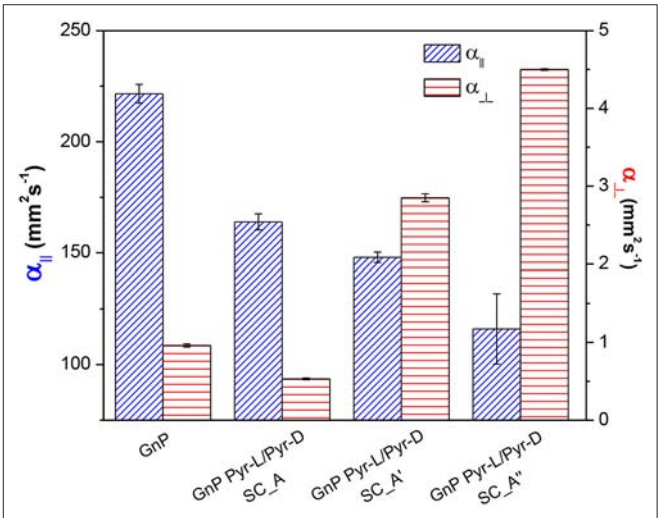

FIGURE 9 | In-plane ($\alpha_{\parallel}$) and cross-plane ($\alpha_{\perp}$) thermal diffusivities for pristine and functionalized GnP nanopapers, with different contents of Pyr-L/Pyr-D SC.

preferential orientation was observed for pristine GnP. This is evidenced by the strongly variable intensity distribution of the 002 basal plane for graphite *vs.* the azimuthal angle, with the characteristic two maxima is opposite positions, confirming a very large fraction of the GnP flakes is oriented parallel to the plane of the nanopaper. In the presence of Pyr-L/Pyr-D SC, a slightly lower degree of orientation is generally observed, as suggested by a weaker orientation of the diffraction signal for 002 graphitic planes. This limited loss of orientation is particularly clear with in the cases of GnP Pyr-L/Pyr-D SC_A′ and GnP Pyr-L/Pyr-D SC_A″, suggesting that higher concentrations of SC have a role in the self-assembly of GnP nanoflakes during filtration. Furthermore, for GnP Pyr-L/Pyr-D inner diffraction circles are visible, corresponding to the XRD diffraction signals from the SC (**Figure S7**), with no significant preferential orientation (**Figures 8c,d**) and intensity proportional to the SC concentration determined by TGA.

The thermal diffusivity of the nanopapers were analyzed in both cross-plane and in-plane directions. Results reported in **Table 1** and **Figure 9** show a clear reduction of in-plane diffusivity in the presence of SC, which is expected, based on the low thermal conductivity of polymers. Furthermore, this reduction is a direct function of the fraction of SC in the

nanopaper. Conversely, the cross plane diffusivity showed only a slight reduction at the lowest SC content, whereas at higher SC content the diffusivity is increased by a factor of 3 in GnP Pyr-L/Pyr-D SC_A′ and 4.5 in GnP Pyr-L/Pyr-D SC_A″, despite the increasing fraction of the polymeric phase.

The increase in cross-plane diffusivity may partially be related to a loss in nanoflakes orientation. As the fractions of flakes lying on direction tilted with respect to the nanopaper plane are expected to contribute more to the heat transfer across the nanopaper, owing to the well-known anisotropy of graphitic materials. However, in this case, the above commented differences in preferential orientation are not sufficient to explain the change in cross-plane diffusivity. Indeed, the lower degree of orientation was observed for GnP Pyr-L/Pyr-D SC_A, compared to pristine GnP, does not correspond to a better cross plane diffusivity. Furthermore, the significant differences between diffusivities for GnP Pyr-L/Pyr-D SC_A′ and GnP Pyr-L/Pyr-D SC_A″ are not reflected in terms of preferential orientations, proven to be comparable. Therefore, the enhanced efficiency on cross-plane heat transfer appears to be related to the organization of the SC phase, acting as thermal bridge between GnP flakes. In fact, crystallinity and orientation of the macromolecules are well-known to dramatically affect the thermal conductivity of the polymeric materials (Choy et al., 1980, 1993; Singh et al., 2014) and the organization of a thermally stable and highly crystalline SC phase, strongly interacting to the surface of GnP via the pyrene terminal groups, appears to have an effective role in promoting heat transfer between overlapped GnP flakes.

CONCLUSIONS

Non-covalent functionalization of graphite nanoplatelets (GnP) was obtained with *ad hoc* synthesized pyrene chain-ended oligomers of stereoregular polylactic acid (Pyr-L and Pyr-D), exploiting the π-π stacking interactions with GnP surface. Stereocomplexation of Pyr-L and Pyr-D onto GnP was obtained both *via* one-pot preparation from a mixture of GnP/Pyr-L/Pyr-D, as well as by mixing of GnP/Pyr-L and GnP/Pyr-D suspensions, with the former procedure allowing the preparation of better organized SC domains. Nanopapers were prepared at different SC fraction, evidencing the dominant role of the polymeric functionalization in the self-assembly of the GnP flakes. In particular, lower densities and reduced orientations of the nanopapers were induced by the presence of SC, acting as a polymeric cross-linkers between different GnP moieties. Most interestingly, the presence of PLA SC between GnP flakes was found to enhance cross-plane heat transfer in GnP Pyr-L/Pyr-D SC nanopapers, explained in terms of the contribution of local crystallinity to the reduction of thermal resistance at the interface between GnP flakes. Therefore, the possibility to control the thermal conductivity anisotropy of GnP nanostructures, by the self-assembly of organic polymeric functionalization, was demonstrated. The proposed approach can be generally applied to the physical properties modification of engineered nanostructures based on graphene and graphene related materials.

DATA AVAILABILITY

The datasets generated for this study are available on request to the corresponding author.

AUTHOR CONTRIBUTIONS

AF and OM conceived this research work and the experiments within, interpreted the experimental results and led the research activities. ME carried out the synthesis of Pyr-L/Pyr-D, nanopapers, and characterization. MB contributed to the synthesis, data analysis and interpretation of results. MM carried out 2D XRD measurement, data treatment and interpretation. Manuscript was mainly written by MB and AF.

ACKNOWLEDGMENTS

This work has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme grant agreement 639495 — INTHERM — ERC-2014-STG.

The authors gratefully acknowledge Dr. Julio Gomez (Avanzare Innovación Tecnólogica, E) for providing GnP, Dr. Mauro Raimondo (Politecnico di Torino, I) for FESEM analyses, Dr. Salvatore Guastella (Politecnico di Torino, I) for XPS measurements and Dr. Domenica Marabello (University of Turin and CRISDI, Italy) for 2D XRD measurements.

Supramolecular Chemistry

David Margulies

David Margulies has been an Associate Professor at the Weizmann Institute of Science in Israel within the Organic Chemistry Department since 2017. Dr Margulies obtained his Master's and PhD degrees in Organic Chemistry at the Weizmann Institute of Science between 1998 and 2006, under the supervision of Professor Abraham Shanzer. He then moved to Yale University for a Post-doctoral Associate position from 2006 to 2009, before returning to the Weizmann Institute of Science as a Senior Scientist in 2009. Dr Margulies has received numerous honors and awards throughout his research career, including the 2019 NCK Prize for a Young Outstanding Medicinal Chemistry, and the 2018 MSMLG Czarnik Emerging Investigator Award (6th International Conference of Molecular Sensors and Molecular Logic Gates).

Suying Xu

Dr Suying Xu has been an Associate Professor at the Beijing University of Chemical Technology since 2015. Her research focuses on the design of fluorescent probes, the fabrication of nanostructures, as well as the preparation of multifunctional nanomaterials for bioimaging and disease treatment.

Ross S. Forgan

Dr Ross Forgan has been a Royal Society University Research Fellow since 2012 and Reader in Chemistry at the University of Glasgow since 2016. His research into the application of metal-organic frameworks in biomimetic catalysis and nanoscale drug delivery is underpinned by fundamental studies into molecular recognition and self-assembly processes inside nanoporous materials. In 2016 he won a highly prestigious ERC Starting Grant, and he was awarded the Sessler Early Career Researcher Prize in 2018. He is a Fellow of the Royal Society of Chemistry and a founding member of the Royal Society of Edinburgh Young Academy of Scotland.

Meng Li

Meng Li now is an Associate Professor at the North China Electric Power University. She obtained her BSc in 2011 at the East China University of Science and Technology, and completed a combined Master's and PhD degree from 2011 to 2012 with Prof. Weihong Zhu in China. She then worked with Prof. Tony D James to obtain another PhD degree at University of Bath from October 2012 to July 2015. She attended many major international conferences such as the Molecular Sensor and Molecular Logic gates. Her research interests comprise many aspects of supramolecular chemistry, electrochemistry and materials chemistry, including molecular recognition and materials fabrication.

Tsuyoshi Minami

Tsuyoshi Minami obtained his PhD from Tokyo Metropolitan University in 2011, under the direction of Professor Yuji Kubo. During his PhD studies he worked with Professor Tony D. James of the University of Bath on collaborative projects. He was a Postdoctoral Researcher from 2011 to 2013 and a Research Assistant Professor in 2013 at Bowling Green State University, working with Professor Pavel Anzenbacher Jr. He then joined Yamagata University as an Assistant Professor from 2014 to 2016. He has been a lecturer at The University of Tokyo since 2016. His interests include supramolecular analytical chemistry, self-assembled materials, and organic transistors for sensing applications.

Xiao-Peng He

Xiao-Peng He obtained his BSc in Applied Chemistry in 2006 and his PhD in Pharmaceutical Engineering in 2011 from ECUST. He completed a co-tutored doctoral program at ENS Cachan (France) from July 2008 to February 2009. He then carried out his postdoctoral research with Prof. Kaixian Chen (SIMM, CAS) at ECUST from 2011 to 2013. He is now a Professor at the Feringa Nobel Prize Scientists Joint Research Center, School of Chemistry and Molecular Engineering, ECUST, where his research interests span from chemical glycobiology to fluorescent molecular probes and functional materials of different dimensions for disease diagnostics and theranostics.

Robert B. P. Elmes

Rob graduated with a BA Mod (1st Class) in Medicinal Chemistry from Trinity College Dublin in 2007 before he was awarded an IRCSET Embark Scholarship to undertake his PhD under the supervision of Prof. Thorri Gunnlaugsson at TCD. In 2011 Rob moved to The University of Sydney as a Postdoctoral Fellow under the guidance of Prof. Kate Jolliffe before returning to Ireland in late 2014 as a Lecturer in the Department of Chemistry at Maynooth University. Rob's research interests lie in the fields of Supramolecular Chemistry and Chemical Biology where the group is using supramolecular chemistry to develop new drug delivery vehicles, diagnostic tools, therapeutics and chemosensors.

Lupei Du

Lupei Du is currently an Associate Professor at the School of Pharmacy, Shandong University. She obtained her PhD degrees from China Pharmaceutical University in 2006, and her postdoctoral training at the Department of Chemistry, Georgia State University from 2006 to 2009. She joined Shandong University in 2009. Her main research interests include the rational design and synthesis of medicinal molecules and bioactive probes.

Molecular Logic as a Means to Assess Therapeutic Antidotes

*Linor Unger-Angel, Leila Motiei and David Margulies**

Department of Organic Chemistry, Weizmann Institute of Science, Rehovot, Israel

An emerging direction in the area of molecular logic and computation is developing molecular-scale devices that can operate in complex biological environments, such as within living cells, which are beyond the reach of conventional electronic devices. Herein we demonstrate, at the proof-of-principle level, how concepts applied in the field of molecular logic gates can be used to convert a simple fluorescent switch (YES gate), which lights up in the presence of glutathione s-transferase (GST), into a medicinally relevant INHIBIT gate that responds to both GST and beta-cyclodextrin (β-CD) as input signals. We show that the optical responses generated by this device indicate the ability to use it as an enzyme inhibitor, and more importantly, the ability to use β-CD as an "antidote" that prevents GST inhibition. The relevance of this system to biomedical applications is demonstrated by using the INHIBIT gate and β-CD to regulate the growth of breast cancer cells, highlighting the possibility of applying supramolecular inputs, commonly used to control the fluorescence of molecular logic gates, as antidotes that reverse the toxic effect of chemotherapy agents. We also show that the effect of β-CD can be prevented by introducing 1-adamantanecarboxylic acid (Ad-COOH) as an additional input signal, indicating the potential of obtaining precise, temporal control over enzyme activity and anticancer drug function.

Keywords: molecular logic gates, fluorescent molecular probes, supramolecular chemistry, enzyme inhibitors, thiazole orange-based protein identifiers (TOPIs), glutathione s-transferase (GST), cyclodextrin host, adamantyl guest

INTRODUCTION

Molecular logic gates constitute a wide range of molecular switches that respond to diverse input signals according to the rules of Boolean logic. Since the inception of the first molecular AND logic gate (de Silva et al., 1993), a wide range of "digital" optical switches (de Ruiter and van der Boom, 2011; de Silva and Uchiyama, 2011; Magri and Mallia, 2013; Ling et al., 2015; Akkaya et al., 2017; Katz, 2017; Erbas-Cakmak et al., 2018; Pilarczyk et al., 2018) and related pattern-generating devices (Rout et al., 2012, 2013, 2014; Sarkar et al., 2016; Hatai et al., 2017; Lustgarten et al., 2017; Pode et al., 2017) have been developed and used for various applications, including information processing (de Ruiter and van der Boom, 2011; de Silva and Uchiyama, 2011; Ling et al., 2015; Akkaya et al., 2017; Katz, 2017; Erbas-Cakmak et al., 2018; Pilarczyk et al., 2018), user identification (Rout et al., 2013; Lustgarten et al., 2017; Andréasson and Pischel, 2018), cryptography (Sarkar et al., 2016; Lustgarten et al., 2017), and sensing (Ling et al., 2015; Wu et al., 2017; Erbas-Cakmak et al., 2018; Magri, 2018). These input-dependent systems were initially considered as potential alternatives to conventional transistors and circuits (de Silva et al., 1993). However, as the area of molecular computing progressed, and as the challenges associated with building molecule-based circuits revealed, this field has undergone a paradigm shift. It is now believed that although

molecular logic gates may not be able to compete with the speed and power of silicon, a key advantage of using such systems lies in their molecular scale, which enables them to target and sense small biomolecules (e.g., proteins) and to operate in living cells and tissues, where silicon-based devices cannot access (de Silva, 2013). Examples of such systems include molecular logic gate-based photodynamic therapy agents designed to be less harmful to neighboring healthy tissue (Erbas-Cakmak and Akkaya, 2013; Erbas-Cakmak et al., 2013, 2015; Turan et al., 2018), as well as "digitally activated" drug models (Amir et al., 2005; Wang et al., 2010; You et al., 2015; Pode et al., 2017) that release an active pharmaceutical in response to combinations of biomarkers. We have recently shown that "digital" control over prodrug activation can also be achieved by controlling communication between proteins, rather than modifying the prodrug itself (Peri-Naor et al., 2015a,b). The "smart" therapeutic models mentioned before (Amir et al., 2005; Wang et al., 2010; de Silva, 2013; Erbas-Cakmak and Akkaya, 2013; Erbas-Cakmak et al., 2013, 2015; Peri-Naor et al., 2015a,b; You et al., 2015; Pode et al., 2017; Turan et al., 2018) demonstrate how concepts developed in the area of molecular logic may ultimately lead to the generation of highly selective anti-cancer drugs. The latter may not only minimize the severe side effects of current chemotherapies—these drugs may also prevent the increasing incidence of patients' death when inappropriate doses are mistakenly used.

An alternative approach to preventing the lethal effects of improper chemotherapy treatment has recently emerged. Rather than developing more selective drugs, this approach relies on "chemotherapy antidotes" that compete with the binding of chemotherapy agents to their protein targets and consequently, arrest their fatal effects. Vistogard (uridine triacetate), for example, is an antidote that has recently been approved for treating life-threatening toxicity patients subjected to an overdose of the chemotherapy medication capecitabine (5-fluorouracil or 5-FU) (Cada et al., 2016). Reversing the effect of therapeutic agents can also be achieved by using synthetic agents that interact with the synthetic agonist/antagonist themselves, rather than with their biological target. Such systems could allosterically change the structure of an inhibitor (Taylor et al., 2009; Zhou et al., 2017; Mukherjee et al., 2018) or encapsulate it via supramolecular host-guest interactions (Bom et al., 2002). We have recently developed an allosteric inhibitor that reversibly controls the activity of glutathione s-transferase (GST), and we have used Boolean logic to analyze the inhibitor's function (Peri-Naor et al., 2015a). In parallel, we developed "turn-on" fluorescent molecular probes (i.e., YES gates), termed thiazole-orange-based protein identifier (TOPIs), which detect GST by generating a light output signal. Herein, we show that digital analysis of the response of one of these probes (TOPI-4) to GST and an additional chemical input (β-CD) converts this probe from a simple fluorescent YES gate into an INHIBIT gate. Previous studies have demonstrated the ability to obtain molecular INHIBIT gates that respond to supramolecular hosts as inputs (de Silva et al., 1999; Pischel et al., 2010). In this study, we show that such digital optical responses can be used to monitor GST binding interactions and, as a result, indicate whether β-CD could prevent the molecular logic gate from binding and inhibiting GST. Bearing in mind the wide interest in creating chemotherapy antidotes (Cada et al., 2016), we demonstrate, at the proof-of-principle level, how the toxic effect of this inhibitor on cancer cells can be regulated using external input signals.

MATERIALS AND METHODS

All reagents and solvents were obtained from commercial suppliers and used without further purification. Recombinant human GST P1-1 was obtained from the Israel Structural Proteomics Center (Weizmann Institute of Science, Rehovot, Israel). 1-Adamantanecarboxylic acid and β- cyclodextrin were purchased from Sigma-Aldrich. Enzymatic assays were carried out using a BioTek synergy H4 hybrid multiwell plate reader in clear flat-bottom polystyrene 384-well microplates (Corning). Fluorescence measurements were carried out using a BioTek synergy H4 hybrid multiwell plate reader in clear and black flat-bottom polystyrene NBS 384-well microplates (Corning).

GST Activity Measurements

The GST activity was measured spectrophotometrically in aqueous phosphate buffer (5 mM, pH 6.5) using chloro-2,4-dinitrobenzene (CDNB) and Glutathione (GSH) as substrates. The concentrations of GST-P1-1, GSH, and CDNB were 20 nM, 350 μM, and 700 μM, respectively. In a typical experiment, TOPI-4 and various concentrations of β-CD were incubated in microplate wells and then GST-P1-1, GSH, and CDNB were subsequently added. The formation of S-(2,4-dinitrophenyl)-glutathione was monitored using a microplate reader at $\lambda = 340$ nm.

Controlling GST Activity With β-CD and Ad-COOH

TOPI-4 (500 nM) was incubated with various concentrations of β-CD and Ad-COOH for 10 min and then GST-P1 (20 nM) was added. Finally, GSH (350 μM) and CDNB (720 μM) were added and the initial kinetic velocities (V_0) were measured. Data are expressed as mean values ± std. deviation of triplicate measurements.

Controlling the Fluorescence Response With β-CD and Ad-COOH

TOPI-4 (100 nM) was incubated with various concentrations of β-CD and Ad-COOH for 10 min and then GST-P1 (90 nM) was added. The fluorescence measurements were recorded after 30 min of incubation in aqueous phosphate buffer (5 mM, pH = 6.5) using a microplate reader and an excitation wavelength of 500 nm. Data are expressed as mean values ± std. deviation of triplicate measurements.

MTT Cytotoxicity Assays

MDA-MB-231 cells were cultured in RPMI (Roswell Park Memorial Institute) media supplemented with 10% FBS (Fetal Bovine Serum), L-glutamine, and antibiotics. Cells (9×10^3 cells/well) were seeded in 96-well plates. The next day, the cells

were incubated with different concentrations of TOPI-4 (100 nM-40 μM) for 24 h, after which, MTT reagent (5 mg/mL) was added and the cells were incubated at 37°C for another 5 h. Then, the medium was slowly removed without breaking the formazan crystals. Next, 100 μL of SDS-DMF solution (80 g of SDS in 400 mL of 1:1 DMF:H_2O) was added to stop the reduction reaction. Finally, the absorbance values at 570 nm were recorded, the data were analyzed using Graphpad Prism 7.0 and fitted to a sigmoidal dose response plot. The ED_{50} value of TOPI-4 was estimated to be 10.3 ± 0.1 μM and this concentration was used in further experiments to test the ability of β-CD to reverse the cell toxicity effect of TOPI-4.

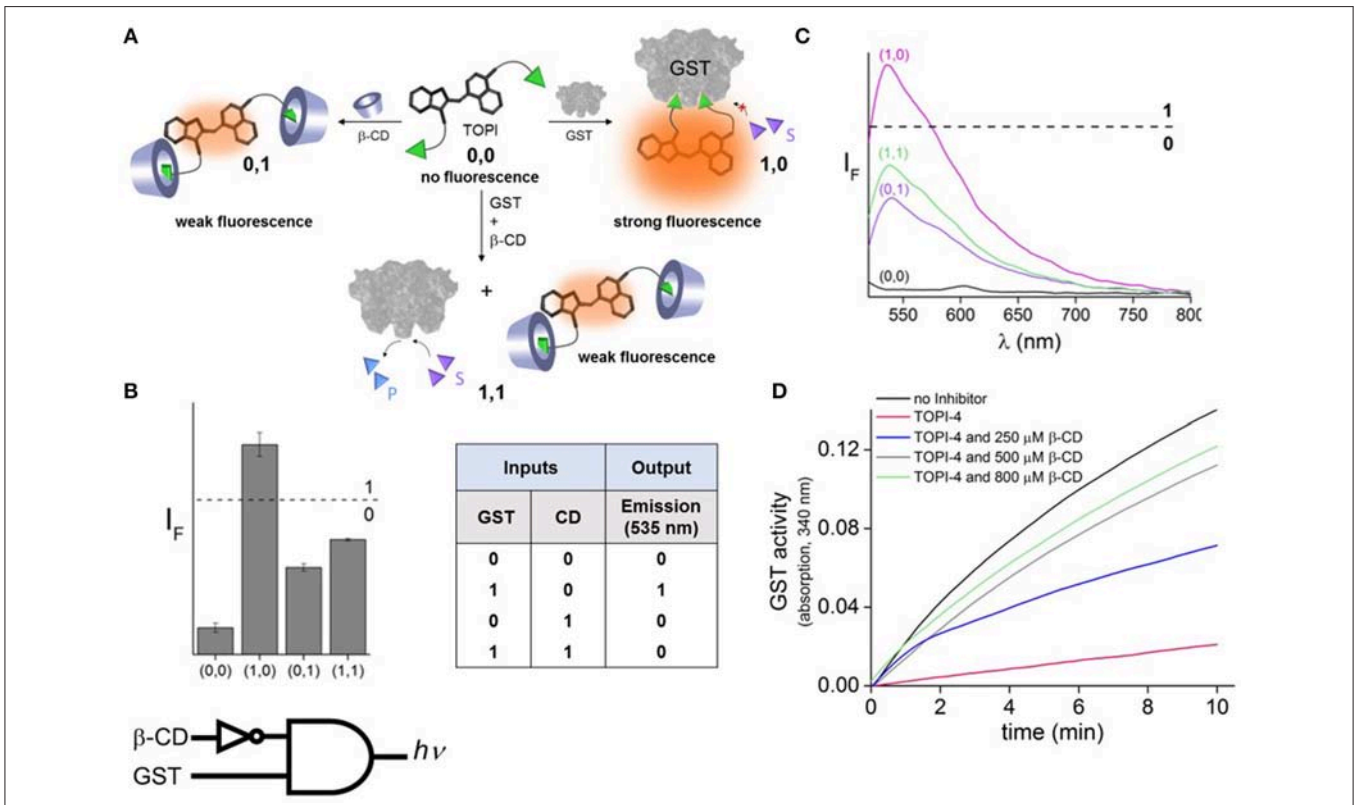

FIGURE 2 | (A) Schematic illustration showing how the binding of TOPI-4 to GST and/or β-CD inputs affects the catalytic activity of GST and the emission of the probe, which results in an optical INHIBIT gate function. S and P correspond to the substrate and product, respectively. **(B)** The corresponding bar plot and truth table. The results are expressed as the mean values ± std. deviation of the triplicate measurements. **(C)** The fluorescence response of TOPI-4 (100 nM) to different combinations of the GST (90 nM) and/or β-CD (1 mM) inputs. **(D)** Enzymatic activity of GST (20 nM) in the absence and presence of TOPI-4 (500 nM) and with increasing concentrations of β-CD. $\lambda_{ex}/\lambda_{em}$ = 500/535 nm.

RESULTS AND DISCUSSIONS

To demonstrate the feasibility of creating molecular logic gate-based chemotherapy antidotes, we exploited the inhibitory effect of bivalent, "turn-on" fluorescent molecular probes, termed TOPIs, recently developed by our group. In an earlier study, we showed that the binding of the two ethacrynic amide (EA) units of TOPI-4 (**Figure 1A**) to the two active sites of GST restricts the torsional motion of the probe, which leads to a "turn-on" emission signal (**Figure 1B**; Unger-Angel et al., 2015). This enhanced emission was selectively observed in biofluids and cancer cells with elevated levels of GSTs, indicating the potential of using such probes in medical diagnosis (Unger-Angel et al., 2015). GSTs are well-known targets for cancer therapy, and ethacrynic acid-based inhibitors have been considered as anti-cancer drug candidates (Allocati et al., 2018). This prompted us to investigate whether the fluorescent TOPI-4 probe could also act as a switchable GST inhibitor that, in addition to sensing GST and cancer cells (Unger-Angel et al., 2015), could be used to regulate GST activity and consequently, cancer cell death. In particular, we expected that analyzing the optical response of TOPI-4 to GST and an additional supramolecular host that interacts with TOPI-4 would indicate the host's ability to disrupt the GST-TOPI-4 binding interactions and the consequent inhibition of GST activity (**Figure 2A**). To prevent the inhibitory effect of TOPI-4 by a supramolecular "antidote," we selected

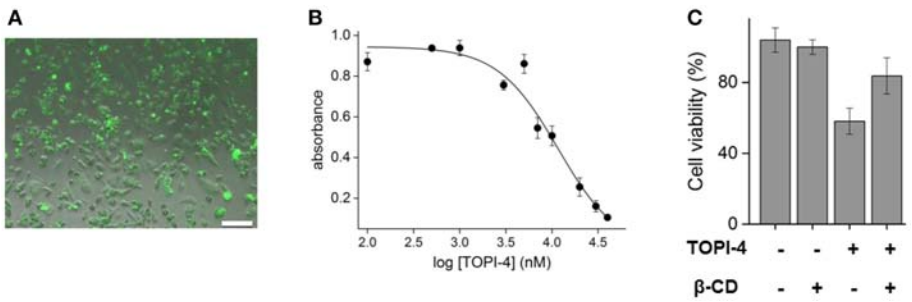

FIGURE 3 | (A) Fluorescence image of MDA-MB-231, overexpressing GST, incubated with TOPI-4 (10 μM). The scale bar is 100 μm. **(B)** Results of an MTT assay that measures the viability of MDA-MB-231 cells under increasing concentrations of TOPI-4. The absorption at 570 nm reflects the number of viable cells. **(C)** Cell viability scores of MDA-MB-231 cells treated with TOPI-4 (10 μM) and/or β-CD (750 μM).

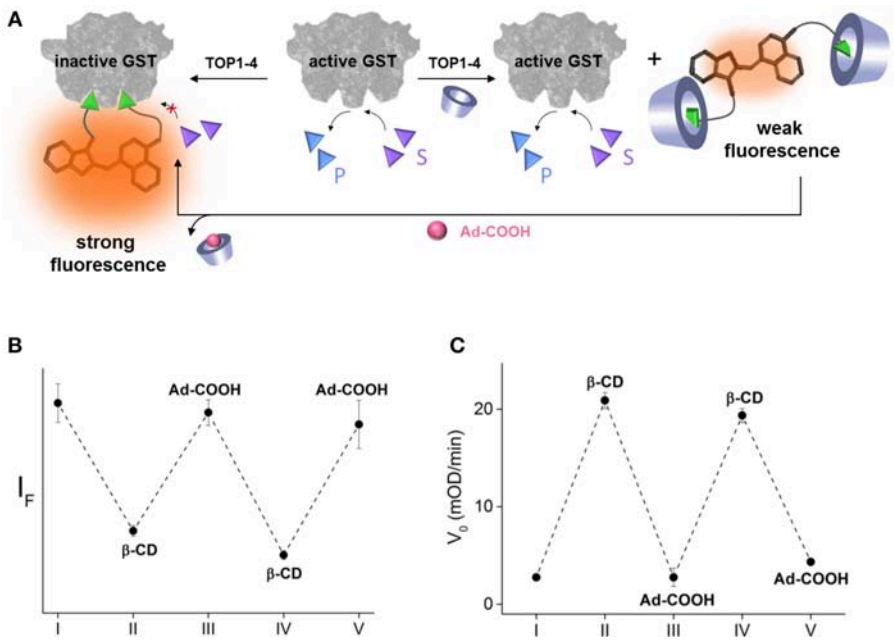

FIGURE 4 | (A) Schematic representation of the way GST activity can be controlled by using Ad-COOH as an additional input that competes with the binding of β-CD to the TOPI-4 inhibitor. **(B)** Emission intensity measured by combining TOPI-4 with GST-P1-1 and different combinations of β-CD and Ad-COOH: (I) no input, (II) β-CD (1 mM), (III) β-CD (1 mM) and Ad-COOH (1.5 mM), (IV) β-CD (3 mM), and Ad-COOH (1.5 mM), and (V) β-CD (3 mM) and Ad-COOH (5 mM). **(C)** Initial velocity (V_0) measured by combining TOPI-4 with GST-P1-1 and different combinations of β-CD and Ad-COOH: (I) no input, (II) β-CD (800 μM), (III) β-CD (800 μM), and Ad-COOH (1 mM), (IV) β-CD (2.5 mM) and Ad-COOH (1 mM), and (V) β-CD (2.5 mM) and Ad-COOH (3.3 mM). $\lambda_{ex}/\lambda_{em}$ = 500/535 nm.

beta-cyclodextrin (β-CD) as the external input. β-CD was chosen as an input for two main reasons. First, this supramolecular host is known to form complexes with a variety of hydrophobic guests, about the size of the EA groups (Crini, 2014). Therefore, we expected that β-CD would form a complex with TOPIs, disrupt their binding to GST, and possibly limit their ability to penetrate cells. Second, β-CD is a non-toxic agent that has been tested for various medical applications (Bom et al., 2002; Del Valle, 2004; Loftsson et al., 2005). Hence, by using β-CD as an "antidote," we aimed to demonstrate the relevance of this study to real-life applications. **Figure 2A** shows the way this additional β-CD input should convert TOPI-4 from a simple fluorescence switch (i.e., a YES gate), which previously responded to GST only (Unger-Angel et al., 2015), into a molecular INHIBIT gate whose fluorescence output depends on the combinations of GST and β-CD as inputs. Importantly, because the GST-TOPI-4 interaction should always be accompanied by enzyme inhibition, we expected that obtaining an optical INHIBIT function would indicate the ability of β-CD to serve as an "antidote" that prevents GST inhibition by TOPI-4 (**Figure 2A**, state 1, 1 vs. 1, 0). For simplicity, **Figure 2A** illustrates the formation of a 1:2 TOPI-4: β-CD complex. Note, however, that other modes of interaction that can prevent inhibition (e.g., binding of β-CD to the TO core) may also occur. The rationale behind the different optical states (**Figure 2A**) and the corresponding truth table (**Figure 2B**) is as follows: In the absence of the GST and β-CD inputs (state: 0, 0), TOPI-4 is not fluorescent (output: 0), owing to an intramolecular motion between the benzothiazole and the quinoline rings. The binding of TOPI-4 to GST (state: 1, 0), however, inhibits the enzyme and concomitantly restricts the intramolecular motion, which leads to a strong fluorescence response (output: 1). The interaction of TOPI-4 with β-CD alone (state: 0, 1) less significantly affects the intramolecular twisting of TOPI-4, which results in a weaker fluorescence signal (output: 0). Finally, when both GST and β-CD inputs are present (state: 1, 1), β-CD prevents the EA groups of TOPI-4 from binding to the two active sites of the GST dimer. Consequently, the probe remains in a low fluorescence state (outputs: 0) and GST remains active. The anticipated optical responses were measured experimentally (**Figure 2C**). As expected, the maximal fluorescence intensity obtained upon adding GST alone was not observed when other combinations of inputs were present in the solution. Importantly, the INHIBIT gate responses revealed similar fluorescence outputs for states (0, 1) and (1, 1), which indicates the possibility of using β-CD as an "antidote" that prevents the formation of the GST-TOPI-4 complex. Note that although this digital analysis of TOPI-4's optical responses provides an efficient analytical tool to distinguish among bimolecular interactions, the relatively small differences between the fluorescence intensity values generated for state (1, 1) (55%), state (1, 0) (100%), and (0, 1) (41%) would complicate using this INHIBIT gate to construct advanced molecular computation devices. For example, it would complicate integrating this gate with another gate that responds to light as an input. This research direction, however, is beyond the scope of this study.

The effect of β-CD on GST inhibition was confirmed by performing an enzymatic assay that follows the conjugation of two GST-specific substrates: chloro-2,4-dinitrobenzene (CDNB) and glutathione (GSH) (**Figure 2D**; Peri-Naor et al., 2015a). With this assay, the formation of the product (GSH-CDNB conjugate) was followed by monitoring the absorbance at 340 nm in the presence and absence of TOPI-4, as well as in the presence of TOPI-4 and increasing concentrations of β-CD. The results show that whereas 500 nM of TOPI-4 strongly inhibited the enzyme, in the presence of β-CD (800 μM) GST remained active, confirming that the supramolecular interactions between the β-CD host and the TOPI-4 guest disrupt the function of the TOPI-4 inhibitor.

To demonstrate the relevance of these results to therapeutic applications, breast cancer cells (MDA-MB-231) overexpressing GST were treated with increasing doses of TOPI-4, imaged using a fluorescence microscope, and their viability was measured by using a MTT assay following ∼24 h of incubations. The results show that TOPI-4 exhibits good cell permeability (**Figure 3A**) and that it inhibits cancer cell growth (**Figure 3B**) with an ED_{50} value of 10 μM. In the next step, we investigated whether, in addition to regenerating GST activity (**Figure 2D**), β-CD can serve as an "antidote" that reduces the TOPI-4-induced cell toxicity. **Figure 3C** shows the viability scores obtained upon subjecting breast cancer cells to 10 μM TOPI-4 with and without β-CD (750 μM). As a control, the number of viable cells was also measured in the presence of only β-CD. The results show that whereas TOPI-4 eradicated nearly 50% of the viable cells, in the presence of β-CD the cell viability increased to ∼85%, indicating the potential of using supramolecular inputs of this class as "antidotes". Notably, the β-CD "antidote" did not fully reverse the effect of the inhibitor on cells. Although this incomplete recovery of cell viability is consistent with the incomplete reactivation of GST in the enzymatic assay (**Figure 2D**), it could also result from non-specific interactions between the GST-TOPI-4 complex and other proteins, which leads to partial dissociation of the inhibitor-antidote complex in a cellular environment. Alternatively, it may indicate that, in addition to GST inhibition, other factors contribute to the TOPI-4-induced cytotoxicity.

In addition to demonstrating a model of a drug-antidote system, these results demonstrate a potential means to establish precise, temporal control over enzyme function. Inspired by the way that enzyme activities were reversibly controlled using DNA-based devices (Saghatelian et al., 2002; Harris et al., 2011; Peri-Naor et al., 2015a), we investigated the possibility of making our system reversible by introducing an adamantane (Ad) derivative as another chemical input. We expected that a water-soluble 1-adamantanecarboxylic acid (Ad-COOH) would compete with the binding of β-CD to the EA binders of TOPI-4, which would release the caged inhibitor and enable it to inhibit GST (**Figure 4A**). Ad-COOH was chosen for this goal, owing to the ability of Ad-derivatives to bind β-CD strongly and selectively (Wenz et al., 2006). In addition, Ad derivatives, similar to β-CDs, are generally non-toxic and have been tested as therapeutics (Štimac et al., 2017). The ability to obtain precise, supramolecular control over the binding of TOPI-4 to GST was demonstrated by adding GST to TOPI-4 incubated with increasing concentrations of β-CD and Ad-COOH and measuring the fluorescence

responses (**Figure 4B**). The results show that the successive addition of an excess of β-CD and Ad-COOH led to a sequential decrease and increase in the fluorescence of TOPI-4, respectively, which is expected from the changes in the interaction between the fluorescent probe and the GST enzyme (**Figure 4A**). Next, we measured the initial velocity (V_0) of the GST-catalyzed reaction measure after adding GST to a solution containing the CDNB and GSH substrates and increasing concentrations of β-CD and Ad-COOH (**Figure 4C**). Strikingly, whenever one of these inputs was introduced in excess, the effect of the other input was reversed, confirming the ability to control GST activity by using a supramolecular host-guest switching mechanism (**Figure 4A**). We believe that regulating intracellular enzymatic activities with similar mechanisms could also provide a means to establish precise, temporal control over cell growth. Research in this direction is underway in our laboratory.

CONCLUSIONS

In conclusion, we have shown how the optical responses of a molecular logic gate revealed the possibility of using it to regulate enzyme function and consequently, cytotoxicity. Although much progress needs to be made in terms the inhibitor's affinity and selectivity in order to apply this system as therapeutics, this model system demonstrates a unique, supramolecular approach to achieving chemotherapy antidotes and switchable enzyme functions. Most importantly, it shows how concepts developed in the area of molecular logic gates, such as the use of supramolecular hosts as inputs that control the fluorescence responses of molecular logic gates (de Silva et al., 1999; Pischel et al., 2010), could be used to construct assays that track biomolecular interactions. Our results show the potential of using such assays for the generation of "smart" therapeutics, in which the function of enzymes and/or drugs can be controlled with external, non-toxic input signals. We hope that this study will inspire the development of other molecular computation devices that can operate in a complex biological environment, such as within living cells, and consequently, can perform tasks that are beyond the ability of conventional electronic computers.

AUTHOR CONTRIBUTIONS

LU-A, LM, and DM designed the project. LU-A synthesized the probe, performed the experiments, and analyzed the data. LM and DM wrote the manuscript.

Zhang X, Zhang L, Ma W-W, Zhou Y, Lu Z-N and Xu S (2019) A Near-Infrared Ratiometric Fluorescent Probe for Highly Selective Recognition and Bioimaging of Cysteine. Front. Chem. 7:32. doi: 10.3389/fchem.2019.00032

A benzothiazole-based near-infrared (NIR) ratiometric fluorescent probe (**HBT-Cys**) was developed for discriminating cysteine (Cys) from homocysteine (Hcy) and glutathione (GSH). The probe was designed by masking phenol group in the conjugated benzothiazole derivative with methacrylate group that could be selectively removed by Cys, and therefore an intramolecular charge transfer (ICT) fluorescence was switched on in the NIR region. In the absence of Cys, the probe exhibited a strong blue fluorescence emission at 431 nm, whereas a NIR fluorescence emission at 710 nm was significantly enhanced accompanied by a decrease of emission at 431 nm in the presence of Cys, allowing a ratiometric fluorescence detection of Cys. The fluorescence intensity ratio (I_{710nm}/I_{431nm}) showed a good linear relationship with Cys concentration of 1–40 μM with the detection limit of 0.5 μM. The sensing mechanism was explored based on MS experimental analysis and DFT theoretical calculation. Moreover, the fluorescent probe was successfully used for fluorescence bioimaging of Cys in living cells.

Keywords: NIR ratiometric fluorescent probe, cysteine, benzothiazole derivative, living cells imaging, intramolecular charge transfer

INTRODUCTION

It has been known that small molecular biothiols, such as L-cystein (Cys), homocysteine (Hcy), and glutathione (GSH) played vital roles in the maintenance of redox homeostasis, intracellular signal transduction, and human metabolism (Shahrokhian, 2001; Giles et al., 2003). Cys is a metabolic product of Hcy and a precursor of the antioxidant GSH, and its normal intracellular level remains to be 30–200 μM (Liu et al., 2014). The deficiency of Cys could cause edema, leucocyte loss, liver damage as well as neurotoxicity, whereas the excess levels of Cys might relate to cardiovascular and Alzheimer's diseases (Lipton et al., 2002; Shao et al., 2012; Dorszewska et al., 2016; Qi et al., 2018). Hence, it has attracted intense interest in the development of novel strategy for detection and imaging of the intracellular Cys, which will further contribute to the better understanding the pathology of associated diseases and their early diagnosis and treatment.

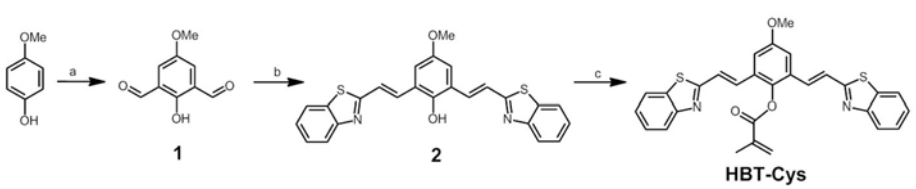
Design and synthesis of small molecule-based fluorescent probe received much attention in molecule recognition and fluorescence signaling in living biosystems due to many advantages of fluorescence technique, such as high sensitivity and selectivity, simplicity, *in vivo* bioimaging (De Silva et al., 1997; Chen et al., 2010, 2016; Chan et al., 2012; Yang et al., 2013; Li et al., 2014; Niu et al., 2015). For bioimaging application, the development of fluorescent probes with near-infrared (NIR, 650–900 nm) emission is more promising due to the merits of deeper tissue penetration and minimum interference from the indigenous fluorescence background of biosystem (Escobedo et al., 2010; Nolting et al., 2011; Yuan et al., 2013; Guo et al., 2014). Additionally, the ratiometric fluorescent probes could provide an inherent reliability originating from its effective self-calibration advantage by monitoring two well-resolved emissions (Kikuchi et al., 2004; Demchenko, 2010; Lee et al., 2015). Although a number of fluorescent probes for Cys detection and imaging have been reported, most of them could not discriminate Cys from Hcy/GSH due to their similar molecular structures and reactivity (Chen et al., 2017, 2018; Li et al., 2017; Liu X. et al., 2017; Nawimanage et al., 2017; Wang F. et al., 2017; Wang Q. et al., 2017, 2018a; Wu et al., 2017; Yin et al., 2017; Yue et al., 2017a,b; Zhang et al., 2017, 2018a,b; Hou et al., 2018; Kim et al., 2018; Ren et al., 2018; Song et al., 2018; Tian et al., 2018; Wang et al., 2018b; Wang J. et al., 2018; Wang L. et al., 2018; Sheng et al., 2019). Several ratiometric fluorescent probes for Cys have been developed (Lv et al., 2014; Feng et al., 2017; Liu G. et al., 2017; Wang F. et al., 2017; Wang L. et al., 2018 Wu et al., 2018; Yue et al., 2018; Zhu et al., 2018), but only a few of them showed the fluorescence emission in NIR region (Feng et al., 2017; Zhu et al., 2018). Therefore, the development of NIR ratiometric fluorescent probe for selective detection of Cys is still a challenging task.

Recently, we have found that the π-conjugation extended benzothiazole derivatives exhibited short-wavelength fluorescence emission in non-polar solvent but the NIR emission in polar solvent, where the NIR fluorescence originated from the deprotonation of phenol group switching on an intramolecular charge transfer (ICT) process (Zhang et al., 2016b). In this work, we envisaged that the masking of phenol group in conjugated benzothiazole derivatives with methacrylate moiety, a Cys-selective recognition site, will result in a short-wavelength emission but a NIR fluorescence will appear in the presence of Cys due to the Cys-selectively induced deprotection, and therefore will allow a NIR ratiometric fluorescence detection of Cys. Accordingly, a new conjugated benzothiazole derivative (**HBT-Cys**, **Scheme 1**) was synthesized and developed as a novel NIR ratiometric fluorescent probe for Cys detection. The probe distinguished Cys well from GSH/Hcy in a ratiometric manner in aqueous solution and successfully applied in living cells imaging.

MATERIALS AND METHODS

All the chemicals are analytical grade that was used without purification and purchased from Sinopharm Chemical Reagents Corp. (Shanghai, China). Phosphate buffered saline (PBS, pH = 7.4) was prepared from K_2HPO_4 (0.1 M) and KH_2PO_4 (0.1 M). The stock solution of the probe **3** was prepared in DMF and all of others species solutions were prepared in deionized water. ^{1}H NMR and ^{13}C NMR spectra were recorded on a Bruker AVANCE III 400 MHz spectrometer. Mass spectra were obtained on AB Sciex MALDI-TOF/TOF^{TM} MS. Fluorescence spectra were measured on Edinburgh FS5 spectrofluorometer with Ex/Em slit widths of 5 nm. The absolute fluorescence quantum yields were obtained on Edinburgh FS5 spectrofluorometer equipped with an integrating sphere (EI-FS5-SC-30). Absorption spectra were obtained on a SHIMADZU UV-1800 spectrophotometer. Confocal fluorescence imaging experiments in living Hela cells were carried out with a Carl Zeiss LSM 700 microscope. Theoretical calculations were performed based on the Gaussian 09 package (Frisch et al., 2010). The ground state and the first singlet excited state geometries of the compounds were optimized in the gas phase using density functional theory (DFT) and time-dependent density functional theory (TDDFT) at the B3LYP/6-31+G(d) level, respectively. The fluorescence emission properties were calculated using TDDFT based on the optimized first singlet excited state geometries, respectively.

HeLa cells were cultured in Dulbecco's Modified Eagle Medium (DMEM) supplemented with 10% fetal bovine serum at 37°C in a 95% humidity atmosphere under 5% CO_2 environment. Then the cells were seeded in confocal microscope culture dishes with a density of 2×10^5 cells per well. The cells were then incubated with probe **HBT-Cys** (20 μ M) for 120 min at 37°C, washed with PBS buffer (10 mM) three times to remove free probe. In the control experiments, the cells were pretreated with NEM (1 mM) for 30 min at 37°C, followed by washing with PBS for three times, and incubated with probe **HBT-Cys** (20 μM) for 120 min at 37°C. In another control experiment, the cells were pretreated with NEM (1 mM) for 30 min at 37°C, followed by washing with PBS three times, then incubated with Cys (200 μM) for 30 min, and further incubated with probe **HBT-Cys** (20 μ M)



SCHEME 1 | Synthesis of **1**, **2**, and **HBT-Cys**. Reagents and conditions: **(a)** hexamethylenetetramine, TFA, 110○C, 72 h; **(b)** 2-methylbenzothiazole, AcO_2, 145°C, 56 h; pyridine, 115°C, 2 h; water, 100°C, 6 h; and **(c)** methacryloyl chloride, acetone, K_2CO_3, r.t., 8 h.

for 120 min at 37°C, respectively. All the cells were washed with PBS three times to remove free probe and then imaged at blue and red channels, respectively in a Carl Zeiss LSM 700 microscope.

The synthesis procedures are illustrated in **Scheme 1**. The compound **1** was facilely synthesized according to the similar procedure described previously (Zhang and Liu, 2016a). Briefly, under an N_2 atmosphere, 4-methoxylphenol (20 mmol) and hexamethylenetetramine (60 mmol) were dissolved in TFA (15 mL) and refluxed at 110°C for 72 h. The mixture was then cooled down to room temperature and poured into a 3 M HCl solution (120 mL). The crude product was obtained by filtration and further purified by column chromatography (silica gel, CH_2Cl_2) to give **1** as a yellow solid (**Figures S3, S4**). Yield: 19%. ^{1}H NMR (400 MHz, DMSO-d_6), δ (ppm): 11.09 (s, 1H), 10.24 (s, 2H), 7.60 (s, 2H), 3.82 (s, 3H). ^{13}C NMR (100 MHz, DMSO-d_6), δ (ppm): 55.89, 121.34, 124.31, 152.12, 156.45, 191.70.

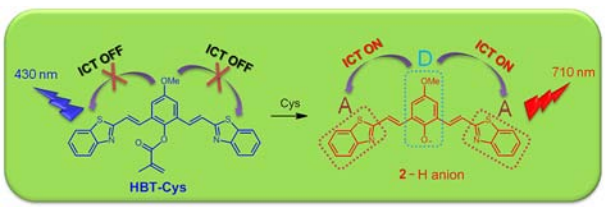
Under an N_2 atmosphere, compound **1** (4 mmol) and 2-methylbenzothiazole (16 mmol) were refluxed in acetic anhydride (3 mL) at 145°C for 56 h. After cooling to room temperature, the solid was obtained by filtration and thoroughly washed by water. The obtained solid was further dissolved in pyridine (19 mL) and refluxed at 115°C for 2 h, then water (10 mL) was added and stirred at 100°C for another 6 h. After cooling down to room temperature, the crude product was collected by filtration and thoroughly washed by CH_2Cl_2 to give **2** as a yellow solid (**Figures S5, S6**). Yield: 72%. ^{1}H NMR (400 MHz, DMSO-d_6), δ (ppm): 9.55 (s, 1H), 8.12 (d, J = 4 Hz, 2H), 8.02-7.98 (m, 4H), 7.68 (d, J = 16 Hz, 2H), 7.53 (t, J = 8 Hz, 2H), 7.45 (t, J = 8 Hz, 4H), 3.86 (s, 3H); ^{13}C NMR (100 MHz, DMSO-d_6), δ (ppm): 55.60, 113.19, 122.12, 122.19, 122.42, 125.32, 125.90, 126.44, 132.05, 133.93, 147.90, 153.12, 153.40, 166.72. MALDI-TOF-MS: m/z calcd for $C_{25}H_{18}N_2O_2S_2$, 442.08; found 442.8298 $[M + H]^+$ (**Figure S9**).

Compound **2** (0.1 mmol) was dissolved in acetone (200 mL) and methacryloyl chloride (0.13 mmol in 5 mL acetone) was slowly added dropwise under stirring at 0°C in the presence of K_2CO_3 (2.0 mmol). Then the mixture was warmed to room temperature and stirred for another 8 h. The reaction mixture was filtrated and the filtrate was concentrated in vacuum. The residue was dissolved in CH_2Cl_2 and then washed with water and the organic layer was dried with $MgSO_4$. After removing $MgSO_4$ by filtration, the crude product was obtained by evaporation under reduced pressure and then purified by column chromatography (silica gel, CH_2Cl_2/ethyl acetate = 30:1 v/v) to give **HBT-Cys** as yellow solid (**Figures S7, S8**). Yield: 45%. ^{1}H NMR (400 MHz, $CDCl_3$), δ (ppm): 8.03 (d, J = 8 Hz, 2H), 7.86 (d, J = 8 Hz, 2H), 7.52-7.46 (m, 6H), 7.41 (t, J = 8 Hz, 2H), 7.28 (s, 2H), 6.61 (s, 1H), 5.99 (s, 1H), 3.92 (s, 1H), 2.20 (s, 3H). ^{13}C NMR (100 MHz, $CDCl_3$), δ (ppm): 18.67, 55.81, 112.86, 121.59, 123.13, 124.90, 125.86, 126.61, 128.52, 130.24, 130.99, 134.14, 135.07, 141.26, 153.31, 157.64, 165.86, 166.61. MALDI-TOF-MS: m/z calcd for $C_{29}H_{22}N_2O_3S_2$, 510.11; found 511.2485 $[M + H]^+$, 533.2472 $[M + Na]^+$ (**Figure S10**).

RESULTS AND DISCUSSIONS

Design and Synthesis

To design a selective fluorescent probe for Cys, a methacrylate group was chosen as the recognition site which can specifically react with Cys *via* conjugate addition/cyclization reaction (Yang et al., 2011; Ma et al., 2017). The conjugated benzothiazole derivatives displayed the large Stokes' shifted NIR fluorescence emission in deprontonated phenolate anion form due to the strong electron-donating ability of phenolate anion induced



SCHEME 2 | The proposed sensing mechanism of the probe **HBT-Cys** toward Cys.

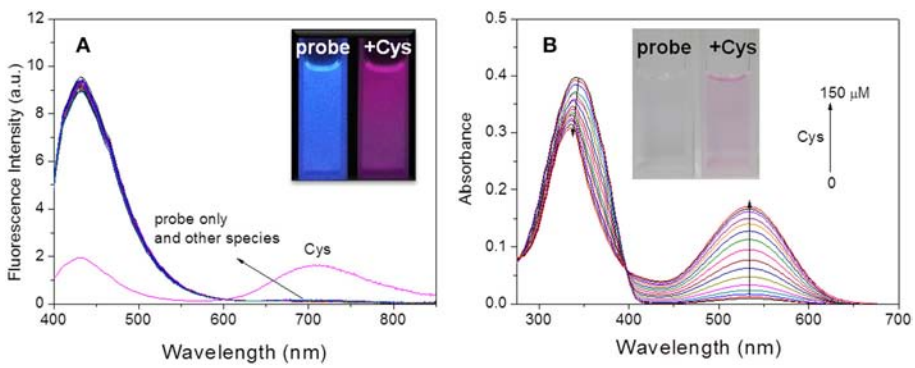


FIGURE 1 | Fluorescence spectra of **HBT-Cys** (10 μM) in the absence and presence of 15 equiv. of various amino acids and biologically relevant species **(A)**. Absorption spectra of **HBT-Cys** (10 μM) upon addition of 0–150 μM Cys **(B)**. Insets are the fluorescence **(A)** and solution **(B)** color change of the probe in the absence and presence of Cys, where the fluorescence in **(A)** was obtained by exposing the solution under UV lamp at 365-nm. The measurements were performed in aqueous PBS buffer solution (pH = 7.4, 50% DMF) and the excitation wavelength was 396 nm for fluorescence measurement.

an occurrence of ICT (Karton-Lifshin et al., 2012; Zhang et al., 2016b), but showed a short-wavelength fluorescence in the neutral phenol form, which allowed a ratiometric detection manner based on two emissions. The novel fluorescent probe **HBT-Cys** was thus readily synthesized by combining methacrylate group into conjugated benzothiazole derivative. As shown in **Scheme 1**, the 2,6-diformyl-4-methoxylphenol (**1**) was firstly synthesized from commercially available 4-methoxylphenol *via* Duff reaction, then the conjugated benzothiazole derivative (**2**) was obtained by a direct condensation reaction between **1** and commercially available 2-methylbenzothiazole, and finally the probe **HBT-Cys** was easily afforded by treating **2** with methacryloyl chloride in acetone. The chemical structures of the probe **HBT-Cys** and intermediate compounds were characterized by ^{1}H NMR, ^{13}C NMR, and MALDI-TOF-MS.

Spectral Properties

The conjugated benzothiazole derivative **2** showed a short-wavelength emission at 500 nm in $CHCl_3$ but a NIR emission at 730 nm in DMF with fluorescence quantum yield of 0.36 and 0.24, respectively (**Figure S1**). The NIR fluorescence emission was observed at 710 nm with a fluorescence quantum yield of 0.085 even in the PBS buffer solution (pH = 7.4, containing 50% DMF). These excellent fluorescence properties allowed compound **2** as a suitable platform to construct the fluorescent probe. As expected, the probe **HBT-Cys** showed a short-wavelength emission at 431 nm in the PBS buffer solution (pH = 7.4, containing 50% DMF), but a NIR fluorescence located at 710 nm appeared with decrease of the short-wavelength emission in the presence of Cys (**Figure 1A**). In contrast, the fluorescence spectra of the probe **HBT-Cys** showed no distinct change upon addition of others species such as common amino acids (GSH, Cys, Hcy, Asp, Asn, Ser, Pro, Ala, Gly, Val, Leu, lle, Thr, Arg, Glu, Gln, Tyr, His, Met, Phe, Trp, Lys, Tau), cations (Na^+, K^+, Ca^{2+}, Mg^{2+}), anions (SO_4^{2-}, NO_3^-, Cl^-), Na_2S, mercaptoacetic acid and glucose. An obvious fluorescence color change from blue to red was observed in the presence of Cys (**Figure 1A**). This indicates that the probe **HBT-Cys** exhibited a high selectivity toward Cys in aqueous solution. Meanwhile, the probe **HBT-Cys** only displayed a strong absorption at 343 nm in the PBS buffer solution (pH = 7.4, containing 50% DMF), and the peak at 343 nm gradually

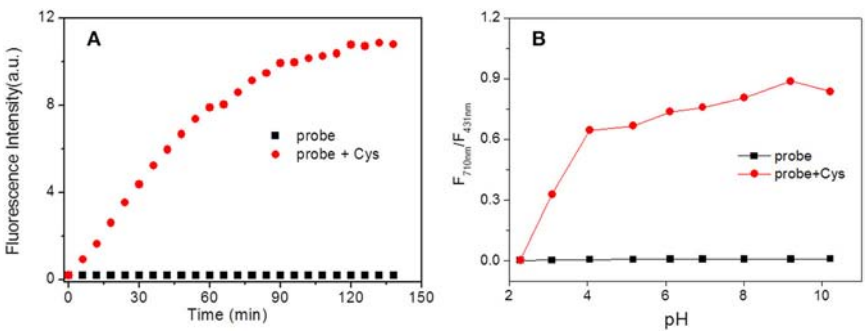

FIGURE 3 | Time **(A)** and pH **(B)** effect on fluorescence intensity of **HBT-Cys** in the absence and presence of Cys. The fluorescence intensity measured at 710 nm in **(A)**. The measurements were performed in aqueous PBS buffer solution (pH = 7.4, 50% DMF) and the excitation wavelength was 396 nm for fluorescence measurement.

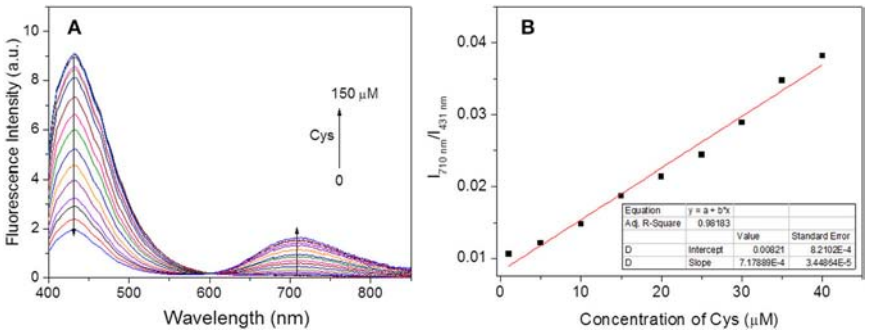

FIGURE 4 | Evolution of fluorescence spectra of **HBT-Cys** (10 μM) with addition of various amount of Cys (0–150 μM) **(A)** and the corresponding linear relationship of fluorescence intensity ratio (I_{710nm} /I_{431nm}) vs. concentration of Cys (0–40 μM) **(B)**. The measurements were performed in aqueous PBS buffer solution (pH = 7.4, 50% DMF) and the excitation wavelength is 396 nm for fluorescence measurement.

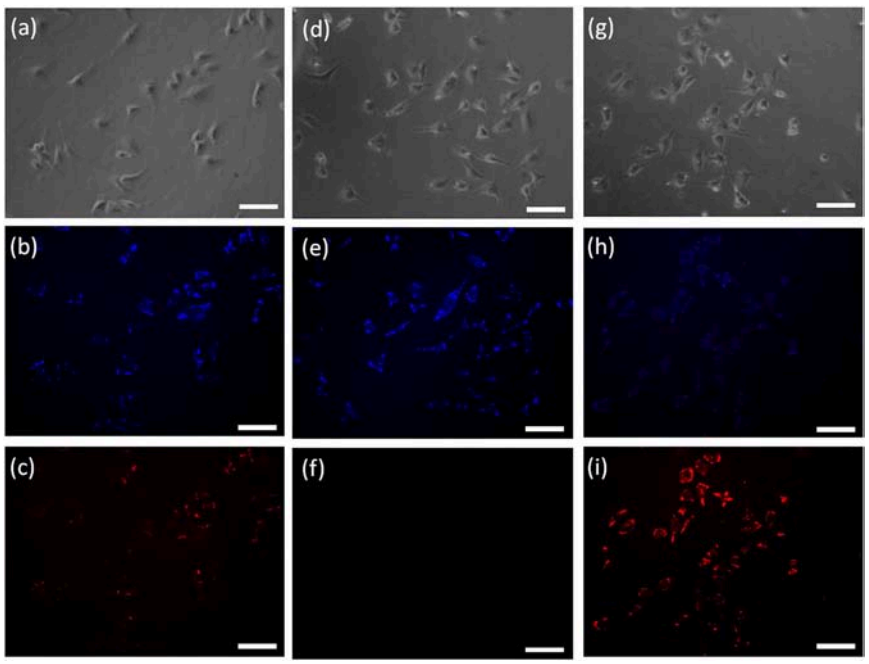

FIGURE 5 | Confocal fluorescence images of living Hela cells incubated with the probe **HBT-Cys** (20 μM) for 120 min at 37°C: cells without treatment **(a–c)**, cells with pre-treatment of NEM (1 mM) **(d–f)**, and cells with pre-treatment of NEM (1 mM) and further addition of 200 μM Cys **(g–i)**. **(a,d,g)** are the bright-field images; **(b,c,e,f,h,i)** are the fluorescence images at blue and red channels, respectively. The scale bar represented 100 μm.

decreased with a significant increase of the absorption at 533 nm upon addition of various amounts of Cys, where an isosbestic point was observed at 396 nm and the solution color turned pink from colorless (**Figure 1B**). No significant absorption spectral change was observed in the presence of others species. These spectral properties suggested that the **HBT-Cys** could serve as a NIR ratiometric fluorescent probe for high selective detection of Cys over Hcy/GSH.

Sensing Mechanism

To confirm that probe **HBT-Cys** has been transformed into **2** in the presence of Cys as shown in **Scheme 2**, ESI-MS mass analysis of a mixture solution of the probe **HBT-Cys** (10 μM) with 10 equiv. Cys was conducted. A prominent peak at m/z = 441 corresponding to the $[\mathbf{2}–H]^-$ anion was observed (**Figure S2**), suggesting the fact that Cys took the methacrylate moiety away from probe **HBT-Cys**. The DFT calculation was further performed to gain better insights into the NIR fluorescence and signaling mechanism. **Figure 2** presented the optimized ground state structures of both the probe **HBT-Cys** and **2**–H anion. Obviously, the π electrons of the probe **HBT-Cys** were well-delocalized on the whole molecular skeleton on both the lowest unoccupied molecular orbital (LUMO) and the highest occupied molecular orbital (HOMO). When the π electrons of **2**–H anion

were still delocalized on the whole molecular skeleton on the LUMO, they mainly localized on the phenolate group on the HOMO, implying a potential ICT process from the phenolate donor (D) to two benzothiazole acceptors (A) as shown in . It has been known that the phenol moiety is a latent electron donor but acts as a strong electron donor when it transformed into phenolate, and could therefore switch on an ICT emission (Karton-Lifshin et al., 2012; Zhang et al., 2016b). Based on the TD-DFT calculation on the excited state, the fluorescence emission wavelengths were predicted to be 739 nm for the **2**–H anion. The well-reproduction of the experimental result implied that the reliability of present theoretical calculation level. Thus, the signaling mechanism could be rationalized as Cys induced removal of methacrylate group and switch on of ICT emission, shown in **Scheme 2**.

Response Time and pH Influence

The time-dependent fluorescence response of the probe **HBT-Cys** with and without Cys was performed, respectively. As shown in **Figure 3A**, the NIR fluorescence intensity at 710 nm was dramatically increased over 60 min and leveled off after about 120 min in the presence of Cys. Without Cys, the NIR fluorescence of the probe **HBT-Cys** displayed no significant changes, suggesting that the probe itself is stable enough under experimental condition. Thus, the spectral measurements of **HBT-Cys** were carried out after 120 min upon addition of Cys in the solution.

The pH influence on the fluorescence of the probe both in the absence and presence of Cys were investigated. Without Cys, the fluorescence intensities ratio (I_{710nm}/I_{431nm}) displayed negligible changes over the range of pH 2.0–10.0 (**Figure 3B**). However, in the presence of Cys, the I_{710nm}/I_{431nm} ratio showed a drastic enhancement after pH $>$ 3 and remained to be almost constant over whole pH region examined. This revealed that the present probe could work in a broad pH region (pH 3.0–10.0) and suitable for imaging under physiological conditions.

Ratiometric Fluorescence Detection and Imaging of Cys

Under the optimal experimental conditions, the ratiometric fluorescence titrations toward Cys were performed. With excitation at 396 nm (an isosbestic point in absorption spectra, **Figure 1B**), it could be seen that the fluorescence emission gradually decreased at 431 nm and increased at 710 nm with increasing Cys amounts up to 150 μM (**Figure 4A**). The I_{710nm}/I_{431nm} ratios followed a good linear relationship ($R^2 = 0.9818$) with Cys concentration ranging from 1–40 μM (**Figure 4B**). The detection limit was estimated to be 0.5 μM according to S/N = 3. Hence, the probe **HBT-Cys** could detect Cys quantitatively by ratiometric fluorescence method with excellent sensitivity.

To evaluate the potential practical applications of probe **HBT-Cys**, the fluorescence imaging of Cys in living HeLa cells were also performed with a Carl Zeiss LSM 700 microscope, where dual blue and red channels were monitored, respectively (**Figure 5**). When HeLa cells were incubated with the probe **HBT-Cys** (20 μM) for 120 min at 37°C, both blue and red fluorescence emissions were observed in two channels (**Figures 5b,c**), where the NIR emission resulted from the intracellular Cys induced removal of methacrylate group in the probe. In the control experiment, HeLa cells were pretreated with N-ethylmaleimide (NEM, a known scavenger for Cys, 1 mM for 30 min), and thereafter incubated with probe **HBT-Cys** (20 μM) for another 120 min. While the blue fluorescence remained, there was no fluorescence in the red channel (**Figures 5e,f**). Then the NEM-pretreated HeLa cells were further sequentially incubated with Cys (200 μM) for 30 min, the probe **HBT-Cys** (20 μM) for 120 min at 37°C. As a result, a bright fluorescence in the red channel was again observed inside cells accompanied by a weak fluorescence in the blue channel (**Figures 5h,i**). These results suggested that the probe **HBT-Cys** can serve as a promising fluorescent probe for Cys imaging in living cells.

CONCLUSIONS

In summary, a benzothiazole-based NIR ratiometric fluorescent probe **HBT-Cys** was developed for selective detection of Cys over Hcy and GSH in aqueous solution. The probe was designed by masking the phenol group in the conjugated benzothiazole derivative through methacrylate group that acts both as a trigger of the ICT fluorescence and recognition site for Cys. Upon addition of Cys, the NIR fluorescence emission at 710 nm was significantly increased with decrease of the fluorescence emission at 431 nm. The fluorescence intensity ratio (I_{710nm}/I_{431nm}) showed a linear relationship with Cys concentration of 1–40 μM with the detection limit of 0.5 μM. Based on mass analysis and DFT calculation, the signaling mechanism of Cys induced removal of methacrylate group and switch-on of the ICT fluorescence was proposed. The fluorescent probe was also successfully used for bioimaging of Cys in living cells, which would provide guidelines for design of novel ratiometric fluoresencent probes in future.

AUTHOR CONTRIBUTIONS

LZ and W-WM were responsible for designing and performing the experiments. YZ and Z-NL were responsible for the characterization of compounds. SX and XZ were responsible for drafting and discussing the manuscript.

FUNDING

This work was financially supported by the State Key Laboratory of Fine Chemicals, Dalian University of Technology (KF 1715), Shanghai Municipal Natural Science Foundation (16ZR1401700), and the Fundamental Research Funds for the Central Universities (PYBZ1827).

Uncovering the Structural Diversity of Y(III) Naphthalene-2,6-Dicarboxylate MOFs Through Coordination Modulation

Sarah L. Griffin[1,2], *Claire Wilson*[1] *and Ross S. Forgan*[1]*

[1] WestCHEM School of Chemistry, University of Glasgow, Glasgow, United Kingdom, [2] EPSRC Centre for Innovative Manufacturing in Continuous Manufacturing and Crystallisation, University of Strathclyde Technology and Innovation Centre, Glasgow, United Kingdom

Metal-organic frameworks (MOFs)—network structures built from metal ions or clusters and connecting organic ligands—are typically synthesized by solvothermal self-assembly. For transition metal based MOFs, structural predictability is facilitated by control over coordination geometries and linker connectivity under the principles of isoreticular synthesis. For rare earth (RE) MOFs, coordination behavior is dominated by steric and electronic factors, leading to unpredictable structures, and poor control over self-assembly. Herein we show that coordination modulation—the addition of competing ligands into MOF syntheses—offers programmable access to six different Y(III) MOFs all connected by the same naphthalene-2,6-dicarboxylate ligand, despite controlled synthesis of multiple phases from the same metal-ligand combination often being challenging for rare earth MOFs. Four of the materials are isolable in bulk phase purity, three are amenable to rapid microwave synthesis, and the fluorescence sensing ability of one example toward metal cations is reported. The results show that a huge variety of structurally versatile MOFs can potentially be prepared from simple systems, and that coordination modulation is a powerful tool for systematic control of phase behavior in rare earth MOFs.

INTRODUCTION

Research revolving around metal-organic frameworks (MOFs)—network structures wherein metal ions or clusters are connected by organic linkers into diverse topologies (Furukawa et al., 2013)—has rapidly increased in recent years following publication of landmark materials in the late 1990s (Chui et al., 1999; Li et al., 1999), with there being ~70,000 MOF structures reported in the Cambridge Structural database as of 2016 (Moghadam et al., 2017). The reason for this interest can be attributed to the permanent porosity and vast range of structural and chemical properties that can be imparted on MOFs, leading to an array of applications from gas storage and separation (Yang and Xu, 2017) to drug delivery and biosensing (Abánades Lázaro and Forgan, 2019). As more MOFs are discovered it is becoming apparent that there is a large range of fascinating topologies accessible, showing diversities in their coordination, solvation, and porosity.

A considerable amount of research focuses on the discovery and synthesis of new frameworks, utilizing a wide range of metals—most commonly transition metals—and organic linkers. We have studied the modulated self-assembly of Zr(IV) (Marshall et al., 2016) and Sc(III) (Marshall et al., 2018) MOFs in detail, yet studies into the synthesis of new yttrium materials appear to be somewhat limited. Whilst yttrium is a *d* block metal, it is considered as a rare earth (RE) metal and displays coordination chemistry similar to the lanthanides when in the Y(III) oxidation state. As such, there are several reports of lanthanide doped Y-MOFs, for example MIL-78 (Serre et al., 2004) and MIL-92 (Surblé et al., 2005), with the possibility of utilizing the inherent luminescence of europium and terbium to impart nitroaromatic detection and tunable photoluminescence properties on the otherwise non-luminescent materials (Singha et al., 2015; Zheng et al., 2015). Of the single metal Y-MOFs reported, several exhibit permanent porosity and high thermal and water stability, leading to a range of potential applications (Weng et al., 2006; Luo et al., 2008; Jiang et al., 2010; Gong et al., 2012; Duan et al., 2013; Kim et al., 2015; Bezrukov and Dietzel, 2017; Mohideen et al., 2018). For example, a 1,2,4,5-tetrakis(4-carboxyphenyl)benzene based Y-MOF has been utilized for indoor moisture control (Abdulhalim et al., 2017), whilst a framework based on a hexa-carboxylate linker showed selective adsorption of C_2H_2 and CO_2 over CH_4 (Liu et al., 2017).

Much like in the synthesis of many other MOFs, coordination modulation—the addition of monotopic linkers as capping agents or crystallization promotors (McGuire and Forgan, 2015)—has been used in the synthesis of Y-MOFs in order to achieve highly crystalline material. Coordination modulation is routinely implemented in the synthesis of MOFs, most commonly enhancing crystallinity and allowing the isolation of single crystals, although under certain conditions, coordination modulation can also control particle size, allowing for the synthesis of nanomaterials (Guo et al., 2012; Chen et al., 2018), or introduce defects throughout a structure whilst maintaining the overall topology (Wu et al., 2013). It should be noted that the use of different modulators in syntheses does not tend to have an effect on the topology of the resultant material. For example, in the case of Zr-MOFs of the UiO topology, the use of different modulators, such as L-proline, benzoic and acetic acid, still results in the formation of the UiO structure, merely with different physical or chemical properties (Schaate et al., 2011; Marshall et al., 2016). Unlike their transition element counter parts however, RE elements have less predictable coordination geometries, resulting in a greater variety of coordination geometries. As a result there is much more difficulty in the prediction of rare earth MOF structures compared to transition metal-based MOFs (Pagis et al., 2016), with coordination modulation potentially perturbing self-assembly to allow isolation of new structures (Decadt et al., 2012). For example, Eddaoudi et al. have introduced 2-fluorobenzoic acid as an efficient modulator of RE MOFs, isolating for example Y-MOFs containing hexanuclear (**Figure 1A**) (Xue et al., 2013, 2015; Luebke et al., 2015) and nonanuclear (**Figure 1B**) (Guillerm et al., 2014; Abdulhalim et al., 2017; Chen et al., 2017) secondary building units (SBUs).

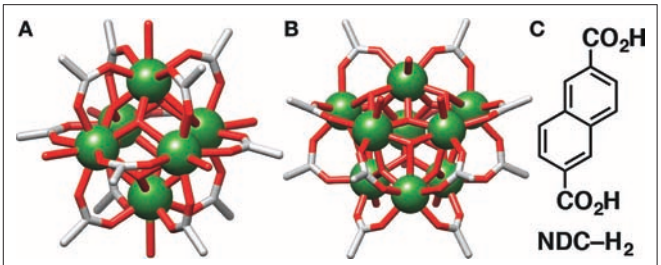

FIGURE 1 | Examples of 12-connected **(A)** $[Y_6(OH)_8(RCO_2)_{12}(H_2O)_6]^{2-}$ and **(B)** $[Y_9(O)_2(OH)_{14}\ (RCO_2)_{12}(H_2O)_7]^{3-}$ SBUs accessible through coordination modulation. **(C)** Chemical structure of the naphthalene-2,6-dicarboxylic acid (NDC-H_2) linker.

Herein, we report an extensive study into the effects of coordination modulation on the crystallization of naphthalene-2,6-dicarboxylic acid (NDC-H_2, **Figure 1C**) Y-MOFs. Contrary to many modulated syntheses in which modulation does not affect overall topology, in this case the use of different modulators led to the crystallization of a range of phases containing Y(III) and 2,6-NDC^{2-}, each exhibiting different coordination, solvation, and void space. The selected modulators ranged in pH, size and functionality. Several of the Y-MOFs were synthesized in bulk with phase purity via solvothermal synthesis, with multiple syntheses also successfully being carried out via microwave assisted heating, considerably reducing synthesis time. The luminescent properties of one of the MOFs were also examined, studying the sensing abilities of the framework in the presence of a variety of metals ions.

RESULTS AND DISCUSSION

Use of different modulators allowed isolation of six different framework structures wherein Y^{3+} cations are linked by 2,6-NDC^{2-} units (see SI, section Synthesis). A summary of synthetic conditions is given in **Table 1**.

Subjecting YCl_3 and 2,6-NDC-H_2 to solvothermal synthesis in DMF at 120°C resulted in the isolation of $\mathbf{[Y_2(NDC)_3(C_3H_7NO)_2]_n}$ **(1)**. **1** is a 3D coordination polymer, which crystallizes in the monoclinic space group $P2_1/c$. The asymmetric unit contains two crystallographically independent Y^{3+} ions having the same connectivity, three 2,6-NDC^{2-} linkers and two DMF molecules. One dimensional chains of Y^{3+} cations running down the crystallographic *c* axis (**Figure 2A**) are connected by carboxylate units of the linkers, with three NDC^{2-} units bridging adjacent metal ions in the $(\eta^1{:}\eta^1{:}\mu_2)$ motif seen in the related $Sc_2(BDC)_3$ MOF (Miller et al., 2005; Perles et al., 2005). The larger size of Y^{3+} compared to Sc^{3+} leads to coordination of one DMF molecule, making the Y^{3+} molecules seven-coordinate (**Figure 2B**), and distancing them further from one another along the chain (Y···Y ∼4.8 Å) than in $Sc_2(BDC)_3$ (Sc···Sc ∼4.4 Å). The chains connect into a net with diamond-shaped pores into which the DMF molecules protrude (**Figure 2C**).

TABLE 1 | Summary of synthetic conditions used to prepare single crystals of Y-NDC MOFs **1**–**6**.

MOF	Y source	Modulator	Solvent	T	Time
1	$YCl_3{\cdot}6H_2O$[a]	None	DMF	120°C	24 h[b]
2	$Y(NO_3)_3{\cdot}6H_2O$	H_2O (2 equiv)	DMF	120°C	24 h
3	$Y(NO_3)_3{\cdot}6H_2O$	HNO_3 (16 equiv)	DMF	120°C/16°C	24 h/72 h
4	$Y(NO_3)_3{\cdot}6H_2O$	Acetic Acid (40 equiv)	DMF	120°C	24 h[c]
5	$Y(NO_3)_3{\cdot}6H_2O$	2-Fluorobenzoic acid (8 equiv)/HNO_3 (40 equiv)	DMF/H_2O (5:1)	120°C	2 h[c]
6	$Y(NO_3)_3{\cdot}6H_2O$	Tartaric acid (0.5 equiv)	DMF/H_2O/EtOH (2:1:1)	80°C	24 h

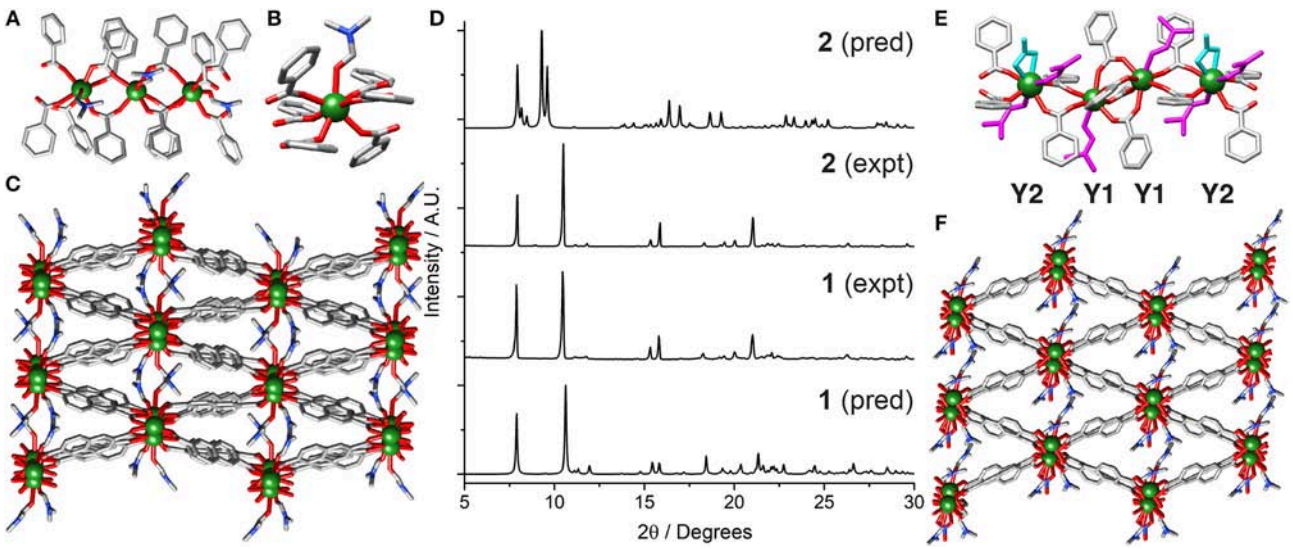

FIGURE 2 | Crystal structure of **1**. **(A)** The one-dimensional chain SBU. **(B)** The coordination sphere of Y1. **(C)** The overall packing structure showing potential porosity. **(D)** Stacked PXRD patterns of bulk samples of **1** and **2** compared to their predicted patterns, confirming crystals of **2** were isolated from material with bulk composition of **1**. Crystal structure of **2**. **(E)** One-dimensional chain SBU with coordinating nitrate (cyan) and DMF (magenta). **(F)** Packing structure showing structural relationship with **1**. H atoms and disorder removed for clarity in all crystal structure images.

The synthesis of **1** can be successfully scaled up to produce the material in bulk with high crystallinity and phase purity, as shown by powder X-ray diffraction (PXRD), which was carried out on a washed and dried sample, showing a close match to the pattern predicted from the crystal structure (**Figure 2D**). Rapid microwave synthesis (Lin et al., 2012) of **1** is also possible. Yttrium chloride was used rather than yttrium nitrate in order to produce single crystals suitable for structure determination X-ray diffraction, however the same structure is produced when using yttrium nitrate (**Figure S1**).

In a synthesis using $Y(NO_3){\cdot}6H_2O$ and NDC-H_2 doped with two additional equivalents of water, it was possible to isolate crystals of $\mathbf{[Y_3(NDC)_4(C_3H_7NO)_4(NO_3)]_{\mathit{n}}}$ **(2)**, from a bulk solid that was shown by PXRD to comprise almost entirely **1** (**Figure 2D** and **Figure S2**). Structure **2** crystallizes in the triclinic space group $P\bar{1}$, with the asymmetric unit containing one and a half Y^{3+} ions, two 2,6-NDC^{2-} linkers, one and a half coordinated nitrate molecules and two coordinated DMF molecules. The unit cell contains two crystallographically independent Y^{3+} centers, one of which is disordered across two crystallographically equivalent positions through an inversion center. The structure is related to **1**; it is comprised of 1D chains of single metal ions, repeating in a $[Y1{\cdots}Y1{\cdots}Y2]_n$ fashion over the independent Y^{3+} ions (**Figure 2E**). The Y1 centers are linked by four bridging NDC^{2-} units with carboxylate groups in the $(\eta^1{:}\eta^1{:}\mu_2)$ motif, with each Y1 linked to an adjacent Y2 by two carboxylates in the same $(\eta^1{:}\eta^1{:}\mu_2)$ motif and the seven-coordinate geometry completed by a DMF solvent molecule. As such, the Y2 centers coordinate to four carboxylate oxygen atoms (two bridging from each Y1 center) with the coordination sphere filled by two DMF molecules and one bidentate nitrate anion, making it eight-coordinate. The Y2 ions are disordered across an inversion center, resulting in two distinct positions 1.3213(3) Å apart with associated disorder of the coordinated ligands. Along the chain, which has the sequence Y1Y1Y2Y1Y1Y2, the Y1···Y1 distance is 4.1635(1) Å,

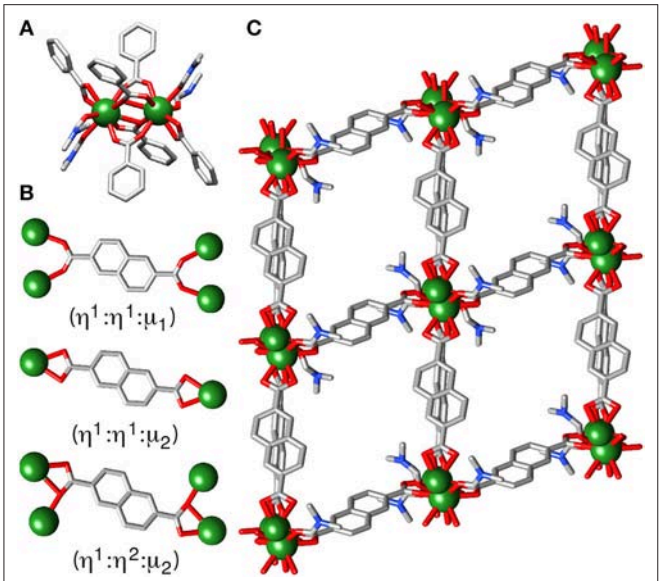

FIGURE 3 | The crystal structure of **3**. **(A)** The dimeric SBU. **(B)** The differing coordination modes of the crystallographically independent NDC^{2-} ligands. **(C)** The packing structure viewed down the *a* axis. H atoms removed for clarity.

while the Y1···Y2 distances are longer and asymmetric, with one Y1···Y2 distance of 5.1434(2) Å and the other of 5.4725(2) Å, likely because Y1···Y1 are connected via four carboxylate groups from four linkers whereas Y1···Y2 are connected by only two carboxylate groups from two linkers. The overall structure looks similar to **1**, with diamond-like pores containing DMF and nitrate ligands pointing into potential pore space (**Figure 2F**).

Attempts to produce phase pure samples of **2**, by deliberate addition of 16 equivalents of nitric acid as a source of nitrate into solvothermal syntheses, resulted in the isolation of $\mathbf{[Y_2(NDC)_3(C_3H_7NO)_4]_n}$ **(3)**, which has a significantly different structure but contains no nitrate. The structure, which crystallizes in the triclinic $P\bar{1}$ space group, has discrete dimeric SBUs (**Figure 3A**) rather than 1D chains of Y^{3+} ions. The asymmetric unit consists of a nine-coordinate Y^{3+} ion, one and a half 2,6-NDC^{2-} linkers and two coordinated DMF molecules. Four NDC^{2-} linkers bridge the binuclear SBU, two with the $(\eta^1{:}\eta^1{:}\mu_2)$ motif and two with the $(\eta^1{:}\eta^2{:}\mu_2)$ motif, with adjacent pairs of Y^{3+} ions in the SBU separated by 3.9933(2) Å and related by an inversion center. The Y^{3+} ions also coordinate to a linker in a terminal bidentate $(\eta^1{:}\eta^2{:}\mu_1)$ motif (**Figure 3B**) and two DMF molecules, making them nine-coordinate. The bridging linkers form square grid-like sheets along the *bc* plane, with the terminal linkers connecting the sheets in an offset manner to form a 3D net with a calculated void space [N_2 probe, Mercury 3.10.3 (Macrae et al., 2008)] of 31.9%, with continuous channels running through the framework along the *a* axis (**Figure 3C**). A discrete complex, $[Y_2(3,5\text{-DHB})_2(CH_3CO_2)_4(H_2O)_4]$ (DHB = dihydroxybenzoate), with a closely related coordination arrangement to the dimeric SBU in **3**, has been observed previously (Dan et al., 2006).

The synthesis of **3** differs from the others in that crystallization occurs at room temperature after the reaction solution has been heated to 120°C for 24 h. Upon removing the reaction jar from the oven, the clear yellow solution (previously colorless) was left undisturbed in a chilled room for a further 3 days, wherein crystallization of block crystals occurred. The reaction was successfully scaled up, proven both visually and by SCXRD, however the framework is not stable to solvent loss as demonstrated by a change in PXRD pattern, highlighting the decomposition (**Figure S3**). Structurally analogous MOFs have been prepared from Ce, Eu, and Tb, which also decompose in air (Wang et al., 2002), although a Nd derivative has shown sufficient stability to allow gas uptake, with $S_{BET} = 150\ m^2g^{-1}$ (Wang et al., 2015).

Subsequently, carboxylate-based modulators were examined. Incorporation of 40 equivalents of acetic acid into the synthesis resulted in the isolation of $\mathbf{[Y(NDC)(CH_3CO_2)(C_3H_7NO)]_n}$ **(4)** as a phase pure material. **4** crystallizes in the triclinic space group $P\bar{1}$, with the asymmetric unit containing an eight-coordinate Y^{3+} ion, one 2,6-NDC^{2-} linker, a coordinated acetate and a DMF molecule. The structure is related to **1**, with one-dimensional chains of Y^{3+} ions bridged by NDC^{2-} linkers, but one NDC^{2-} ligand is replaced by two acetate ligands (**Figure 4A**). The structure can be thought of as containing chains of dimers; two equivalent Y^{3+} ions, related by an inversion center, are bridged by carboxylate units from two NDC^{2-} ligands in the $(\eta^1{:}\eta^1{:}\mu_2)$ motif and two acetates in the $(\eta^1{:}\eta^2{:}\mu_2)$ motif. These dimers are linked to one another by two further NDC^{2-} carboxylates, also in the $(\eta^1{:}\eta^1{:}\mu_2)$ motif, with the Y^{3+} coordination sphere being completed by a DMF molecule. The Y···Y distance within the "dimer" is 3.8689(9) Å, while the Y···Y distance to the adjacent "dimer" in the chain is 5.570(1) Å. **4** has a similar packing arrangement to **1**, with diamond-shaped pores down the *b* axis filled with DMF molecules (**Figure 4B**). Unlike **2**, the sample can be prepared in bulk, with phase purity confirmed by PXRD (**Figure 4C**).

The combination of 2-fluorobenzoic acid, nitric acid, and water as co-modulators for RE MOFs has previously resulted in isolation of MOFs with UiO-66 (Xue et al., 2013) and MIL-88 (Wei et al., 2017) nets, as well as novel topologies (Guillerm et al., 2014). With Y^{3+} and NDC^{2-}, a structure related to MIL-88C is formed, $\mathbf{(CH_3)_2NH_2[Y_3(NDC)_3(HCOO)_3(OH)]_n}$ **(5)**. Structure **5** crystallizes as hexagonal plates (**Figure 4D**) in the $P\bar{3}$ space group, with the asymmetric unit containing one seven-coordinate Y^{3+} ion, one 2,6-NDC^{2-} linker, one formate and one third of a dimethylammonium ion (both generated by decomposition of DMF), and one third of a hydroxyl ion. The framework is comprised of $[Y_3(\mu_3\text{-OH})(RCO_2)_6]$ trimeric SBUs [**Figure 4E**, Y1···O1C = 2.2986(3) Å] linked by NDC^{2-} linkers into the MIL-88C topology (**Figure 4F**). The SBUs, which lie in the *ab* plane, are further connected via two bridging formates per Y^{3+} ion to form a 2D sheet; the distance between neighboring clusters, measured between the oxygen atoms of adjacent bridging μ_3-OH ligands (O1C), is

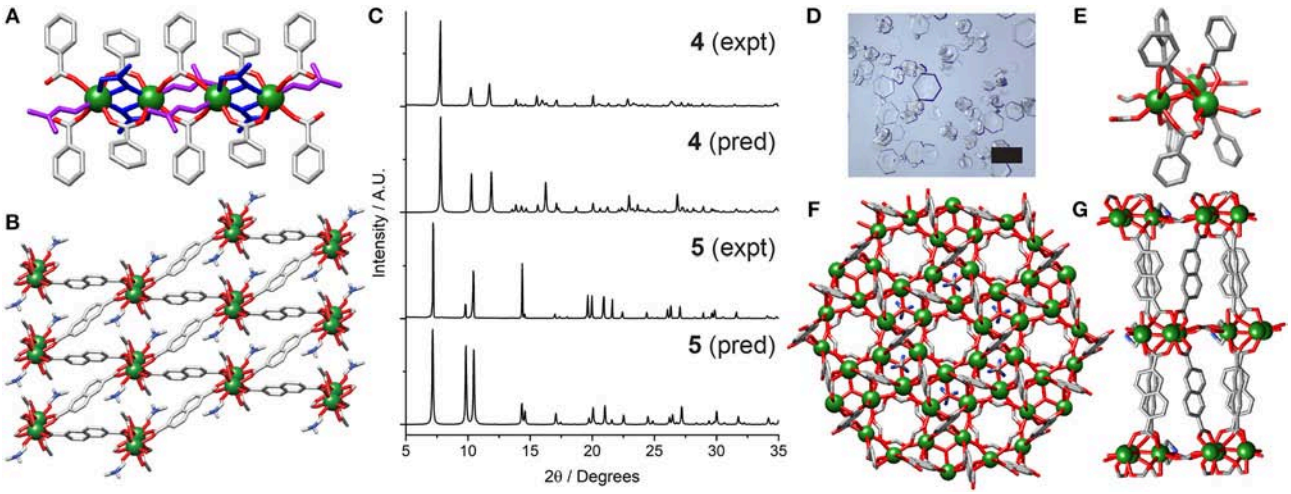

FIGURE 4 | Crystal structure of **4**. **(A)** One dimensional chain SBU, with coordinated acetate (blue) and DMF (magenta). **(B)** Packing structure viewed down the *b* axis. **(C)** Stacked PXRD patterns of **4** and **5** compared to their predicted patterns. **(D)** Optical image of the hexagonal plates of **5**, which give rise to preferred orientation related peak height discrepancies in the PXRD pattern of bulk samples. Scale bar 500 μm. Crystal structure of **5**. **(E)** Trigonal SBU showing bridging formates. **(F)** Packing structure showing solvent inaccessible voids between SBUs. **(G)** Hexagonal packing arrangement viewed down the *c* axis.

10.376(2) Å. Disordered dimethylammonium ions sit in the plane of the clusters, forming NH···O hydrogen bonds to oxygen atoms of the linking formates [N1S···O1F = 3.0180(5) Å] and NDC^{2-} linkers [N1S···O1 = 3.0100(3) Å]. The overall structural formula can be confirmed by ^1H NMR spectroscopic analysis of digested samples, clearly showing the presence of dimethylammonium cations and formate anions with integral ratios consistent with the overall formula (**Figure S6**). The structure has pockets of void space totaling 20.3% of the framework, with the bridging formates preventing a continuous solvent accessible pore (**Figure 4G**). Whilst similar to MIL-88C type structures, the higher coordination number of Y compared to transition metals results in the additional coordination of the formate groups to link the SBUs, expected to limit the breathing nature of **5**, a property associated with transition metal linked MIL-88C materials (Horcajada et al., 2011). The crystal structure of the analogous Er-MOF has recently been reported, with the Y-MOF identified by PXRD (Wei et al., 2017).

Tartaric acid has previously been shown to be an efficient modulator in the synthesis of a mixed metal Y-BDC MOF in a mixed EtOH/water solvent system (Abdelbaky et al., 2014), and so conditions (heating to 80°C for 24 h) inspired by this were implemented with Y^{3+} and NDC^{2-}. Single crystals of $\mathbf{[Y_2(NDC)_3(C_2H_5OH)(H_2O)_3]_n{\cdot}3(C_3H_7NO)}$ **(6)** could be isolated from the resulting gel. **6** crystallizes in the triclinic space group $P\bar{1}$; the crystal structure was determined from a selected crystal and does not represent the bulk material, which, after washing and drying, PXRD analysis confirms to be predominantly **1** (**Figure S7**). The asymmetric unit of **6** contains two Y^{3+} ions, three 2,6-NDC^{2-} linkers, a coordinated ethanol molecule and three coordinated water molecules. Chains of single Y^{3+} ions run along the *bc* plane throughout the framework (**Figure 5A**), alternating in a -Y1-Y1-Y2-Y2- fashion. Each Y^{3+} is bridged by two NDC^{2-} carboxylates in the (η^1:η^1:μ_2) motif and is also bridged by a bidentate NDC^{2-} carboxylate in a (η^1:η^1:μ_1) arrangement. The difference between Y1 and Y2 lies in coordinated solvents; Y1 is coordinated to one water molecule and one ethanol molecule, whilst Y2 is coordinated to two water molecules. Within the linear metal chain there are three different but similar Y-Y distances—Y1···Y1 = 4.742(2) Å, Y2···Y2 = 4.731(2) Å, and Y1···Y2 = 4.8846(2) Å,—highlighting the similarity of the eight-coordinate Y^{3+} ions.

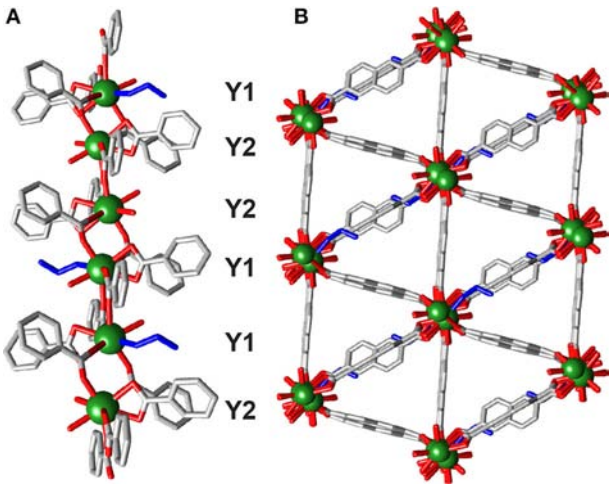

FIGURE 5 | The crystal structure of **6**. **(A)** One dimensional chain SBU, with coordinating ethanol colored blue. **(B)** Packing structure showing significant void space, with ordered DMF guests removed for clarity.

The chains are connected in an approximately hexagonal manner by the NDC^{2-} ligands to form a framework with a 29% void space [N_2 probe, Mercury 3.10.3 (Macrae et al.,

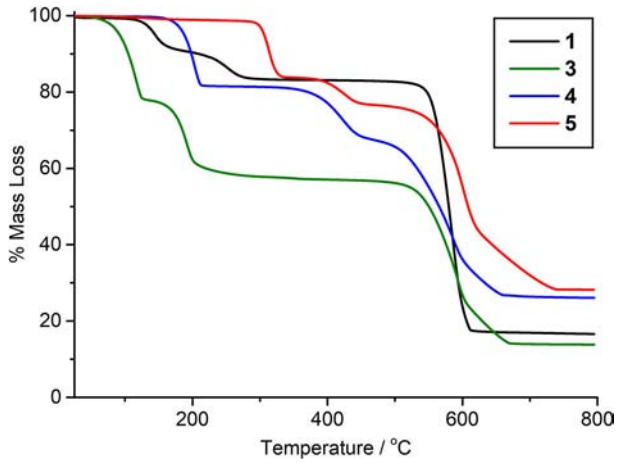

FIGURE 6 | Thermogravimetric analysis in air of **1**, **3**, **4**, and **5**.

2008)], running in disconnected sheets along the *bc* plane (**Figure 5B**) and containing ordered DMF solvent molecules. It was unfortunately not possible to prepare a phase-pure sample of **6**.

By simple modification of synthetic conditions, six different MOFs have been characterized from a single metal-ligand system, with counterions, solvents, and most importantly modulators playing key roles in directing structure formation. Of the six, the syntheses of frameworks **1**, **4,** and **5** were successfully scaled up to produce the materials in bulk with high crystallinity and phase purity, as shown by PXRD which was carried out on washed and dried samples. The predicted and experimental powder patterns show good overlap, while minor discrepancies in peak intensities can be attributed to preferential orientation of the packed powder samples. These three frameworks were also successfully produced through microwave-assisted synthesis. Each was carried out on the same scale as that of the bulk solvothermal synthesis and produced crystalline, phase pure material in 2 h and under compared to 24 h solvothermally (**Figures S4** and **S5**). Compounds **2** and **6** crystallize alongside **1** under specific conditions, while **3** can also be scaled up, but appears to be unstable to drying.

1, **4**, and **5** can be produced in bulk and have potential voids if solvents can be successfully removed. As such, thermogravimetric analysis was carried out on bulk samples (**Figures S8** and **S9**), along with an undried sample of **3**, which is unstable to solvent removal, to assess its bulk composition (**Figure 6**). The TGA profile of **1** shows the stepwise loss of its two DMF molecules, with a mass loss of 8.6% followed by another of 7.5% between 115°C and 290°C. The final weight loss of 66.2% between 525°C and 618°C can be attributed to the organic linkers. Analysis of **4** shows a similar initial loss of coordinated DMF between 154°C and 214°C, followed by a stepped 55.3% mass loss between 340°C and 670°C arising from the loss of acetate and linkers. **5** shows a first weight loss of 16.2% between 287°C and 336°C which closely correlates with the loss of dimethylammonium cations and formate anions.

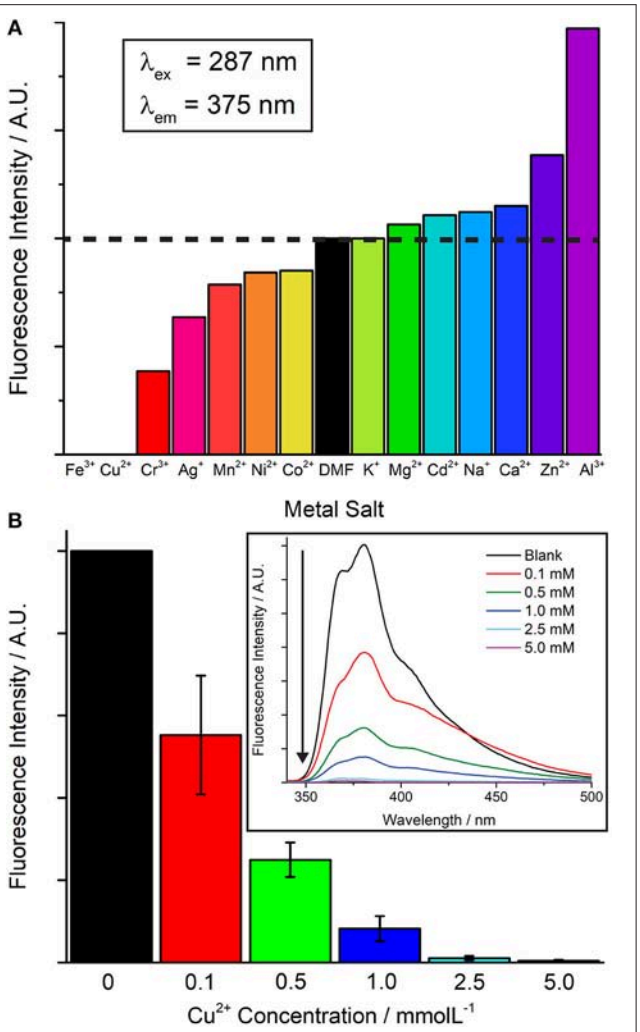

FIGURE 7 | (A) Changes in luminescence of samples of **5** when contacted with 5 mM DMF solutions of metal nitrates. **(B)** Concentration dependence of turn-off sensing of Cu^{2+}. Experiments carried out in triplicate, typical spectra for Cu^{2+} sensing shown as an inset.

The following two-step loss of 55.5% can be attributed to the loss of NDC^{2-} linkers and hydroxide. Due to decomposition of **3** on solvent removal, the material was not fully dried before analysis. As such, the initial 22.1% weight loss between 55°C and 126°C arises from encapsulated DMF. The subsequent mass loss of 20.2% correlates with the loss of coordinated DMF, and is followed by a 43.7% mass loss due to organic linkers, confirming the bulk composition suggested by the single crystal structure.

Despite the ability to remove solvent molecules from the materials, none were found to be porous to N_2 at 77 K. Removal of coordinated DMF from **1** and **4** presumably results in framework collapse, although it is noted that during the peer review period, a Ce(III) analog of **1** was reported which could be desolvated at 300°C to a phase that was porous to CO_2 (Atzori et al., in press). For **5**, whilst the framework does show void space, it is possible that access

to the void channels is blocked due to charge-balancing dimethylammonium ions lying in the cluster layer of the framework.

The luminescence properties of **5** were investigated in DMF solution in the presence of a variety of metal nitrates, with differing extents of cation exchange with the dimethylammonium ions a possible mechanism for fluorescent sensing. The excitation of the free NDC-H_2 linker at $\lambda = 287$ nm leads to an emission maximum at $\lambda = 375$ nm, with a shoulder at $\lambda = 364$ nm, dictating the excitation wavelength for **5**. Finely ground framework **5** (2 mg) was immersed in 5 ml of 5 mM DMF solutions of $M^{x+}(NO_3)_x$ ($M = Ag^+$, Al^{3+}, Cd^{2+}, Ca^{2+}, Cr^{3+}, Co^{2+}, Cu^{2+}, Fe^{3+}, Mn^{2+}, Mg^{2+}, Ni^{2+}, K^+, Na^+, Zn^{2+}) and sonicated for 30 min. The luminescence of **5** can be seen to vary to some degree in the presence of all the metal nitrates (**Figure 7A**). Soaking in Fe^{3+} and Cu^{2+} solutions led to complete quenching of luminescence, whereas Al^{3+} and Zn^{2+} solutions gave rise to a considerable increase in luminescence. The presence of Cd^{2+} and Zn^{2+} notably leads to a shift in the intensity ratio between the 364 and 375 nm peaks, along with the appearance of a new shoulder peak at 350 nm (**Figure S10**).

To examine any potential structural changes, the crystallinity of **5** was examined via PXRD after soaking of the samples for 3 days in the metal nitrate solutions. The crystallinity of **5** is retained in the presence of all metals except Fe^{3+}, where the sample becomes completely amorphous (**Figure S11**). The concentration dependence of Cu^{2+} turn-off sensing was examined, with significant quenching still observed at 0.1 mM concentrations of Cu^{2+} (**Figure 7B**).

CONCLUSIONS

Through the use of a range of different modulators, a series of six yttrium frameworks with the naphthalene-2,6-dicarboxylate linker have been synthesized, each exhibiting different coordination, solvation, and void space. Unlike transition metal frameworks in which coordination modulation can be used to enhance crystallinity or impart structural properties whilst maintaining topology, the same technique when used with yttrium leads to a range of polymorphs, with the modulator instead acting as a structural director. The resultant frameworks show considerable structural diversity and high thermal stabilities, with framework **5** presenting interesting luminescence properties in the presence of metal nitrate solutions. This technique could unlock a vast myriad of new yttrium frameworks, with this work generating six structures resulting from just one linker, and a seventh recently published using 2,6-difluorobenzoic acid as modulator (Liu et al., 2018). The combination of modulation along with alternative linkers, varying in their functionality, length, and connectivity, could lead to diverse further interesting frameworks.

DATA AVAILABILITY STATEMENT

The data which underpin this work are available at http://dx.doi.org/10.5525/gla.researchdata.728.

AUTHOR CONTRIBUTIONS

RSF and SLG devised the Project. SLG carried out the research, CW carried out crystallographic analysis, and RSF supervised the project. All authors contributed to the writing of the manuscript.

FUNDING

RSF thanks the Royal Society for receipt of a URF. We thank EPSRC (EP/K503058, EP/L50497X, EP/M506539, and EP/M508056/1) and the EPSRC Centre for Innovative Manufacturing in Continuous Manufacturing and Crystallisation (EP/K503289/1) for funding this work.

ACKNOWLEDGMENTS

We thank the EPSRC National Crystallographic Service for single crystal data collections (Coles and Gale, 2012). We thank Dr. Ross Marshall for his early contribution to the project, conducting preliminary syntheses and providing useful discussion.

Non-conjugated polymers with luminescence emission property have recently drawn great attention due to their promising applications in different areas. Most traditional organic synthetic non-conjugated polymers required complicated synthesis. Herein, we report a non-conjugated biomass material, carboxymethylated nanocellulose (C-CNC), which is found to be practically non-luminescent in dilute solutions, while being highly emissive when aggregated as nanosuspensions. We propose that the luminescence of C-CNC originates from the through-space conjugation of oxygen atoms and carboxyl groups of C-CNC. Thus, a clearer mechanism of clusteroluminescence was provided with the subsequent experiments. The effects of concentration of C-CNC, solvent, temperature and pH have also been investigated. In addition, ethylenediamine (EDA) has been employed to "lock" C-CNC material via the bonding of amide groups with carboxylic groups. As prepared C-CNC/EDA confirmed that the clusteroluminescence was attributed to the amide moieties and through-space conjugation between oxygen and carbonyl moieties. Density functional theory (DFT) calculations have also been employed to confirm the luminescence mechanism. It is believed that such clustering-triggered emission mechanism is instructive for further development of unconventional luminogens.

Keywords: carboxymethylated nanocellulose, clustering-triggered emission, carboxyl groups, space conjugation, nanomaterials

INTRODUCTION

Over several decades, fluorescent organic molecules and nanomaterials have attracted much attention and interest due to their special photophysical properties and wide applications in areas such as bioimaging, organic light-emitting diodes (OLEDs), light-emitting electrochemical cells (LECs), and phototherapy reagents, etc (Schwartz et al., 2007; Qin et al., 2012; Wang et al., 2012; Cheng et al., 2015; Li et al., 2018c). Initially, fluorescent organic molecules are widely employed in inorganic ion detection, drug analysis, etc (Bian et al., 2014; Li et al., 2018b). However, most of the reported probe molecules have suffered from the aggregation-caused quenching (ACQ) effect and faced the problem of poor solubility, biocompatibility, and solid-state luminescence, which has greatly limited their potential applications (O'Brien et al., 2010; Wu and Butt, 2016; Huang et al., 2019). Until 2001, Tang and co-workers raised the concept of aggregation-induced emission (AIE), and reported AIE luminogens (Luo et al., 2001). Compared to ACQ molecules, AIE luminogens could turn from non-luminescent or weak fluorophors into strong emitters when they are aggregated into nanoparticles in poor solvents or fabricated into thin films in solid state

(Xing et al., 2007; Yamaguchi et al., 2017). Therefore, many AIE luminogens have been synthesized to understand the luminous mechanism due to their unique luminescence (Chen et al., 2013; Qiu et al., 2018). Most AIE luminogens are generally constructed by aromatic groups and conjugated subunits, which function as chromophore centers (Yuan et al., 2014). However, achieving organic fluorescent nanomaterials with aggregation-induced emission is not an easy task as lots of aggregation-induced emission luminogens required complicated synthesis or toxic starting materials.

Recently, some non-conventional luminogens such as non-conjugated polymers, which are free of aromatic building blocks, have been reported due to their unique clustering-triggered emission (CTE) (Yuan and Zhang, 2017; Chen et al., 2018a). Compared to the conventional AIE luminogens, the CTE luminogens are generally more hydrophilic, easy to prepare, and biocompatible, making them ideal for biological and medical applications (Qin et al., 2017; Dou et al., 2018). Typically, these polymers have electron-rich heteroatoms, such as nitrogen (N), oxygen (O), sulfur (S), phosphorus (P) (Zhao et al., 2015; Zhou et al., 2016; Shang et al., 2017). Therefore, the luminescence mechanism may be attributed to clustering of these electronics-rich atoms and subsequent electron cloud overlaps to form extend conjugation to rationalize the unique AIE properties (Shen et al., 2012; Zhu et al., 2015). Moreover, it is found that some natural products also have visible light in concentrated and solid state conditions, such as dendrimers, starch, amino acids and sodium alginate, etc (Wang and Imae, 2004; Ye et al., 2017; Dou et al., 2018; He et al., 2018). Such CTE materials have huge potential in sensing and cell imaging technologies, which could contribute to the development of nano-luminescence materials (Jin et al., 2016; Ma et al., 2016; Li et al., 2017).

Most clustering-triggered emission (CTE) luminogens have been fabricated by precipitation of precursor organic molecules and polymers (Mohamed et al., 2015; Li et al., 2017; Lu et al., 2017). However, few works have explored the luminescence of natural products with low cost and good biocompatibility (Zhao et al., 2016). In this work, we studied the luminescence behavior of carboxymethylated nanocellulose (C-CNC) with rich carboxyl groups (Dong and Roman, 2007; Yang et al., 2016). The as-prepared C-CNC showed excitation/polarity-dependent fluorescence emission, indicating their potential in differentiating solvents with different polarities. Additionally, the effects of concentration of C-CNC, solvent, temperature, pH and amination with EDA have been investigated. Density functional theory (DFT) calculations have also been employed to understand the clusteroluminescent emission that could be attributed to through-space conjugation between oxygen atoms and carbonyl groups (Miao et al., 2016; Zhu et al., 2016). These results should be highly implicative for further understanding the emission of CTE luminogens.

EXPERIMENTAL SECTION

Chemicals and Instruments

The experimental reagents used in this research were isopropyl alcohol, methano, ethanol absolute, N,N-dimethylformamide, tetrahydrofuran, ethylenediamine, monochloroacetic acid, hydrochloric acid, degreased cotton, sodium chloride, sodium hydroxide, sodium carbonate, sodium perborate, and pH buffer. All these materials were AR grade and purchased from Tianjin Kermel Chemical Reagent. Ethanol absolute, N,N-dimethylformamide and tetrahydrofuran were analytical of chromatographic grade. The water used in all experiments was ultrapure water, produced using a Smart-RO ultrapure water system (Hitech Instruments Co., Ltd., Shanghai, China).

The instruments were used as follows: mass flow meter; F97Pro fluorescence spectrophotometer; DF-101S heat collection-constant temperature type magnetic stirrer, Mettler Toledo electronic balance; SHENGYANG Ultrasonic Cleaner, TH21 Heating thermostat.

Characterization

The scanning electron microscopy (SEM) images on the C-CNC were observed with the magnification of 2500–100 000 times via the HitachiS-4800 SEM. After the samples were sonicated for 10–15 min and then dripped onto the conductive adhesive film, the acceleration voltage of this process was 0.5–30 kV. The crystal structure of the sample at an acceleration voltage of 200 kV was observed using a JEM-2100 transmission electron microscope (TEM).

The crystalline phase of the sample was characterized by X-ray diffraction (XRD, Bruker D8 advance) at a wide angle (10–90°) scan in steps of 0.01 degrees. And the functional group on the surface of C-CNC was measured by Fourier transform infrared spectrometer (FT/IR-200, JASCO, Japan), and for each sample, a scan of 50 mg of the sample in the range of 4,000–500 cm^{-1} was recorded with a wave number accuracy of 0.01 cm^{-1}. The X-ray photoelectron spectrum (XPS) of the sample was measured on a MultiLab 2000 XPS (Thermo VG Scientific). ^1H NMR spectra were recorded on an AVANCE III HD 500 MHz spectrometer (Bruker Corp., Karlsruhe, Germany) with D_2O. Theoretical calculations were carried out using the B3LYP/6-31G(d) basis set and density functional theory (DFT). The fluorescence lifetimes of C-CNC were measured on a FLS980 spectrometer (Edinburgh Instruments, UK). The quantum yield (Φ) was determined by a FLS920 spectrometer with an excitation wavelength of 360 nm at 25°C (Edinburgh Instruments, UK). Dynamic light scattering (DLS) was measured on a ZEN3700 (Malvern, UK).

The Preparation of C-CNC

C-CNC was synthesized according to the reported methods (Hebeish et al., 2010). Three gram finely degreased cotton was dispersed in 180 mL isopropanol and mechanically stirred at 25°C for 30 min. A calculated volume of 8 mL 50% NaOH (w/v) was added dropwise over about 10 min and the mixture was continuously stirred at 25°C for 60 min. Monochloroacetic acid (0.4 g) dissolved in 15 mL of isopropyl alcohol and then neutralized with the equivalent amount of Na_2CO_3. After the temperature rose to 60°C, the above mixture continued to stir for 60 min. At the end of this process, the mixture was filtered and suspended in 150 mL of 80% methanol and then neutralized with acetic acid. After the reaction, the sample was washed three times with methanol and dried to obtain C-CNC.

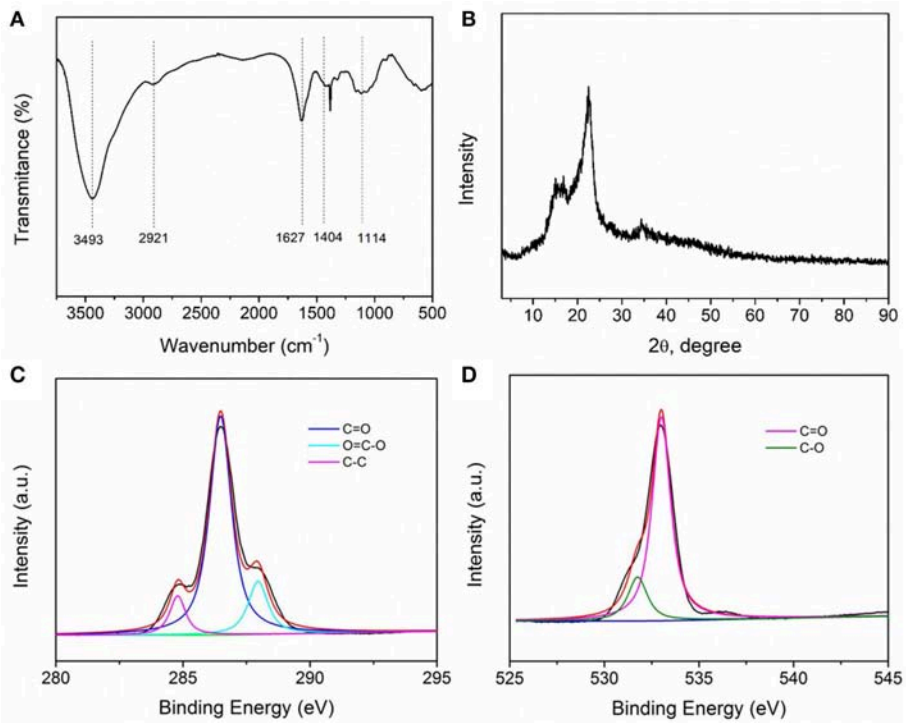

FIGURE 1 | (A) FTIR spectra of C-CNC, **(B)** X-ray diffraction pattern of C-CNC, **(C)** C 1s XPS spectrum of C-CNC, **(D)** O 1s XPS spectrum of C-CNC.

Subsequently, C-CNC was purified by precipitation and freeze dried for further use. The carboxyl group content measured by conductivity was 0.6 mmol/g (**Figure S1**).

The Preparation of C-CNC/EDA

C-CNC (100 mg) and EDA (4 μL) were dissolved in deionized water (50 mL) and mixed uniformly. Then the solution was transferred to a pressure bottle (100 mL) and heated at 100°C for 8 h in a vacuum oven. After the reaction, the reactors were cooled down to room temperature naturally. The prepared sample was directly measured using a fluorescence spectrophotometer.

RESULTS AND DISCUSSION

Characterizations

Fourier Transform Infra-Red (FTIR) spectroscopy was initially employed to understand the structure of C-CNC (**Figure 1A**). A plurality of broad peaks in the 1,000–1,200 cm^{-1} region correspond to -C-O-C- stretching vibration. For the bending vibration mode of -CH_2, the spectrum of C-CNC showed a peak at 2,921 cm^{-1}. The broad peaks in the 3,200–3,600 cm^{-1} region correspond to -OH stretching vibrations. For C-CNC, the main spectra of the peaks at about 1,404 cm^{-1} corresponds to COO- symmetrical stretching vibrations and the peaks at about 1,627 cm^{-1} ascribed to the asymmetric stretching vibrations of COO-. A peak at 3,493 cm^{-1} appeared in the spectrum, ascribed to the -OH stretching vibrations for C-CNC.

As shown in **Figure 1B**, XRD characterization of the C-CNC was performed to investigate the phase structure of the sample. The diffraction peaks of C-CNC at 15.1°, 16.8°, 22.5°, and 34.3° corresponding to the (1-10), (100), (200), (004) crystallographic planes, which indicates the C-CNC belongs to the typical type of cellulose I (Li and Renneckar, 2011; Rafieian and Simonsen, 2014; Du et al., 2016). XPS measurement was examined to further study the chemical state changes of the C-CNC. It can be seen from **Figure 1C** that the high-resolution C 1s XPS spectra of the sample. For the C-CNC, the peak at 288.9 eV (C1) is typically ascribed to the sp^2-bonded carbon (O-C=O). The peak at 287.8 eV (C2) is considered to C=O bond. And the peak at 284.6 eV (C3) could be ascribed to sp^2 C-C bonds. These results confirm the existence of carboxyl groups in C-CNC. The XPS O 1s spectra can be seen from **Figure 1D** with peaks at 530.78 eV and 532.88 eV, corresponding to C-O and C=O bond in the carboxyl group of C-CNC (You et al., 2017). A representative SEM image of the C-CNC can be seen from **Figure S2a**, which shows a rugged surface (Querejeta-Fernandez et al., 2014). **Figure S2b** shows a typical transmission electron microscope (TEM) image of C-CNC. The C-CNCs in water show a substantially clear dispersion with a rod-like morphology (Habibi et al., 2010; Majoinen et al., 2014). The Raman spectrum of C-CNC presents that there is no visible raman peaks with large slits of C-CNC, which may be due to the poor fluorescent intensity of C-CNC solutions (**Figure S3**).

Fluorescent Tests of C-CNC

As a starting point for our research, excitation-dependent fluorescence emission of C-CNC was observed (**Figure S4**). We could see that the bathochromic shift in fluorescence

when the excitation wavelength was increased from 320 to 360 nm. Additionally, it found a slight difference at 320 nm, which might be attributed to the cluster size of C-CNC. Upon addition of organic solvent, C-CNC might form aggregates in different sizes. Aggregates in different size might have different through-space conjugated structures, which made these aggregates with different excitation and emission wavelengths. Additionally, these through-space conjugated structures had a high molecular energy gap and were mainly located in deep UV region, as they cannot form a big conjugated area. As a result, exposure of the sample to different wavelengths meant different energy-matched aggregates would be excited. However, the shape of fluorescence emission did not substantially change with excitation wavelength for normal molecularly dispersed organic chromophores. This result might be attributable to polydisperse through-space-conjugation units consisting of carbonyl moieties (Dou et al., 2018; Ma et al., 2018). Moreover, the 360 nm was selected as the

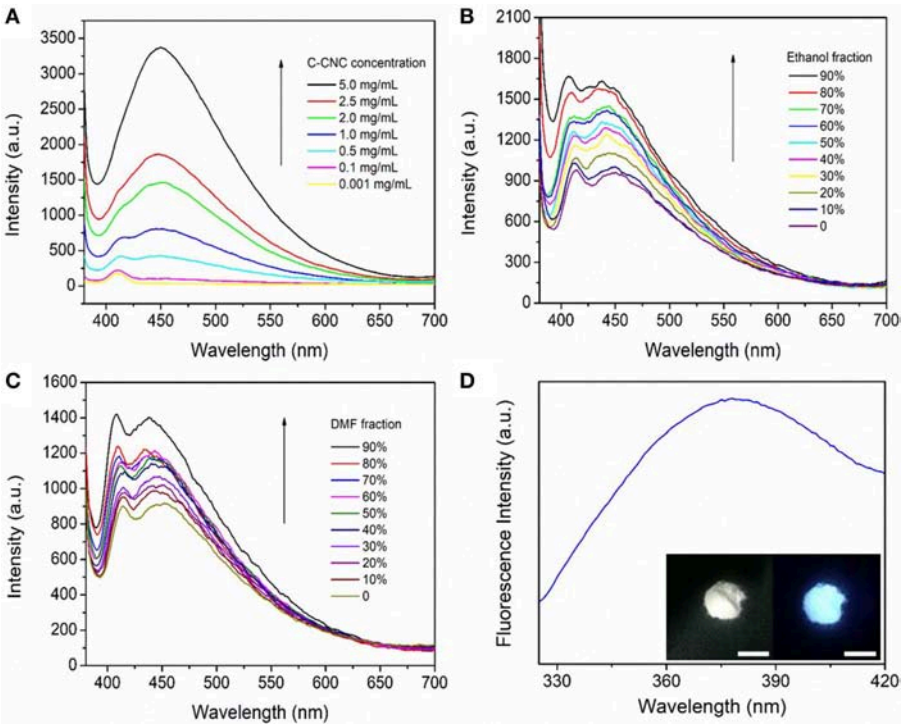

FIGURE 2 | (A) Fluorescence emission of C-CNC at different concentrations in water (excitation wavelength = 360 nm), **(B)** Fluorescence emission of C-CNC (0.5 mg/mL) in mixtures of ethanol and water (excitation wavelength = 360 nm), **(C)** Fluorescence emission of C-CNC (0.5 mg/mL) in mixtures of DMF and water (excitation wavelength = 360 nm), **(D)** Fluorescence emission of C-CNC in the solid state (excitation wavelength = 300 nm). FIGURE 3 | (A) Fluorescence of C-CNC (0.5 mg/mL) in water at different temperatures (25–65°C), (excitation wavelength = 360 nm), **(B)** Fluorescence intensity of C-CNC (excitation wavelength = 360 nm), I_t is fluorescence intensity after UV irradiation and I_0 is fluorescence intensity without UV irradiation.

excitation wavelength with its nice emission intensity in the subsequent experiments.

To get insight into the clustering of C-CNC, the absorption spectra of different concentrations of C-CNC were examined (Qin et al., 2017; Chen et al., 2018b). At low concentrations, we could only see the single maximum absorption peak of C-CNC. With the concentration of C-CNC slowly increasing, a new red-shifted peak appears at 340 nm (**Figure S5a**) (Ma et al., 2018). When the C-CNC reached an optimum concentration of 0.5 mg/mL, the peak intensity increased significantly (**Figure S5a**). These results provide a likelihood for the presence of aggregation in concentrated solutions of C-CNC (Chen et al., 2018b). And the apparent peak of C-CNC around 340 nm was found under excitation (**Figure S5b**). As shown in **Figure 2A**, there was a similar trend between fluorescence and UV-vis spectra of C-CNC solutions. Enhancement of fluorescence was also observed when the concentration of C-CNC was increased, with higher concentrations triggering constant fluorescence enhancement. When the C-CNC concentration reached 5.0 mg/mL, the fluorescence was significantly enhanced, indicating a positive correlation and fluorescence emission of C-CNC (**Figure S5c**). It can be seen from **Figure 2B** that the fluorescence was very low when C-CNC was dissolved in good solvent water. However, the fluorescence intensity gradually increased, as the poor solvent ethanol was added to the C-CNC aqueous solution (Zhou et al., 2016; Qin et al., 2017; Yang et al., 2017). When the fraction of ethanol is 90%, the fluorescence of C-CNC is increased by 1.6 times, which provides conclusive evidence that C-CNC produces cluster-induced luminescence. Moreover, other organic solvents such as N,N-dimethylformamide (DMF) and tetrahydrofuran (THF) had also been employed to verify the clustering-triggered emission. The C-CNC showed fluorescence enhancement as the DMF and THF concentration increased, indicating an interaction between the fluorophore and the solvent (**Figures 2C** and **S5d**), namely, the polarity of the solvent affected the fluorescence emission (Zhao et al., 2015; Miao et al., 2016; Gu et al., 2018). C-CNC showed strong fluorescence emission in the solid state with a quantum yield of 7.8% (**Figure 2D**), meanwhile, the C-CNC aqueous solution exhibited a quantum yield of 12.3% (Crosby and Demas, 1971). Furthermore, the excited state of C-CNC is a double exponential decay process with an average fluorescence lifetime of 3.16 ns, demonstrating its excellent optical properties (**Figure S6**). In the control experiment, the nanocellulose did not show fluorescence enhanced with the

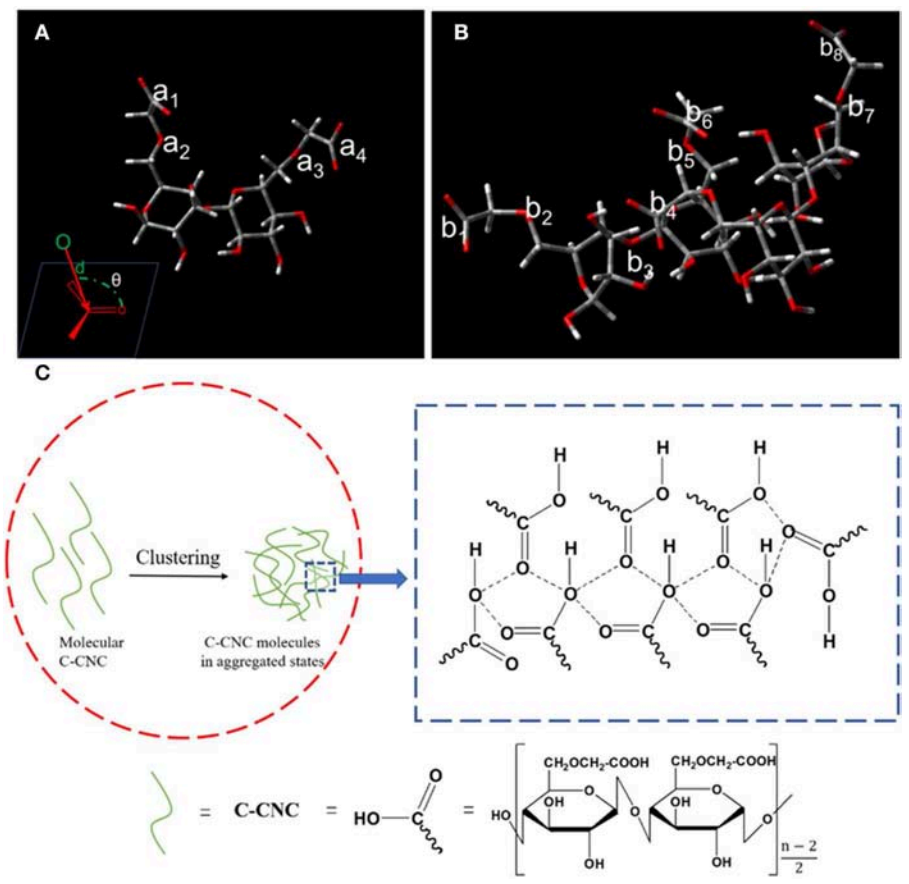

FIGURE 4 | Optimized conformations of C-CNC **(A)**, inset: proposed model of n → π* interaction and C-CNC dimer, **(B)** in water, red sticks = oxygen atoms, gray sticks = carbon atoms, **(C)** Schematic illustration of the emission mechanism of C-CNC.

ethanol concentration increased, which suggested the carboxyl groups were the luminance center of C-CNC (**Figure S7**).

In order to further understand the interactions of carboxyl groups on C-CNC, acid-base stability of C-CNC was also investigated at different pH solutions. Generally, C-CNC showed nice stability in an acidic environment (**Figure S8a**). However, it was found that the fluorescence intensity decreased slightly in an alkaline environment of C-CNC (**Figure S8b**). As shown in **Figure S8c**, the fluorescence intensity of C-CNC was highest at pH = 4, which may be ascribed to the through-space conjugation of carbonyl groups, especially hydrogen bonds increase, leading to the fluorescence enhancement. However, in basic environment, the interactions of carbonyl groups diminished due to the electrostatic repulsion, which resulted in reduced clustering of C-CNC. These results further verify the CTE mechanism of C-CNC.

Subsequently, the emission of C-CNC was measured at different temperatures to determine the effect of temperature. When the temperature was raised from 25 to 65°C, a slight decrease was observed in fluorescence emission (**Figure 3A**). Additionally, the prepared C-CNC was measured by the DLS. It was found that the mean diameter of C-CNC at 25°C was 7.8 nm, however, the mean diameter was decreased to 6.2 nm at 65°C, indicating that the aggregates were reduced after heating (**Figure S9**). This slight change could be ascribed to the fact that an increase in temperature would disturb the interaction of the carbonyl groups, resulting in the interruption of C-CNC clusters, which is consistent with the literature (Ma et al., 2018). In addition, the photostability of C-CNC was examined. Compared with the traditional dyes, fluorescence materials with AIE properties generally show better photostability (Ma et al., 2018). After 20 min of UV irradiation, the fluorescence intensity of C-CNC decreased by about 8% (**Figure 3B**). These results demonstrate that C-CNC possess good anti-photobleaching ability, which is of great importance for further applications.

To further decipher the emission mechanism, DFT calculations were used to investigate the clusteroluminescence. A two-molecule unit was used as the model for calculations. The configurations of C-CNC and C-CNC dimers in water were optimized using DFT, B3LYP/6-31G(d) (**Figures 4A,B**). The intramolecular distance (d) (a_1-a_2, a_3-a_4, **Figure 4A**, inset) of adjacent oxygen and carbonyl moieties was 2.54 Å and 2.54 Å, respectively. The Bürgi-Dunitz trajectory (a_1-a_2 and a_3-a_4) for nucleophilic addition (θ, **Figure 4A**, inset) was about 143° and 88° in individual C-CNC molecules. This indicated that the lone pair (n) on the oxygen atom did not effectively interpenetrate the empty π* orbital of the carbonyl group and through-space conjugation did not occur (Feng et al., 2016; Wang et al., 2017). In **Figure 4B**, the DFT simulation illustrated that the intramolecular distance between adjacent oxygen and carbonyl moieties did not change a lot after formation of the C-CNC dimer. The intramolecular distance between b_1-b_2, b_3-b_4, b_5-b_6, b_7-b_8 was 2.54 Å, 2.47 Å, 2.50 Å and 2.50 Å, respectively. However, the Bürgi-Dunitz trajectory for nucleophilic addition (θ) changed a lot. The θ of b_1-b_2, b_3-b_4, b_5-b_6, b_7-b_8 was 100°, 113°, 119° and 111°, respectively. These results indicated a sub-van der Waals contact (d < 3.22 Å), with the carbon of the acceptor carbonyl group along the Bürgi-Dunitz trajectory for nucleophilic addition (95° < θ < 125°), which caused effective n → π* interaction and through-space electronic interactions. As a result, LUMO orbitals were lowed. The theoretical calculations confirmed that clusteroluminescence can be attributed to through-space conjugation of oxygen atoms and carbonyl moieties caused by clustering of C-CNC (**Figure 4C**).

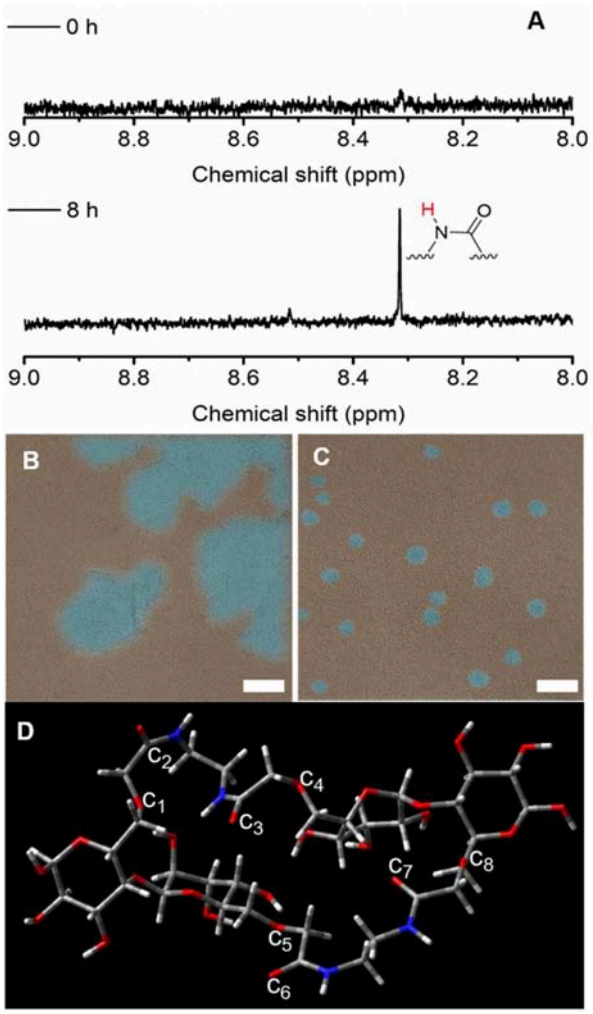

FIGURE 5 | (A) Partial ^{1}H NMR spectra of C-CNC and ethylenediamine in D_2O before (top) and after (bottom) reaction, **(B)** TEM images of aqueous solution of C-CNC and ethylenediamine before and **(C)** after reaction, scale bars = 10 nm, **(D)** Optimized conformation of C-CNC/EDA, red sticks = oxygen atoms, gray sticks = carbon atoms.

Encouraged by this result, we continued our experiment to further confirm the interaction of carboxyl groups for the CTE phenomenon. In this experiment, we used ethylenediamine to react with carboxyl groups on C-CNC in water with

different reaction time (Gómez et al., 2017). The prepared C-CNC/EDA was monitored by ^{1}H NMR. In **Figure 5A**, it was found that no peaks were observed in the region of 8.2–8.4 ppm, but a new peak at ∼8.32 ppm, which was attributed to amide units, indicating that C-CNC/EDA was successfully prepared. In a control experiment, ^{1}H NMR of C-CNC did not show a change in the region of 8.2–8.4 ppm in the absence of ethylenediamine (**Figure S10**). TEM images before the reaction showed only dried random C-CNC aggregates and no nanodots (**Figure 5B**). After the reaction, TEM images of samples that had not undergone any separation or purification clearly showed nanodots with an average diameter of 5 nm (**Figure 5C**). This is further evidence for the amidation reaction between C-CNC and ethylenediamine. As expected, the fluorescence of C-CNC/EDA enhanced with the increase of reaction time compared with C-CNC and ethylenediamine (**Figure S11**). The chemical reactions occurred between the amino group of ethylenediamine and the carboxyl group of C-CNC, which were used to "lock" C-CNC, resulting in promoting the clustering of C-CNC. The results further demonstrate that the enhanced emission of C-CNC may be due to the interactions of carboxyl groups on C-CNC. To further verify the mechanism, DFT, B3LYP/6-31G(d) calculation was used. The distance (d) of c_1-c_2 c_3-c_4, c_5-c_6, and c_7-c_8 was 2.46 Å, 2.44 Å, 2.44 Å and 2.46 Å, respectively (**Figure 5D**). The Bürgi-Dunitz trajectory (θ) of c_1-c_2 c_3-c_4, c_5-c_6, and c_7-c_8 was 125°, 124°, 89° and 91°, respectively. Compared with the C-CNC cluster, it was surprisingly found that less O and carbonyl C couples formed effective $n \rightarrow \pi^*$ interaction in the C-CNC/EDA, which was inconsistent with our hypothesis. Therefore, such high fluorescence intensity may be attributed to the introduction of amide units, leading to through-space interaction of amide groups electrons resembling to those of aromatic structure caused by hydrogen bond (Feng et al., 2016). These results demonstrate that the enhanced fluorescence was caused by through-space conjugation of amide introduced. Furthermore, C-CNC was also investigated for its chiroptical properties. Interestingly, both C-CNC and C-CNC/EDA showed chirality (**Figure S12**), neither C-CNC nor C-CNC/EDA induced significant changes at detected concentrations, indicating that the chirality can be maintained very well after chemical modifications (Li et al., 2018a). The chirality of C-CNC could be further investigated for chiral sensing applications in future research.

CONCLUSION

Biomass material, C-CNC, was used to prepare CTE nanomaterials via a chemical carboxylation method. The C-CNC had a good quantum yield of 7.8% and 12.3% in solid state and aqueous solutions, respectively. It also had a lifetime of 3.16 ns and showed excitation/polarity-dependent emission. Both experimental and DFT calculations have been employed to confirm that the clusteroluminescent emission originates from the intermolecular through-space conjugation between oxygen atoms and carbonyl groups on C-CNC. In addition, the prepared C-CNC/EDA also confirmed that the clusteroluminescence was attributed to the amide moieties and through-space conjugation between oxygen and carbonyl moieties. We believe our work not only provides an easy and green preparation of CTE nanomaterials, but gives a new possible mechanism of fluorescence emission of non-conjugated materials.

DATA AVAILABILITY

The raw data supporting the conclusions of this manuscript will be made available by the authors, without undue reservation, to any qualified researcher.

AUTHOR CONTRIBUTIONS

ML designed the experiments, analyzed experimental results, and wrote the manuscript. XL and XA carried out the experiments. ZC and HX analyzed experimental results and provided guidance.

FUNDING

The present work is supported by the National Natural Science Foundation of China (Grant #: 21607044). This work was also supported by Natural Science Foundation of Hebei Province (Grant #: B2017502069) and the Fundamental Research Funds for the Central Universities (Grant #: 2018MS113).

A Saccharide Chemosensor Array Developed Based on an Indicator Displacement Assay Using a Combination of Commercially Available Reagents

*Yui Sasaki, Zhoujie Zhang and Tsuyoshi Minami**

Institute of Industrial Science, University of Tokyo, Tokyo, Japan

Herein, a very simple colorimetric chemosensor array is reported for saccharides (D-glucose, D-fructose, D-xylose, D-galactose, D-mannose, L-rhamnose, and *N*-acetyl-D-gluosamine). While various types of chemosensors for saccharides have been investigated extensively to-this-date, tremendous additional efforts are still required on a regular basis for the syntheses of new chemosensors. Complicated syntheses would be a bottleneck, given that artificial receptor-based chemosensing systems are not so popular in comparison to biomaterial-based (e.g., enzyme-based) sensing systems. Toward this end, chemosensor array systems using molecular self-assembled materials can avoid the abovementioned synthetic efforts and achieve simultaneous qualitative and quantitative detection of a number of guest saccharides. Using a practical approach, we focus on an indicator displacement assay (IDA) to fabricate a chemosensor array for colorimetric saccharide sensing. On this basis, 3-nitrophenylboronic acid (3-NPBA) spontaneously reacts with catechol dyes such as alizarin red S (ARS), bromopyrogallol red (BPR), pyrogallol red (PR), and pyrocatechol violet (PV), and yields boronate ester derivatives with color changes. The addition of saccharides into the aqueous solution of the boronate esters induces color recovery owing to the higher binding affinity of 3-NPBA for saccharides, thus resulting in the release of dyes. By employing this system, we have succeeded in discriminating saccharides qualitatively and quantitatively with a classification success rate of 100%. Most importantly, our chemosensor array has been fabricated by only mixing low cost commercially available reagents *in situ*, which means that complicated synthetic processes are avoided for saccharide sensing. We believe this simple colorimetric assay that uses only commercially available reagents can create new, user-friendly supramolecular sensing pathways for saccharides.

INTRODUCTION

To-this-date, the analysis of monosaccharides has been proven particularly important in the field of food chemistry because the monitoring of foodstuff quality and the investigation of illegal additions of saccharides into fruit juices or honey are highly required (Tůma et al., 2011). Monosaccharides, such as D-(+)-glucose (Glc), D-(−)-fructose (Fru), D-(+)-xylose (Xyl), D-(+)-galactose (Gal),

D-(+)-mannose (Man), L-(+)-rhamnose (Rha) and *N*-acetyl-D-(+)-glucosamine (NAcGlc) are generally contained in food or beverages (Martínez Montero et al., 2004), and are conventionally analyzed using instrumental methods (e.g., high-performance liquid chromatography (HPLC) (Schmid et al., 2016) and/or mass spectrometry (MS) (Žídková and Chmelík, 2001) owing to their increased accuracy and reliability. Unfortunately, these methods are associated with increased-costs that incur owing to the use of expensive equipment, relatively complicated procedures, and the necessity of trained personnel. In the efforts to simplify the detection of saccharides, optical chemosensors have been researched extensively (Sun and James, 2015; You et al., 2015). Chemosensors exhibit color and/or fluorescence changes by capturing guest molecules. Accordingly, we can easily recognize the evoked results by simple visual inspection. However, conventional methods used to develop a single chemosensor require a complicated multi step synthesis process (Liu et al., 2015). The latter would prevent the increase of the popularity of the chemosensors in the field of analytical science and industry. In this regard, a molecular self-assembly (Bull et al., 2013) inspired by nature is utilized to prepare saccharide chemsensors *in situ* (Miyaji and Sessler, 2001; Strongin et al., 2001; Sasaki et al., 2017). Herein, we only used a combination of commercially available and inexpensive reagents for the preparation of saccharide chemosensors. This means that 3-nitrophenylboronic acid (3-NPBA) (Hall, 2011) is employed as the saccharide receptor and a catechol dye, such as alizarin red S (ARS), bromopyrogallol red (BPR), pyrogallol red (PR), and pyrocatechol violet (PV), is used as the indicator (Minami et al., 2016) (**Figure 1**). First, mixing the 3-NPBA and catechol dyes yields boronate esters accompanied by color changes (Springsteen and Wang, 2001; Kubo et al., 2005). Subsequently, a color recovery can be observed by the addition of saccharides because of the dissociation of boronate esters between 3-NPBA and dyes (Ma et al., 2009). This indicator displacement assay (IDA) (Nguyen and Anslyn, 2006), that is used as a sensor array, provides a finger print-like response to saccharides and leads to excellent discrimination results (Maximilian Bojanowski et al., 2017). These results indicate that the smart and appropriate combination of general reagents minimizes synthetic efforts in laboratories, thereby allowing a simplified and easy preparation of supramolecular chemosensors.

MATERIALS AND METHODS

Materials

ARS, Fru, Glc, Xyl, and NAcGlc, were purchased from FUJIFILM Wako Pure Chemical Corporation (Osaka, Japan). Additionally, 3-NPBA, BPR, PR, PV, Gal, Man, and Rha, were purchased from the Tokyo Chemical Industry Co. Ltd. (Tokyo, Japan). Disodium hydrogenphosphate dodecahydrate and sodium dihydrogenephosphate dihydtare were purchased from the Kanto Chemical Co. Inc. (Tokyo, Japan). Diluted solutions used for all photophysical experiments were prepared using Mill-Q water (18.4 MΩ).

Measurements

UV-vis spectra were measured by a Shimadzu UV-2600 spectrophotometer. UV-vis spectra were recorded within the wavelength range from 350 to 800 nm. Scans were acquired under ambient conditions at 25°C. Saccharide titrations were conducted in a phosphate buffer solution (100 mM) with a pH of 7.4 at 25°C. Titration isotherms were obtained from the changes in the absorption maximum at 455 nm for ARS, 540 nm for BPR, 535 nm for PR, and at 497 nm for PV, respectively. Titration curves, obtained by plotting the change in absorption, were analyzed using non-linear least-squares methods and the equations for the one to one binding model and the IDA model (Hargrove et al., 2010). Equations 1 and 2 were used to fit the UV-vis measurement results,

$$[H]_t = [H] + \frac{K_G\,[H]}{1+K_G\,[H]}\,[G]_t + \frac{K_I\,[H]}{1+K_I\,[H]}\,[I]_t \quad (1)$$

$$A = \frac{[I]_t}{1+K_I\,[H]}\left(\varepsilon_I\, b + \varepsilon_{HI}\, b\, K_I\,[H]\right) \quad (2)$$

where $[G]_t$, $[H]_t$, $[I]_t$, are the total concentrations of saccharides (as the guests), 3-NPBA (as the host), and for the catechol dyes (as the indicators), respectively. Moreover, K_I and K_G are the binding constants of the indicator to the host and the guest to the host, respectively. Furthermore, [H] donates the unknown concentration of the host. The [H] value could be determined using K_I and K_G, and with the use of the experimentally obtained values $[G]_t$, $[H]_t$, and $[I]_t$. Additionally, ε_I and ε_{HI} are the molar absorptivities of the indicator and the complex of the host and the indicator, respectively. Equivalently, A and b are the saccharide concentration-dependent absorbance and the thickness of the cuvette, respectively.

The array experiment for qualitative and quantitative analyses was performed in 384-well microplates. The fluids [phosphate buffer (100 mM) at pH 7.4, ARS, BPR, PR and PV (40 μM), 3-NPBA (6 mM), and the analyte solutions (100 mM)], were eliminated with a contact-free dispenser as follows. Each experiment was carried out in 24 repetitions. Each well received 90 μL of the buffer solution which contained the catechol dyes and 3-NPBA. Subsequently, 10 μL of analyte solutions or water were dispensed. After this period, the plate was shaken for 3 min. UV-vis spectra were measured by a Biotek SYNERGY H1 microplate reader. The UV-vis spectra were recorded from 400 to 620 nm. The resulting absorption data were applied to the Student's *t*-test to exclude four outlier data points (from the total of 24 repetitions) (Minami et al., 2012). The coefficient of variability of the data was lower than 6%. In the case of qualitative analyses, the obtained data was analyzed using linear discriminant analyses (LDA) (Anzenbacher et al., 2010) without any further pretreatment. The semi quantitative analyses were conducted using LDA after an analysis-of-variance (ANOVA) test. A support vector machine with a principal component analysis preprocessing (PCs = 3) was used for the quantitative assay of the Glc and Fru mixtures.

RESULTS AND DISCUSSION

First, the complexation of catechol dyes and 3-NPBA in a phosphate buffer (100 mM) at pH 7.4 at 25°C was investigated using UV-vis titration experiments. As shown in **Figure 2**, the absorption spectra of the catechol dyes were shifted as a function of increasing the concentration of 3-NPBA. For example, a significant blue shift ($\Delta\lambda = 46$ nm) was observed in the case of ARS. These responses indicate the formation of the dynamic covalent bond (i.e., boronate esterification), which is identified by fast-atom-bombardment (FAB) mass spectrometry (see the **Supplementary Material**). The associated constants (K_Is) of

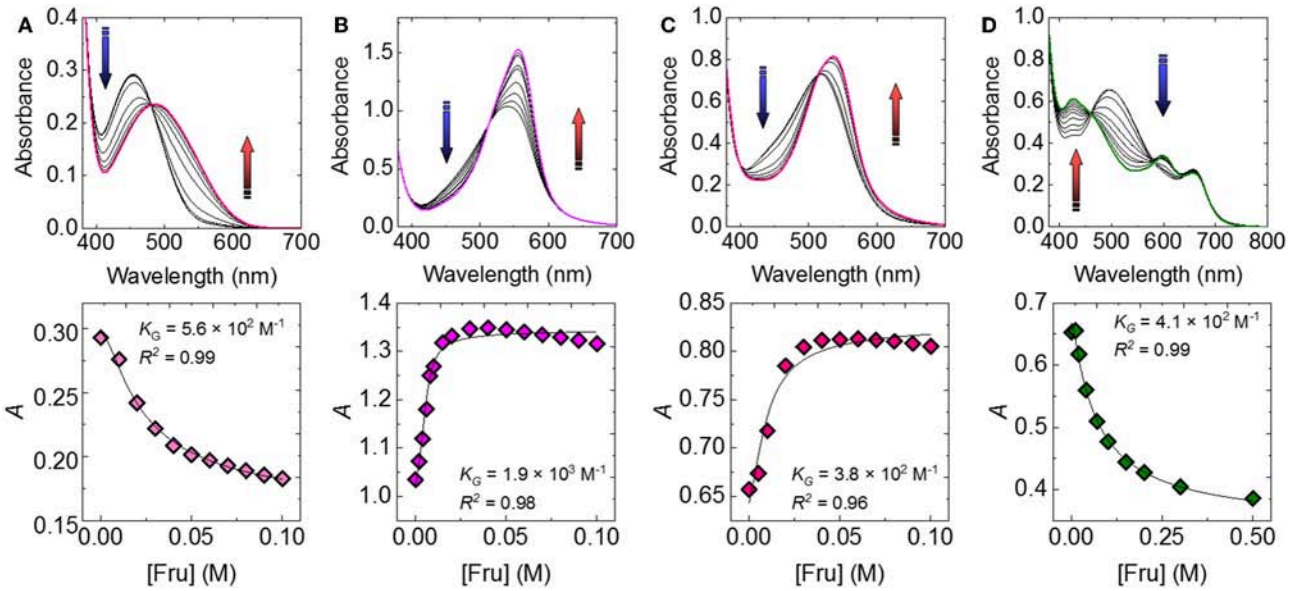

FIGURE 3 | UV-vis spectra of the catechol dye (40 μM)-3-NPBA (6 mM) complex upon the addition of Fru in a phosphate buffer solution (100 mM) at a pH of 7.4 and at 25°C for **(A)** ARS-3-NPBA, **(B)** BPR-3-NPBA, **(C)** PR-3-NPBA, and **(D)** PV-3-NPBA.

these complexes were estimated to be 2.1 × 10^3 M^{-1} for ARS, 4.8 × 10^2 M^{-1} for BPR, 6.7 × 10^2 M^{-1} for PR, and 4.6 × 10^3 M^{-1} for PV.

Subsequently, we attempted to detect seven types of monosaccharides (Fru, Glc, Xyl, Gal, Man, Rha, and NAcGlc) which are generally contained in food or beverages. **Figure 3**

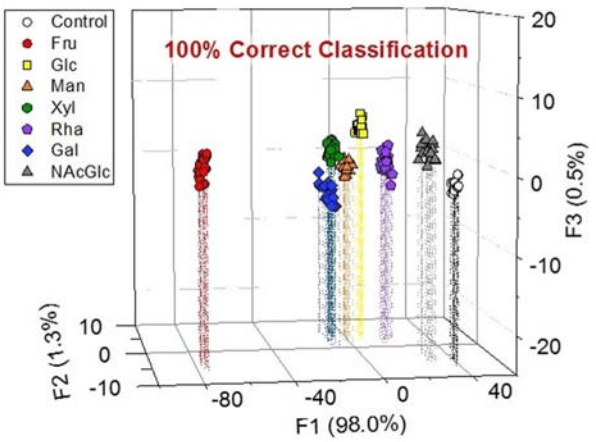

FIGURE 5 | LDA plot for the response of the colorimetric chemosensor array showing the seven types of saccharides (and control) in a phosphate buffer solution at a pH of 7.4 at 25°C. [Saccharide] = 100 mM. Twenty repetitions were measured for each analyte. The cross-validation routine shows a classification success rate of 100%.

shows the UV-vis titration results of Fru as example. The spectral shift by the incremental Fru concentration was observed to be accompanied by the recovery of the color. The observed recovery suggests that the complexation of 3-NPBA and saccharide occurred on the basis of IDA. Importantly, colorimetric finger print-like responses were obtained by changing the combination of catechol dyes and saccharides (**Figure 4**). The binding constants between 3-NPBA and saccharides in the presence of catechol dyes are summarized in **Table 1**. The calculate K_Gs were comparable to previously reported colorimetric saccharide chemosensors based on PBAs (Koumoto and Shinkai, 2000; Springsteen and Wang, 2002). From the standpoint of the pattern recognition algorithm, the cross-reactive selectivity is very useful in discriminating various analytes with a high classification accuracy.

Because the finger print-like response encouraged us to fabricate the chemosensor array, we decided to attempt a high-throughput saccharide sensing test. Among the pattern recognition algorithms, we employed LDA as one of the available supervised methods to a) reduce the dimensionality and b) classify the multivariate data. To discriminate analyte patterns, a mathematical model is firstly constructed using a training dataset, which is subsequently evaluated by cross-validation protocols. In our case, a leave-one-out cross-validation protocol (i.e., the jackknife method) was conducted to evaluate the level of correct classification of the observations within the clusters (Anzenbacher et al., 2010). In this assay, 20 repetitions were conducted to confirm reproducibility. We succeeded in discriminating eight clusters (control and seven saccharides, with a total of 160 data points) with a classification success rate of 100% (**Figure 5**). Interestingly, the position of the Fru cluster is far from the control cluster, most probably owing to the fact that Fru induced the strongest colorimetric response among the tested saccharides. Thus, we can conclude that the LDA plots reflect appropriately the colorimetric responses of the tested saccharides. According to the result of ANOVA (**Supplementary Figure 15**), the contribution of BPR for discrimination is much higher than the other three dyes. It seems that the relatively high contribution of BPR caused the high F1 value. However, the contribution of the other three dyes is not ignorable. In the absence of ARS, PR or PV, we could not achieve 100% correct classification. Therefore, LDA using four dyes with 3-NPBA is required to discriminate target saccharides.

Although Musto et al., previously reported a qualitative discrimination of saccharides with the use of a colorimetric assay (Musto et al., 2009), quantitative assays for saccharides have not been fully investigated. We thus attempted to apply a semi quantitative assay for Fru and Glc. Beverages, such as fruit juices and wines, generally contain saccharides at concentrations in the range of several tens to hundreds of mM (Han et al., 2016). The LDA was also conducted as the pattern recognition in the semi quantitative assay. This means that the LDA score plots for concentrations in the range of several tens of mM of Fru and Glc were clearly discriminated with classification success rates of 100% (**Figure 6**). The notable point of the assay is that these cluster positions possess significant trends depending on the saccharide concentrations, which is in agreement with the results of the UV-vis spectroscopic titrations.

From the viewpoint of practical sensing applications, a regression assay for complexed media is necessary. Finally, we demonstrated a quantitative assay for a mixture of Fru and Glc. In this assay, various mixture samples containing eight different concentrations of each saccharide were prepared and were injected in the colorimetric sensor chip. The concentration of Fru was adjusted to gradually decrease, while the concentration of Glc was gradually increased relative to Fru. Owing to the complicated optical responses of the chemosensor array, we employed a support vector machine algorithm (SVM) (Hamel, 2009). The SVM is a powerful analytical method for a quantitative assay, such as the simultaneous prediction of species and concentrations. This method enables the creation of a linear regression line even though an original inset dataset does not show a linear correlation (e.g., analysis of mixed components). The measured UV-vis spectra of chemosensors were analyzed by the SVM, and then unknown concentrations of saccharides in the mixtures were predicted (**Supplementary Figure 20**). The predicted concentrations (circle dots in **Supplementary Figure 20**) closely exist on the calibration regression linear line. This indicates that we predicted successfully the saccharide concentrations in the mixtures. The relatively low values of the root-mean-square errors (RMSEs) also indicate the high accuracy of the model and its predictive capacity. To the best of our knowledge, this is the first example that accomplishes colorimetric regression analyses of saccharides in mixtures using only a simple and an appropriate combination of commercially available reagents.

CONCLUSION

In summary, we demonstrated the qualitative and quantitative detection of monosaccharides with a simple colorimetric chemosensor array. Owing to the reduced complexity of

TABLE 1 | Binding constants (K_G M^{-1})[a] on the basis of the indicator displacement assay.

Dye	Fru	Gal	Glc	Xyl	Man	NAcGlc	Rha
ARS	560 ± 71	110 ± 11	52 ± 4	41 ± 6	<10	<10	17 ± 2
BPR	1900 ± 39	230 ± 24	150 ± 6	110 ± 5	110 ± 13	<10	46 ± 4
PR	380 ± 38	<10	<10	<10	<10	<10	<10
PV	410 ± 49	33 ± 6	16 ± 1	12 ± 2	<10	<10	<10

[a]*Binding constants were calculated using the change in the UV-vis absorption upon the addition of the analyte in a phosphate buffer solution (100 mM) at a pH of 7.4 at 25°C. All the errors of the binding constants are <19%. Five repetitions were measured for each analyte.*

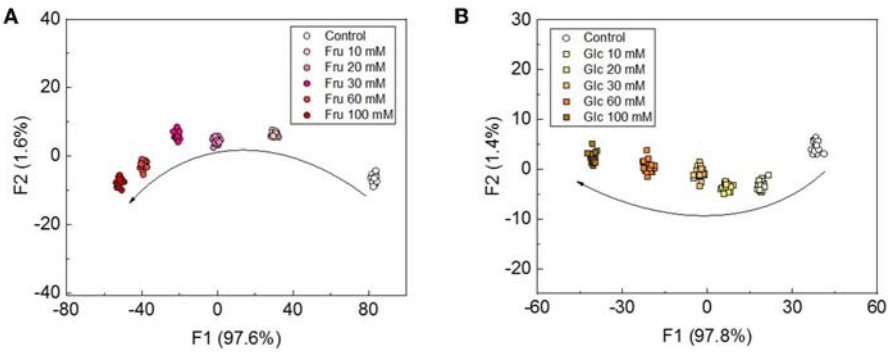

FIGURE 6 | LDA plots for the semi-quantitative assay for **(A)** Fru and **(B)** Glc at the concentration range of 0-100 mM. Twenty repetitions were measured for each concentration.

conventional complicated synthetic methods, the molecular self-assembled system was employed to prepare chemosensors *in situ*. Accordingly, the chemosensor array was fabricated by mixing low-cost, commercially available reagents, such as 3-NPBA, and four types of catechol dyes. The various combinations of these compounds with saccharides generated multi-color response patterns based on the IDA. In the case of the qualitative assay based on the LDA, we succeeded in discriminating of eight distinct groups (control and seven types of saccharides) with a classification success rate of 100%. Furthermore, semi quantitative and quantitative assays for Fru and Glc were conducted and resulted in highly accurate discrimination and prediction. We believe that the simple methods proposed here can be readily conducted by specialists and non-specialists of supramolecular and analytical chemistry, and could contribute to the increase in popularity of chemosensors.

AUTHOR CONTRIBUTIONS

YS performed the spectroscopic and the high-throughput array experiments and wrote the manuscript. ZZ performed the spectroscopic experiments and calculated the binding constants. SVM was also performed by ZZ. TM conceived the entire project.

The construction of targeted and activatable materials can largely improve the precision of disease diagnosis and therapy. However, the currently developed systems either target a transmembrane antigen or are activatable to release imaging and/or therapeutic reagents intracellularly. Here, we develop a simple thin-layer glycomaterial through the self-assembly between fluorescent glycoprobes, in which the carbohydrate-targeting reagent and the fluorophore are linked to each other by polyethylene glycol with a suitable chain length, and thin-layer manganese dioxide. The fluorogenic material developed is both capable of targeting a transmembrane glycoprotein receptor and fluorescently activatable by intracellular biothiols. The shell thickness of the material was determined to be important for achieving the biothiol-induced activation of fluorescence. This research might provide insight into the development of precision-enhanced self-assembled materials for disease theranostics.

Keywords: fluorescence, precision, imaging, activatable, receptor

INTRODUCTION

Carbohydrate–protein interactions are responsible for the activation of many biological and disease-relevant signaling pathways (Lee and Lee, 1995). During the process of a certain number of diseases, transmembrane receptors that are selective for carbohydrates (monosaccharides or oligosaccharides) are overexpressed (Kampen, 2011). As a result, glycomaterials, which are prepared by covalently or non-covalently conjugating carbohydrates to a variety of different material substrates including polymers, nanoparticles, and thin-layer materials, have been developed for targeted disease diagnosis and therapy (Ji et al., 2016; Zhang et al., 2017; Fu et al., 2018).

Recently, the use of thin-layer materials, such as graphene oxide and graphene-like materials, for biomedical applications has emerged as a topical research area (Chung et al., 2013; Shareena et al., 2018). Among the advanced materials developed, thin-layer molybdenum disulfides and oxides have been proven to be of good biocompatibility with low *in vitro* and *in vivo* toxicity to construct theranostic materials (Liu et al., 2014, 2015; He and Tian, 2016; Yadav et al., 2019).

Thin-layer manganese dioxide (MnO_2), which can be readily degraded to form manganese ions, has been extensively used to construct activatable sensing and therapeutic materials in response to the reducing microenvironments or low pH inside cancer cells (Zhao et al., 2014; Fan et al., 2015; Chen et al., 2016).

While previous studies mainly focused on the development of materials that can target a transmembrane antigen or are activatable for controlled release of imaging and therapeutic agents, here we develop a thin-layer glycomaterial for both targeted and activatable imaging of cells. Self-assembly between fluorescent glycoprobes and thin-layer MnO_2 produces fluorogenic glycomaterials, which can target a transmembrane glycoprotein receptor to deliver the glycoprobes inside cells. Then, degradation of the thin-layer MnO_2 backbone by intracellular biothiols activates the glycoprobe fluorescence, enabling the targeted, activatable functional cell imaging.

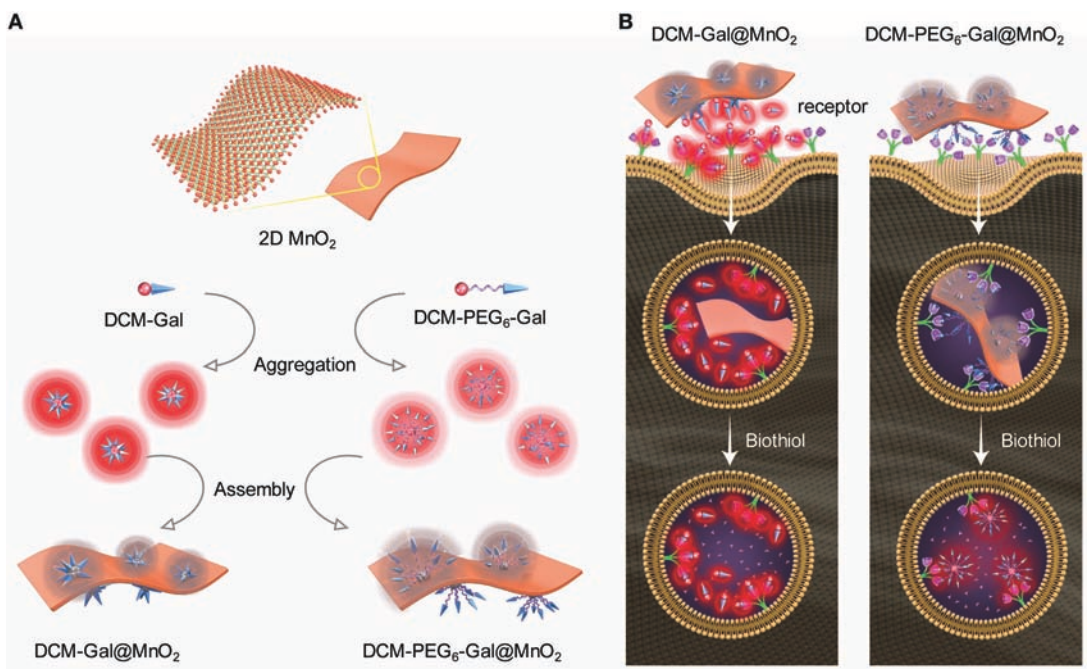

FIGURE 2 | Schematic illustration of **(A)** aggregation and then self-assembly of the glycoprobes with thin-layer MnO_2, producing the thin-layer glycomaterials with different shell thicknesses, and **(B)** the different fluorescence activation mode of the glycomaterials after endocytosis by cells that express asialoglycoprotein receptors.

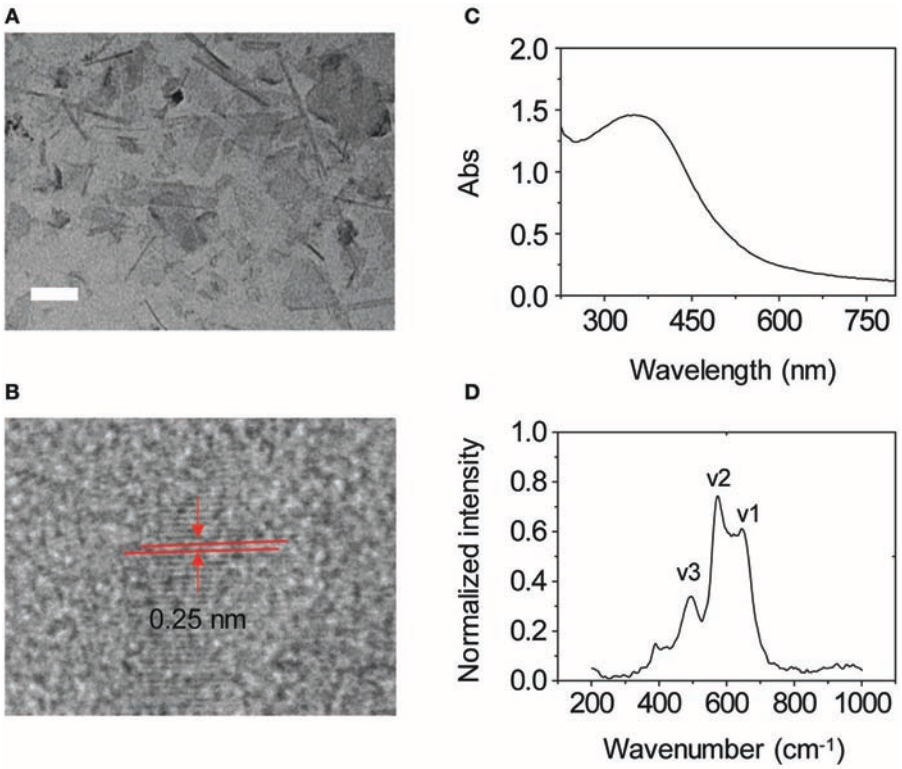

FIGURE 3 | (A) Representative high-resolution transmission electron microscopic (HRTEM) image of thin-layer MnO_2 (scale bar = 50 nm). **(B)** An enlarged view of an HRTEM image of thin-layer MnO_2. **(C)** UV–vis absorption spectrum of thin-layer MnO_2 (100 μg ml^{-1} dissolved in Tris-HCl buffer). **(D)** Raman spectrum of thin-layer MnO_2 (100 μg ml^{-1} dissolved in Tris-HCl buffer).

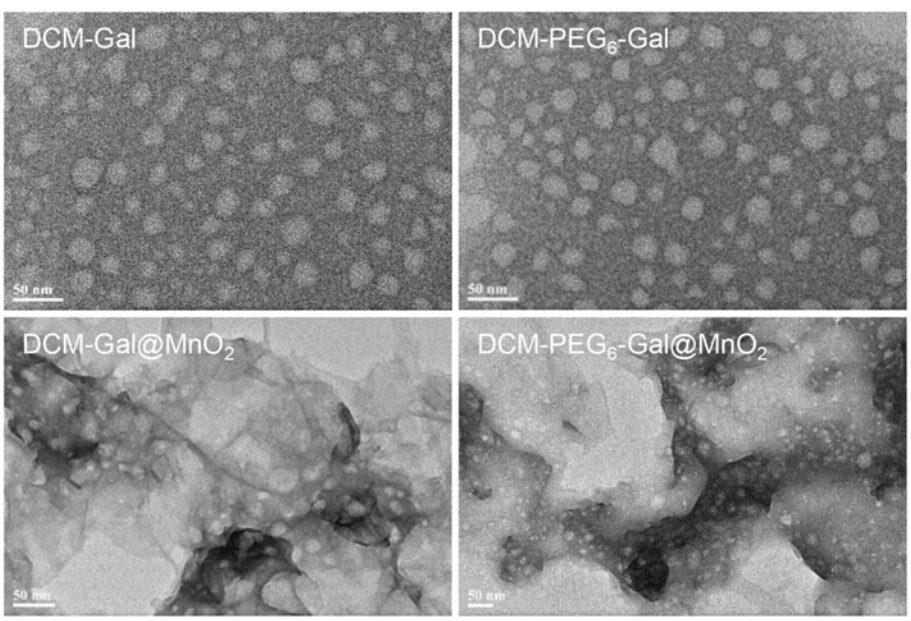

FIGURE 4 | Representative HRTEM images of DCM-Gal, DCM-PEG_6-Gal, DCM-Gal@MnO_2 (DCM-Gal/MnO_2 = 10 μM/10 μg ml^{-1} dissolved in Tris-HCl buffer), and DCM-PEG_6-Gal@MnO_2 (DCM-PEG_6-Gal/MnO_2 = 10 μM/10 μg ml^{-1} dissolved in Tris-HCl buffer).

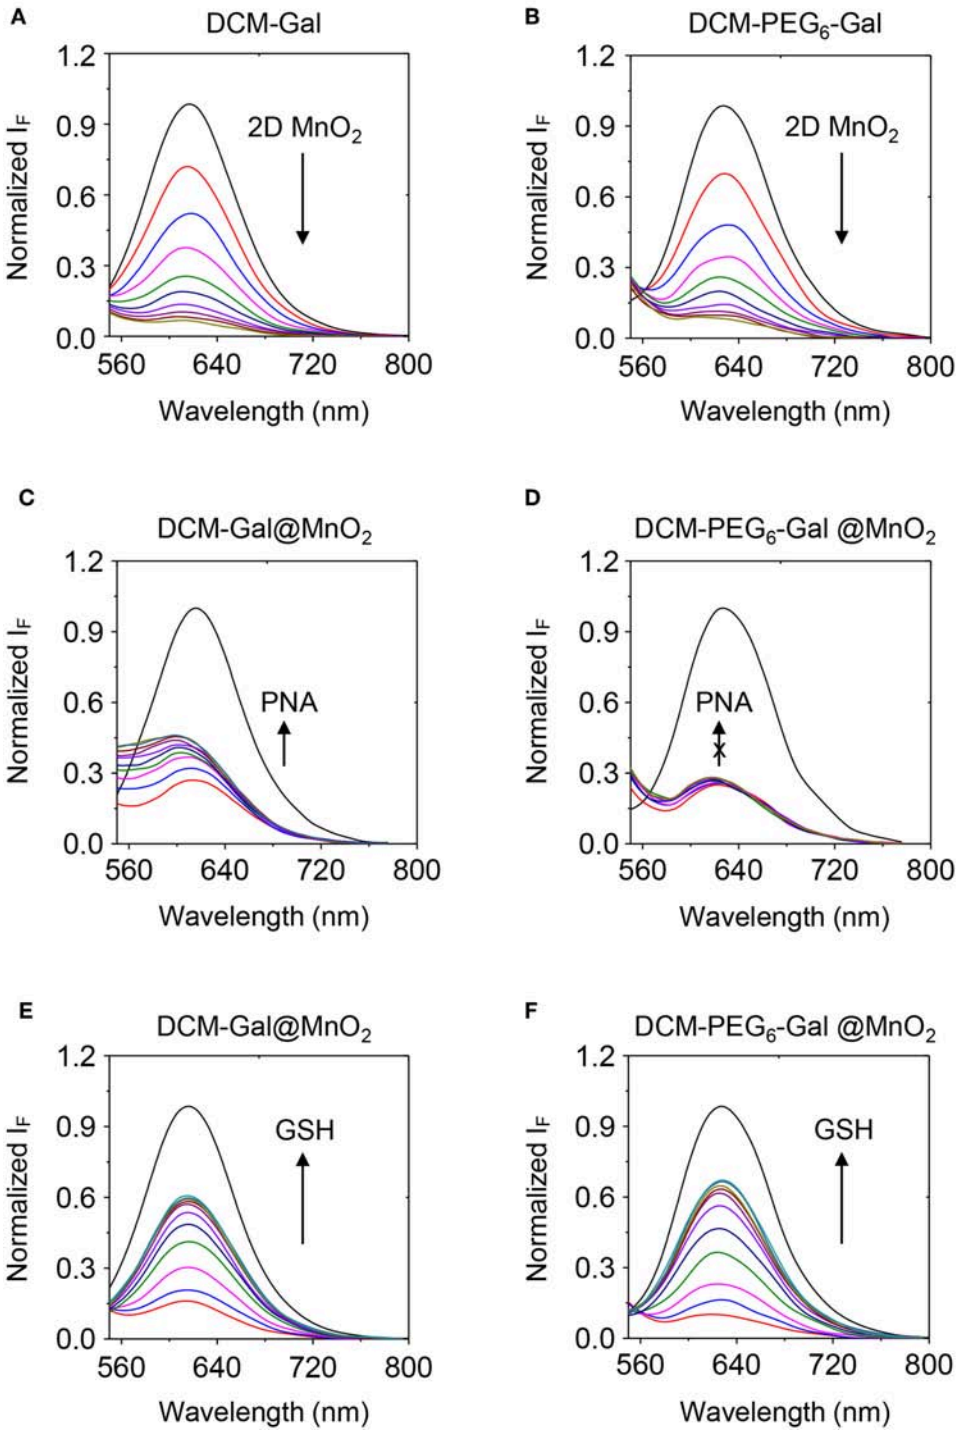

FIGURE 5 | Fluorescence spectra of **(A)** DCM-Gal (10 μM) and **(B)** DCM-PEG_6-Gal (10 μM) with increasing thin-layer MnO_2 (from top to bottom curve: 0–40 μg ml^{-1}, interval: 4 μg ml^{-1}). Fluorescence spectra of **(C)** DCM-Gal@MnO_2 (DCM-Gal/MnO_2 = 10 μM/40 μg ml^{-1}) and **(D)** DCM-PEG_6-Gal@MnO_2 (DCM-PEG_6-Gal/MnO_2 = 10 μM/20 μg ml^{-1}) with increasing PNA (peanut agglutinin, from bottom to top curve: 0–40 μM, interval: 5 μM). Fluorescence spectra of **(E)** DCM-Gal@MnO_2 (DCM-Gal/MnO_2 = 10 μM/40 μg ml^{-1}) and **(F)** DCM-PEG_6-Gal@MnO_2 (DCM-PEG_6-Gal/MnO_2 = 10 μM/40 μg ml^{-1}) with increasing GSH (γ-glutathione, from bottom to top curve: 0–500 μM, interval: 50 μM).

Importantly, we demonstrate that the shell thickness is crucial for achieving the biothiol-responsive fluorescence activation of the thin-layer glycomaterials.

RESULTS AND DISCUSSION

Two DCM (dicyanomethylene-4H-pyran)-based glycoprobes [DCM-Gal (Ji et al., 2016) and DCM-PEG_6-Gal] with linkers of different lengths connecting a DCM and a galactose epitope were used (**Figure 1**). An experimental section and original NMR spectral copies of new compounds are presented in **Supplementary Material**. The presence of a hexa-PEG linkage in the structure of DCM-PEG_6-Gal could facilitate the formation of a PEG shell on the surface of thin-layer materials in order to enhance the stability of the material in complex biological environments (**Figure 2A**). We envision that while the material composite formed between DCM-Gal and thin-layer MnO_2 might dissociate directly after interaction with the asialoglycoprotein receptor (ASGPr) that selectively recognizes galactoconjugates, that formed between DCM-PEG_6-Gal and thin-layer MnO_2 could be more stable during receptor-mediated endocytosis for stimuli-activated fluorescence imaging (**Figure 2B**).

To prove our hypothesis, the glycoprobes were used for self-assembly in Tris-HCl buffer with thin-layer MnO_2 prepared by the previously reported method (Zhao et al., 2014). In its representative high-resolution transmission electron microscopy (HRTEM) images, we observed thin-flake objects, suggestive of the formation of thin-layer MnO_2 (**Figure 3A**). The orthogonal distance (~0.25 nm) between two consecutive slabs of [MnO_6] is characteristic of the typical birnessite-type MnO_2 (**Figure 3B**; Kim et al., 2017). In the UV spectrum of the thin-layer MnO_2, a predominant absorbance peak at ca. 380 nm was detected (**Figure 3C**), which is attributable to the d–d transition of Mn ions in the MnO_6 octahedra of the thin-layer material (Kai et al., 2008). Raman spectroscopy was also used for material characterization. Three typical bands at 647, 575, and 497 cm^{-1} were observed, which are characteristic of the ν_1 (the symmetric stretching vibration of the Mn–O bond in the MnO_6 octahedral plane), ν_2 (the stretching vibration mode of Mn–O in the MnO_6 octahedral basal plane), and ν_3 (the deformation mode of the metal–oxygen chain of Mn–O–Mn in the MnO_2 octahedral lattice) vibrational features of thin-layer MnO_2, respectively (**Figure 3D**; Julien et al., 2003, 2004). We also observed that both DCM-Gal and DCM-PEG_6-Gal form nanoparticles (**Figure 4**), whereas after assembly, the particles were determined to be adhered onto the surface of thin-layer MnO_2 (**Figure 4**).

Subsequently, fluorescence spectroscopy was used for the analysis of the self-assembly. We observed a gradually decreased fluorescence of both DCM-Gal (**Figure 5A**) and DCM-PEG_6-Gal

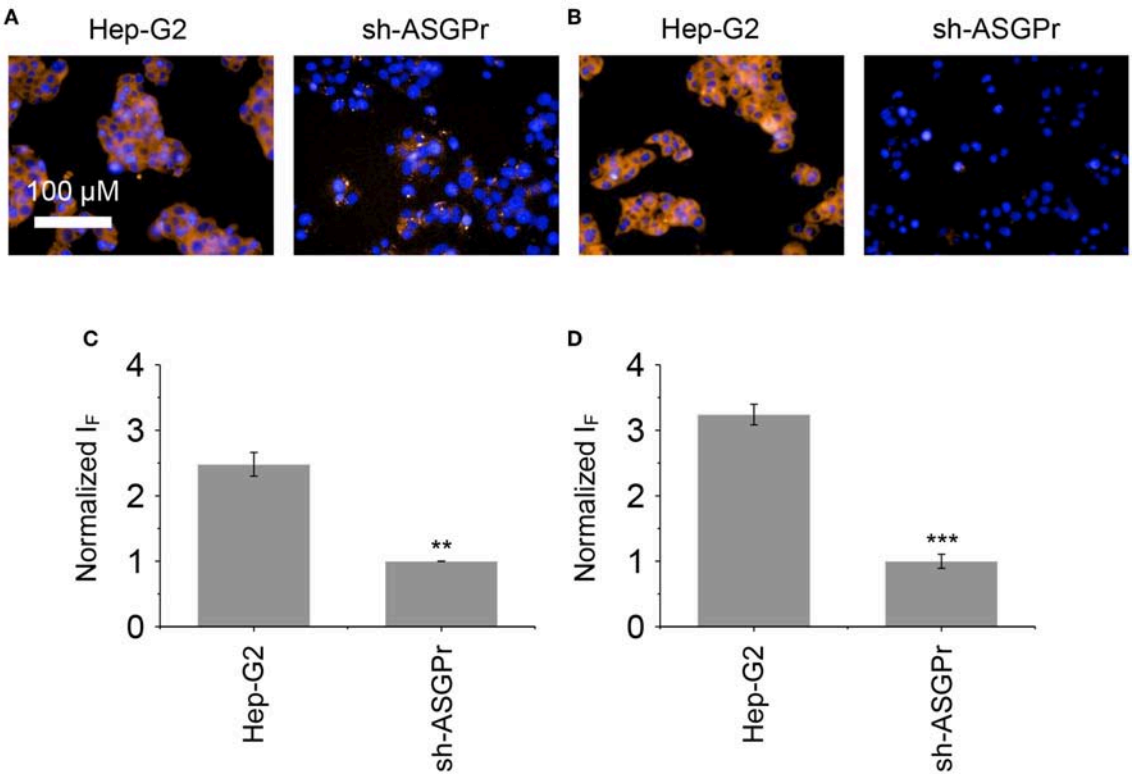

FIGURE 6 | Fluorescence imaging **(A)** and quantification **(C)** of Hep-G2 and sh-ASGPr cells after incubation with DCM-Gal@MnO_2 (DCM-Gal/MnO_2 = 10 μM/32 μg ml^{-1}). Fluorescence imaging **(B)** and quantification **(D)** of Hep-G2 and sh-ASGPr cells after incubation with DCM-PEG_6-Gal@MnO_2 (DCM-PEG_6-Gal/MnO_2 = 10 μM/32 μg ml^{-1}). $^{**}P < 0.01$, $^{***}P < 0.005$. Error bars mean S. D. ($n = 3$). Excitation and emission channels used were 460–490 and 560–630 nm, respectively. (**Figure 5B**) in the presence of increasing thin-layer MnO_2. This suggests the adsorption of the glycoprobes onto the surface of the material, leading to fluorescence quenching (Zhao et al., 2014). To test its stability toward a carbohydrate-binding protein, we added peanut agglutinin (PNA) that selectively recognizes the galactose epitopes on the surface of the material composite. Interesting, while a gradual fluorescence enhancement was observed for the DCM-Gal@MnO_2 group with increasing PNA (**Figure 5C**), which is in accordance with our previous observations that complexation between glycoprobe and PNA competitively removes the probe molecules from the surface of the quenching material, the quenched fluorescence of DCM-PEG_6-Gal remained almost unchanged (**Figure 5D**). This suggests the importance of the hexa-PEG shell for the protection of the material composite from disassociation upon interaction with a galactose-selective lectin. In contrast, the fact that the presence of GSH led to the fluorescence enhancement of both glycomaterials, which is the result of degradation of the thin-layer MnO_2 backbone, suggests their ability for activatable fluorescence sensing and imaging (**Figures 5E**,**F**).

Next, the glycomaterials were used for cell imaging. Hep-G2 cells that highly express ASGPr as well as GSH, and a previously established Hep-G2 cell line with a reduced ASGPr expression by gene transfection (Fu et al., 2018), were used to test the receptor-targeting capacity of the materials. We determined that the fluorescence of both materials was produced mainly in Hep-G2 rather than in sh-ASGPr cells, suggesting their good receptor-targeting property because of the exposure of galactose epitopes on the surface (**Figure 6**; Burgess et al., 1992). Then, we used Hep-G2 cells with a depleted GSH concentration by pretreatment with NEM (a known GSH scavenger) to measure the fluorescence activity of the materials. A similar level of fluorescence was determined in Hep-G2 cells with or without GSH for the DCM-Gal@MnO_2 group (**Figures 7A**,**C**). In contrast, the fluorescence of DCM-PEG_6-Gal@MnO_2 in Hep-G2 cells with endogenous GSH was much stronger than in those with depleted GSH (**Figures 7B**,**D**). These results preliminarily suggest that while the DCM-Gal@MnO_2 ensemble disassociates upon interaction with ASGPr, DCM-PEG_6-Gal@MnO_2, because of the presence of a hexa-PEG shell, remained much more stable upon receptor-mediated endocytosis. However, the subsequent presence of a high concentration of intracellular GSH led to material degradation, thus enabling activatable fluorescence imaging (**Figure 2B**).

CONCLUSIONS

We have shown in this research that by properly modulating the shell thickness of self-assembled, thin-layer glycomaterials can enable targeted and activatable imaging of cells. The glycomaterial coated with a hexa-PEG shell can effectively protect the material ensemble from disassociation after incubation with a lectin that selectively recognizes the carbohydrate epitopes on the material surface. In the subsequent cell imaging assay, we also observed that the fluorescence activation of the thickly shelled glycomaterial was dependent on the presence intracellular

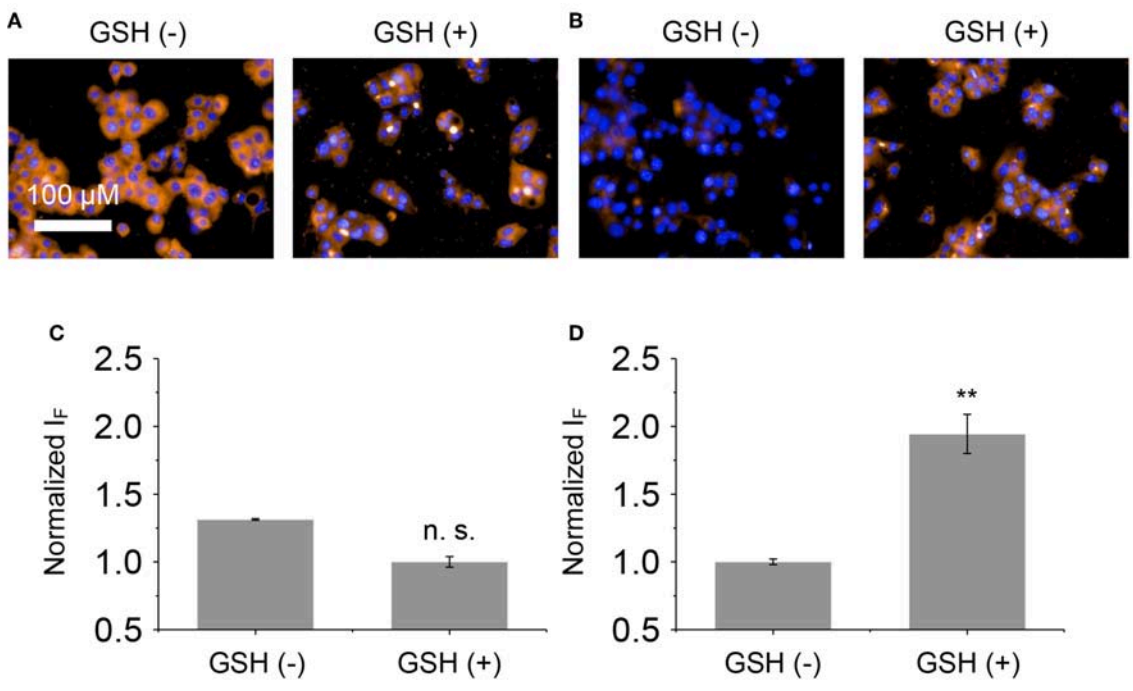

FIGURE 7 | Fluorescence imaging **(A)** and quantification **(C)** of Hep-G2 treated with DCM-Gal@MnO_2 (DCM-Gal/MnO_2 = 10 μM/32 μg ml^{-1}) pretreated with NEM (N-ethylmaleimide is a known GSH quencher, 500 μM) or GSH (300 μM). Fluorescence imaging **(B)** and quantification **(D)** of Hep-G2 treated with DCM-PEG_6-Gal@MnO_2 (DCM-PEG_6-Gal/MnO_2 = 10 μM/32 μg ml^{-1}) pretreated with NEM (500 μM) or GSH (300 μM). n.s., not significant; $^{**}P < 0.01$. biothiols, while that which lacks the protective shell was directly dependent on the expression of transmembrane glycoprotein receptors irrespective of the intracellular GSH concentration. This implies the importance of properly adjusting the shell thickness of self-assembled thin-layer materials in order to enhance the precision of functional cell imaging. We are currently using this concept for the construction of other thin-layer MnO_2-based materials for the analysis of the biothiol level in different types of cancer cells such as leukemia cells.

Kumawat LK, Abogunrin AA, Kickham M, Pardeshi J, Fenelon O, Schroeder M and Elmes RBP (2019) Squaramide—Naphthalimide Conjugates as "Turn-On" Fluorescent Sensors for Bromide Through an Aggregation-Disaggregation Approach. Front. Chem. 7:354. doi: 10.3389/fchem.2019.00354

The syntheses of two new squaramide-naphthalimide conjugates (**SQ1** and **SQ2**) are reported where both compounds have been shown to act as selective fluorescence "turn on" probes for bromide in aqueous DMSO solution through a disaggregation induced response. **SQ1** and **SQ2** displayed a large degree of self-aggregation in aqueous solution that is disrupted at increased temperature as studied by ^{1}H NMR and Scanning Electron Microscopy (SEM). Moreover, the fluorescence behavior of both receptors was shown to be highly dependent upon the aggregation state and increasing temperature gave rise to a significant increase in fluorescence intensity. Moreover, this disaggregation induced emission (DIE) response was exploited for the selective recognition of certain halides, where the receptors gave rise to distinct responses related to the interaction of the various halide anions with the receptors. Addition of F^- rendered both compounds non-emissive; thought to be due to a deprotonation event while, surprisingly, Br^- resulted in a dramatic 500–600% fluorescence enhancement thought to be due to a disruption of compound aggregation and allowing the monomeric receptors to dominate in solution. Furthermore, optical sensing parameters such as limits of detection and binding constant of probes were also measured toward the various halides (F^-, Cl^-, Br^-, and I^-) where both **SQ1** and **SQ2** were found to sense halides with adequate sensitivity to measure μM levels of halide contamination. Finally, initial studies in a human cell line were also conducted where it was observed that both compounds are capable of being taken up by HeLa cells, exhibiting intracellular fluorescence as measured by both confocal microscopy and flow cytometry. Finally, using flow cytometry we were also able to show that cells treated with NaBr exhibited a demonstrable spectroscopic response when treated with either **SQ1** or **SQ2**.

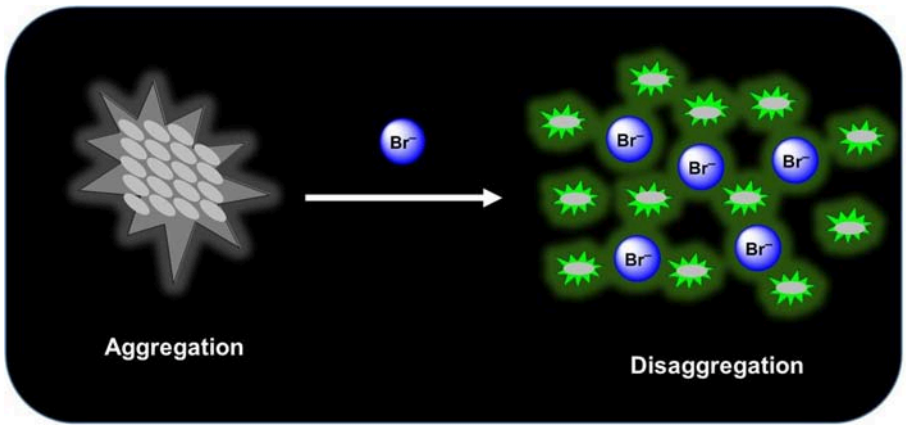

GRAPHICAL ABSTRACT |

INTRODUCTION

Anion sensing has been a key area of supramolecular chemistry since the introduction of the field in the early 1970's (Beer and Gale, 2001; Gunnlaugsson et al., 2006; Duke et al., 2010; Busschaert et al., 2015; Gale et al., 2016; Langton et al., 2016). In particular the recognition and sensing of halides has garnered considerable research interest due to their prevalence in biological and ecological settings (Verkman, 1990; Cametti and Rissanen, 2009, 2013; Evans and Beer, 2014; Ashton et al., 2015). While chloride and fluoride have captivated much of the research interest due to their major roles in cellular homeostasis, acid/base equilibria, and pollution concerns other halides such as bromide have been largely ignored. This is surprising given the clinical symptoms of bromide intoxication (also known as bromism), a once common disease where large doses of bromide were found to impair neuronal transmission and cause nausea and vomiting, abdominal pain, coma, and paralysis (Olson and System, 2004). Although now rare, bromism cases continue to be reported due to non-prescription bromide-based medications being available over the counter where a recent case resulted in extremely high levels of bromide intoxication (serum bromide level of 1,717 mg/L) (Hoizey et al., 2003). Moreover, from an environmental standpoint, bromide pollution can result in reaction between chlorine and naturally occurring organic matter in drinking-water, forming brominated, and mixed chloro-bromo by products such as trihalomethanes or halogenated acetic acids (Gribble, 2004). Indeed, the World Health Organization reports that while low levels of bromide pollution do not seem to have detrimental effects on humans or animals (World Health Organization, 2009), bromate (formed in water during ozonation) is a known carcinogen (World Health Organization, 2005). However, the selective binding and sensing of bromide is made challenging by its intermediate size and hydration energy between chloride and iodide (Marcus, 1991), and reported examples in the literature remain scarce (Kang and Kim, 2005; Suksai et al., 2005; Vlascici et al., 2018). One of the few examples, reported by Qian and co-workers, developed a rhodamine based fluorescent probe capable of selective sensing of iodide and bromide in aqueous solution based on a metal ion removal and anion ligand exchange mechanism (Xu et al., 2012). Nyokong and co-workers reported the use of GSH-capped quantum dots (QDs) covalently linked to a nickel tetraamino-phthalocyanine complex where the covalent binding of the QDs to the Ni complex induced fluorescence quenching before with introduction of Br– restoring the fluorescence (Adegoke and Nyokong, 2013). Most recently, Beer and co-workers developed a redox-active ferrocene functionalized rotaxane with a halogen bonding anion binding site that was capable of selective Br^- sensing over Cl^- in the presence of water as measured by ^1H NMR and electrochemical measurements (Lim and Beer, 2019).

Much of the literature surrounding anion sensors relies on a binding event that disrupts/enhances some type of electron transfer mechanism such as photoinduced electron transfer (PET), internal charge transfer (ICT), excited state intramolecular proton transfer (ESIPT), fluorescence resonance energy transfer (FRET), etc. to yield a measurable fluorescence response (de Silva et al., 1997; Wu et al., 2011; Fan et al., 2013; Lee et al., 2015; Kumawat et al., 2017; Sedgwick et al., 2018). Some more recent reports take advantage of aggregation induced emission (AIE) (Hong et al., 2011), whereby recognition of an anion causes aggregation of the sensor thereby reducing molecular rotation and inducing large fluorescence perturbations (Peng et al., 2009; Ma et al., 2019). The opposite sensing mechanism, disaggregation induced emission (DIE), where dis-assembly of a non-fluorescent aggregate releases individual fluorescent molecules has received much less attention even though the process from aggregation to disaggregation generally causes a recovery or enhancement of fluorescence signals, and thus provides a useful method to design "turn-on" probes (Zhai et al., 2014). Recognition events that induce a fluorescence increase are preferable from the perspective of industrial/medical application where such a facile "turn-on" response can give naked-eye real-time information. Indeed, a recent report from O'Shea and co-workers detailed the use of an amphiphilic BF_2-azadipyrromethene (NIR-AZA) DIE probe

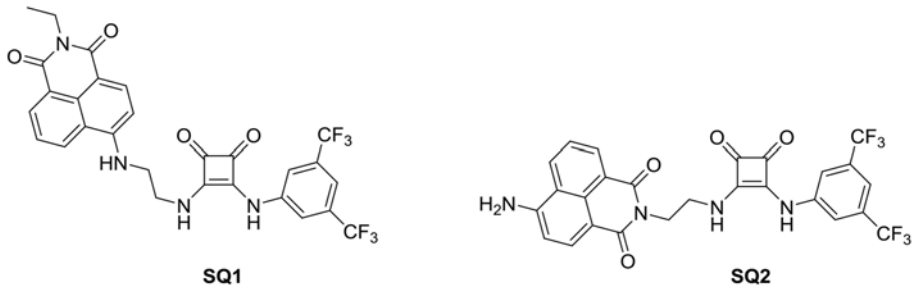

FIGURE 1 | Chemical structures of probes **SQ1** and **SQ2**.

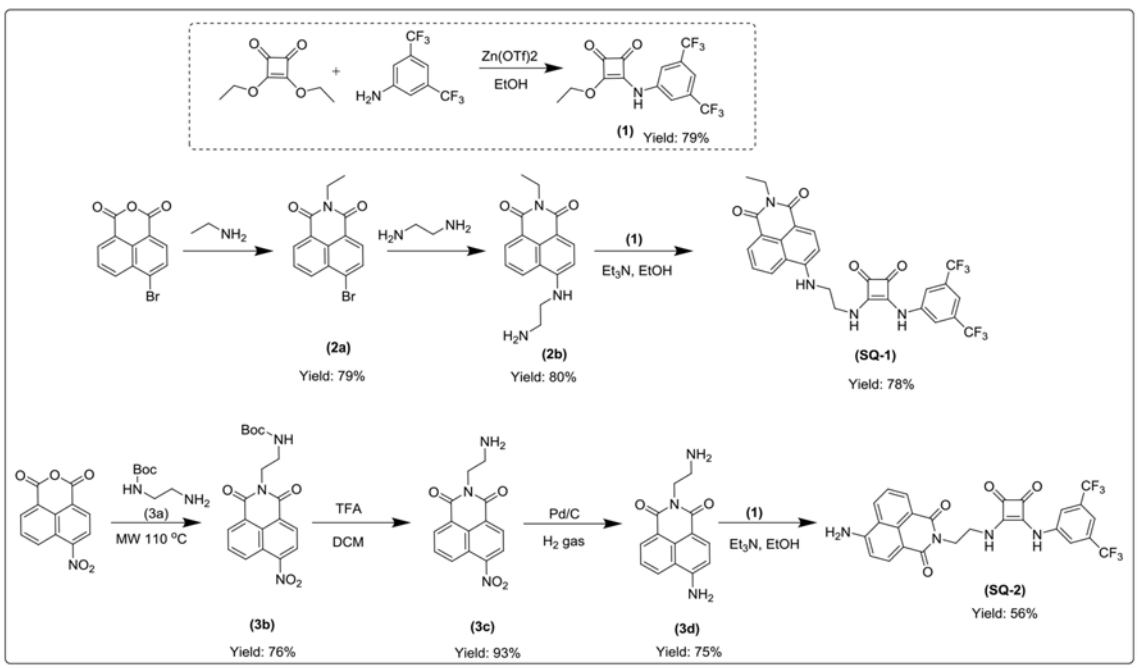

SCHEME 1 | Syntheses of **SQ1** and **SQ2**.

where a membrane selective fluorescence "off to on" switching event allowed visualization of dynamic cellular events in real-time (Wu et al., 2018). Here the authors exemplify how DIE can be exploited to produce a signal in response to a biological event specific to the plasma membrane, allowing real-time visualization of cell-cell contacts through pairs of filopodia.

From our work on squaramides we are familiar with the self-assembly/aggregation of these molecules due to bidirectional H-bonding interactions in addition to π-π stacking brought about by the aromatic cyclobutenedione ring (Elmes et al., 2013, 2014, 2015; Busschaert et al., 2014; Elmes and Jolliffe, 2014; Qin et al., 2016; Marchetti et al., 2018). Moreover, we have also gained considerable experience working with the naphthalimide fluorophore which has fluorescence properties that are highly dependent upon aggregation (Elmes and Gunnlaugsson, 2010; Elmes et al., 2012; Ryan et al., 2012, 2015; Ao et al., 2017). Indeed, Scanlan, Gunnlaugsson and co-workers have recently shown glycosylated naphthalimide and naphthalimide Tröger's bases that act as fluorescent aggregation probes for the Con A protein where both structures self-assemble in solution to form supramolecular structures by head-to-tail π-π stacking and extended hydrogen bonding interactions (Calatrava-Pérez et al., 2019). Inspired by this work, we envisaged that a naphthalide-squaramide conjugate may also aggregate efficiently in solution and such aggregation behavior may be modulated upon anion recognition where a disruption of a H-bonding network would reverse self-assembly. Thus, we set about designing a small family of squaramide-naphthalimide conjugates in which we wished to vary the position of the squaramide in relation to the naphthalimide to place the squaramide at either the "head" or the "tail" of the structure (**Figure 1**). As shown in **Scheme 1** our design incorporated a short linker with a significantly hydrophobic side arm that we expected may aid in the aggregation behavior of the sensors in polar solvents.

Herein, we report the synthesis of compounds **SQ1** and **SQ2** where we have exploited their aggregation behavior and found

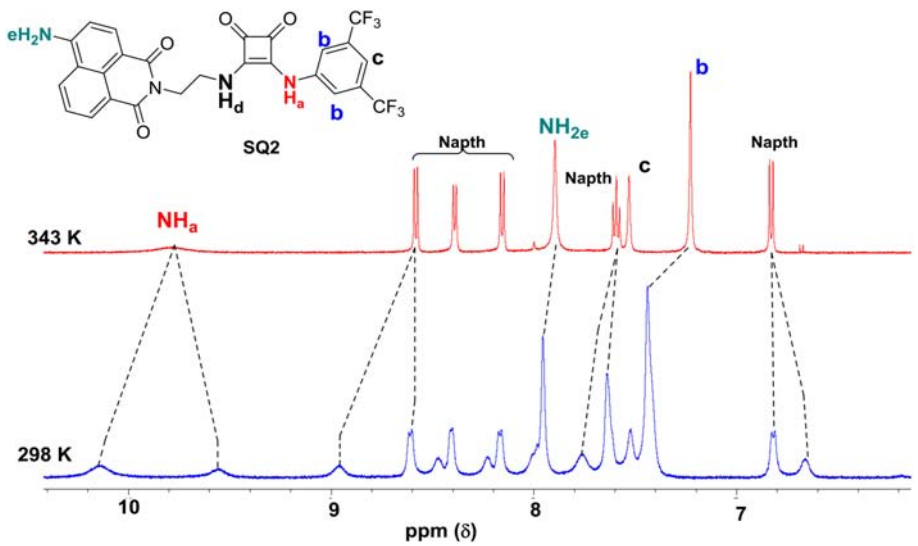

FIGURE 2 | Disaggregation response of probes **SQ2** (5.0×10^{-3} M) at different temperatures. in DMSO-d_6.

differing fluorescence responses to various halides in solution. We have discovered that both **SQ1** and **SQ2** behave as DIE based sensors in solution show differing responses to various anions but with an unexpectedly selective fluorescence "turn on" response to bromide. Moreover, initial results obtained with the HeLa cell line demonstrate that the effect can also be observed in the complex biological environment of a human cell.

RESULTS AND DISCUSSIONS

Synthesis

The syntheses of compounds **SQ1** and **SQ2** were achieved using the synthetic pathway outlined in **Scheme 1**. Briefly, **SQ1** was synthesized by amination of 4-bromo-1,8-naphthalimide **2a** using ethylenediamine before nucleophilic addition of the resulting intermediate **2b** to 3,5-bis(trifluoromethyl)phenyl squarate monoester **1** to yield **SQ1** in 78% yield. Similarly, **SQ2** was formed from an initial reaction of 4-nitro-1,8-naphthalic anhydride **3** with *N*-Boc-ethylenediamine **3a** to yield intermediate **3b** before subsequent TFA mediated deprotection of the Boc group **3c** and catalytic reduction of the nitro group yielded compound **3d** that was also reacted with 3,5-bis(trifluoromethyl)phenyl squarate monoester **1** to yield **SQ2** in 56% yield. All compounds and intermediates were fully characterized by ^{1}H NMR, ^{13}C NMR, HRMS and IR spectroscopy (see **Supporting Information**). However, during NMR characterization it was noted that the ^{1}H NMR spectra of both **SQ1** and **SQ2** gave rise to complex spectra exhibiting significantly broadened peaks. Indeed, as discussed above, it is well-known that squaramides benefit from several characteristics that make them amenable for use in self-assembled materials, in particular their structural rigidity, aromaticity and ability to form strong two-dimensional hydrogen bonds (Storer et al., 2011; Wurm and Klok, 2013). Similarly, naphthalimides, with their extended planar, aromatic structure are well known to partake in π-π stacking; a characteristic that renders the photophysical properties of napthalimides sensitive to such stacking events (Duke et al., 2010; Banerjee et al., 2013). In order to investigate the self-assembly behavior of **SQ1** and **SQ2** several techniques such as ^{1}H NMR, fluorescence measurements and SEM were utilized.

Aggregation Behavior Measured by ^{1}H NMR and SEM Spectroscopy

The ^{1}H NMR spectra of **SQ1** and **SQ2** in *d6*-DMSO was measured at both 298 and 343 K. Both spectra clearly showed substantial differences between room and high temperatures where the spectra of **SQ1** and **SQ2** at 298 K appear broad and complex, as discussed above, signifying some degree of aggregation is occurring. Conversely, upon heating the samples to 343 K large changes in the spectra are observed whereby the signals become sharp and well-resolved allowing complete characterization of all ^{1}H signals at this temperature. For example, **Figure 2** exemplifies the apparent differences between the ^{1}H NMR spectrum of **SQ2** at 298 and 343 K. Interestingly, signals associated with the naphthalimide moiety appear to resolve from two broad signals per proton to become one well-resolved signal for each proton. Moreover, the signals associated with the 3,5-bis(trifluoromethyl)phenyl portion of the molecule appear to undergo significant chemical shift changes, particularly the protons at the 2 and 6 position (H_b) ($\Delta\delta = 105$ Hz. Similarly, the CH_2 directly attached to the squaramide moiety also resolves from two signals to one but does not fully resolve to the expected multiplicity and remains broad (**Figure S20**). Perhaps most striking is the fact that the squaramide NH signals appear as two distinct signals in the ^{1}H NMR (10.1 and 9.56 ppm) at 298 K but are resolved to one broad signal at 9.78 ppm at 343 K. Taken together the evidence from the above study suggests that the entire molecule is taking part in aggregation behavior with the

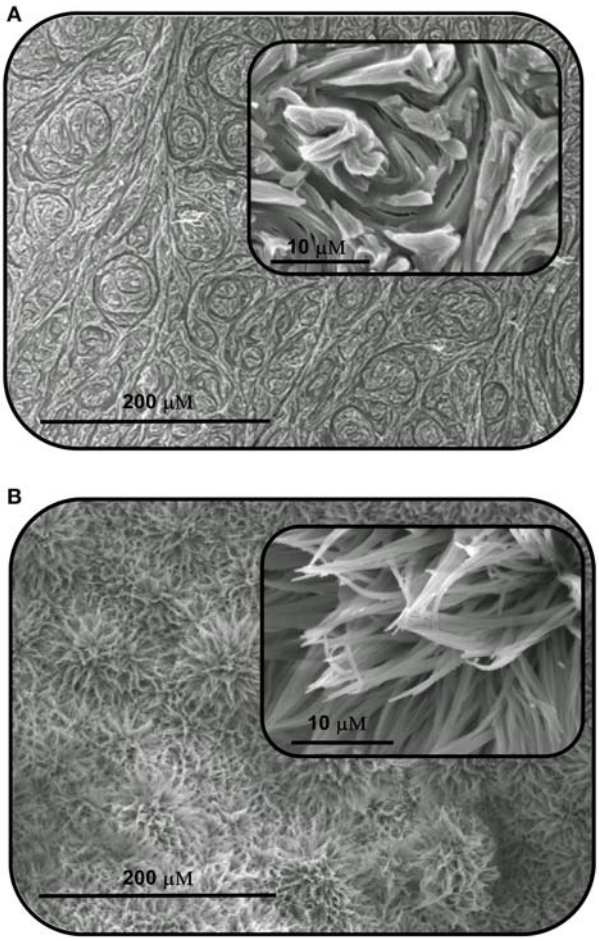

FIGURE 3 | Scanning electron microscopy (SEM) images of the aggregates formed by self-assembly of **(A) SQ1** and **(B) SQ2** in DMSO.

squaramide, naphthalimide and 3,5-bis(trifluoromethyl)phenyl portions all playing a role. Similar behavior was observed in the cases of both **SQ1** and **SQ2** (**Figure S19**).

In order to further probe the aggregation characteristics of both compound, attempts were made to grow crystals from concentrated DMSO solutions. Unfortunately, in our hands the compounds did not crystallize and instead formed what appeared to be amorphous solids. The morphological features of these solids were thus analyzed by scanning electron microscopy (SEM), and as shown in **Figure 3**, the SEM images exhibit interesting and distinct morphology on the nanoscale. **SQ1** appeared as "swirls" that propagate throughout the entire material. Conversely, **SQ2** formed showed a sponge like structure that at higher magnification appears to be composed of small nanofilaments. Although firm conclusions cannot be drawn on the exact molecular interactions that give rise to such interesting morphology it is clear that a high degree of aggregation is occurring that appears to be in an ordered fashion to give rise to such patterns.

Both **SQ1** and **SQ2** were examined using UV/Vis spectroscopy and fluorescence emission spectroscopy. The UV/Vis absorption spectrum of **SQ1** in DMSO showed three absorption maxima at 280, 340, and 445 nm with extinction coefficient values of 32,642, 19,559, and 15,439 M^{-1} respectively. Similarly, **SQ2** showed an almost identical spectrum to **SQ1** with maxima also at 280, 340, and 445 nm and with extinction coefficients of 34,785, 20,405, and 13,717 M^{-1}, respectively. Furthermore, both compounds exhibited fluorescence emission at *ca.* 525 nm. With the aggregation behavior observed in the previous section, we also undertook a thermal study to investigate if the fluorescence of **SQ1** and **SQ2** could be modulated by disaggregation. A temperature dependent fluorescence study was thus undertaken in 5% aq. DMSO. As seen in **Figure 4**, both **SQ1** and **SQ2** exhibited a sharp increase in fluorescence 220–300% as a function of temperature. These results support the ^{1}H NMR results above where we suggest that both **SQ1** and **SQ2** aggregate in solution but, upon heating, disassemble thus allowing the fluorescence intensity to increase. Interestingly, upon cooling the emission does not decrease to its original value. This may suggest that once disrupted the self-aggregation behavior is not reversible under these conditions (**Figure S23**). A fluorescence dilution study was also conducted, where it was observed that the fluorescence intensity of both **SQ1** and **SQ2** at 525 nm is linear to concentration (from 0.05 to 5 μM) and suggests that aggregation occurs at very low concentrations (**Figure S24**).

With the observed properties exhibited by **SQ1** and **SQ2** and the known propensity of squaramides to bind strongly to halides and other anionic species (Prohens et al., 1998, 2001; Piña et al., 2008; Amendola et al., 2010; Busschaert et al., 2012; Delgado-Pinar et al., 2012; Jin et al., 2013), we expected that introduction of anionic analytes may also disrupt the self-aggregation of the **SQ1** and **SQ2**. If indeed disruption was to occur, we expected some modulation of their photophysical properties would result and potentially give rise to a new class of anion sensors based on disaggregation.

Anion Induced Disaggregation

To investigate the ability of anions to disrupt the self-aggregation of **SQ1** and **SQ2** a series of ^{1}H NMR experiments were carried out. Initial qualitative measurements were undertaken using a screening experiment in which 30 equiv. of several anions (AcO^-, $H_2PO_4^-$, SO_4^{2-}, F^-, Cl^-, Br^-, and I^- as their tetrabutylammonium salts) were added to the receptors in solution (0.5% H_2O in DMSO-d_6). These preliminary results showed significant changes of the spectra of both **SQ1** and **SQ2**. Dramatic changes were observed in the ^{1}H NMR spectra of both receptors in the presence of AcO^-, F^-, $H_2PO_4^-$, and SO_4^{2-} where addition of these anions led to the disappearance of the NH signal (H_a) as shown in **Figure 5** for **SQ2** and also either broadened (AcO^- and F^-) or sharpened ($H_2PO_4^-$ and SO_4^{2-}).

Stark color changes of the solutions of **SQ1** and **SQ2** were observed upon the addition of F^- from yellow to red. The disappearance of the NH signal (H_a) and the stark color change suggests that deprotonation of the squaramide/naphthalimide may be responsible. We further confirmed this deprotonation behavior by observation of bifluoride (HF_2^-) in the ^{1}H NMR spectra of **SQ1** and **SQ2** upon the addition of F^- as shown in **Figure 5** for receptor **SQ1**. Moreover, distinct changes were

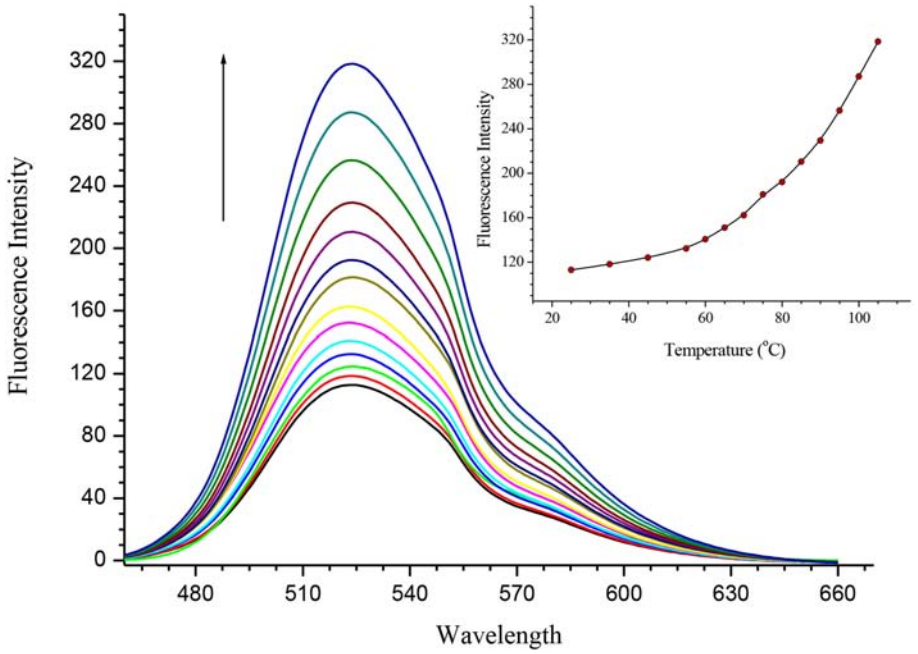

FIGURE 4 | Fluorescence temperature study demonstrating the disaggregation response of **SQ2** (5.0×10^{-6} M) in 5% aq. DMSO from 25° to 110°C.

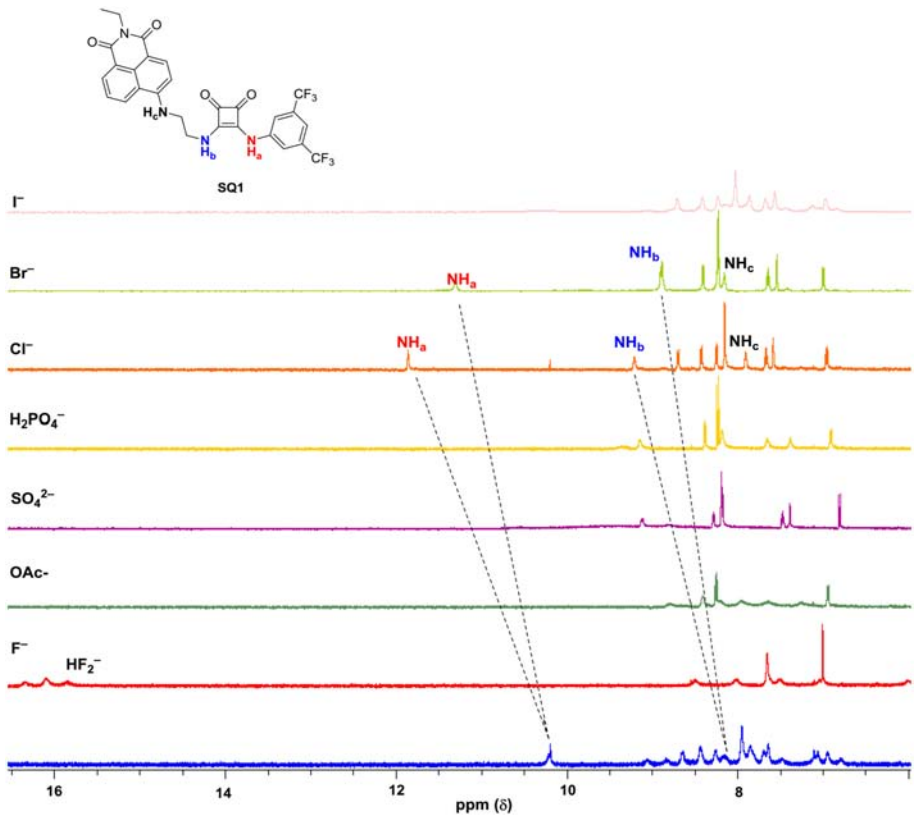

FIGURE 5 | ^{1}H NMR stackplot of **SQ1** with various anions (30 equivalents) in 0.5% H_2O in DMSO-d_6 at 298 K.

observed in the ^{1}H NMR spectra of **SQ1** and **SQ2** upon the addition of Cl^- and Br^-. For example, with **SQ2** these halides led to a large downfield shift of the NH signal (H_a) from 10.2 to 12.1 ppm for Cl^- and to 11.1 ppm for Br^- coupled with a significantly sharpened signal. Similar behavior was observed for **SQ1** (see **Figure S25**). The large downfield shift of the NH signal suggests a classical H-bonding interaction between Cl^- and Br^- and the NH protons of the squaramides. To further investigate the binding interaction of halides with **SQ1** and **SQ2** more detailed ^{1}H NMR spectroscopic titrations were carried out with halides F^-, Cl^-, Br^-, and I^- as their tetrabutylammonium salts with the resulting data fit to a 1:1 binding model using the open access BindFit software program (Thordarson, 2011; Lowe et al., 2012; Brynn Hibbert and Thordarson, 2016) to provide the apparent stability constants (K_a), which are summarized in **Table 1**.

TABLE 1 | Summary of the halide association constants K_a (M^{-1}) of receptors **SQ1** and **SQ2** in DMSO-d_6 at 273 K according to the ^{1}H NMR titration data.

Receptor	K_a (M^{-1}) (% Error)			
	F^-	Cl^-	Br^-	I^-
SQ1	–[a]	489 (6%)	165 (10%)	–[b]
SQ2	–[a]	221 (9%)	99 (9%)	–[b]

[a] *Addition of F^- resulted in deprotonation and prevented an association constant from being determined.*

[b] *Spectral changes were too minor to provide an accurate association constant. A series of equilibria may occur in solution under the reported conditions (e.g., aggregate disruption, anion binding to the monomer; anion binding to the aggregate etc.) thus these data, that have been fitted to a 1:1 binding model, are included to give a comparison of analogous squaramide anion receptors previously reported Busschaert et al., 2012; Bao et al., 2018.*

As an example, **Figure 6** shows the changes observed in the ^{1}H NMR spectrum of **SQ1** upon the addition of Cl^- (20 equiv.). A gradual downfield shift of the NH signal (H_a) from 10.2 to 11.8 ppm in the ^{1}H NMR spectrum was observed upon the increasing concentration of Cl^-. These changes together with increased spectral resolution observed over the entire spectrum upon the addition of Cl^-, clearly support a classical H-bonding interaction between Cl and the NH protons (H_a) of the receptors.

Overall, both **SQ1** and **SQ2** were found to bind to Cl^- and Br^- with moderate affinities with **SQ1** showing a slightly increased affinity for both anions compared to **SQ2** where the position of the squaramide at the "tail" of the naphthalimide seems to be optimal for both anions. Similarly, both receptors exhibited a preference for Cl^- over Br^- while I^- showed an almost complete lack of binding in both cases. Conversely, as previously discussed F^- resulted in receptor deprotonation thus the data could not be fit to a suitable ^{1}H NMR binding model. Analysis of the ^{1}H NMR spectra of the complexes also provided further evidence for the disaggregation of **SQ1** and **SQ2** in the presence of Cl^- and Br^- where the bound receptors gave rise to a well-resolved spectrum with sharp signals that could be clearly attributed to the proposed target structures. In addition, the signal for the CH_2 protons directly attached to the squaramide moiety in both

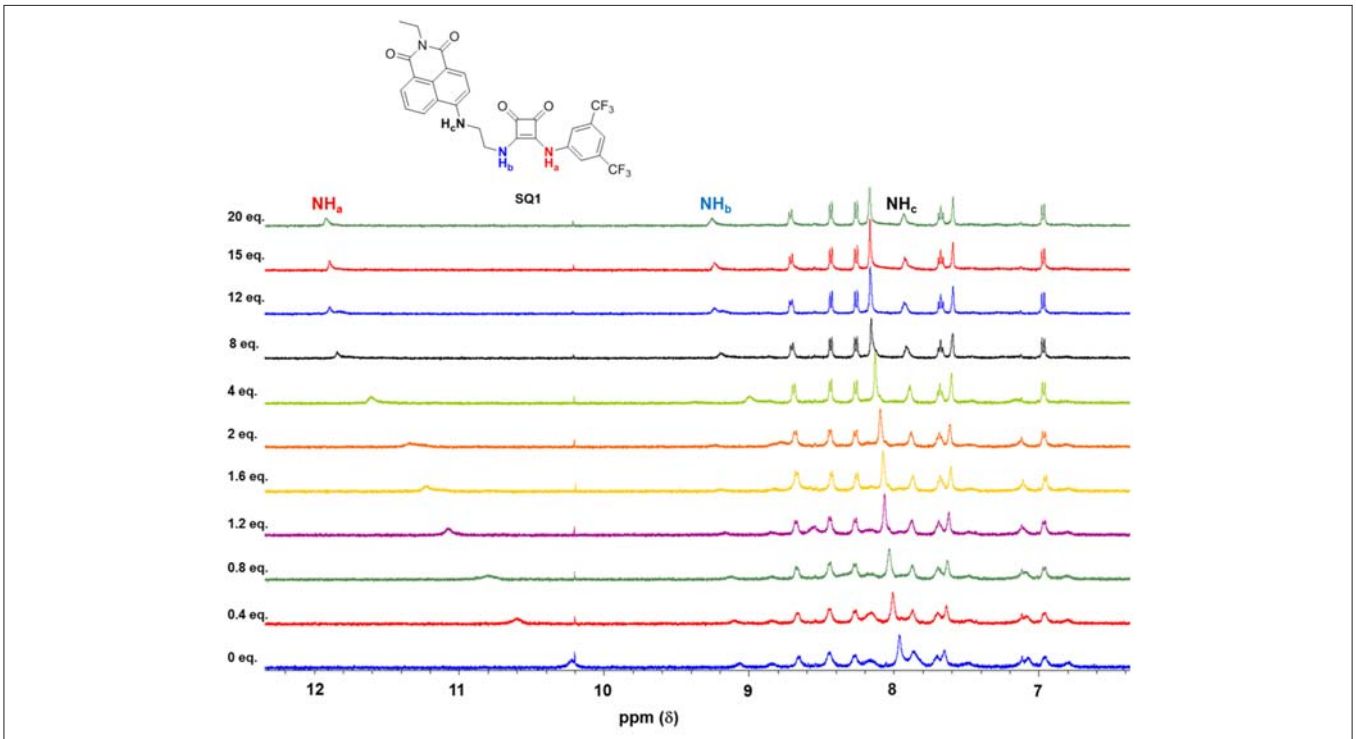

FIGURE 6 | Changes in the ^{1}H NMR spectrum (NH_a, NH_b, NH_c identified) of **SQ1** upon the addition 0–20 equivalents of anions as tetrabutylammonium (TBA) chloride in DMSO-d_6.

cases resolved from two broad signals to one single signal with significantly improved resolution (**Figures S20, S21**).

While conducting the ^{1}H NMR experiments we also noticed samples containing Cl^- and Br^- exhibited significantly more intense fluorescence than the parent receptors in solution when irradiated with UV light. This chance observation led us to investigate the fluorescence behavior of **SQ1** and **SQ2** upon titration with the halides in more detail.

Having observed such stark changes in the ^{1}H NMR titrations of **SQ1** and **SQ2** in the presence of halides we next wished to investigate their excited state properties in the presence of F^-, Cl^-, Br^-, and I^-. Titrations were performed in 5% aq. DMSO with addition of aliquots of the anions as their tetrabutylammonium salts. Both receptors exhibited emission with maxima at ca. 525 nm in solution. As shown in **Figure 7** additions of the halides resulted in varying effects. In the presence of I^- minor changes were observed where a small increase in emission intensity (20–25%) was observed up to a concentration of 20 mM. Addition of F^-, on the other hand, was found to result in a large decrease in emission intensity (80–85%) culminating in the both **SQ1** and **SQ2** largely appearing as non-fluorescent. We ascribe this behavior to the deprotonation observed in the NMR titrations and similar behavior was also observed in the presence of basic non-halide anions such as AcO^-, $H_2PO_4^-$, SO_4^{2-}. Most strikingly, however, was the observation of large fluorescence increases in the presence of both Cl^- and Br^- where the addition of Cl^- resulted in a 98 and 170% enhancement of emission from **SQ1** and **SQ2,** respectively, while, unexpectedly, Br^- resulted in a 500 and 600% enhancement of emission from **SQ1** and **SQ2,** respectively. From the previous temperature dependent fluorescence study, we suggest that the emission enhancement is as a result of the disaggregation of **SQ1** and **SQ2** in solution where aggregation induced self-quenching is disrupted allowing the release of monomers in solution and thus a recovery in fluorescence. Moreover, these responses were also clearly visible to the naked eye under UV illumination (**Figure 7B**). In order to investigate the effect of water on the fluorescence response, qualitative titrations were also performed in non-aqueous DMSO and in 20% aq. DMSO. We observed that the selective response to Br^- in pure DMSO was similar to that seen in 5% aq DMSO while in 20% aq. DMSO the response was considerably less defined. These results suggest that water concentration has a significant effect on the aggregation behavior of both **SQ1** and **SQ2** and thus their ability to act as halide sensors in fully aqueous environments (**Figures S27**, **28**).

Nevertheless, in order to investigate the sensing responses of **SQ1** and **SQ2** in more detail, fluorescence titrations were performed with 0.0–100.0 equivalent increments of halides in 5% aq. DMSO. As seen in the qualitative experiments the fluorescence intensity of both receptors is quenched by 80–85% upon addition of F^- while minor fluorescence enhancements are observed for I^-. However, a larger degree of enhancement (98–170%) is observed upon addition of Cl^- and, most interestingly, we observed a 500–600% increase in fluorescence intensity centered at 525 nm upon addition of Br^- (**Figure 8**).

These results demonstrate that both **SQ1** and **SQ2** show a selective fluorescence response toward Br^- when compared against other halides. This result is particularly unexpected given the NMR studies above where the binding of **SQ1** and **SQ2** to Cl^- appears to be considerably stronger when measured by ^{1}H NMR titration. Moreover, the desired "OFF-ON" fluorescence response paves the way for **SQ1** and **SQ2** to be used as selective bromide sensors with potential industrial/medical application. Limit of detection (LOD) values were estimated using a standard deviation method (LOD) = (3 S/m, in which S is the standard deviation of blank measurements, n = 11, and m is the slope of the linear equation) (Kumar et al., 2016), where **SQ1** and **SQ2** were found to exhibit LOD values in the μM range; values that are adequate to measure trace levels of halide contamination. A summary of the fluorescence quenching/enhancement characteristics and LOD values for **SQ1** and **SQ2** in the presence of the halides are listed in **Table 2**.

Evaluation of SQ1 and SQ2 in a Human Cell Line

With the observed spectroscopic responses and the potential application of **SQ1** and **SQ2** as bromide sensors we also

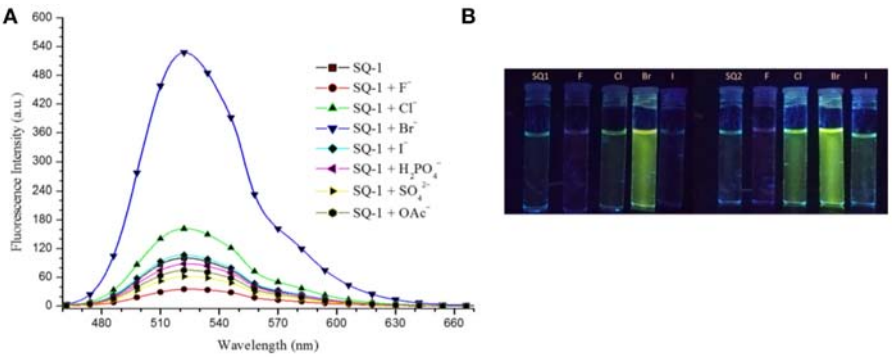

FIGURE 7 | (A) Fluorescence response of **SQ1** (5 μM) in 5% aq. DMSO toward different TBA anions (20 mM). (λ_{ex}. 435 nm). **(B)** Fluorescence response of **SQ1** and **SQ2** toward various halides in 5% aq DMSO after UV illumination as seen by the naked eye.

wished to evaluate their biocompatibility in a human cell line. Gale and co-workers have recently reported analogous naphthalimide-squaramide conjugates for use as anion receptors and transmembrane anion transporters where they found that the most active anion transporter [which also contained a 3,5-bis(trifluoromethyl)phenyl squaramide moiety] was readily internalized in human lung carcinoma A549 cells and exhibited no toxicity up to a concentration of 100 μM as determined using a CCK-8 assay (Bao et al., 2018). Thus we set out to conduct an initial evaluation of **SQ1** and **SQ2** uptake and behavior in cells. Firstly, the ability of **SQ1** and **SQ2** to be internalized into cells was assessed using confocal microscopy in HeLa cells, a widely-used cervical carcinoma cell line. HeLa cells (0.5×10^5) were incubated with either **SQ1** or **SQ2** (either 20, 5, or 1 μM) at 37°C for 1 h before the cells were fixed, and mounted for microscopy. **Figure 9** shows examples of cells incubated with **SQ1** and **SQ2** at 5μM, demonstrating successful uptake, as all cells in the sample emitted strong green fluorescence. **SQ1** and **SQ2** appear to localize in the cytoplasm as co-localization studies with the nucleic acid stain DAPI (blue) suggest that neither **SQ1** nor **SQ2** enter the nucleus. Uptake of both compounds was also investigated in a more quantitative manner using flow cytometry where, again, both **SQ1** and **SQ2** were rapidly taken up by HeLa cells. Resulting histogram plots show an increase in mean fluorescence intensity in a concentration-dependent manner and a clear shift for the entire cell population, demonstrating that all cells successfully internalized the compounds (**Figure 9**).

Cellular viability in the presence of **SQ1** and **SQ2** was measured using an MTT assay where the results showed that the % viability of HeLa cells decreased in a dose-dependent manner in the presence of **SQ1** and **SQ2,** with **SQ2** showing higher levels of cytotoxicity compared to **SQ1**. **SQ1** appeared to be largely non-toxic up to 1 μM while **SQ2** at 1 μM showed % cell viability at 28% (±20%) (see **Figure S42**). Gale and co-workers reported no toxicity up to a concentration of 100 μM for their 1,8-naphthalimide–squaramide conjugates, while **SQ1,** which is structurally very similar to the compounds reported by Gale, was shown to be considerably more cytotoxic under these conditions (Bao et al., 2018). Finally, we wished to determine whether the Br^- sensing abilities of these compounds could be measured *in cellulo*. As mentioned above O'Shea (Wu et al., 2018) and others (Zhai et al., 2014) have already exploited a disaggregation approach to sensing in a biological environment, thus we sought to investigate if **SQ1** and **SQ2** could measure bromide contamination in cells. Indeed, as shown in **Figure 10**, flow cytometry analysis was able to show a further increase in fluorescence intensity for cells incubated with **SQ1** or **SQ2** in the presence of sodium bromide (50 mM) compared to those incubated with the squaramide receptors in the absence of sodium bromide.

CONCLUSIONS

The field of molecular recognition continues to grow with ever more elegant receptors being reported that are capable of selective recognition for various anions using a diverse set of

TABLE 2 | Summary of the fluorescence quenching/enhancement characteristics and the Limit of Detection (LOD) values obtained for **SQ1** and **SQ2** in the presence of halides.

Probe	Anions	Fluorescence response	Detection limit (LOD = 3σ/slope)
SQ1	F^-	80% Quenching	6.25×10^{-6} M

In addition, histogram plots for FL-1 are also shown to illustrate the clear shift in FL-1 for the entire cell population (untreated cells (black), 100 nM, 1, 10 uM).

approaches. Indeed, with our experience of studying squaramide based probes we have attempted to uncover an alternative approach for selective detection of a somewhat neglected halide; Br^-. In this study we have reported the synthesis of two new squaramide-naphthalimide conjugates based on a "head to head" or "head to tail" design. We initially discovered that both probes **SQ1** and **SQ2** displayed a large degree of self-aggregation in aqueous DMSO solution that could be disrupted at increased temperature as studied by ^1H NMR and SEM. Moreover, we also discovered that the fluorescence behavior of both receptors was highly dependent upon the aggregation state and disruption of aggregation by increasing temperature gave rise to a significant increase in fluorescence intensity. We therefore exploited this disaggregation induced emission response for the recognition of halides, where we discovered that the receptors gave rise to distinct responses related to the interaction of the various halide anions with the receptors. Addition of F^- rendered both compounds non-emissive; thought to be due to a deprotonation event while, surprisingly, Br^- resulted in a dramatic 500–600% fluorescence enhancement thought to be due to a disruption of compound aggregation and allowing the monomeric receptors to dominate in solution. Furthermore, optical sensing parameters such as limits of detection and binding constant of probes were also measured toward the various halides (F^-, Cl^-, Br^-, and I^-) where both **SQ1** and **SQ2** were found to sense halides with adequate sensitivity to measure μM levels of halide contamination. Finally, initial studies in a human cell line were also conducted where it was observed that both compounds are easily taken up by HeLa cells, exhibiting strong intracellular fluorescence as measured by both confocal microscopy and flow cytometry. We were also able to demonstrate that **SQ1**- or **SQ2**- containing Hela cells treated with NaBr exhibited increased fluorescence intensity. While the observed increases in fluorescence intensity were modest in relation to those observed in the spectroscopic titrations described above, cell cytometry analysis allowed some distinction to be made. Given the complex environment of the cellular cytoplasm, the fully aqueous environment and the presence of intracellular Cl^- at high concentrations (ranging from 5 to 80 mM in mammalian cells) (Andersen, 2013) it is not surprising that the response is considerably less pronounced. Solvent effects are also likely to play a major role in the anion response. To the best of our knowledge, **SQ1** and **SQ2** are the first such fluorescent sensors capable of sensing Br^- *in cellulo* and we are currently working toward sensors with an improved bromide sensitivity and cellular cytotoxicity profile.

EXPERIMENTAL SECTION

3-((3,5-bis(trifluoromethyl)phenyl)amino)-4-ethoxycyclobut-3-ene-1,2-dione (1)

A solution of 3,5-bis(trifluoromethyl)aniline (1.835 mL, 11.75 mMol, 1eq) in EtOH (5 mL) was slowly added to a mixture of diethyl squarate (1.74 mL, 11.75 mMol, 1 eq) and zinc triflate (0.85 g, 2.35 mMol, 0.2 eq) in 5 mL EtOH. The reaction was stirred at room temperature overnight. The precipitate was collected by suction filtration and washed with EtOH and Et_2O to yield the product as an off-white amorphous solid (3.28 g, 79%). **^{1}H NMR,** (DMSO-d_6, 500.13 MHz) δ (ppm), J (Hz): 1.41 (t, J = 7.1, 3H, CH_3), 4.79 (q, J = 7.1, 2H, CH_2), 7.78 (s, 1H, phenylene H), 8.03 (s, 2H, phenylene H), 11.19 (br, 1H, NH); **^{13}C NMR** (DMSO-d_6, 125.76 MHz): δ (ppm): 184.9, 179.7, 140.6, 131.7, 131.4, 131.2, 126.8, 124.6, 122.4, 119.9, 116.8, 70.5, 15.8; **HRMS** (ESI) calcd. for $C_{14}H_{10}F_6NO_3$ $[M + H]^+$ 354.056, found 354.0554; **ν_{max} (KBr)/cm^{-1}:** 3,254, 3,185, 3,100, 3,062, 3,004, 1,816, 1,717, 1,603, 1,476, 1,453, 1,278, 1,233, 1,170, 1,101, 1,042, 997, and 936.

6-bromo-2-ethyl-1H-benzo[de]isoquinoline-1,3(2H)-dione (2a)

4-Bromo-1,8-naphthalic anhydride (2.0 g, 7.33 mMol, 1 eq) was mixed with ethylamine (0.57 mL, 8.66 mMol, 1.2 eq) in EtOH (10 mL). The reaction mixture was refluxed at 80°C for 24 h. The precipitate was collected by suction filtration and washed with EtOH and Et_2O to yield the product as a light tan amorphous solid (1.74 g, 79%). **^{1}H NMR,** (DMSO-d_6, 500.13 MHz) δ (ppm), J (Hz): 1.21 (t, J = 7.0, 3H, CH_3), 4.06 (q, J = 7.0, 2H, CH_2), 7.99 (t, J = 8.0, 1H, phenylene H), 8.21 (d, J = 7.8, 1H, phenylene H), 8.32 (d, J = 7.8, 1H, phenylene H), 8.55 (q, J = 7.8, 2H, phenylene H); **^{13}C NMR** (DMSO-d_6, 125.76 MHz): δ (ppm): 163.1, 163.1, 133.0, 132.0, 131.8, 131.4, 130.3, 129.5, 129.3, 128.8, 123.3, 122.5, 35.4, 13.5; **HRMS** (ESI) calcd. for $C_{28}H_{20}Br_2N_2NaO_4$ $[2M + Na]^+$ 628.968, found 628.9599; **ν_{max} (KBr)/cm^{-1}:** 3,086, 2,979, 2,939, 1,921, 1,779, 1,740, 1,693, 1,612, 1,587, 1,568, 1,505, 1,456, 14,35, 1,401, 1,371, 1,354, 1,339, 1,325, 1,244, 1,227, 1,201, 1,170, 1,150, 1,095, 1,061, 1,044, 1,021, and 961.

6-((2-aminoethyl)amino)-2-ethyl-1H-benzo[de]isoquinoline-1,3(2H)-dione (2b)

6-bromo-2-ethyl-1H-benzo[de]isoquinoline-1,3(2H)-dione (1 g, 3.288 mMol, 1 eq) was stirred at room temperature overnight in neat ethylenediamine (10 mL, excess) to yield a dark orange liquid. The crude product was slowly added to deionized water (50 mL) and left to stir at room temperature for 2 h. The precipitate was collected by suction filtration and washed with H_2O to yield the product as a yellow amorphous solid (0.748 g, 80%). **^{1}H NMR,** (DMSO-d_6, 500.13 MHz) δ (ppm), J (Hz): 1.11 (t, J = 7.0, 3H, CH_3), 2.82 (t, J = 6.4, 2H, CH_2), 3.32 (t, J = 6.4, 2H, CH_2), 3.97 (q, J = 7.1, 2H, CH_2), 6.73 (d, J = 8.5, 1H, phenylene H), 7.60 (m, 1H, phenylene H), 8.18 (d, J = 8.5, 1H, phenylene H), 8.36 (dd, 1H, phenylene H), 8.63 (dd, 1H, phenylene H); **^{13}C NMR,** (DMSO-d_6, 125.76 MHz) δ (ppm): 13.7, 34.7, 46.7, 104.3, 108.1, 120.6, 122.3, 124.6, 129.0, 129.8, 131.0, 134.6, 151.3, 163.1, 164.0; **HRMS** (ESI) calcd. for $C_{16}H_{18}N_3O_2$ $[M + H]^+$ 284.139, found 284.1389; **ν_{max} (KBr)/cm^{-1}:** 3,358, 2,979, 1,676, 1,612, 1,586, 1,550, 1,461, 1,430, 1,396, 1,370, 1,349, 1,249, 1,188, 1,152, 1,121, 1,104, 1,066, 965, and 918.

Tert-butyl(2-aminoethyl)carbamate (3a)

To a 500 mL round bottom flask was added ethylenediamine (13.4 mL, 161.86 mMol, 10 eq) in $CHCl_3$ (100 mL). A solution of di-tert-butyl dicarbonate (4.4 g, 37.56 mMol, 1 eq) in $CHCl_3$ (50 mL) was added dropwise over 2 h at 0°C and stirred at room for 24 h. The reaction mixture was washed with brine, the organic layer was washed with de-ionized H_2O and dried over $MgSO_4$. The filtrate was concentrated in vacuo to yield an off-white liquid. (2.012 g, 34%). **^{1}H NMR,** (DMSO-d_6, 500 MHz) δ (ppm), J (Hz): 1.36 (s, 9H, CH_3), 2.51 (d, J = 6.5, 2H, CH_2), 2.90 (d, J = 5.8, 2H, CH_2), 6.71 (s, 1H, NH); **^{13}C NMR** (DMSO-d_6, 125.76 MHz): δ (ppm): 28.7, 31.7, 42.0, 44.1, 77.8, 79.6, 156.1.

Tert-butyl(2-(6-nitro-1,3-dioxo-1H-benzo[de]isoquinolin-2(3H)-yl)ethyl)carbamate (3b)

Tert-butyl (2-aminoethyl) carbamate (0.565 mL, 3.54 mMol, 1 eq) was slowly added dropwise to a solution of 4-Nitro-1,8-naphthalic anhydride (0.86 g, 3.54 mMol, 1 eq) in EtOH (20 mL). The reaction mixture was left to react in a 35 mL microwave tube for 1 h at 110°C, 1 mbar and 300 watts. The precipitate was collected by suction filtration and washed with EtOH and Et_2O to yield the product as a peach amorphous solid (1.047 g, 76%). **^{1}H NMR,** (DMSO-d_6, 500.13 MHz) δ (ppm), J (Hz): 1.22 (s, 9H, CH_3), 3.27 (t, J = 6.0, 2H, CH_2), 4.14 (t, J = 6.0, 2H, CH_2), 6.88 (t, J = 6.3, 1H, NH), 8.09 (t, J = 8.1, 1H, phenylene H), 8.55 (d, J = 8.0, 1H, phenylene H), 8.62 (m, 2H, phenylene H), 8.71 (d, J = 8.4, 1H, phenylene H); **^{13}C NMR** (DMSO-d_6, 125.76 MHz): δ (ppm): 28.5, 38.0, 77.9, 123.1, 123.5, 124.6, 127.3, 128.9, 129.0,

129.9, 130.5, 132.0, 149.5, 156.2, 162.8, 163.6; **HRMS** (ESI) calcd. for $C_{19}H_{19}N_3NaO_6$ $[M + Na]^+$ 408.117, found 408.1144; **ν_{max} (KBr)/cm^{-1}:** 3,401, 3,070, 2,977, 2,935, 1,714, 1,702, 1,623, 1,593, 1,584, 1,523, 1,447, 1,410, 1,365, 1,341, 1,272, 1,233, 1,255, 1,192, 1,169, 1,148, 1,064, 992, and 968.

2-(2-aminoethyl)-6-nitro-1H-benzo[de]isoquinoline-1,3(2H)-dione (3c)

Tert-butyl (2-(6-nitro-1,3-dioxo-1H-benzo[de]isoquinolin-2(3H)-yl)ethyl)carbamate (1.02 g, 2.647 mMol, 1 eq) was dissolved in (TFA: DCM, 50: 50) (6 mL) and was stirred at room temperature overnight. The solvent was removed under reduced pressure to yield a beige amorphous solid (0.70 g, 93%). **^{1}H NMR,** (DMSO-d_6, 500 MHz) δ (ppm), *J* (Hz): 3.17 (q, *J* = 5.6, 2H, CH_2), 4.33 (t, *J* = 5.6, 2H, CH_2), 7.81 (br, 2H, NH_2), 8.13 (m, 1H, phenylene H), 8.58 (d, *J* = 7.9, 1H, phenylene H), 8.66 (m, 2H, phenylene H), 8.76 (dd, 1H, phenylene H); **^{13}C NMR** (DMSO-d_6, 125 MHz): δ (ppm): 37.9, 38.2, 123.2, 123.4, 124.7, 127.2, 128.9, 129.4, 130.1, 130.6, 132.2, 149.7, 163.3, 164.0; **HRMS** (ESI) calcd. for $C_{14}H_{12}N_3O_4$ $[M + H]^+$ 286.082, found 286.0800; **ν_{max} (KBr)/cm^{-1}:** 3,078, 1,712, 1,595, 1,525, 1,465, 1,437, 1,384, 1,348, 1,247, 1,151, 1,093, 1,058, 1,020, and 981.

6-amino-2-(2-aminoethyl)-1H-benzo[de]isoquinoline-1,3(2H)-dione (3d)

Pd/C (∼0.2 g) was added to a solution of 2-(2-aminoethyl)-6-nitro-1H-benzo[de]isoquinoline-1,3(2H)-dione (1.00 g, 3.50 mMol) dissolved in MeOH (40 mL). The reaction was placed under a H_2 atmosphere and left to stir at room temperature for 3 h. The reaction was filtered through a pad of celite and washed with excess MeOH, the filtrate was removed under reduced pressure to yield a mustard amorphous solid (0.673g, 75%). **^{1}H NMR,** (DMSO-d_6, 500.13 MHz) δ (ppm), *J* (Hz): 3.12 (s, 2H, CH_2), 4.27 (t, *J* = 6.0, 2H, CH_2), 6.86 (d, *J* = 8.4, 1H, phenylene H), 7.48 (s, 2H, NH_2), 7.67 (m, 1H, phenylene H), 7.77 (br, 2H, NH_2), 8.21 (d, J = 8.4, 1H, phenylene H), 8.44 (dd, 1H, phenylene H), 8.63 (dd, 1H, phenylene H); **^{13}C NMR,** (DMSO-d_6, 125.76 MHz) δ (ppm): 37.62, 38.36, 108.01, 108.63, 119.84, 122.43, 124.46, 129.94, 130.46, 131.52, 134.52, 153.40, 163.89, 164.96; **HRMS** (ESI) calcd. for $C_{14}H_{14}N_3O_2$ $[M + H]^+$ 256.108, found 256.1055; **ν_{max} (KBr)/cm^{-1}:** 3,419, 3,362, 3,259, 3,017, 1,636, 1,582, 1,531, 1,485, 1,429, 1,402, 1,378, 1,353, 1,311, 1,247, 1,203, 1,172, 1,128, 1,016, 964, and 907.

6-((2-((2-((3,5-Bis(Trifluoromethyl)Phenyl)Amino)-3,4-Dioxocyclobut-1-en-1-yl)Amino)Ethyl)Amino)-2-Ethyl-1H-Benzo[de]Isoquinoline−1,3-(2H)-Dione (SQ-1)

A solution of 3-((3,5-bis(trifluoromethyl)phenyl)amino)-4-ethoxycyclobut-3-ene-1,2-dione (0.436 g, 1.235 mMol, 1 eq) in EtOH (8 mL) was added slowly to a mixture of 6-((2-aminoethyl)amino)-2-ethyl-1H-benzo[de]isoquinoline-1,3(2H)-dione (0.35 g, 1.235 mM, 1 eq) and Et_3N (0.689 mL, 4.94 mMol, 4 eq) in EtOH (12 mL). The reaction was stirred at room temperature overnight. The precipitate was collected by suction filtration and washed with EtOH and ether. Product as a yellow amorphous solid with 78% yield (0.575 g). ^{1}H NMR at 343K, (DMSO- d_6, 500 MHz) δ (ppm), *J* (Hz): 1.18 (t, *J* = 7.0, 3H, CH_3), 3.70 (q, *J* = 5.5, 2H, CH_2), 3.95 (t, *J* = 5.5, 2H, CH_2), 4.04 (q, *J* = 7.0, 2H, CH_2), 6.91 (d, *J* = 8.5, 1H, phenylene H), 7.47 (s, 1H, phenylene H), 7.63 (m, 2H, phenylene H), 7.80 (br, 2H, NH), 7.89 (s, 1H, phenylene H), 8.25 (d, *J* = 8.5, 1H, phenylene H), 8.39 (d, J = 7.0, 1H, phenylene H), 8.58 (d, *J* = 8.3, 1H, phenylene H), 9.68 (br, 1H, NH); ^{13}C NMR at 343K, (DMSO-d_6, 125.76 MHz) δ (ppm): 13.6, 30.9, 34.6, 43.2, 44.2, 104.6, 109.1, 114.7, 118.3, 120.8, 122.5, 124.7, 128.6, 129.8, 130.9, 134.2, 141.5, 150.7, 163.1, 163.9, 171.2, 181.3; HRMS (ESI) calcd. for $C_{28}H_{21}F_6N_4O_4$ $[M + H]^+$ 591.146 found 591.1439; ν_{max} (KBr)/cm-1: 3,292 (broad), 3,086, 2,982, 1,796, 1,687, 1,581, 1,548, 1,459, 1,348, 1,278, 1,249, 1,180, 1,130, 1,067, 999, and 932.

6-amino-2-(2-((2-((3,5-bis(trifluoromethyl)phenyl)amino)-3,4-dioxocyclobut-1-en-1-yl)amino)ethyl)-1H-benzo[de]isoquinoline-1,3(2H)-dione (SQ-2)

A solution of 3-((3,5-bis(trifluoromethyl)phenyl)amino)-4-ethoxycyclobut-3-ene-1,2-dione (0.14 g, 0.39 mMol, 1 eq) in EtOH (8 mL) was slowly added to a mixture of 6-amino-2-(2-aminoethyl)-1H-benzo[de]isoquinoline-1,3(2H)-dione (0.1 g, 0.39 mmol, 1 eq) and Et3N (0.217 mL, 1.56 mMol, 4 eq) in EtOH (10 mL). The reaction was stirred at room temperature overnight. The precipitate was collected by suction filtration and washed with EtOH and Et2O to yield the product as an olive green amorphous solid (0.123 g, 56%). ^{1}H NMR at 343K, (DMSO-d_6, 500.13 MHz) δ (ppm), *J* (Hz): 3.90 (s, 2H, CH_2), 4.31 (t, *J* = 6.0, 2H, CH_2), 6.82 (d, *J* = 8.4, 1H, phenylene H), 7.22 (s, 2H, NH_2), 7.52 (s, 1H, phenylene H), 7.58 (t, *J* = 8.0, 1H, phenylene H), 7.89 (s, 2H, phenylene H), 8.15 (d, *J* = 8.4, 1H, phenylene H), 8.37 (d, *J* = 7.1, 1H, phenylene H), 8.57 (d, *J* = 8.4, 1H, phenylene H), 9.77 (br, 1H, NH); ^{13}C NMR at 343K, (DMSO-d_6, 125.76 MHz) δ (ppm): 27.9, 42.9, 108.7, 114.8, 118.4, 119.9, 120.3, 122.2, 122.5, 124.2, 124.7, 129.0, 130.3, 131.3, 134.3, 141.7, 153.3, 163.3, 164.6, 171.4, 181.3; HRMS (ESI) calcd. for $C_{52}H_{33}F_{12}N_8O_8$ $[2M + H]^+$ 1125.223, found 1125.2226; ν_{max} (KBr)/cm^{-1}: 371, 3,254, 1,796, 1,692, 1,636, 1,599, 1,528, 1,476, 1,434, 1,378, 1,308, 1,276, 1,250, 1,184, 1,129, 1,068, 1,000, and 933.

DATA AVAILABILITY

The datasets generated for this study are available on request to the corresponding author.

AUTHOR CONTRIBUTIONS

RE, LK, and MS designed the study and wrote the manuscript. RE and MS supervised the study. AA and LK synthesized and characterized the compounds and

carried out all spectroscopic titrations. OF performed the SEM studies. MS, MK, and JP carried out the biological studies. All authors discussed the results and commented on the manuscript.

ACKNOWLEDGMENTS

LK wishes to acknowledge the Irish Research Council for a Government of Ireland Postdoctoral Research Fellowship (GOIPD/2017/1091). MK also acknowledges the Irish Research Council for a Government of Ireland Postgraduate Scholarship (GOIPG/2015/3488). JP thanks Maynooth University for the award of a Hume Scholarship. Science Foundation Ireland are acknowledged for the funding of a Clariostar plate reader and Mass Spec facilities through the Opportunistic Infrastructure Fund (16/RI/3399).

Aggregation-Induced Emission: Lighting Up hERG Potassium Channel

*Xiaomeng Zhang, Tingting Liu, Qi Li, Minyong Li and Lupei Du**

Key Laboratory of Chemical Biology (MOE), Department of Medicinal Chemistry, School of Pharmacy, Shandong University, Jinan, China

Based on the scaffold of astemizole and E-4031, four AIE light-up probes (**L1–L4**) for Human Ether-a-go-go-Related Gene (hERG) potassium channel were developed herein using AIE fluorogen(TPE). These probes showing advantages such as low background interference, superior photostability, acceptable cell toxicity, and potent inhibitory activity, which could be used to image hERG channels at the nanomolar level. These AIE light-up probes hoped to provide guidelines for the design of more advanced AIE sensing and imaging hERG channels to a broad range of applications.

Keywords: AIE light-up probes, hERG channel, cell imaging, fluorophore, pharmacophore

INTRODUCTION

The potassium channels encoded by the hERG (human ether-a-go-go related gene) mediate the rapidly activating delayed rectifier K+ current (I_{Kr}), which plays a key role in repolarization of the ventricular action potential (Perrin et al., 2008). A number of drugs were withdrawn from the market because of their blockade on the hERG channel, such as Cissapride, Tefenadine, Astemisole, and Grepafloxacin (Roden, 2004; Du et al., 2007; Yamakawa et al., 2012). They can induce long QT syndrome, which may degenerate into ventricular fibrillation and sudden death (Roden, 2004; Babcock and Li, 2013). Therefore the study of hERG inhibition has become an important part of modern safety pharmacology. Today, FDA guidelines expect that all drugs should be measured the affinity with hERG channel to evaluate their cardiotoxicity (Brown, 2004). Recently, many studies have shown that various cancer cell lines express hERG channels, whereas, corresponding normal cell lines do not express significant hERG protein, such as neuroblastoma, breast cancer, and colon cancer cells (Bianchi et al., 1998; Cherubini and Crociani, 2000; Pillozzi et al., 2002). hERG channels are in connection with some progresses, such as increasing tumor cell proliferation, invasion and lymphatic spread, reducing cell differentiation (Jehle et al., 2011). In these tumor cells, the hERG protein can be used as a biomarker for malignant transition.

In order to analyze the hERG channels, there is a stringent demand for a simple and safe method to image hERG channels. Such studies will conduce to a better understanding of the role of hERG channels in cancer cells and further improve the diagnosis and treatment of cancer. Among imaging technologies, fluorescence imaging is considered as one of the most significant methods in the medical research and life science field. Using fluorescence imaging, it is possible to directly visualize hERG channels. What counts is that fluorescent probe is a significant factor in fluorescence imaging. Nowadays, there have various fluorescent probes using in living cells and biological system by scientists from the fluorescence imaging field (Liu et al., 2016, 2017). However, many fluorescent probes show different fluorescent behaviors in dilute and concentrated solutions. The fluorescence intensity is often weakened or quenched at high concentrations, which is mechanistically related with the "formation of aggregates,"

a phenomenon widely known as "aggregation-caused quenching" (ACQ) (Ding et al., 2013). Although scientists have made great efforts to overcome this phenomenon, ACQ effect is still an obstacle to the application of fluorescent probes to image biological target.

Tang's group found a novel fluorescent effect in 2001, a phenomenon named as "aggregation-induced emission," (AIE) which was completely opposite to the ACQ effect. They discovered there was no fluorescence when hexaphenylsilole (HPS) was dissolved in a fine solvent but there was strong fluorescence when it was dissolved in a poor solvent (Hong et al., 2011). When hexaphenylsilole is in free state, intramolecular rotation occurs, and there is no emission, but intramolecular rotation is restricted when it is in aggregated state, leading to fluorescence. Since then, quite a number of AIEgens have emerged and have been used in biological imaging, chemical sensing, smart materials and optoelectronic devices. Among the AIEgens, tetraphenylethene (TPE) derivatives (Shi et al., 2012; Ding et al., 2013) have been widely applied in rational design of AIE probes. AIE light-up probes offer superior photostability

and higher signal reliability comparing with conventional probes because of their higher resistance to photobleaching (Wang et al., 2016b).

RESULTS AND DISCUSSION

Chemistry

In general, the typical fluorescent probe consists of three parts: a fluorophore, a pharmacophore, and a linker (Cohen et al., 2002; Chen et al., 2014; Mizukami et al., 2014). In consideration of

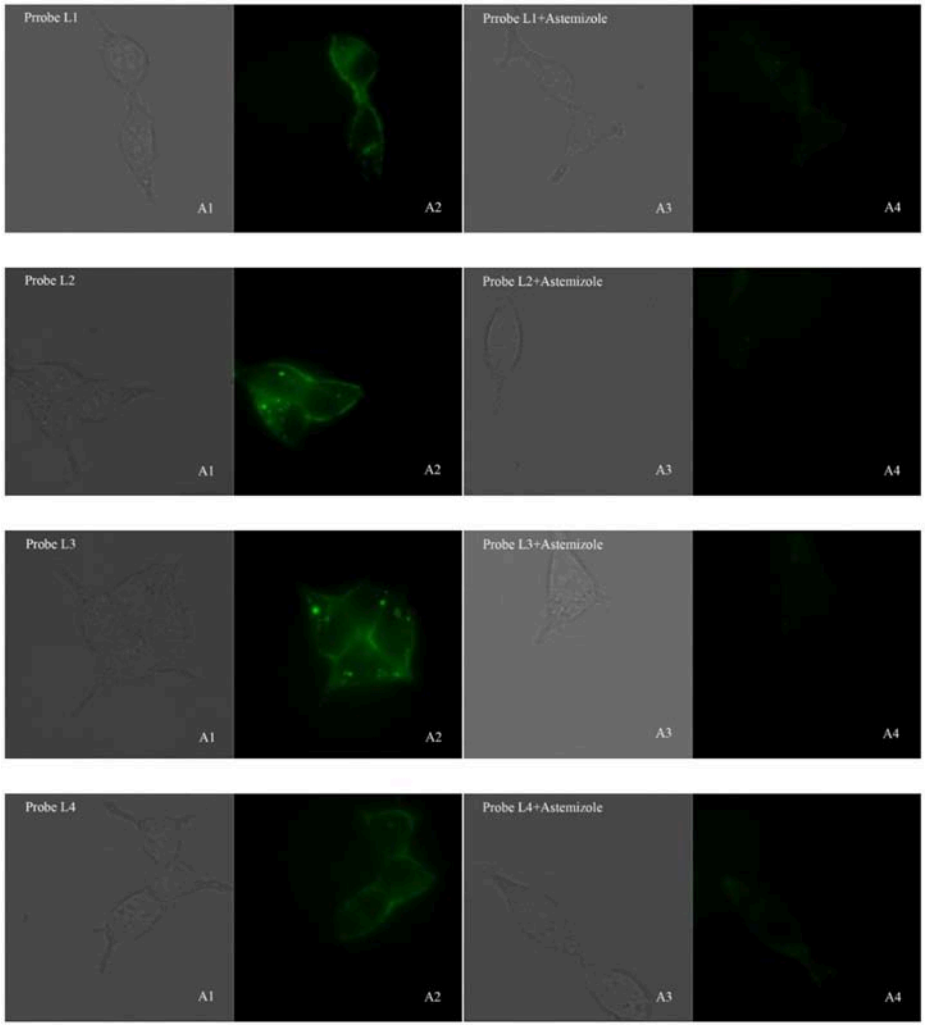

FIGURE 3 | Fluorescence microscopy imaging of hERG transfected HEK293 cells incubated with 5 μM probe **L1**, 5 μM probe **L2**, 1 μM probe **L3**, 5 μM probe **L4** (A1, bright field; A2, GFP channel), respectively. The imaging of inhibition of the hERG channels was accomplished by incubating astemizole (50, 50, 10, 50 μM) with probe **L1** (5 μM), **L2** (5 μM), **L3** (1 μM), and **L4** (5 μM) (A3, bright field; A4, GFP channel). All cells were incubated with each probe at 37°C for 10 min and washed immediately. The background was adjusted by ImageJ software. Imaging was performed using a Zeiss Axio Observer A1 microscope with a 63 × objective lens.

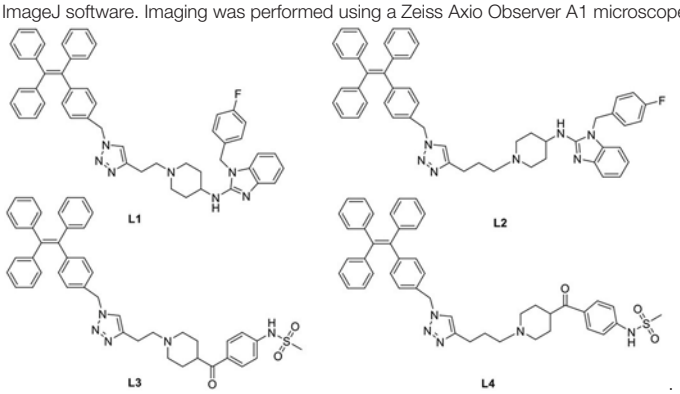

good fluorescent properties of TPE, it has been chosen as the fluorophore in the rational design for hERG channels probe. For pharmacophore, Astemizole and E-4031, the potent inhibitors of hERG channel, were chosen (Yamakawa et al., 2012; Wang et al., 2016a). For purpose of keeping the inhibitory activity of the probe, the major interaction sites of inhibitor's bonding were retained. Then the "click" reaction between the azoyl group on the fluorescence group and the acetylene group on

the recognition group was carried out by copper (I) in order to generate the turn-on probe (Liang et al., 2015). The small molecule fluorescent probes (**L1–L4**) for the hERG channels were illustrated in **Scheme 1**. When the probe is in freestate, the benzene ring can rotate freely, and the molecules in excited state release energy in a nonradiative manner. However, the free rotation of the benzene rings is limited after the probe binding hERG channel, and the excited molecules mostly release energy as fluorescence (**Scheme 2**).

Spectroscopic Properties of the Probes

Subsequently, the spectroscopic properties of the probes (**L1, L2, L3, L4**) were measured in 10 μM solution in PBS (pH = 7.4). The results indicated that all probes had similar fluorescent properties because of the same fluorophore (**Table 1**, **Figures 1**, **2**).

Binding Affinity of Probes

Afterwards, the inhibitory activities of the probes against the hERG potassium channel were evaluated utilizing radio-ligand binding assays by hERG transfected HEK293 cells. The results showed that probe **L3** displayed best inhibitory activity against the hERG channel, and the calculated IC_{50} and K_i values are 0.32 and 0.18 nM, respectively, which are slightly lower than astemizole (11.25 and 6.32 nM). Probe **L4** also showed lower inhibitory activity than astemizole, with IC_{50} values of 1.05 nM. Probes **L1** and **L2** showed potent inhibitory activity against hERG channel, with IC_{50} values of 120.50 and 155.90 nM, respectively, although lower than that of astemizole (See **Table 2**).

Cytotoxicity Assay

The cytotoxicity of these probes was evaluated by CCK-8 assays using hERG transfected HEK293 cells. The results indicated that the IC_{50} of probes **L1–L4** were 3.55 ± 0.28, 2.43 ± 0.12, and 7.03 ± 0.14 μM in hERG-HEK293 cells (See **Table 3**).

Fluorescent Image Assay

In consideration of their good fluorescent properties, acceptable cell toxicity, and potent inhibitory activity, probes **L1–L4** were utilized to image living cell in order to assess the capability of our probes for screening hERG channel. hERG transfected HEK293 cells were used to the imaging of probes **L1–L4** for hERG channels. Before we used probe to image cells, cell autofluorescence, and the effect of astemizole on cell autofluorescence were conducted (see **Supplementary Material**). The imaging results make clear that the autofluorescence of cells could be negligible in both the presence and absence of astemizole (**Figure S9**), which indicated the autofluorescence of the cells and astemizole would not interfere with the imaging of cells using probes **L1–L4**. The fluorescent imaging results demonstrated that these probes can label hERG-HEK293 cells with rapid responses and strong fluorescence to image hERG channels (**Figure 3**). Meanwhile, we chose a potent inhibitor of the hERG channels (astemizole) to incubate the cells with each probe. The fluorescence intensity was significantly decreased when the cells were co-incubated with astemizole and probe because of the inhibition of hERG channels by astemizole, which indicated that the hERG channels can be selectively labeled by the probe. Particularly, a complex washing procedure is not required because of their turn-on mechanism, which facilitated the experimental process. In conclusion, the results indicated that these probes all possess superior selectivity for hERG channels and could be used in the detection of hERG potassium channel.

CONCLUSIONS

AIEgens are an emerging class of fluorophore with unique photophysical properties whose applications are attracting increasing attention. We designed four fluorescent probe for hERG channels based on AIE effect, with good fluorescent properties and acceptable cytotoxicity. The affinity for the hERG channel showed that the probes **L1–L4** have higher affinity for the hERG channel, especially the probe molecule **L3** (IC_{50} = 1.05 nM, K_i = 0.59 nM), which has a stronger affinity for the hERG potassium channel than the positive drug astemizole (IC_{50} = 11.25 nM, K_i = 6.32 nM). The probes **L1–L4** can be utilized to the localization and visualization of hERG channel, and they have been successfully utilized to label the hERG channels in hERG- HEK293 cells at the nanomolar level. These probes are anticipated to set up a screening system for hERG channels. But two aspects are deemed essential for these AIE light-up probes for hERG channels, these AIE light-up probes used blue green emissive TPE fluorogens, which have limited application in *in vivo* studies that require deep penetration and low autofluorescence. One choice is to design red or FR/NIR emissive AIEgens with desirable functionalities. The alternative option is to choose red or FR/NIR emissive fluorophore which can greatly widen the scope of fluorescent probe for hERG channels *in vivo* applications.

AUTHOR CONTRIBUTIONS

XZ, ML, and LD conceived and designed the experiments. XZ, TL, and QL performed the experiments. XZ, ML, and LD analyzed the data. XZ wrote the manuscript. LD retouched the document.

FUNDING

The present project was supported by grants from the Shandong Natural Science Foundation (No. ZR2017MH101) and the Key Research and Development Project of Shandong Province (No. 2017CXGC1401).

SUPPLEMENTARY MATERIAL

The Supplementary Material for this article can be found online at: https://www.frontiersin.org/articles/10.3389/fchem.2019.00054/full#supplementary-material

Theoretical and Computational Chemistry

Vera Krewald

Vera Krewald obtained her PhD under the supervision of Prof. F. Neese and Dr D. A. Pantazis at the MPI for Chemical Energy Conversion in Mülheim/Ruhr, Germany, having worked on the water splitting reaction in natural photosynthesis. After a Marie-S.-Curie postdoctoral stay in Prof. L. González's group at the University of Vienna, Austria, she began independent research as a 50th Anniversary Prize Fellow at the University of Bath, UK, in 2017. Since December 2018, she is a tenure track Professor at TU Darmstadt, Germany. Research in her group focusses on the electronic structure analysis of open-shell transition metal complexes for reactions such as nitrogen activation, water oxidation and oxygen reduction.

Manuel Hitzenberger

Manuel Hitzenberger was born in Innsbruck in 1984 and is currently a postdoctoral researcher at the Technical University of Munich at the chair of Theoretical Biophysics - Molecular Dynamics. He studied Chemistry at the Leopold-Franzens University Innsbruck, where he graduated in 2012 from the Institute of General, Inorganic and Theoretical Chemistry. In 2017 he obtained his PhD, also at the University of Innsbruck, specializing in QM/MM-MD simulations of biomacromolecules. Today, his main research interests lie in the fields of membrane protein dynamics, protein – ligand docking, and multi-scale approaches to molecular dynamics.

Heather J. Kulik

Heather J. Kulik is an Assistant Professor in Chemical Engineering at MIT. She received her BE in Chemical Engineering from Cooper Union in 2004 and her PhD in Materials Science and Engineering from MIT in 2009. Following postdocs at Lawrence Livermore and Stanford, she returned to MIT. Her work has been recognized by a Burroughs Wellcome Fund Career Award at the Scientific Interface, an Office of Naval Research Young Investigator Award, a DARPA Young Faculty Award, an AAAS Marion Milligan Mason Award, the NSF CAREER, the ACS OpenEye Award for Outstanding Junior Faculty in Computational Chemistry, and the Journal of Physical Chemistry Lectureship, among others.

Jane R. Allison

Jane obtained a BSc (Hons) from the University of Canterbury in 2003 and a PhD from Cambridge University in 2008, where she worked with Prof. Chris Dobson. After working as a postdoc with Prof. Wilfred van Gunsteren at ETH Zürich, she returned to New Zealand in 2012 to become a Lecturer at Massey University. She was awarded a Rutherford Discovery Fellowship in 2015, and in 2018, moved to the University of Auckland, where she is an Associate Professor and an Associate Investigator with the Maurice Wilkins Centre for Molecular Biodiscovery and the Biomolecular Interaction Centre at the University of Canterbury.

Krzysztof B. Beć

Krzysztof B. Beć obtained his PhD degree in 2014 in Physical and Theoretical Chemistry from the University of Wrocław. His research involved thin-film IR spectroscopy, optical constants, and computational methods. He worked with Professor Yukihiro Ozaki as a Postdoctoral Fellow and Research Assistant Professor at Kwansei Gakuin University, Japan where he developed applications for simulation of NIR spectra and contributed to the development of ATR-FUV spectroscopy and its applications (polymer-carbon nanostructure composites). He continues his work in basic and applied spectroscopy in Prof. Christian W. Huck's team at University of Innsbruck, Austria.

Matthew G. Quesne

Dr Matthew George Quesne obtained his PhD from Manchester University, under the supervision of Dr Samuel de Visser, for modelling homogeneous catalysts. In 2014, he joined Dr Tomasz Borowski's group (Krakow, Poland) where he used MD, QM/MM and cluster model techniques to simulate enzyme catalyzed reactions. In 2016, Dr Quesne moved to Prof. Richard Catlow's group at Cardiff University where he studied CO2 activation by various materials and in March he started a position at the UK Catalysis Hub. Dr Quesne has published 29 high impact peer reviewed articles as well as three book chapters. He has over 800 citations and an H-index of 18.

Steric Switching From Photochemical to Thermal N_2 Splitting: A Computational Analysis of the Isomerization Reaction $\{(Cp^*)(Am)Mo\}_2(\mu\text{-}\eta^1\text{:}\eta^1\text{-}N_2) \rightarrow \{(Cp^*)(Am)Mo\}_2(\mu\text{-}N)_2$

*Vera Krewald**

Theoretische Chemie, Fachbereich Chemie, TU Darmstadt, Darmstadt, Germany

A μ-η^1:η^1-N_2-bridged Mo dimer, $\{(\eta^5\text{-}C_5Me_5)[N(Et)C(Ph)N(Et)]Mo\}_2(\mu\text{-}N_2)$, cleaves dinitrogen thermally resulting in a crystallographically characterized bis-μ-N-bridged dimer, $\{(\eta^5\text{-}C_5Me_5)[N(Et)C(Ph)N(Et)]Mo\}_2(\mu\text{-}N)_2$. A structurally related Mo dimer with a bulkier amidinate ligand, ([N(^{i}Pr)C(Me)N(^{i}Pr)]), is only capable of photochemical dinitrogen activation. These opposing reactivities were rationalized as steric switching between the thermally and photochemically active species. A computational analysis of the geometric and electronic structures of intermediates along the isomerization pathway from $Mo_2(\mu\text{-}\eta^1\text{:}\eta^1\text{-}N_2)$ to $Mo_2(\mu\text{-}\eta^2\text{:}\eta^1\text{-}N_2)$ and $Mo_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$, and finally $Mo_2(\mu\text{-}N)_2$, is presented here. The extent to which dispersion affects the thermodynamics of the isomers is evaluated, and it is found that dispersion interactions play a significant role in stabilizing the product and making the reaction exergonic. The concept of steric switching is further explored with theoretical models with sterically even less demanding ligands, indicating that systematic ligand modifications could be used to rationally design the N_2 activation energy landscape. An analysis of electronic excitations in the computed UV-vis spectra of the two complexes shows that a particular type of asymmetric excitations is only present in the photoactive complex.

INTRODUCTION

Catalytic nitrogen fixation with well-defined molecular complexes remains a grand challenge despite decades of research in this field. The research field is driven by the vision that a molecular catalyst capable of catalytically transforming nitrogen atoms from the dinitrogen molecule into ammonia or chemicals of higher economic value would contribute to a more sustainable chemical industry not dependent on fossil resources (Crossland and Tyler, 2010; Broda et al., 2013; Tanabe and Nishibayashi, 2013; Lee et al., 2014; Burford and Fryzuk, 2017; Burford et al., 2017; Connor and Holland, 2017; Creutz and Peters, 2017; Eizawa and Nishibayashi, 2017; Kuriyama and Nishibayashi, 2017; Roux et al., 2017). Industrial

ammonia production with the Haber-Bosch process is overall energy efficient, but relies on fossil H_2 for the steam reforming step (Schlögl, 2008). While a molecular catalyst for NH_3 production may never be efficient enough to replace the highly optimized Haber-Bosch process, research in this area results in valuable insights into the fundamental principles and electronic structure requirements for N_2 activation. This in turn may not only be relevant for fertilizer production, but also for alternative fuels that are based on nitrogen instead of carbon (Schlögl, 2010) (Grinberg et al., 2016; Chen et al., 2018). Catalysts that produce ammonia from dinitrogen are based on molybdenum, iron and cobalt (Roux et al., 2017), with many more elements known to be capable of binding N_2 and activating the strong N-N bond (Burford and Fryzuk, 2017; Klopsch et al., 2017). Strategies toward the development of molecular N_2 fixation catalysts operating at ambient or close to ambient conditions encompass a better understanding of the nitrogenase cofactor in nature (Lancaster et al., 2011; Spatzal et al., 2011; Sippel and Einsle, 2017), the development of molecular complexes and catalysts that activate or split N_2 (Dance, 2010; MacLeod and Holland, 2013; MacLeod et al., 2016; Djurdjevic et al., 2017; Eizawa et al., 2017; Sickerman et al., 2017), and the elucidation of the electronic structure of such complexes with computational and spectroscopic studies (Himmel and Reiher, 2006; Studt and Tuczek, 2006; Christian et al., 2007; Huss et al., 2013; Weymuth and Reiher, 2014). Ideally, the complexes will either fully cleave the N_2 molecule or activate the bond sufficiently that the nitrogen atoms are prepared for subsequent chemical reactions, and be part of a complete catalytic cycle with reasonable turnover numbers and turnover frequencies.

Over the past decade, Sita et al. have synthesized and characterized an extensive isostructural series of dinitrogen-bridged dimers which are capable of thermal or photochemical dinitrogen activation (Hirotsu et al., 2007a). The M-(μ-N_2)-M cores, where M = Ti (Fontaine et al., 2010), V (Keane et al., 2014); Zr (Hirotsu et al., 2007b), Nb (Keane et al., 2014), Mo (Fontaine et al., 2010); Hf (Hirotsu et al., 2007b), Ta (Hirotsu et al., 2007a; Keane et al., 2014), W (Fontaine et al., 2010), are stabilized by a common ligand sphere composed of a Cp* ligand and an amidinate ligand on each metal, see **Figure 1A** (Yonke et al., 2011a,b; Keane et al., 2013; Farrell et al., 2016; Duman and Sita, 2017). The amidinate ligand can be functionalized at the N-donor atoms or central carbon. Common N-functionalizations are Et and ^{i}Pr, and common C-functionalizations are Me, NMe_2 (i.e., a guanidinate), and Ph. In this paper, the ligand modifications will be denoted as {C-functionalization–N-functionalization}, e.g., {Me–^{i}Pr} for the ligand {N(^{i}Pr)C(Me)N(^{i}Pr)}$^-$. The M-(μ-N_2)-M cores are side-on bridging with a non-planar diamond core for Zr and Hf, and end-on bridging with a linear or near-linear core for Ti, V, Nb, Ta, Mo, and W (Keane et al., 2014).

Most of the complexes in Sita's series are thermally active, i.e., activate or split the N-N bond to yield monomeric metal nitride or dimeric μ-N-bridged complexes initially (Fontaine et al., 2010; Keane et al., 2015; Duman and Sita, 2017). Two complexes based on Mo and W are photoactive, i.e., result in complexes with M_2(μ-N) and M_2(μ-N)$_2$ cores upon irradiation with a mercury pressure lamp, see **Figure 1B** (Keane et al., 2015).

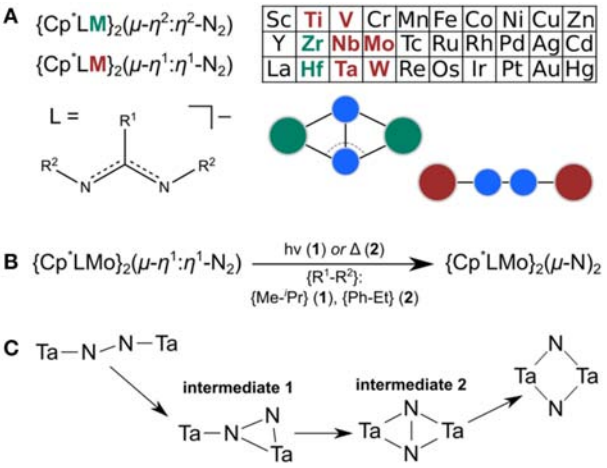

FIGURE 1 | (A) Overview of Sita's series of N_2-bridged complexes; Zr and Hf complexes are non-planar μ-η^2:η^2-N_2-bridged whereas all other known complexes have linear μ-η^1:η^1-N_2-bridged cores. **(B)** Capacity of the molybdenum complexes **1** and **2** for thermal or photochemical dinitrogen activation. **(C)** Isomerization path predicted computationally (Zhang et al., 2011) for the Ta congener using a simplified ligand framework.

Photochemical activation of N_2 (Krewald, 2018) in a well-defined molecular complex was first observed in 2001 (Solari et al., 2001), and has since been shown in several N_2-bridged dimers based on Mo (Curley et al., 2008; Miyazaki et al., 2014; Keane et al., 2015), W (Keane et al., 2015), Re (Schendzielorz et al., 2019), and Os (Kunkely and Vogler, 2010). Nitrogen photoactivation itself is currently not well-understood with only one time-resolved spectroscopy (Huss et al., 2013) and few computational investigations (Reiher et al., 2004; Krewald and González, 2018) available. The appeal of a light-driven step in nitrogen splitting lies in high spatio-temporal reaction control, high selectivity by depositing a well-defined amount of energy into the catalyst, and potentially the use of sunlight as a free and green source of energy.

For the Mo and W complexes with the {Me–^{i}Pr} ligand, Sita et al. showed that they are thermally stable at up to 100°C in hydrocarbon solution, but are sensitive to irradiation from a Rayonet carousel of medium-pressure Hg lamps (Keane et al., 2015). Through photolysis in the presence of a Group 14 alkyl- or aryl-substituted chloride (i.e., R_3ECl, E = C, Si, Ge), terminal imido products and metal dichloride precursors of the starting complexes are formed. The imido product can react with CO_2 to form isocyanate derivatives $R_3EN{=}C{=}O$ and a metal oxo complex, which can be transformed into the metal dichloride precursor, thus completing the chemical cycle (Keane et al., 2015). Although the photochemical activation of N_2 is in principle a desirable reaction, the authors noted that for these particular complexes the reactions were slow and suffered from poor energy efficiency and atom economy. Because the underlying photophysics and photochemistry of nitrogen photofixation are poorly understood in general (Krewald, 2018), Sita et al. subsequently sought to enable the thermal pathway by reducing the steric demands of the {Me–^{i}Pr} ligand in the photochemically active Mo and W dimers (Duman et al., 2016).

Steric hindrance as a design feature has been exploited in dinitrogen activation before, e.g., by Cummins et al., who have shown that an undesired mono-μ-N product of their $[(N(^tBu)(Ar))_3Mo(\mu\text{-}N_2)Mo(N(^tBu)(Ar))_3]$ complex is avoided (Laplaza and Cummins, 1995; Johnson et al., 1997), unlike in other dinitrogen-splitting complexes (Solari et al., 2001). Similarly, a well-established body of work by Power et al. among others exploits the cumulative effects of dispersion interactions in sterically crowded systems to stabilize otherwise energetically unfavorable complexes (Liptrot et al., 2016; Liptrot and Power, 2017). Seminal work by Grimme has provided the computational basis to explore these effects *in silico* (Grimme, 2004, 2011; Grimme et al., 2011b).

For the Ta, Nb, and Hf congeners an extensive study focused on the link between steric demand and nitrogen activation capacity (Fontaine et al., 2010; Keane et al., 2014). Expanding on these principles, thermal dinitrogen activation in both the Mo and W complexes could indeed be achieved by modifying the amidinate ligand substitution pattern from {Me–^{i}Pr} to {Ph–Et} (Duman et al., 2016). Again, the isomerization from a linear to a diamond-shaped core was observed and some of the resulting products were crystallized (Duman et al., 2016). It is not immediately obvious whether the difference in reactivity is mainly due to steric or electronic factors. The set of $M_2(\mu\text{-}\eta^1\text{:}\eta^1\text{-}N_2)$ complexes with M = Mo, W are experimentally characterized as having singlet ground states for both the {Me–^{i}Pr} and the {Ph–Et} ligands (Fontaine et al., 2010; Keane et al., 2015; Duman et al., 2016). For the $M_2(\mu\text{-}N)_2$ cores, diamagnetic character is also dominant; however for the molybdenum dimer with {Me–^{i}Pr} ligands strong paramagnetic shifting of the ^{1}H resonances in the NMR spectra is observed in solution despite SQUID magnetometry data on the solid state sample supporting a closed-shell configuration (Keane et al., 2015). Overall, the crystallographic core geometries and electronic structure properties of the starting complexes are rather similar, warranting a more detailed look at their isomerization reactions.

The isomerization of the Ta dimer from a linear to a diamond-shaped core originally suggested by Fontaine et al. (2010) was explored computationally by Morokuma et al. with a simplified ligand system (Cp instead of Cp*; {H–Me} amidinate ligands) (Zhang et al., 2011). According to this study, the linear core, $M_2(\mu\text{-}\eta^1\text{:}\eta^1\text{-}N_2)$, transforms into an end-on/side-on bridging core, $M_2(\mu\text{-}\eta^2\text{:}\eta^1\text{-}N_2)$, then into a side-on/side-on bridging dimer, $M_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$, before fully breaking the N-N bond and forming a diamond-shaped core, $M_2(\mu\text{-}N)_2$; see **Figure 1C** (Zhang et al., 2011).

In this contribution, computational analyses based on density functional theory are used to elucidate the ground state geometries and electronic structures of the linear molybdenum complexes $\{(\eta^5\text{-}C_5Me_5)[N(^iPr)C(Me)N\text{-}(^iPr)]Mo\}_2(\mu\text{-}N_2)$ (**1**) and $\{(\eta^5\text{-}C_5Me_5)[N(Et)C(Ph)N\text{-}(Et)]Mo\}_2(\mu\text{-}N_2)$ (**2**). The relevant intermediates along the isomerization paths to molybdenum dimers with diamond-shaped cores are identified and characterized to evaluate the idea of steric switching along the isomerization paths. The relevance of dispersion corrections for all intermediates is discussed, and suggestions for complexes with further reduced steric bulk are made. To gain some insight into the photoactivity of the complex with bulkier ligands, the electronic UV-vis absorption spectra are predicted and differences to the spectrum obtained for the thermally active compound are discussed. It is found that a group of transitions with asymmetric MLCT and LMCT character is present in the photoactive, but absent in the thermally active compound. This contribution aims to provide computational insight into the previously unclear ground state electronic structure of the complexes with linear Mo-N-N-Mo cores and identifies possible reasons for the observed differences in reactivity of these structurally similar complexes which may be of relevance for future experimental studies on the complexes' thermodynamic and kinetic properties as well as their photophysical and photochemical processes.

MATERIALS AND METHODS

All calculations were performed with the ORCA program package as unrestricted Kohn-Sham calculations (Neese, 2012). Geometries were optimized with the BP86(Perdew, 1986; Becke, 1988) density functional using the resolution of the identity approximation, the def2-TZVP basis set for molybdenum and nitrogen atoms with def2-ECP for molybdenum atoms, the def2-SVP basis for carbon and hydrogen atoms, and the def2/J auxiliary basis (Andrae et al., 1990; Weigend and Ahlrichs, 2005; Weigend, 2006). The grid size was increased to 7 in ORCA nomenclature, and the integration accuracy was set to 7.0. Tight SCF and optimization convergence criteria were chosen. The CPCM implicit solvent model with benzene ($\varepsilon = 2.28$) was used. Grimme's atom-pairwise dispersion correction with Becke-Johnson damping (D3BJ) was used (Grimme et al., 2010, 2011a), except where explicitly excluded as mentioned in the main text.

For the relative energies of spin states, single point energy calculations were performed with the density functionals PBE0 (Adamo and Barone, 1999), TPSSh (Staroverov et al., 2003), B3LYP (Lee et al., 1988; Becke, 1993), M06 (Zhao and Truhlar, 2008), including the chain-of-spheres approximation and the def2/JK basis set (Weigend, 2008; Neese et al., 2009b). To confirm the predicted geometries along the isomerization paths as true minima, the absence of any imaginary frequencies was verified with frequency calculations using the same computational details as for the geometry optimizations, except for the omission of the CPCM solvent model. To obtain a full thermodynamic picture, enthalpies, entropies and Gibbs free enthalpies were taken from these calculations, supplemented with electronic energy calculations with the B3LYP or PBE0 functional using the RIJCOSX approximation with the def2/JK auxiliary basis set.

The UV-vis spectra of the linear complexes were predicted with TD-DFT using various density functionals due to the absence of a calibration study for similar molybdenum dimers. Even though compared with the experimental spectrum of $\{(\eta^5\text{-}C_5Me_5)[N(^iPr)C(Me)N\text{-}(^iPr)]Mo\}_2(\mu\text{-}N_2)$, the predicted spectra are shifted to higher energies by ca. 1 eV, the main features are reproduced satisfactorily. Using otherwise identical settings for the electronic structure calculations as for the single point calculations above, the density functionals tested are BP86

(Perdew, 1986; Becke, 1988), TPSS (Tao et al., 2003), TPSSh (Staroverov et al., 2003), B3LYP (Lee et al., 1988; Becke, 1993), PBE0 (Adamo and Barone, 1999), CAM-B3LYP (Yanai et al., 2004), LC-BLYP (Iikura et al., 2001), and ωB97X (Chai and Head-Gordon, 2008). The Tamm-Dancoff approximation(Hirata and Head-Gordon, 1999) was used and 100 roots were calculated (Neese and Olbrich, 2002). The solvent modeled was methyl cyclohexane ($\varepsilon = 2.071$). All line spectra are generated with the ORCA utility program *orca_mapspc* with spectral broadening of 2,500 cm^{-1}.

RESULTS

Geometries and Electronic Structures of Molybdenum Dimers With Linear and Diamond-Shaped Cores

The starting complexes are $\{(\eta^5\text{-}C_5Me_5)[N(^i Pr)C(Me)N\text{-}(^i Pr)]Mo\}_2(\mu\text{-}N_2)$, $\mathbf{1}_{lin}$, which is photoactive, and $\{(\eta^5\text{-}C_5Me_5)[N(Et)C(Ph)N\text{-}(Et)]Mo\}_2(\mu\text{-}N_2)$, $\mathbf{2}_{lin}$, which is thermally active. They may be formally viewed as two Mo(II), d^4, with a neutral N_2 bridge, or as two Mo(IV), d^2, with a N_2^{4-} bridge (Fontaine et al., 2010). A crystal structure is only available for $\mathbf{2}_{lin}$, where the N-N bond length of 1.288 Å corresponds approximately to a dinitrogen double bond (Holland, 2010). As noted by Fontaine et al., the true electronic configuration probably lies somewhere in-between the oxidation states that can be assigned formally (Fontaine et al., 2010).

The crystal structures of the product complexes $\{(\eta^5\text{-}C_5Me_5)[N(^i Pr)C(Me)N\text{-}(^i Pr)]Mo\}_2(\mu\text{-}N)_2$, $\mathbf{1}_{dia}$, and $\{(\eta^5\text{-}C_5Me_5)[N(Et)C(Ph)N\text{-}(Et)]Mo\}_2(\mu\text{-}N)_2$, $\mathbf{2}_{dia}$, show diamond-shaped Mo_2N_2 cores. Formally, the molybdenum ions are now oxidized to Mo(V), d^1, implying that in principle a singlet and a triplet ground state are accessible. In the solid state, magnetic data obtained from SQUID magnetometry indicate a closed-shell electronic structure for $\mathbf{1}_{dia}$. Notably, the ^1H NMR resonances of solutions of $\mathbf{1}_{dia}$ are subject to paramagnetic shifting whereas for $\mathbf{2}_{dia}$ no indication for open-shell character is found (Keane et al., 2015; Duman et al., 2016). The N-N distances are >2.5 Å and thus no residual bonding interaction is to be expected. The crystallographic Mo-Mo distances on the other hand are slightly shorter than twice Pauling's covalent bond radius for Mo (1.371 Å). At 2.676 and 2.648 Å, respectively, they are in the range of distances expected for a Mo-Mo single or double bond (Pauling and Kamb, 1986; Shin and Parkin, 1998; Neary and Parkin, 2017). Both diamond cores are to some extent asymmetric: the molybdenum ions in $\mathbf{1}_{dia}$ have different bond lengths with the bridging nitrogen atoms ($Mo^1\text{-}N^{1,2}$: 1.850 Å, $Mo^2\text{-}N^{1,2}$: 1.964 Å), whereas each molybdenum in $\mathbf{2}_{dia}$ has two different bond lengths with the nitrogen bridges (1.892, 1.927 Å) (Keane et al., 2015; Duman et al., 2016). From a purely structural point of view, the two complexes have strikingly similar geometries that do not indicate any major influence of the ligand sphere on the geometry of the Mo_2N_2 core.

The structural parameters obtained for $\mathbf{1}_{lin}$ from a geometry relaxation are in good agreement with those of related complexes such as $\mathbf{2}_{lin}$ (**Figure 3**). In the absence of a crystal structure for $\mathbf{1}_{lin}$, no direct comparison to experimental data is possible. The geometry optimization of $\mathbf{2}_{lin}$ results in excellent agreement with the available crystal structure. The N-N distance is found to be 1.247 Å (exp.: 1.288 Å) and the Mo-N bond lengths are predicted to within 0.03 Å. In both linear molybdenum dimers, the Mayer bond orders indicate a N-N double bond (1.64) and bonds that are in-between single and double bonds for the M-N interaction (1.39, see **Table 1**).

TABLE 1 | Computed Mayer bond orders along the isomerization coordinate of **1** and **2**, including for the singlet (s) and triplet (t) configurations of $\mathbf{1}/\mathbf{2}_{dia}$.

Cpd.	Mo-Mo	Mo-N	Mo-N	Mo-N	Mo-N	N-N
1_{lin}	0.32	1.39	0.12	1.39	0.12	1.60
1_{int-1}	0.26	1.31	0.14	1.23	0.36	1.24
1_{int-2}	0.35	1.14	0.69	1.12	0.61	0.88
1_{dia} (s)	0.70	1.23	1.23	1.23	1.23	<0.1
1_{dia} (t)	0.43	1.56	1.53	1.00	1.02	<0.1
2_{lin}	0.31	1.39	0.11	1.39	0.11	1.64
2_{int-1}	0.27	1.19	0.17	1.15	0.51	1.14
2_{int-2}	0.33	1.13	0.68	1.09	0.64	0.89
2_{dia} (s)	0.73	1.13	1.36	1.36	1.13	<0.1
2_{dia} (t)	0.42	1.47	1.66	1.11	0.94	<0.1

For the product $\mathbf{1}_{dia}$, the geometry relaxation with a singlet electronic configuration yields a symmetric diamond core with a Mo-Mo distance of 2.633 Å, a N-N distance of 2.744 Å, and Mo-N bond lengths of 1.901 Å. This structure is clearly at odds with the crystallographically determined asymmetry of the core, in which the two molybdenum ions have different bond lengths with the bridging nitrogen atoms. Therefore, a separate geometry relaxation was performed using the triplet state of $\mathbf{1}_{dia}$. This resulted in a geometry that contains one Mo center with shorter Mo-N bond lengths (1.818, 1.821 Å) and one Mo center with longer Mo-N bond lengths (1.978, 1.980 Å). While overall an improvement in relation to the experimentally found structure, the Mo-Mo distance is now somewhat overestimated (calc: 2.770 Å, exp: 2.676 Å, **Figure 3A**).

The singlet and triplet geometries of $\mathbf{1}_{dia}$ are energetically separated by 7.4 kcal/mol at the level of theory of the geometry optimization, which would indicate that the higher-lying triplet state is not significantly populated. Although without careful calibration it is uncertain whether any given density functional yields accurate spin state energetics, hybrid functionals may be considered as somewhat more suitable in this case. Single point energy calculations show a consistently smaller separation between the singlet and triplet state geometries, with the singlet state remaining lower in energy (PBE0: 1.9 kcal/mol, TPSSh: 4.1 kcal/mol, B3LYP: 2.0 kcal/mol, M06: 3.9 kcal/mol). It must be stressed, however, that a reliable estimate of the energy separation could only be achieved with highly accurate methods such as DLPNO-CCSD(T) in combination with a large basis set (Neese et al., 2009a; Paulechka and Kazakov, 2017; Saitow et al., 2017). The Mayer bond orders of the singlet state are reflective of the symmetric core (Mo-Mo: 0.70, all Mo-N: 1.23). The triplet state features a significantly reduced Mo-Mo bond strength (0.43) and asymmetry in the Mo-N bond orders (1.53, 1.56; 1.02, 1.00). The

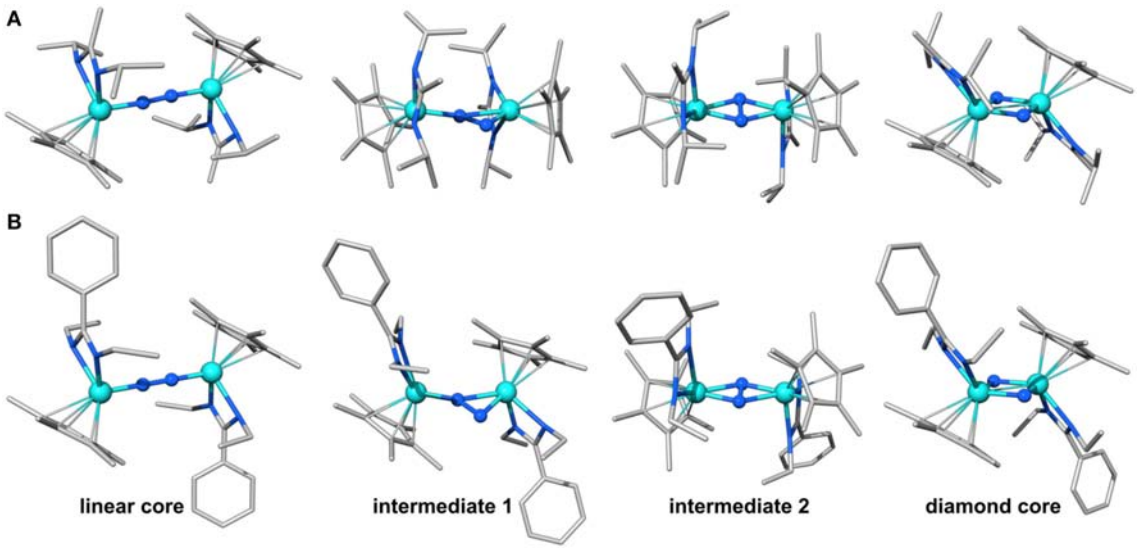

FIGURE 2 | Geometries predicted along the isomerization path of **1 (A)** and **2 (B)**. Color code for atoms is Mo: light blue, N: blue, C: gray, H omitted for clarity.

Mulliken spin populations of the triplet state are 0.50 and 1.43, which is indicative of a degree of spin delocalization between a Mo(VI) center and a Mo(IV) center, respectively.

For the product $\mathbf{2}_{dia}$, a geometry optimization with an electronic singlet state configuration reproduces the crystal structure parameters very well, see **Figure 3B**. The distortion of the diamond core is accompanied by different bond distances to the amidinate-N donor atoms (2.200, 2.220 Å), all of which are longer than in the starting complex $\mathbf{2}_{lin}$ (2.130–2.137 Å). The Mayer bond orders indicate a single bond between the two metals (0.73) and strong Mo-N interactions that mirror the asymmetry of the core (1.13, 1.36 for each Mo).

Naturally, the question arises whether a triplet state can also be found for $\mathbf{2}_{dia}$, and what its energetic separation from the singlet state would be. There is no experimental indication for any open-shell character of this complex. Nevertheless, the geometric and electronic structure resulting from the triplet state relaxation of $\mathbf{2}_{dia}$ is surprisingly similar to that of $\mathbf{1}_{dia}$ in its triplet state. The Mo-Mo distance is elongated to 2.762 Å, and asymmetric Mo centers with respect to their interaction with the bridging nitrogen atoms are found (1.812, 1.835, 1.998, 1.966 Å). Similarly, the Mo-Mo Mayer bond order is reduced to 0.42, and the Mo center with short M-N bonds has higher bond orders (1.47, 1.66) than that with longer M-N bonds (1.11, 0.94). The Mulliken spin populations (0.46, 1.38) match those found for the triplet state of $\mathbf{1}_{dia}$. The relative total energies of the singlet and triplet state of $\mathbf{2}_{dia}$ are increased compared with $\mathbf{1}_{dia}$ with the singlet state again remaining the more stable one (BP86: 8.3 kcal/mol, PBE0: 4.0 kcal/mol, TPSSh: 5.5 kcal/mol, B3LYP: 4.01 kcal/mol, M06: 6.15 kcal/mol). Although a clear differentiation between the relative abundance of singlet and triplet state for the diamond cores in **1** and **2** will require further experimental information coupled to high accuracy computations, the present results corroborate that a triplet state may be more readily accessible in $\mathbf{1}_{dia}$ than in $\mathbf{2}_{dia}$. The small energy differences between singlet and triplet states are furthermore in agreement with the experimental observation that changes in the environment, e.g., crystal structure vs. solution phase, may well be sufficient to introduce a spectroscopically significant amount of the higher spin state in $\mathbf{1}_{dia}$ (Keane et al., 2015).

Isomerization Paths

The structures of the molybdenum dimers with the same multiplicity are strikingly similar, regardless of the ligand sphere. Merely from the inspection of their geometries and electronic structures it is therefore not obvious why $\mathbf{1}_{lin}$ requires activation with light to achieve the transformation to the diamond-shaped core whereas $\mathbf{2}_{lin}$ is capable of thermal isomerization. The next step toward elucidating this difference in reactivity was therefore to identify intermediates along the isomerization pathway. This may also lead to a better understanding of the atomic-level realization of "steric switching" (Duman et al., 2016) from the photochemical to the thermal process. Morokuma et al. evaluated a four-step isomerization path for the Ta complexes with a simplified ligand sphere ({H–Me}, i.e., R^1: H, R^2: Me), as sketched in **Figure 1C** (Zhang et al., 2011). It involves a change in dinitrogen coordination from $Ta_2(\mu\text{-}\eta^1\text{:}\eta^1\text{-}N_2)$ to $Ta_2(\mu\text{-}\eta^2\text{:}\eta^1\text{-}N_2)$ in intermediate 1 and subsequently to $Ta_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ in intermediate 2 with a residual N-N bond, before fully breaking the N-N interaction in $Ta_2(\mu\text{-}N)_2$. Given that the geometries and reactivities of the complexes in the Sita series are largely similar, these intermediates represent a reasonable starting point for an investigation of the isomerization paths of the Mo dimers.

Indeed, the analogous intermediates were identified for both dimers (**Figures 2**, **3**). Overall, their respective geometries are of striking similarity. Upon formation of $\mathbf{1}/\mathbf{2}_{int-1}$ with a $\mu\text{-}\eta^2\text{:}\eta^1\text{-}N_2$ bridge, the N-N distance increases to ca. 1.30 Å in

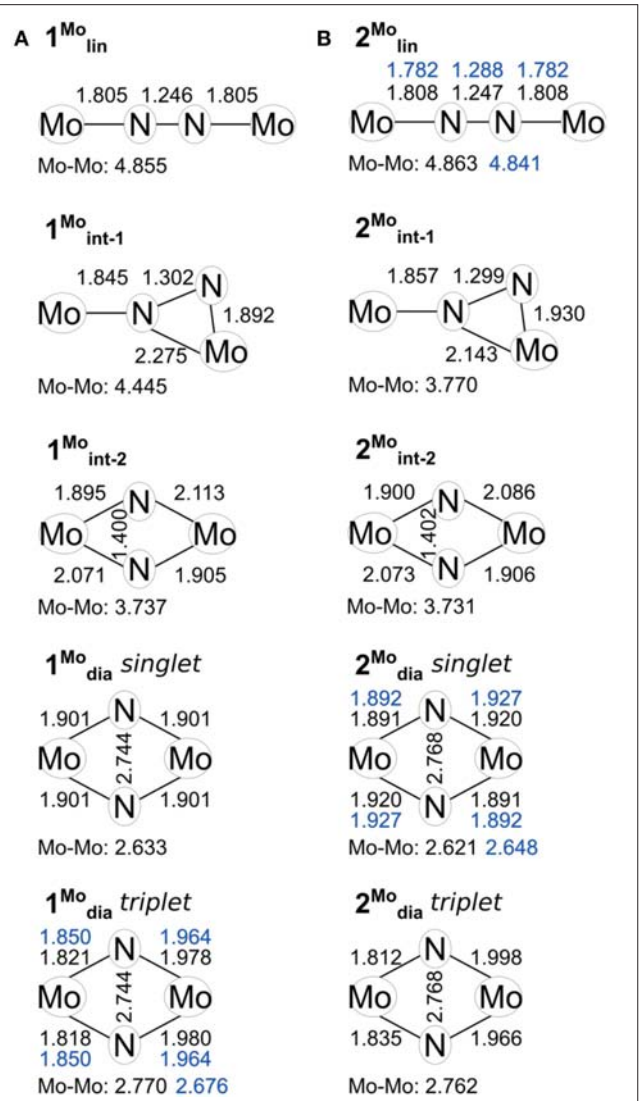

FIGURE 3 | Key geometric parameters computed for the isomers of **1 (A)** and **2 (B)**, including the core geometries of **1**/**2**$_{dia}$ in their triplet states. Values found in crystal structures where available are given in blue.

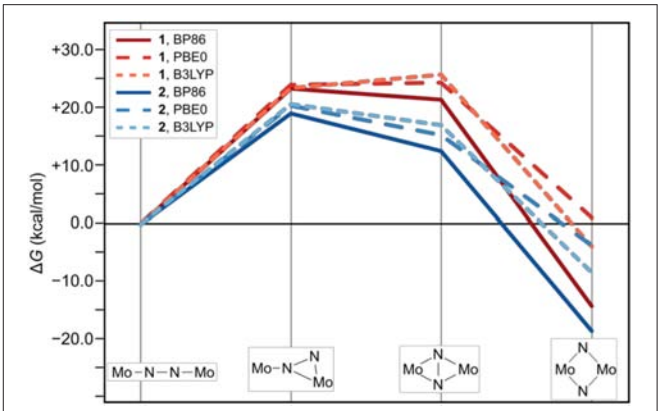

FIGURE 4 | Thermodynamic profile of the isomerization paths for **1** (red) and **2** (blue). Data points for which the electronic structures are calculated with PBE0 and B3LYP are long-dashed and short-dashed, respectively.

both complexes, concomitant with a significant reduction in N-N bond order (**Table 1**). The Mo-N bond lengths of the η^1-coordinated Mo are 1.845 Å (**1**$_{int-1}$) and 1.857 Å (**2**$_{int-1}$), thus increased by only ca. 0.05 Å compared to the linear precursors. As expected, the η^2-coordinated Mo-N interactions are significantly longer than the previous η^1-distances at now 1.892 Å (**1**$_{int-1}$) and 1.930 Å (**2**$_{int-1}$) for the 'short' and 2.275 Å (**1**$_{int-1}$) and 2.143 Å (**2**$_{int-1}$) for the "long" interactions. Despite the latter distances being relatively long, the bond orders support a very weak bond (**Table 1**). In the second intermediates, **1**/**2**$_{int-2}$ with a μ-η^2:η^2-N_2 unit, the nitrogen-nitrogen distances are ca. 1.40 Å and the Mayer bond orders indicate that a single N-N bond is still present (0.88, 0.89). Both Mo_2N_2 cores show asymmetry in the Mo-μ-N bond lengths: similar to the singlet form of **2**$_{dia}$, each Mo ion has a short (ca. 1.9 Å) and a long (ca. 2.1 Å) separation from the bridges. The bond orders show a discrepancy in the interaction strength of less than half a single bond.

The thermodynamic profiles of the isomerization paths in **Figure 4** show that the formation of all intermediates is endergonic. At the level of theory used for optimizing the geometries and obtaining the Hessians, the first intermediates are predicted at ΔG values of 23.5 kcal/mol (**1**$_{int-1}$) and 19.1 kcal/mol (**2**$_{int-1}$). The formation of the second intermediates is only slightly less endergonic for **1**$_{int-2}$ at 21.7 kcal/mol, but significantly less so for **2**$_{int-2}$ at 12.5 kcal/mol. Finally, the driving force for the overall isomerization appears to be the formation of the dimers with diamond-shaped cores at −14.3 kcal/mol for **1**$_{dia}$ and −18.7 kcal/mol for **2**$_{dia}$ according to the ΔG values predicted at this level of theory. To verify whether the electronic structure description would have a significant influence on the overall profiles, single point energy calculations with the two hybrid functionals PBE0 and B3LYP were carried out. The resulting reaction profiles, using the thermodynamic data calculated with the BP86 density functional, shows that the change in ΔG for **1**/**2**$_{int-1}$ is <2 kcal/mol while **1**/**2**$_{int-2}$ are predicted to be 3–5 kcal/mol less stable. More importantly, however, the product with a diamond-shaped Mo_2(μ-N)$_2$ core for **1** is calculated to be significantly less exergonic (−3.9 kcal/mol with B3LYP) or even endergonic (+1.0 kcal/mol for PBE0). In contrast, while the product of the isomerization reaction for **2** is also less stabilized with hybrid functionals it is clearly still exergonic at −8.5 kcal/mol with B3LYP or −3.8 kcal/mol with PBE0.

The reaction profiles thus show that isomerization can in principle occur in both complexes, albeit at higher cost for intermediate formation and a significantly lower driving force in complex **1** compared with complex **2**. Comparison with the experimental kinetic data would require the identification of transition states along the isomerization path, which is beyond the scope of this work. The core geometries are strikingly similar and do not readily explain the thermodynamic differences, therefore any attempt to analyze and rationalize the underlying reasons for the experimentally observed "steric switching" must inspect the interactions between the two halves of the ligand

sphere. Indeed, an interesting point was noted when analyzing the contributions from the dispersion correction.

Influence of Dispersion on the Isomerization Path Energetics

Initially, the number and distance of pairs of hydrogen atoms will serve as a measure for steric interactions in the intermediates. This provides an intuitive picture of the steric clashes while at the same time facilitating a quantitative comparison along the isomerization paths. As reference values, hydrogen atoms of the same methyl group are usually <1.8 Å apart; distances between hydrogen atoms attached to adjacent carbon atoms in phenyl and ethyl groups are ∼2.5 Å. **Figure 5** shows the number of H-H distances for the species along the isomerization coordinate in bins of 0.4 Å width between 1.8 and 4.2 Å. The precise numbers, average values and combined lengths for the H-H pairs are given in the SI. Generally, complex **1** has more H-H pairs than complex **2**, in line with the chemical expectations for the "bulky" {Me-^{i}Pr} and "sterically reduced" {Ph-Et} ligand systems. For both complexes the number of H-H contacts increases during the overall isomerization process from $\mathbf{1/2}_{lin}$ to $\mathbf{1/2}_{dia}$ (286 to 330 for **1**, 210 to 236 for **2**). For **1**, the increase stems largely from longer distances (+36 for 3.4–4.2 Å, orange and red in **Figure 5**, cf. +6 for **2** in this range), whereas for **2** the number of shorter distances increases most (+16 for 1.8–2.6 Å, dark and medium blue in **Figure 5**; cf. +15 for **1** in this range). The inter-hydrogen distances between ligands coordinated at different metals in the bins 1.8–2.2 Å (dark blue), 2.2–2.6 Å (middle blue), and 2.6–3.0 Å (light blue) are visualized in **Figure 6** for the linear and diamond-shaped complexes of **1** and **2**. In terms of absolute numbers, these fall in the range of 2.03–2.73 Å for $\mathbf{1}_{lin}$ and 2.15–2.98 Å for $\mathbf{2}_{lin}$; 2.03–2.78 Å for $\mathbf{1}_{dia}$ and 1.96–2.84 Å for $\mathbf{2}_{dia}$.

The effect of these interactions on the relative energetics are expected to be dominated by two factors: destabilization due to closer nuclei positions, and stabilization due to dispersion interactions. Since dispersion interactions are always attractive (Grimme, 2011), and a larger number of interhydrogen contacts is built up along the reaction coordinate, it is clear that dispersion interactions should stabilize the products to a significant extent. In terms of single point energies, dispersion corrections account for a stabilization of ca. −23 kcal/mol for $\mathbf{1/2}_{dia}$ relative to $\mathbf{1/2}_{lin}$, i.e. the energy gain in both complexes is practically identical. The stabilization of intermediates $\mathbf{1/2}_{int-1}$ and $\mathbf{1/2}_{int-2}$ due to dispersion is also almost identical in the two complexes and <10 kcal/mol relative to the linear starting compounds. Therefore, despite an overall larger number of H-H pairs <4.2 Å apart, complex **1** benefits only as much as complex **2** from stabilization through dispersion, implying that each H-H pair in **1** has a smaller effect. The absolute dispersion corrections in all intermediates of **1** are ca. 5 kcal/mol less than for those of **2** (see SI for details).

The effect of omitting dispersion effects can be tested *in silico* by removing the dispersion corrections in the geometry optimizations, which is presented exemplarily for complex **2** starting from the fully optimized structures that included dispersion corrections. As an aside, it is noted that upon removal of dispersion corrections the geometry of intermediate $\mathbf{1}_{int-1}$ could not be optimized despite several attempts; instead the molecule relaxed to a linear Mo–(μ-η^1:η^1-N$_2$)–Mo core. Likewise the optimization of $\mathbf{1}_{dia}$ without dispersion corrections resulted in a frequency analysis with significant imaginary entries that could not be removed, indicating that the structures obtained are not a proper minima on the potential energy surface. For complex **2** with its starting complex, intermediates and product, the changes in geometry range from barely visible by eye inspection to subtle in many of the isomers, while in some the phenyl group rotates (see SI for Cartesian coordinates of all geometries). Comparing the total number of H contacts in the structures optimized with and without dispersion corrections

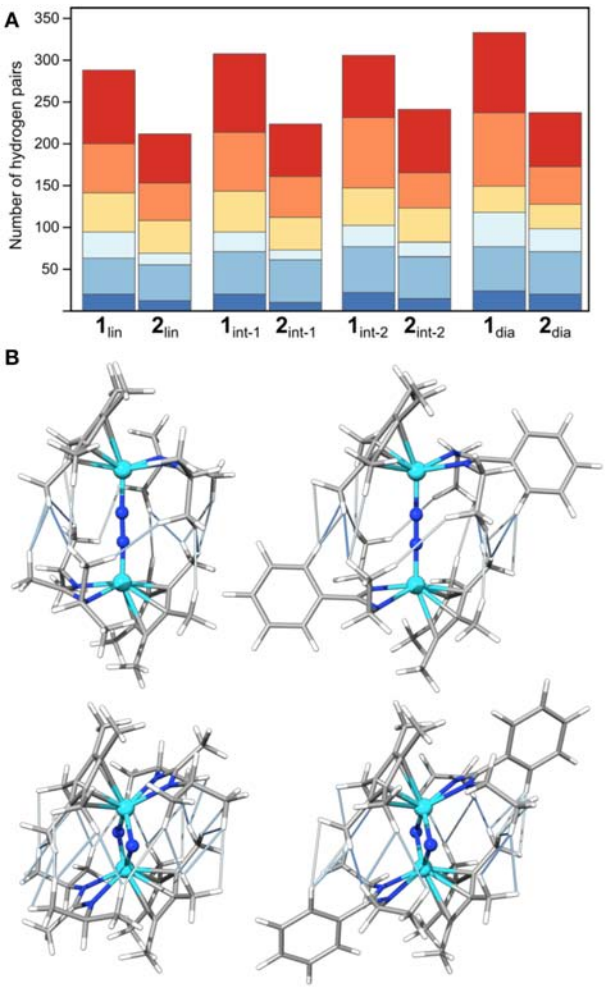

FIGURE 5 | Visualization of the number of hydrogen pairs along the isomerization pathway of **1** and **2, (A)** in terms of absolute numbers in bins of 1.8–2.2 Å (dark blue), 2.2–2.6 Å (middle blue), 2.6–3.0 Å (light blue), 3.0–3.4 Å (yellow), 3.4–3.8 Å (orange), 3.8–4.2 Å (red), and **(B)** as a representation of the actual geometric interactions in $\mathbf{1}_{lin}$ (top left), $\mathbf{1}_{dia}$ (top right), $\mathbf{2}_{lin}$ (bottom left) and $\mathbf{2}_{dia}$ (bottom right); H-H interactions are shown as thin lines in dark blue (1.8–2.2 Å), middle blue (2.2–2.6 Å), and light blue (2.6–3.0 Å). Color code for atoms is Mo: light blue N: blue, C: gray, H light gray.

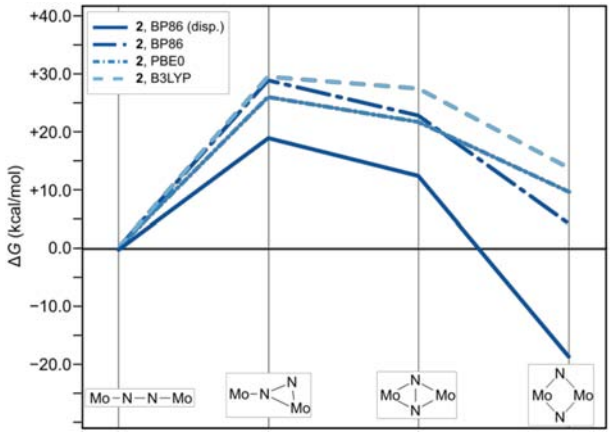

FIGURE 6 | Effect of omitting dispersion corrections on the thermodynamic profile of the isomerization paths of **2**. The thermodynamic profile including dispersion is shown as a solid line for reference; data points for which the electronic structures are calculated with BP are long-dashed-dotted (dark blue), with PBE0 are short-dash-dotted (mid-blue), and with B3LYP short-dashed (light blue).

shows that **2** loses 18 pairs in its linear form and 12 pairs in its diamond form (see **Supporting Information**).

The thermodynamic profiles for all forms of **2** optimized without dispersion corrections show that the isomerization path is significantly destabilized. Dispersion interactions thus have a more pronounced stabilizing effect on the dimer with a diamond-shaped core compared to the starting complex with a linear core, consistent with the increase in H-H pairs with distances smaller than 4.2 Å. The isomerization product of **2** has a ΔG value of 4.1 kcal/mol using the BP86 electronic structure description. An even more distinct destabilization is predicted with the PBE0 ($\mathbf{2}_{dia}$: 9.6 kcal/mol) and B3LYP ($\mathbf{2}_{dia}$: 13.7 kcal/mol) density functionals.

In silico Modifications

With the above information on the isomerization paths for **1** and **2** at hand, *in silico* modifications of the amidinate ligand are carried out. The leading question is whether any further reduction of the steric demands of the ligands would lead to lower energy intermediates. The ligand systems considered are {Me-Et} (**3**) and {Ph-H} (**4**). While a substitution pattern of {H-H} would obviously represent the sterically least demanding amidinate ligand, and thus serve as a sort of base line, geometry optimizations with this ligand were unsuccessful for all steps of the isomerization except intermediate 2. All energetic minima identified showed negative frequencies of significant magnitude ($>>100\ cm^{-1}$) in their Hessians, indicating that these hypothetical structures would not be stable.

The starting compound **3** has a linear core with key geometric parameters that are almost identical to that of the original compounds **1** and **2**. In contrast, the optimized geometry of **4** has a "pre-bent" core with Mo-N-N angles of 163.5 and 163.3°, compared with 177.2–179.1° for the other three complexes discussed here. None of the other key geometric parameters

TABLE 2 | Key interatomic distances in Å of the Mo_2N_2 cores in the hypothetical compounds **3** and **4**.

Cpd.	Mo-Mo	Mo-N	Mo-N	Mo-N	Mo-N	N-N
$\mathbf{3}_{lin}$	4.86	1.81	3.05	1.81	3.05	1.25
$\mathbf{3}_{int-1}$	3.66	1.85	3.08	1.93	2.12	1.31
$\mathbf{3}_{int-2}$	3.72	1.89	2.08	1.89	2.08	1.41
$\mathbf{3}_{dia}$ (s)	2.62	1.91	1.90	1.91	1.90	2.77
$\mathbf{4}_{lin}$	4.83	1.81	3.03	1.81	3.03	1.24
$\mathbf{4}_{int-1}$	3.55	1.84	3.10	1.94	2.16	1.29
$\mathbf{4}_{int-2}$	3.72	1.90	2.06	1.90	2.06	1.40
$\mathbf{4}_{dia}$ (s)	2.63	2.03	1.85	1.80	1.95	2.72

show a great variation between the four substitution patterns, see **Table 2**. Likewise, the degree of N-N bond activation as judged by bond length and Mayer bond order is basically unchanged by different amidinate substitution patterns. The only exception to this is intermediate 1 where the bond order is 1.05 for **3** and 1.07 for **4** vs. 1.24 in **1** and 1.14 in **2**, indicating that a lower steric demand or fewer attractive dispersion interactions allow for a greater weakening of the N-N bond.

As expected from the design concept of lowering the steric bulk, both changes in ligand sphere result in thermodynamic profiles that lie overall energetically below those of the original systems, see **Figure 7**. The isomerization path of complex **3** with the {Me-Et} substitution pattern is consistently situated 1–3 kcal/mol below that of complex **2**. Thus, the formation of intermediate **1** is still the most costly in terms of relative free energies. For complex **4**, however, intermediate 1 lies distinctly lower than intermediate 2, by 2.5 kcal/mol for the PBE0 density functional (2.9 kcal/mol for BP86, 4.2 kcal/mol for B3LYP), therefore achieving a markedly different topology of the isomerization energy surface.

UV-vis Spectra and Photoactivity

The molecular orbital pattern of the starting compounds is largely as expected for linear M-N-N-M complexes based on a ligand field picture. The d and p valence orbitals of Mo and N form σ, π and δ combinations with alternating bonding and antibonding character between adjacent nuclei, i.e., σ-σ-σ, σ-σ*-σ, σ*-σ-σ*, σ*-σ*-σ*, and similarly for the other molecular orbitals (Krewald and González, 2018). The HOMO and HOMO-1 correspond to δ-orbitals dominated by Mo(d) atomic orbital contributions. The LUMO is of π*-π-π* character, i.e., dominated by a π-interaction between μ-N(p) orbitals and π*-interaction between μ-N(p) and Mo(d) orbitals. **Figure 8** shows the π and δ manifold of the Mo_2N_2 core schematically.

To determine any electronic structure differences that may lead to the differences in thermal and photo-reactivity observed for **1** and **2**, their UV-vis spectra are computed and analyzed. While an experimental UV-vis spectrum of $\mathbf{1}_{lin}$ is published, for $\mathbf{2}_{lin}$ no literature reference is available. The UV-vis spectra for $\mathbf{1}_{lin}$ and $\mathbf{2}_{lin}$ were computed with TD-DFT, testing various GGA, meta-GGA, hybrid and range-separated density functionals to achieve a close agreement with the experimental spectrum (see computational details and **Supporting Information**).

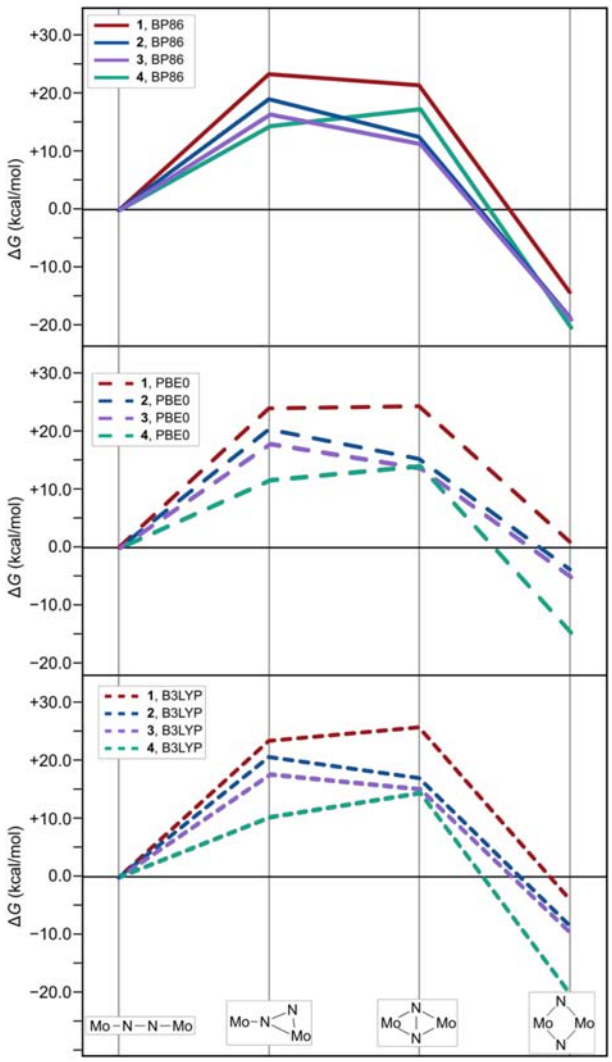

FIGURE 7 | Thermodynamic profiles for **1**, **2**, and {Me-Et} (**3**) and {Ph-H} (**4**) as two systems with further reduced steric bulk. The top, middle and bottom panel show data for electronic structures calculated with the density functionals BP86, PBE0, and B3LYP, respectively.

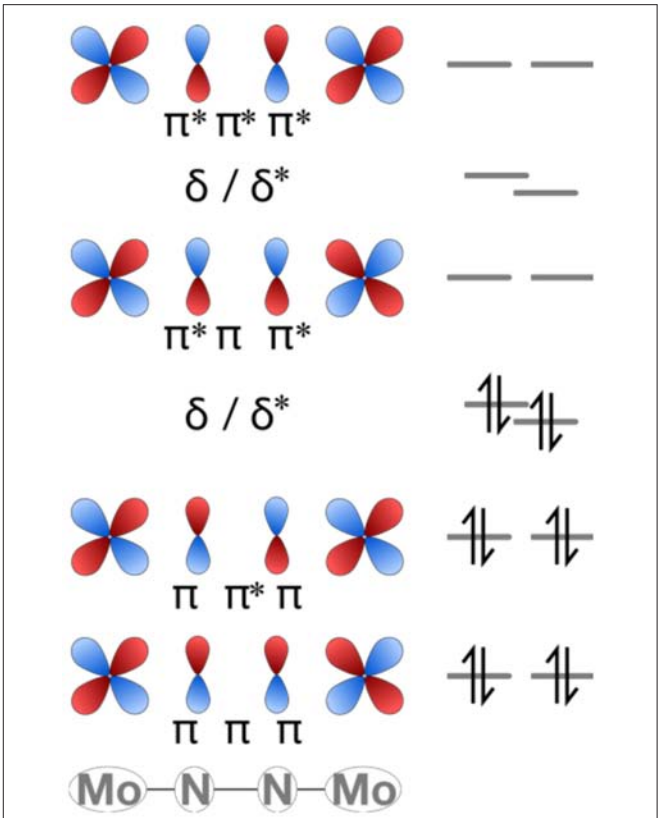

FIGURE 8 | Partial MO diagram of the π and δ manifold for the linear cores of complexes **1** and **2**.

The best visual agreement between the experimental spectrum of $\mathbf{1}_{lin}$ and a calculated counterpart was achieved with the range-separated functional LC-BLYP, although it must be recognized that all spectra obtained with TD-DFT are significantly blue-shifted. To facilitate a visual comparison with the digitized experimental spectrum, a gray line spectrum of the experimental data is also blue-shifted by 7,869 cm^{-1} in **Figure 9A**. It can be seen that the relative energies and intensities of the spectral features at ca. 29,000 cm^{-1} (calc.; exp.: 22,000 cm^{-1}) and 37,500 cm^{-1} (calc.; exp.: 30,000 cm^{-1}) are reproduced well. The signal at 42,500 cm^{-1} (calc.) would then correspond to the shoulder at 35,800 cm^{-1} (exp.) in the experimental spectrum. The second high-intensity signal at ca. 38,800 cm^{-1} in the experimental spectrum cannot be assigned firmly to the calculated spectral features of $\mathbf{1}_{lin}$. The predicted spectrum for $\mathbf{2}_{lin}$ shows overall similar features with a slightly altered intensity distribution.

In the middle and lower panel of **Figure 9A**, the energies and oscillator strengths of the individual transitions predicted for $\mathbf{1}_{lin}$ and $\mathbf{2}_{lin}$ are depicted. At first glance, the line spectra are almost identical. A subtle difference worth noting is a cluster of excitations just below 40,000 cm^{-1} in the calculated spectrum of $\mathbf{1}_{lin}$, in contrast to a solitary transition at slightly lower energy in the calculated spectrum of $\mathbf{2}_{lin}$. In both complexes, the low-energy feature at ca. 29,000 cm^{-1} is due to a metal-to-ligand charge transfer excitation from Mo to the amidinate ligand, as assigned based on the difference density (**Figure 9B**). The first high-intensity feature at ca. 37,500 cm^{-1} in $\mathbf{1}_{lin}$ can be assigned to an LMCT transition from the dinitrogen bridge to the metal ions (14). In contrast, both intense transitions (15, 16) at the same energy in the spectrum of $\mathbf{2}_{lin}$ are due to core-to-amidinate excitations. The second intense signal at 42,500 cm^{-1} is dominated by excitations from a π-π*-π orbital to molybdenum d and amidinate ligand orbitals. A similar character can be assigned to the corresponding feature in the spectrum of $\mathbf{2}_{lin}$.

A possibly very relevant difference between the two complexes is found when assessing the character of the six transitions below 40,000 cm^{-1} in the spectrum of $\mathbf{1}_{lin}$, i.e., transitions 17–22. The first five excitations have difference densities that are distinctly asymmetric. All of them are LMCT transitions, with excitations originating from both amidinate and Cp* ligands.

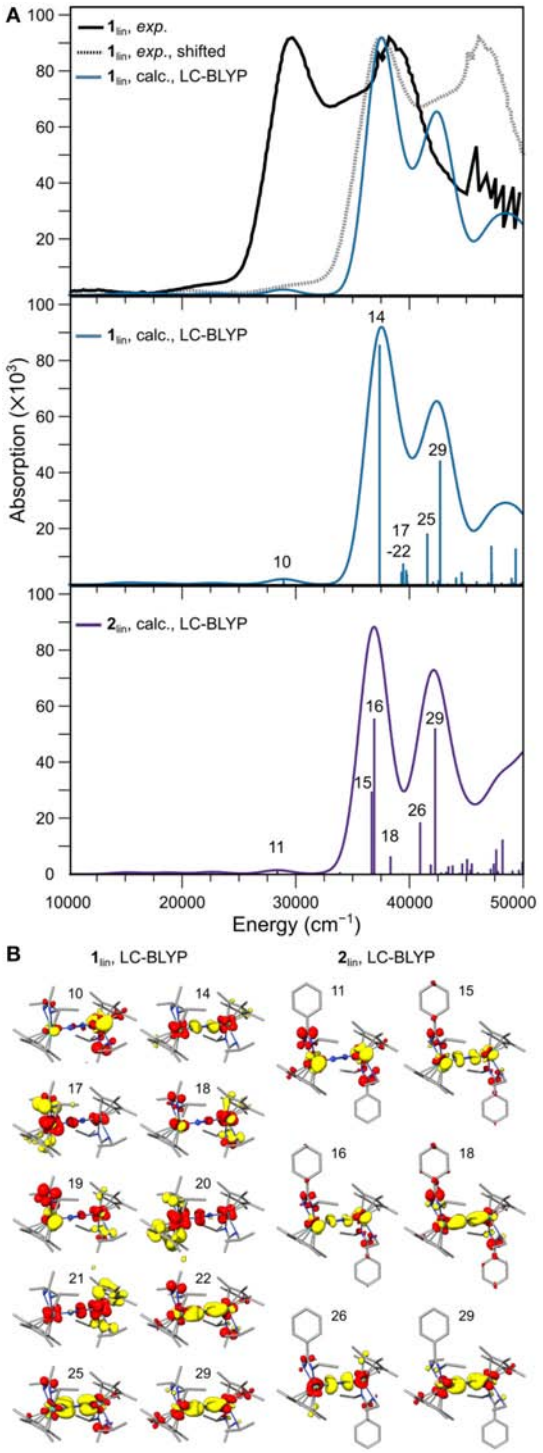

FIGURE 9 | (A) Experimental UV-vis spectrum of $\mathbf{1}_{lin}$ (black: digitized, gray: digitized and blue-shifted) and the broadened line spectrum predicted with TDDFT using the LC-BLYP density functional (top), calculated oscillator strengths and intensities of the individual transitions and broadened line spectrum for $\mathbf{1}_{lin}$ (middle) and $\mathbf{2}_{lin}$ (bottom). **(B)** Difference densities for the individual transitions labeled in **(A)**; yellow and red isosurfaces correspond to density loss and gain, respectively.

The sixth transition is a core-to-amidinate excitation, similar to the transitions assigned to the higher-energy feature. It is important to stress that the character of the features is not dependent on the density functional chosen for the analysis, but that similar characteristics can be assigned based on other density functionals. As can be seen from a comparison of the difference densities of states 22 ($\mathbf{1}_{lin}$) and 18 ($\mathbf{2}_{lin}$), the character of that solitary excitation in the sub-40,000 cm^{-1} energy region in the spectrum of complex $\mathbf{2}_{lin}$ is almost identical. This difference in the spectra of $\mathbf{1}_{lin}$ and $\mathbf{2}_{lin}$, i.e., the fact that there are asymmetric excitations in one complex that are entirely absent in the other, may be the reason that only $\mathbf{1}_{lin}$ is photoactive (Duman et al., 2016). Sita et al. had put forward the idea that during the photo-driven isomerization and/or dissociation of $\mathbf{1}_{lin}$, a ligand may have to temporarily detach (Duman et al., 2016). The asymmetric character of the excitations assigned above align with this hypothesis.

DISCUSSION AND CONCLUSIONS

The Sita complexes are the most complete series of isostructural dinitrogen-bridged compounds that span groups 4–6 across all transition metal rows: Ti, V; Zr, Nb, Mo; Hf, Ta, W (Hirotsu et al., 2007a,b; Fontaine et al., 2010; Yonke et al., 2011a; Keane et al., 2013, 2014, 2015; Duman et al., 2016; Duman and Sita, 2017). The only missing complex is the Cr dimer, which has been attributed to its much smaller covalent radius than the other early transition metals. Besides a Cp* ligand, one guanidinate or amidinate ligand in one of their five variations, with ^{i}Pr or Et at the N-donor atoms and NMe_2, Me, H or Ph at the central carbon, is bound at each metal. This series is of great value for a systematic insight into the fundamental concepts of nitrogen activation due to the variety of metals that is stabilized by ligands of the same family. Comparison of the similarities and differences in this series allows for systematic comparisons of electronic and structural effects in dinitrogen activation. With two members of the series, Sita et al. have shown that by reducing the steric bulk of the substituents in the photochemically active {(η^5-C_5Me_5)[N(^{i}Pr)C(Me)N-(^{i}Pr)]Mo}$_2$(μ-N_2) (**1**) complex to {(η^5-C_5Me_5)[N(Et)C(Ph)N-(Et)]Mo}$_2$(μ-N_2) (**2**), a thermal pathway to dinitrogen splitting becomes accessible (Keane et al., 2015; Duman et al., 2016). In this paper, computational predictions for likely isomerization intermediates were presented and the thermodynamics of the isomerization reaction were analyzed.

It was confirmed that steric bulk has a significant influence on the thermodynamic profile of the isomerization reactions. The ΔG values for the formation of the intermediates during the isomerization of complex **1** with bulkier ligands were found to be several kcal/mol above those for complex **2** with a sterically less demanding ligand sphere. Furthermore, dispersion interactions along the reaction path appear to be highly relevant factor in the overall driving force of the reaction. In geometry optimizations that omitted dispersion effects, the isomerization of **2** was seen to be energetically disfavored, while no stable

intermediates and products were found for the isomerization of **1** without consideration of dispersion effects. In other words, the rearrangement of bonds from approximate double bonds in the linear cores of the starting complexes (Mo-N ca. 1.4, N-N ca. 1.6) and strong single bonds in the diamond-shaped cores of the products (Mo-N ca. 1.2, Mo-Mo ca. 0.7) appears to be almost isoenergetic or perhaps even disfavored. The reactions become overall favorable through the greater dispersion stabilization of the product compared to the starting compound. Since the differences in dispersion correction are approximately equivalent between $\mathbf{1}_{lin}/\mathbf{1}_{dia}$ and $\mathbf{2}_{lin}/\mathbf{2}_{dia}$, the remaining difference in reactivity must be attributed to repulsive effects. Based on experimental observations, it is clear that in at least one intermediate along the isomerization pathway of **1**, dispersion effects are not sufficient to overcome steric hindrances. This will be addressed in forthcoming work.

To further explore the concept of reducing the steric requirements of the ligand sphere, *in silico* modifications with {Me-Et} and {Ph-H} were considered. Indeed, the thermodynamics of the reaction path become even more favorable than for the thermally active system {Ph-Et}. For {Ph-H}, the overall energy landscape of the reaction was even altered. However, this also means that changing the ligand substitution pattern can drastically alter the picture that is generated computationally. Especially for reactions with subtle changes in relative energy caution is in order when truncating the ligand system to lower the computational cost. It appears advisable to test the results for artifacts. The change in relative ΔG values for the intermediates 1 and 2 obtained with different ligand substitutions shows that this approach can be highly effective in engineering an ideal energy landscape for dinitrogen activation. Besides steric tunic, a future target of computational and experimental studies on this isostructural series will likely be electronic tuning through electron-donating or electron-withdrawing substituents.

To better understand the photoactivity of complex **1**, the UV-vis spectra of $\mathbf{1}_{lin}$ and $\mathbf{2}_{lin}$ were computed. Even though the line spectra appear very similar at first glance, the first intense feature is assigned to transitions with different excitation character. In the photoactive complex **1**, there is a single excitation with high oscillator strength due to a LMCT from the bridging N_2 to the molybdenum ions, i.e., shifting electron density away from the N_2 unit and hence likely weakening the dinitrogen bond further. In the photochemically inactive complex **2**, there are two transitions of similar MLCT character shifting electron density from the entire Mo_2N_2 core to the amidinate ligand. While little is known about the photoactive states in dinitrogen photoactivation complexes, a recent study on a rhenium dimer with a PNP pincer ligand (Schendzielorz et al., 2019) identified states in the photoactive region of μ-N_2-to-metal character, i.e., similar to the high-intensity excitation in complex **1**. A similar excitation character was also found for a N_2-bridged photoactive molybdenum pincer complex by Nishibayashi et al. (Miyazaki et al., 2014). If it were confirmed experimentally that irradiation of *only* the first signal results in photoactivation of complex **1**, a general pattern regarding the requirements for successful N_2 photoactivation could emerge that is independent of the ligand platform and metal chosen.

However, the spectrum of complex $\mathbf{1}_{lin}$ also contains a cluster of medium-high intensity transitions that are *not* predicted for the photo-inactive complex $\mathbf{2}_{lin}$. These are due to asymmetric excitations that originate from the ligand sphere of only one molybdenum ion and shift density into the Mo-N-N-Mo π system. The character of these excitations is in line with Sita's hypothesis of a temporary, photo-induced ligand detachment being required for isomerization of the molybdenum dimer and splitting of the N-N bond (Duman et al., 2016).

A better understanding of dinitrogen photoactivation in general will require more spectroscopic studies on the character of the photoactive states and the excited state decay. Additionally, an exhaustive comparison of the photo-activation and thermal activation pathways for the isostructural complexes in Sita's series requires the character(s) of the specific photoactive state(s) to be known so that its features can be related to the transition state structure of the thermal path. However, already at this point, it is interesting to see that despite the geometric similarities of the two complexes, the ligand sphere appears to have a distinct influence on their electronic structures that is mapped in the computed excitation spectra. Further computational and experimental studies, especially in terms of time-resolved spectroscopy, are required to fully elucidate these subtle differences.

DATA AVAILABILITY

The raw data supporting the conclusions of this manuscript will be made available by the author, without undue reservation, to any qualified researcher.

AUTHOR CONTRIBUTIONS

VK designed the research, carried out the required calculations and analyses, and wrote the paper.

ACKNOWLEDGMENTS

A 50th Anniversary Prize Fellowship from the University of Bath (01/2017-11/2018), and the Balena High Performance Computing (HPC) Service at the University of Bath are gratefully acknowledged. Mr. George Nichols is acknowledged for the computation of preliminary UV-vis spectra.

γ-Secretase Studied by Atomistic Molecular Dynamics Simulations: Global Dynamics, Enzyme Activation, Water Distribution and Lipid Binding

Manuel Hitzenberger and Martin Zacharias*

Physics Department T38, Technical University of Munich, Garching, Germany

γ-secretase, an intramembrane-cleaving aspartyl protease is involved in the cleavage of a large number of intramembrane proteins. The most prominent substrate is the amyloid precursor protein, whose proteolytic processing leads to the production of different amyloid Aβ peptides. These peptides are known to form toxic aggregates and may play a key role in Alzheimer's disease (AD). Recently, the three-dimensional structure of γ-secretase has been determined via Cryo-EM, elucidating the spatial geometry of this enzyme complex in different functional states. We have used molecular dynamics (MD) simulations to study the global dynamics and conformational transitions of γ-secretase, as well as the water and lipid distributions in and around the transmembrane domains in atomic detail. Simulations were performed on the full enzyme complex and on the membrane embedded parts alone. The simulations revealed global motions compatible with the experimental enzyme structures and indicated little dependence of the dynamics of the transmembrane domains on the soluble extracellular subunits. During the simulation on the membrane spanning part a transition between an inactive conformation (with catalytic residues far apart) toward a putatively active form (with catalytic residues in close proximity) has been observed. This conformational change is associated with a distinct rearrangement of transmembrane helices, a global compaction of the catalytically active presenilin subunit a change in the water structure near the active site and a rigidification of the protein fold. The observed conformational rearrangement allows the interpretation of the effect of several mutations on the activity of γ-secretase. A number of long-lived lipid binding sites could be identified on the membrane spanning surface of γ-secretase which may coincide with association regions of hydrophobic membrane helices to form putative substrate binding exosites.

Keywords: γ-secretase, familial Alzheimer's disease (fAD), Molecular dynamics (MD), presenilin, nicastrin, amyloid, intramembrane aspartyl proteases, intramembrane proteolysis

INTRODUCTION

The protein complex γ-secretase (g-sec) is the only known intramembrane protease requiring an elaborate interplay between four different proteins: nicastrin (NIC), presenilin (PS), anterior pharynx-defective-1 (APH-1) and presenilin enhancer-2 (PEN-2) (Bai et al., 2015a,b; Langosch et al., 2015; Langosch and Steiner, 2017), rendering it the structurally most complex member of this

functional family and due to its proposed role in Alzheimer's disease (AD) also the most studied one (De Strooper et al., 2012; Fukumori and Steiner, 2016). It has been established that g-sec is able to process a large number of substrates (Beel and Sanders, 2008; Haapasalo and Kovacs, 2011; Langosch et al., 2015) (as of today more than 90 potential substrate molecules are known Langosch et al., 2015) indicating that one role of this protein complex is the removal of partially degraded proteins from the membrane, thereby preventing their accumulation.

The most thoroughly investigated (Langosch et al., 2015; Langosch and Steiner, 2017) target of g-sec mediated cleavage is C99, containing a single-span transmembrane alpha-helix. C99 is the C-terminal fragment of the amyloid precursor protein (APP) and results from the removal of large parts of the APP ectodomain (Zhang et al., 2011). This preprocessing step, in the case of APP mediated by β-secretase (Vassar et al., 1999), is necessary for sterical reasons: Proteins possessing large soluble extracellular domains are unable to get into close contact with the active site of g-sec (Bai et al., 2015b; Langosch et al., 2015; Langosch and Steiner, 2017). The biological role of APP is mostly in the dark (Deyts et al., 2016) but it is well established that sequential C99 processing results in an intracellular peptide (AICD), several short (mostly three amino acid long) peptides and the Aβ40/42/43/46 fragments (Bolduc et al., 2016).

In patients not suffering from familial Alzheimer's disease (FAD), Aβ40 peptides are the main product of C99 cleavage while the longer variants are yielded in much lower quantities (Zhang et al., 2011). This balance, however, seems to be rather delicate and can be shifted toward the production of longer amino acid chains (predominantly Aβ42) by several factors, such as mutations and changes of bilayer composition or temperature (Holmes et al., 2012; Szaruga et al., 2017). The A$\beta > 40$ fragments are known to be more prone to aggregation than the shorter variants and thus have been found to be the main components of amyloid deposits in the brains of AD patients (Hardy and Higgins, 1992; De Strooper et al., 2012; Langosch et al., 2015; Langosch and Steiner, 2017). Over 200 pathogenic Alzheimer's disease related PS mutations have been reported on www.alzforum.org (affecting 135 different amino acids), as well as over 20 that are situated on C99. Another well studied substrate for g-sec is the Notch ligand/receptor complex, which upon cleavage releases an intracellular fragment leading to the expression of various genes. Aberrant activation of this Notch signaling pathway has been found to promote tumor cell proliferation and is linked to several types of cancer (Rao et al., 2009; Krop et al., 2012).

Structurally, g-sec adopts an N_{in} topology, forming a complex with 1:1:1:1 stoichiometry (Bai et al., 2015a,b; Langosch et al., 2015). Because there are two different PS and APH-1 genes - PS-1, PS-2, APH-1a, and APH1b, four different complexes can be formed. PS-1 and APH-1a, however, are the prevalent variants of the respective proteins (Bai et al., 2015b), resulting in NIC:PS-1:APH-1a:PEN-2 being the most common g-sec complex.

Nicastrin (green structure in **Figure 1**), a 709 amino acid (AA) long protein, consisting of one transmembrane helix and a large globular extracellular ectodomain (ECD) is believed to play the role of gatekeeper for g-sec, blocking the access to

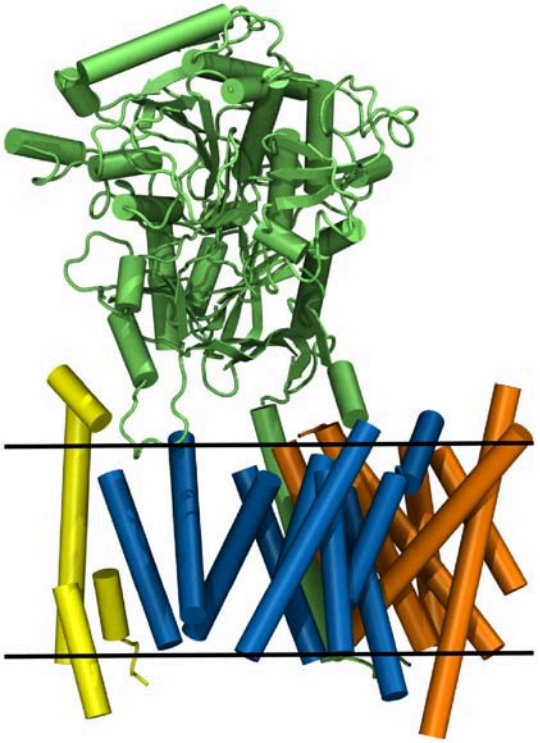

FIGURE 1 | The g-sec complex. Nicastrin (green), presenilin (blue), anterior pharynx-defective-1 (orange), and presenilin enhancer-2 (yellow). The approximate location of the lipid bilayer is indicated by two black lines.

PS for potential substrates with its bulky soluble domain (Bai et al., 2015a; Langosch et al., 2015; Langosch and Steiner, 2017). Presenilin-1 (blue protein in **Figure 1**), a 467 AA long aspartyl protease, contains the two catalytically active residues D257 and D385 (Wolfe et al., 1999). APH-1a (orange in **Figure 1**) consists of 265 residues, functions as a scaffolding protein and binds the transmembrane domain (TMD) of nicastrin (Lee et al., 2004). PEN-2 (yellow in **Figure 1**) has been shown to play a role in the autoproteolytic cleavage of the long cytosolic loop between the transmembrane domains 6 and 7, taking place upon maturation of the g-sec complex (Bai et al., 2015b). With only 101 AA (Francis et al., 2002) it is also the smallest of the four proteins. Even though a lot of insight into the structural and biochemical properties of g-sec has been gained in the last couple of years (De Strooper et al., 2012; Bai et al., 2015a,b; Holmes et al., 2012; Kong et al., 2015; Langosch et al., 2015; Fukumori and Steiner, 2016; Somavarapu and Kepp, 2016; Xu et al., 2016; Langosch and Steiner, 2017; Szaruga et al., 2017), many questions still remain unanswered:

Most soluble proteases cleave their substrates on a (sub)second timescale, whereas g-sec operates much less efficiently, taking minutes to process a single molecule (Kamp et al., 2015; Langosch et al., 2015). Since the chemical process of bond hydrolysis itself takes less than a second in most soluble proteases (Grossman et al., 2011; Langosch et al., 2015), the low turnover rate of g-sec must be the result of a

slow process that is necessary to initiate the actual substrate cleavage. The nature of this process is unknown and could involve substrate positioning, conformational rearrangements, frequent enzyme/ligand dissociations or any combination of the aforementioned. Another interesting question associated with the hydrolysis is raised by the fact that the active site of PS is situated deeply inside the membrane region, usually considered to be highly hydrophobic—a property presumably obstructive to a process involving water molecules.

The mechanism of substrate recognition and discrimination is unknown as well. As of now, no structural or dynamical profile attributable to all known g-sec substrates could be identified (Langosch et al., 2015; Langosch and Steiner, 2017). Since g-sec seems to play a major role in familial Alzheimer's disease (FAD), influencing its behavior and thereby forcing it into an Aβ production line where only the more benign 40AA long variant is produced looks to be a very promising endeavor. While complete g-sec inhibition has been shown to have a detrimental effect on health (De Strooper, 2014), preliminary g-sec modulation studies have shown some promise (De Strooper and Chávez Gutiérrez, 2015). Gaining further insight into the exact physico-chemical processes steering C99 processing will aid rational, structure-based approaches to drug design as well as the development of novel gene-therapeutic strategies.

A milestone in the investigation of g-sec was achieved by Bai et al. reporting three-dimensional structures of the complete γ-secretase complex (Bai et al., 2015a,b). These Cryo-EM experiments also uncovered that g-sec exists in a remarkable conformational diversity: Three distinctively different conformational states of the complex have been discovered. They are mainly differing in the distance of the TMDs 6 and 7—bearing the catalytically active side chains and the relative positioning of PEN-2 to PS-1 (Bai et al., 2015b).

Based on the Cryo-EM structures an anisotropic network model (ANM) has recently been constructed to analyze sterically possible large scale motions of the g-sec complex. These studies identified several hinge sites in g-sec and suggested large scale motions of the nicastrin domain relative to the PS-1 that could be involved in positioning of the substrate and promoting cleavage (Lee et al., 2017). Such large scale domain motions were also found in a combination of atomistic and coarse-grained (CG) Molecular Dynamics (MD) simulations of g-sec structures (Aguayo-Ortiz et al., 2017). In addition, the CG simulations suggested transitions between an inactive conformation with a large distance between two Asp residues involved in catalysis and states with the two Asp residues in a geometry compatible with a catalytically active arrangement that was not observed in shorter atomistic simulations (Somavarapu and Kepp, 2017). In the current study we conducted long time scale atomistic MD simulations starting from Cryo-EM derived structures to investigate local and global g-sec mobility and how it might be related to function but focusing also on water and lipid distribution surrounding the g-sec complex. In simulations of the membrane spanning part of g-sec the studies indicate a transition from an inactive arrangement (large distance between Asp residues involved in catalysis) to a potentially active form with a close distance of the Asp residues including also transient binding of water molecules in the active site. It also gives insight into the sterically possible motions of the PS1 TM helices mediating the transition. The active site but also other regions between TM helices appear to be accessible to water several Angstroms away from the boundary between membrane and the aqueous phase. Analysis of the lipid mobility around the g-sec complex revealed several stable binding regions that indicate binding regions for hydrophobic substrate helices. Finally, we interpret the simulation results in light of the potential role of some known mutations in γ-secretase that interfere with activity due to a putative influence on transitions toward the active conformation.

MATERIALS AND METHODS

Both simulations (henceforth referred to as system 1 and system 2, respectively) that have been conducted for this study were based on the PDB structure 5FN2 (Bai et al., 2015b) since it is the most complete of all available g-sec structures. In 5FN2, not only transmembrane domain 2 (TMD 2) is fully resolved, also a large patch of the loop 2 region connecting TMD 6 to TMD 7 is visible. All other available g-sec PDB structures miss this loop 2 domain spanning from residue 264 to 278. This region is very close to the putative binding site, therefore its structure and dynamics may be important to the functioning of the enzyme. Unfortunately, structural data on the largest part of this intracellular loop 2 region is still missing because it is outside of the membrane and very mobile. Therefore, this 89 amino acid long region (residues 289 to 377) was restored by CHARMM-GUI and cleaved to enable the simulation of the matured complex.

To enable the physically correct positioning of the proteins in the POPC membrane bilayer, the PDB file was submitted to the PPM (Lomize et al., 2012) server. The starting structure and the simulation protocol was then generated by uploading the reoriented structure to the CHARMM-GUI (Jo et al., 2008; Wu et al., 2014) web server.

Since aspartyl proteases require one active aspartate to function as a base and the other one as an acid (Singh et al., 2008), D257 has been protonated. Bai et al. (Bai et al., 2015b) have reported a hydrogen bond between E280 and H163, holding the loop region situated underneath the putative substrate binding site, in place. Because mutation of E280 is the most common cause leading to FAD (Lemere et al., 1996), this structural feature has been stabilized by protonating H163 in the simulations. The rest of the titratable side chains have been left in protonation states, assumed to be the predominant ones under physiological pH. The proteins were embedded in a bilayer consisting of 300 POPC molecules and placed in a periodic simulation box containing 0.15M KCl and approx. 33,000 or 55,000 water molecules, respectively. The target temperature was set to 303.15K, using Langevin dynamics (Goga et al., 2012) with a collision frequency of $1ps^{-1}$ while the system pressure was kept at 1bar by the Berendsen barostat (Berendsen et al., 1984) and a relaxation time of 0.5 ps. By applying the SHAKE algorithm (Ryckaert et al., 1977), the systems could be propagated by 2.0fs every time step. Non-bonded interactions have been calculated explicitly until a distance of 8Å after which long range effects were accounted for by the particle mesh Ewald method (Darden et al., 1993). Prior to simulation, the aqueous layers have been relaxed by

geometry optimization. Preceding a 500ns equilibration phase, the simulation boxes were heated to the target temperature while simultaneously applying pressure and slowly lowering/removing the positional restraints placed on the amino acids and lipid molecules. The proteins were described by the AMBER14SB (Maier et al., 2015) force field, whereas for lipid molecules and water the Lipid14 (Dickson et al., 2014) and TIP3P (Mark and Nilsson, 2001) force fields were used. All simulations were performed utilizing the CUDA (Nickolls et al., 2008) version of the pmemd program, provided with the AMBER16 package (Case et al., 2016). Trajectory analysis and calculation of principle components of motion (PCA) were carried out using cpptraj, which is part of the AMBER16 package (Case et al., 2016) and the results were visualized by VMD (Humphrey et al., 1996). The only difference between the simulations is the absence of the nicastrin ectodomain in system 2 (the TMD of nicastrin was included in both simulations). Due to the bulky nature of the NIC ectodomain, its removal permits a large reduction of simulated amino acids and water molecules. Besides an increase in sampling time due to reduced number of atoms, the putative influence of the NIC ECD to g-sec dynamics could be studied as well. System 1 has been sampled for 1 μs while the evaluation trajectory of system 2 has a length of 3.5 μs.

RESULTS AND DISCUSSION

System 1: Complete γ-Secretase Complex

Atomistic MD simulations were started from the best resolved Cryo-EM structure (pdb entry 5FN2). Root mean square deviations (RMSDs) calculated for the *Cα* atoms of several parts of g-sec compared to the PDB structure indicate that the protein remained close to the experimental structure throughout the simulation (see also **Figure S1**). During the simulation, the membrane spanning parts fluctuated but on average remained within ∼ 2Å of the reference structure (first frame of the sampling trajectory). Since the NIC ECD consists of many mobile loop regions, it naturally exhibits larger deviations than the TMDs situated in the lipid bilayer (which is also more viscous than water). **Figure 2A** depicts the RMSDs associated with system 1.

In the experimental apo conformation of the PDB-entries 5FN3, 5FN4 and 5FN5 the region beyond residues L262, C263 or P264 of TMD 6 in PS1 (depending on the chosen structure) is not resolved, presumably because of high mobility. However, in the inhibitor bound structure (5FN2) the helix kinks at P264 and goes on for several more residues. According to Bai et al., the presence of the inhibitor rigidifies the structure of g-sec, compared to its apo-form. (Bai et al., 2015b). In the simulation, which was started from 5FN2, an unfolding of the helical region beyond C263 was observed and the chain took on a far more mobile structure in the form of a loop region (**Figure S2**). This fits very well to the reported apo-structures of g-sec and confirms that the absence of a binding partner near the active site of PS-1 destabilizes this region.

In order to capture coupled global motions occurring during the MD study, principal component analysis (PCA) has been performed on the 1 μs long sampling trajectory of the complete γ-secretase complex. The most pronounced motions are shown in **Figures 2B–D**. The first principal component revealed that the nicastrin ectodomain consists of two independently moving sub-domains—a small and a large lobe: Most of the TMDs of g-sec and the smaller lobe of the NIC ectodomain are concertedly moving away from the larger globular nicastrin extracellular domain. This behavior indicates potential plasticity of the NIC ectodomain when acting as a binding site for the extracellular terminus of potential substrate proteins (see **Figure 2B**).

Principal component 2 (**Figure 2C**) showed that the complex exhibits an opening and closing motion, changing the size of the cavity formed by the ectodomain and the intracellular TMDs. This behavior has previously been reported in coarse grained simulations (Aguayo-Ortiz et al., 2017), elastic network model calculations (Lee et al., 2017) or by experiment (Elad et al., 2015) and may ensure that a broader range of substrate molecules can be processed: The NIC extracellular region has been indicated as a substrate binding site (Fukumori and Steiner, 2016) and in order to play this role it probably has to be close enough to the lipid bilayer to bind and stabilize the membrane-bound substrate. At the same time, however, the cavity has to remain spacious enough to incorporate a sufficiently large part of the substrate's ectodomain—this is necessary to ensure that the intramembrane domain of the substrate can come into close contact with the active site of presenilin. If the cavity formed by nicastrin and the TMDs was of constant size the number of g-sec substrates would very likely be much lower, since fixed NIC-membrane surface distances would allow for only little variety in substrate ectodomain size.

The third largest combined motion of the g-sec complex was a lateral ectodomain movement with respect to the TMDs (see **Figure 2D**). Upon closer inspection of the mobility of the PS-1 TMD residues in the principal components, it is apparent that TMD2 and the directly connected N-terminal region of TMD3 are very mobile. This finding was not surprising as TMD2 due to its mobility is not visible in many Cryo-EM structures (Bai et al., 2015b), suggesting that TMD2 could function as a possible gate for substrate entry. The video clips of the first three principal components (included as **Supplementary Material**) depict the relative movement of the different domains and helices of g-sec more clearly.

The PCA also showed that the conducted simulation reproduced the relative movement of PS-1 and Pen-2, reported by experiments (Bai et al., 2015b) (Bai et al. used the Pen-2 - PS-1 tilting angles in tandem with the active-inactive conformational change to group the reported Cryo-EM structures into three different structural classes). Similar tilting motions with respect to PS-1 can also be reported for Aph-1a. The extend of these motions observed in the simulation has been compared to the PDB structures: The tilt reported in the Cryo-EM structures (5FN2, 5FN3, 5FN4, and 5FN5) has been evaluated by first, aligning them according to the positions of the C*α* atoms of PS1 TMDs 4, 5, 7, 8, and 9 and then calculating for each structure, the standard deviation of the angles between helix 3 of PEN-2 and the arbitrarily chosen (yet mutual to all structures) z-axis. In the simulation, the sampled angle changes have been measured by aligning TMDs 4, 5, 7, 8, and 9 in each frame of the trajectory and subsequent calculation of the standard deviation of the PEN-2 - z-axis angle as above. The resulting standard

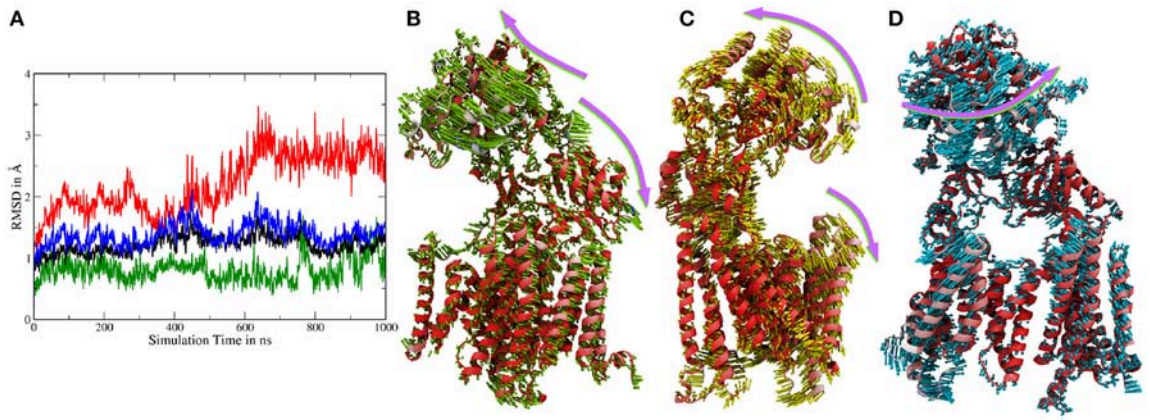

FIGURE 2 | (A) Cα-RMSDs calculated for system 1, with the first frame in the trajectory used as reference. Red: RMSD of complete nicastrin; green: TMD of nicastrin; black: all TMDs; blue: PS-1 TMDs. **(B–D)** Principal component analysis of simulation 1 (full g-sec). The mobility of each residue is depicted by the coloring scheme, ranging from red (least movement) via white to blue. The direction and extend of the movement is indicated by small arrows. Due to its high mobility, the intracellular loop 2 was not included in this evaluation in order to emphasize on nicastrin movement. **(B)**: Mode 1. **(C)**: Mode 2. **(D)**: Mode 3.

deviations obtained for the PDB files and the simulation were in good agreement with each other (2,47° for the PDB structures and 2.24° for system 1). The deviations of the APH-1a tilting were obtained by the same approach, however, this time the vector used to measure the APH-1a angle with respect to the z-axis was defined by calculating the centers of mass of (i) all the extracellular topside C_α atoms of the APH-1a TMDs and (ii) of their intracellularly oriented counterparts. This way a mean tilting angle of all the APH-1a TMDs has been determined. The resulting standard deviations of 0.67° (PDB) and 1.71° were in satisfying agreement with each other but suggested that the relative movement between PS-1 and APH-1a was slightly increased in the simulation, compared to the Cryo-EM structures. Plots showing tilting angles vs. simulation time can be found in the supplementary section (**Figure S3**). **Figures 3A,B** depict representative snapshots from the simulation, highlighting the sampled protein conformations in the simulated complex that compare well with arrangements observed in the PDB structures 5FN3 and 5FN5 (classes 1 and 3, respectively, shown in **Figures 3C,D**).

The first three principal components account for 49% of all motions in the simulations. While the fourth component, being a combination of the motions represented by modes 1 and 3, still represented global movement, all other eigenvectors of the covariance matrix referred to very localized loop rearrangements or fluctuations of terminal TMD regions (see **Figure S3** indicating the contribution of the first 20 modes).

The independent motions of the two nicastrin ectodomain lobes relative to PS-1 was further confirmed by a measurement of the distances and angles between amino acids, located either in the large lobe, the small lobe or the active site of PS-1 (see **Figure 4**). The distance between the large lobe (V328) and the active site of PS-1 (D257) showed two different types of variations: smaller, short lived fluctuations and a much slower but more distinct global movement (indicated by the running average in **Figure 4B**). The mean extend of this distance change witnessed during the simulation lies in the region of 3 to 4Å. It agrees quite well with the distance variation observed in the high-resolution Cryo-EM structures of Bai et al. (2015b), featuring V328-D257 distance deviations of the same magnitude. However, the larger scale changes reported by Elad et al. (2015) (up to 5 nm) have not been observed in our simulation, it is possible that larger scale global motions may require longer simulations beyond the scale of the present study. The angle defined by V328, L121 (in the small lobe) and D257 changes at exactly the same time as the fluctuations between V328 and D257 take place, clearly showing that this relative large lobe - PS-1 movement is decoupled from the movement of the smaller extracellular subdomain.

The distance changes between the small lobe and the PS-1 active site on the other hand, were of severely reduced extend, only exhibiting relatively low fluctuations and virtually no slow relative movement (**Figure 4C**). Another indication of decoupled subdomain dynamics of the ectomonain lobes is represented by **Figure 4D**, where a variation in L88-V295 distance is visible, indicating a conformational change in the nicastrin ectodomain.

It has been reported (Bai et al., 2015b; Aguayo-Ortiz et al., 2017) that PS-1 can adopt two distinct states: One, where the catalytically active side chains are relatively close to each other and a state, characterized by larger D257-D385 distances. For an aspartyl protease to cleave a peptide, besides the presence of the substrate, a water molecule at the right position, as well as two aspartates in a certain (proximal) geometry are required (Singh et al., 2008). During the sampling phase of system 1, PS-1 occupied the active state with a very low distance between both active site aspartates (approx. 8Å). This is surely aided by the fact that D257 was protonated, enabling the formation of a hydrogen bond between both side chains which remains stable for the duration of the simulation. For completion it should be noted that during the equilibration phase, also a different conformation was adopted, where D257 and D385 were separated by a larger margin (= inactive conformation).

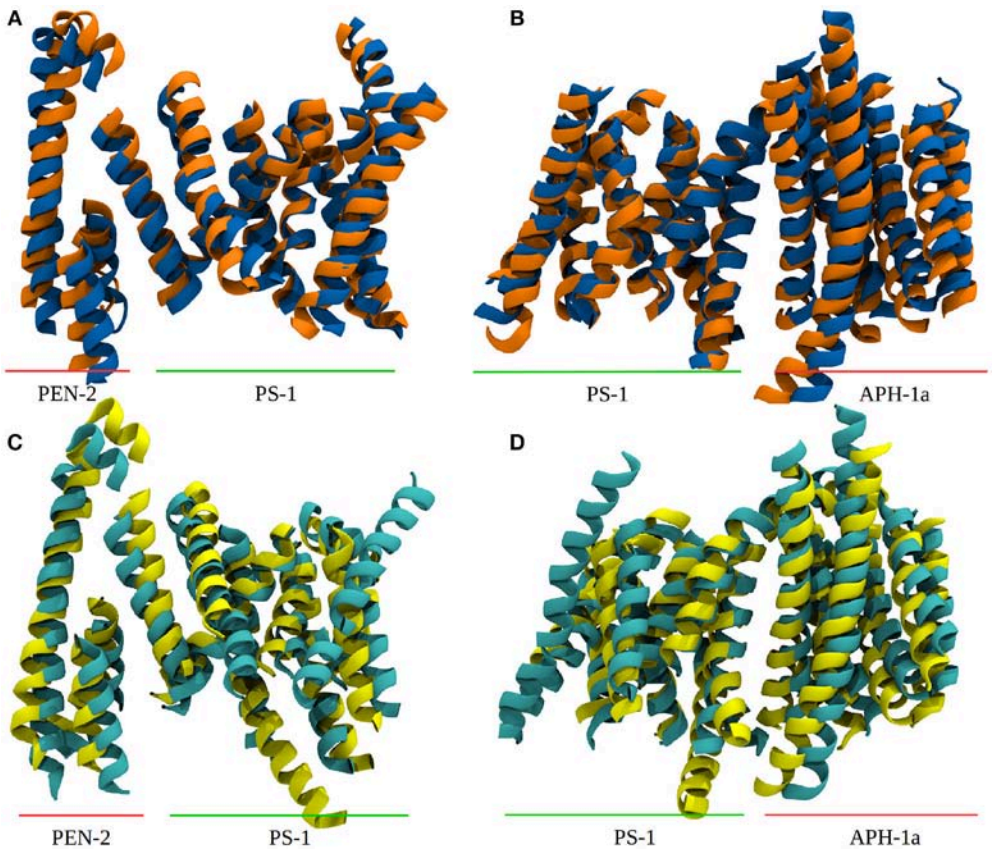

FIGURE 3 | Comparison between system 1 and experimental data. **(A)** Snapshots from system 1, depicting the "in" (blue) and "out" (orange) orientation of Pen-2 by superposition. **(B)** APH-1a tilting with respect to PS-1 in system 1. **(C,D)** Depiction of PDB structures 5FN3 (cyan, class 1) and 5FN5 (yellow, class 3) exhibiting very similar structural diversity. The structures were aligned at the C_α atoms of PS-1 TMDs 1, 5, 8, and 9.

System 2: γ-Secretase Without Ectodomain

In order to improve the sampling of the simulation and to investigate the influence of the ectodomain to γ-secretase dynamics, a 3.5 μs (+500 ns equilibration) long simulation of g-sec without the NIC ECD was conducted. The starting structure was taken from a snapshot of system 1 during equilibration. The NIC ECD was removed and the TMDs were embedded in a lipid bilayer consisting of 300 POPC molecules. During the 3.5 μs sampling phase, PS-1 changed its conformation from inactive to active at around the 1.75 μs mark. The mean active-site aspartate (D385 and D257) separations in the inactive state were found to be 9.1 ± 0.6Å (Cα-Cα, with distances up to 11.6Å) and 8.0 ± 0.7Å (Cγ-Cγ). Plots are shown on **Figure 5A**. The active conformation, on the other hand, was characterized by average Cα-Cα and Cγ-Cγ distances of 8.3 ± 0.6Å and 6.0 ± 1.0Å, respectively (see also **Figure 5A**, where the red and black solid lines denote the mean aspartate distances in active state, while the dashed lines represent mean values for the inactive conformation). Simultaneously with the putative activation of the enzyme, the separation between the TMDs 2 and 3 increased, indicating a conformational change affecting more than one PS-1 TMD.

If one takes a closer look at the catalytic aspartates, it becomes apparent that in active state they can either form a direct hydrogen bond, leading to Cα-Cα distances of 7.5 ± 0.3Å (in 26% of all sampled frames in active conformation) or can be bridged by one water molecule, increasing Cα-Cα separation to 8.6 ± 0.4Å. Snapshots of these respective conformations are shown in **Figures 5B,C**. The observed D257-D385 separations were in good agreement with the experimental data reported by Bai et al. (finding that active site Cα-Cα distances range from 8.0 to 12.7Å) (Bai et al., 2015b). Another interesting structural aspect can be uncovered by comparing the mean conformation of the first 1,000 ns (inactive state) of simulation 2, the mean conformation of the last 1,000 ns (active state) of system 2 and the mean structure resulting from the 1000ns trajectory obtained for system 1 (active state): The respective structures are shown superimposed on **Figure 5D** and indicate that transitioning from inactive to active state coincides with the repositioning of TMDs 1, 6, 7, 8, and 9 while TMD 2 and 3 adopt conformational diverse arrangements. The average structures have been generated by aligning the respective trajectories along the heavy atoms of the proteins and subsequently calculating the mean position of each atom in the simulations. This concerted rearrangement of some of the PS-1 TMDs could be further highlighted by calculating

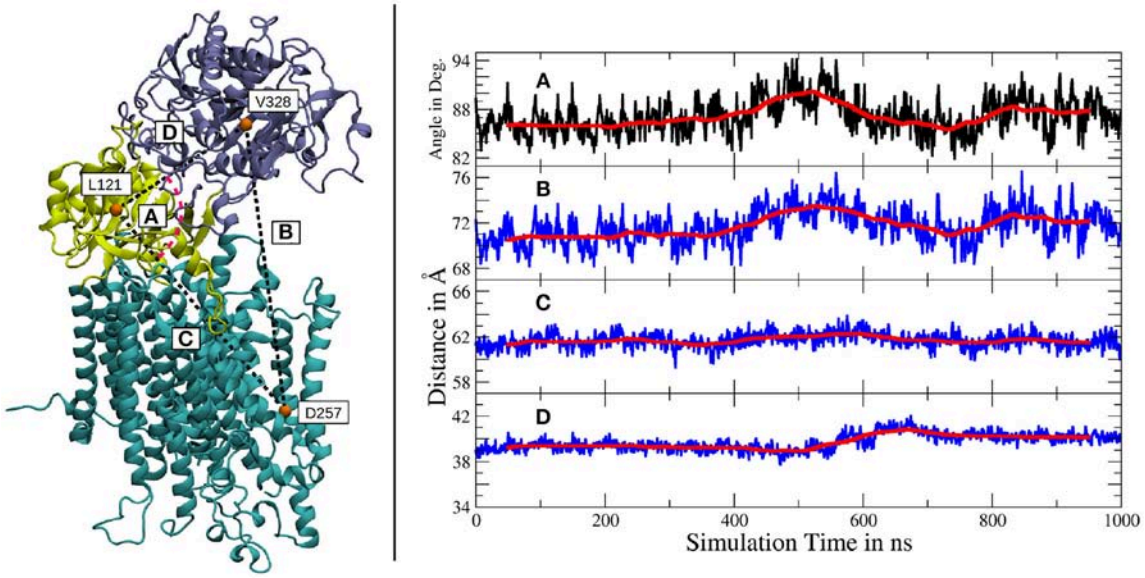

FIGURE 4 | Left panel: Location of the amino acids used for subdomain distance measurements. The large lobe is colored in iceblue, the small lobe in yellow and the intramembrane domains of g-sec are depicted in cyan. Right panel: **(A)** Angle between V328, L121 and D257. **(B)** Distance between V328, situated in the large lobe and D257, one of the catalytically active aspartates. **(C)** Distance change between the small lobe (L121) and the PS-1 active site (D257). **(D)** Distance change between the two ectodomain lobes (L121 and V328). The scaling is the same for all distance plots and a running average (100 points averaging window) has been added for greater clarity (red lines).

RMSDs for every residue in the TMDs in every frame. This was achieved by comparing their positions at each frame to their average position while being in the inactive conformation (the first 1,000 ns of the simulation were taken to calculate the mean inactive structure). The "per-residue RMSDs" depicted on the left hand panel of **Figure 6** indicate that the positional shifts of TMDs 1, 3, 6, 7, 8, and 9 coincided with the inactive to active transition of PS-1. From the positions of the Cα atoms of the active aspartates, it seems as if two different principal rearrangements were leading to distances favorable for substrate cleavage: A slight repositioning and rotation of the N-terminal region of TMD 7 (where D385 is located) and TMD 6 (where D257 is located) moving toward the center of PS-1. Transmembrane domain 2 displayed significant mobility throughout the entire simulation that agreed with the experimental observation that the structure of TMD 2 cannot be resolved in several Cryo-EM structures.

Recording the radius of gyration of PS-1 (right-hand panel on **Figure 6**) demonstrates that the TMD rearrangement upon inactive to active transition was associated with a contraction of PS-1, as the mean radius changed from 14.71Å to 14.46Å.

The contraction of the intracellular side of PS-1 could also be witnessed by a principal component analysis performed on the 3.5μs sampling trajectory including the TMDs of PS-1 and PEN-2: In mode 1 (**Figures 7A,B**) TMDs 1, 6, 7, 9 of PS-1 and the PEN-2 α-helices were moving toward each other, thereby reducing the intra-domain distances (and with them also the separation between D257 and D385). PS-1 TMD 8, on the other hand, moved away from the rest of the presenilin helices.

The second most important of the concerted movements is depicted in **Figures 7C,D**: The distance between the catalytic aspartates remained constant but PS-1 TMDs 4, 5 and to a lesser extend 3 along with PEN-2 moved in different directions than the other PS-1 TMDs. This conformational change was decoupled from the transition between the active and inactive states and confirmed the structural classes reported by Bai et al where PEN-2 tilting also seemed to be independent from the D257-D385 distance (Bai et al., 2015b). Movie clips showing the coupled motions are provided as **Supplementary Material**. The first two modes of the PCA accounted for 47% of the overall mobility sampled by the evaluation trajectory. The remaining modes, however, emphasized strongly on fluctuations of terminal TMD domains, mainly involving TMD 2 (**Figure S4** depicts the contribution of the first 20 modes to the total mobility).

Known pathogenic mutations in PS-1 lead to different results regarding g-sec activity: A change of overall substrate processivity—mainly a decrease, sometimes even to the point of inactivation, or a shift of the ratio of product amyloids (very often increasing Aβ42 levels). Frequently, also a combination of the above effects is witnessed (Sun et al., 2016). Many of the mutations resulting in reduced or abolished g-sec activity are located at the interface of adjacent TMDs. Such mutations can be expected to destabilize presenilin or even prevent correct positioning of the respective TMDs during protein synthesis or folding. It is, however, likely that some of the mutations have a more subtle effect on the PS-1 structure and simply interfere with the relative positioning of the catalytic residues, thereby influencing important conformational changes. One such mutation site is F386, situated on TMD 7, right next to D385. As illustrated in **Figure 8**, the side chain of this residue is very close to five other known mutation sites (Sun et al., 2016;

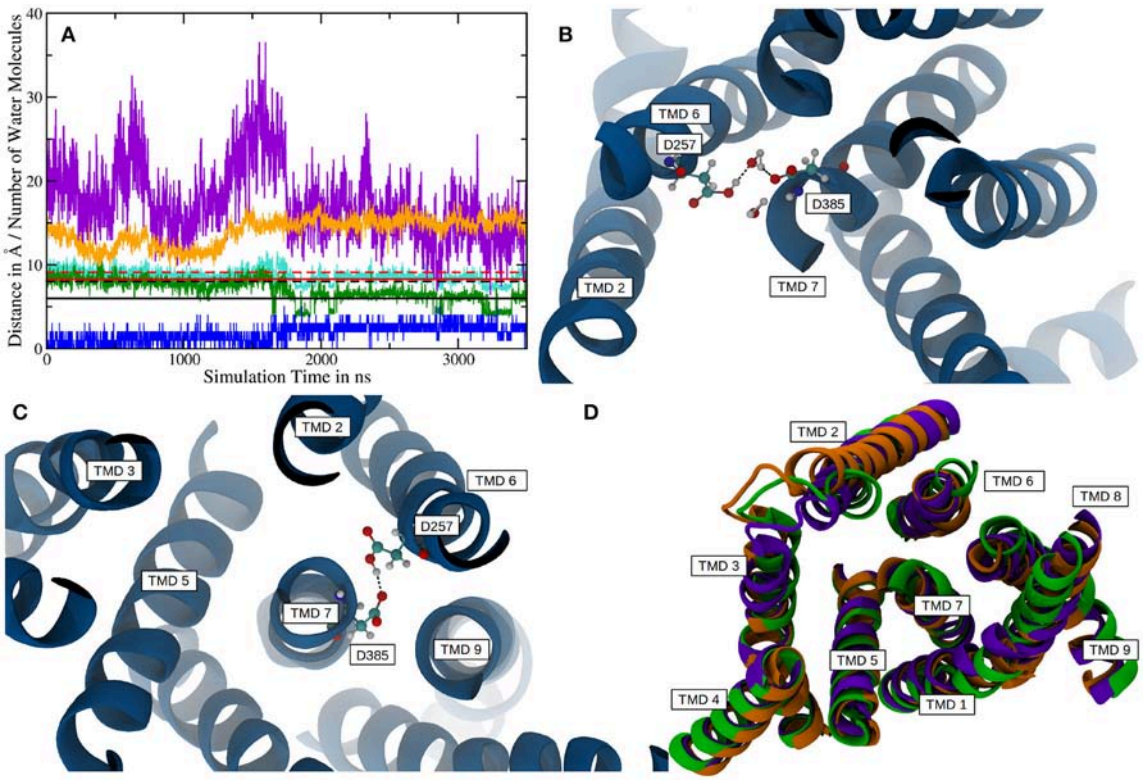

FIGURE 5 | (A) Plot depicting distances between certain residues and the number of water molecules within PS-1 in system 2. The Cα distance between D257 and D385 is shown in cyan with the mean distances for the active (solid line) and inactive (dashed line) given in red. The green plot represents the sampled distances between the Cγ atoms of the catalytic aspartates and the black lines indicate the mean separation in the inactive (dashed) and active (solid) states. The distance between V142 (TMD 2) and S169 (TMD 3) is depicted in orange. The blue line is the number of water molecules within 4Å of D257 and D385 and the purple plot indicates the number of water molecules inside the putative substrate binding area of PS-1. Please note, that the purple graph has been scaled down by a factor of two in order to increase comparability. **(B)** The active site aspartates are bridged via a water molecule at Cα distances of 8.6 ± 0.4Å. **(C)** At a Cα separation of 7.5 ± 0.3Å the two catalytic side chains are forming a hydrogen bond. **(D)** Superposition of the mean structures of inactive PS-1 (system 2, green), active PS-1 (system 2, purple) and system 1 (orange). View from the intracellular side.

The red and green lines denote the mean radii of the inactive and active conformations, respectively.

Szaruga et al., 2017), S390, S230, C92, V89, and P88. While residues P88, V89, C92, and S230 outline the binding pocket of F386, S390 helps to position C92 by acting as a hydrogen bond acceptor. During the simulation, upon activation of the enzyme, F386 "plugged" into the binding cavity, and anchored TMD 7 to TMD 1, thereby impacting the positioning of D385 (see

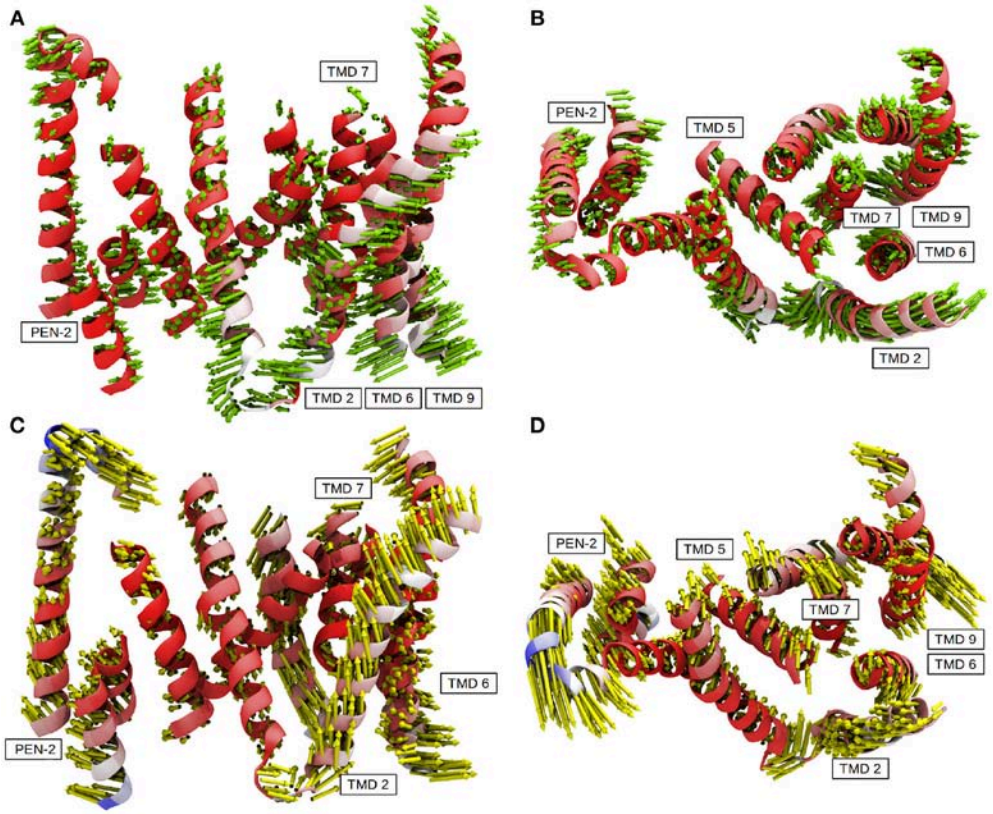

FIGURE 7 | The first two principal components calculated from system 2. **(A)** Mode 1 side view. **(B)** Mode 1 top view (from extracellular side). **(C)** Model 2 side view. **(D)** Mode 2 top view (from extracellular side). Residues colored in red exhibit low mobility while blue indicates strong fluctuations.

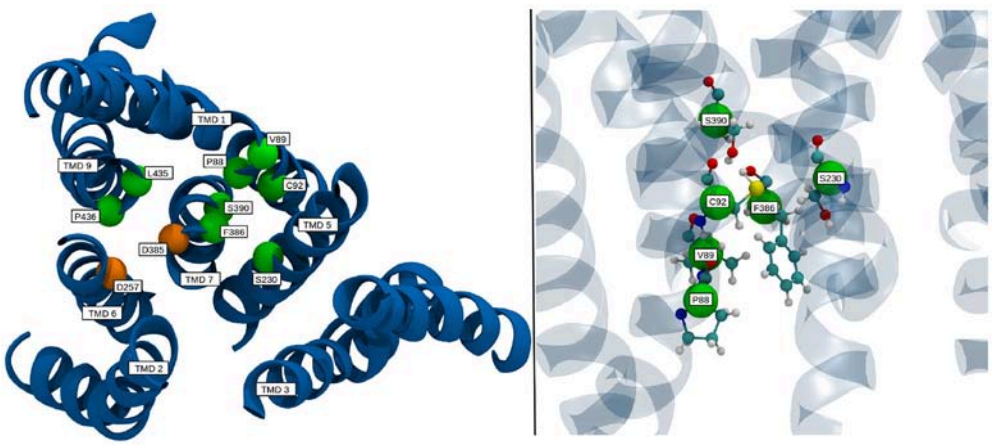

FIGURE 8 | Location of select mutation sites on the TMDs of PS-1 which are known to severely reduce the catalytic activity of γ-secretase. TMDs are colored in blue, mutation sites are depicted as green spheres, while the catalytic residues are shown in orange.

also **Figure 6**). Changing the sterical properties of this binding site or mutating F386 to a serine can be expected to have an impact on this behavior, hinting at why these mutation sites severely lower the catalytic capabilities of g-sec. Residues P88, V89 and C92 are located on TMD 1 which explains why the positioning of parts of TMD 1 is connected to the inactive-active conformation change of PS-1 (see also right panel on **Figure 6**). Other residues that may directly influence the positioning of the catalytically active aspartates are L435 and P436. While the mutation of L435 to a phenylalanine can increase the sterical barrier for TMD 7 twisting, changing P436 into a serine might influence the catalytic capabilities of D257 and D385 because

S436 would be capable of forming hydrogen bonds with their side chains.

In order to assess the stability of the protein complex and compare it to system 1, several C_α RMSDs have been calculated. As can be seen in **Figure 9A**, the fluctuations of the TMDs were considerably higher in system 2, compared to system 1. To isolate the contribution leading to this increased mobility and to improve the comparability to the shorter system 1 simulation, the 3,500 ns long trajectory has been split into two 1,000 ns long trajectories: One trajectory where PS-1 is in inactive state and a second with PS-1 in the (presumably) catalytically active conformation. The transitory part in the middle of the complete trajectory has been left out in order to remove the TMD rearrangements from the dataset (as such a conformational change was not occurring in system 1). The RMSDs resulting from the analysis of these new trajectories showed that the deviations were of the same magnitude as in system 1, with the only exception being the non-PS-1 TMDs in the first 1,000 ns (= inactive state) of the simulation (see **Figure 9B**), suggesting that the inactive conformation of PS-1 may lead to a slightly less stable protein complex.

The primary (known) role of the ectodomain of nicastrin is gate keeping the g-sec complex, thereby prohibiting the processing of substrate TMDs before the shedding of their ectodomains. It is also known that nicastrin plays an essential role in stabilizing the g-sec complex (Zhang et al., 2005). To assess the complex stability compared to the simulation of full γ-secretase, PEN-2 and APH-1a tilting motions have been calculated with the same method as for system 1 and with a standard deviation of 2.68° for PEN-2 and 1.68° for APH-1a the results suggest that the absence of the NIC ECD does not destabilize the rest of the protein assembly (values for system 1 are: 2.24° and 1.71°, respectively). Therefore it seems very likely that the stabilizing effect of NIC is due to its transmembrane helix. To further elucidate the role of the ectodomain of nicastrin, the structure and dynamics of PS-1 in systems 1 and 2 have been evaluated and compared to each other. One way of comparing structural features is through per-residue RMSDs, calculated for each frame in the trajectory. The heatmap plot in **Figure 10A** has been generated by first calculating the RMSDs of all residues in the simulation of system 1 (against the mean structure) in order to establish the "natural" fluctuations of the system (i.e., the noise). In a second step the per-residue RMSDs of simulation 1 were calculated against the mean structure of the last 1,000 ns of simulation 2 (= the active conformation). Subsequently, the per-residue RMSDs of the first step were subtracted from the second data set in order to plot only the (absolute) deviations that occur in addition to the "natural" fluctuations. This plot showed that for the most part, structurally the two simulations were very similar, again with TMD 2 and the N-terminal end of TMD 3 being the exception (and to an extend also TMD 6).

A similar comparison this time, between the inactive conformation of system 2 and simulation 1 resulted in **Figure 10B**. In this case, the heatmap plot indicated larger deviations between the two instances of PS-1: Additionally to TMD 2 (and 3), also the lower parts (= pointing toward the intracellular region) of TMDs 6, 7, 8, and 9 showed significant aberration throughout the trajectory. This structural evaluation fits nicely to the superposition of the mean structures of trajectories 1, 2 (active) and 2 (inactive) in **Figure 5D**, indicating the same structural differences. The dynamics of the two systems can be assessed by calculating B-factors for all PS-1 residues (excluding the very mobile loop 2 region). The resulting plots for systems 1 and 2 are shown on **Figure 10C**.

Evidently, the B-factors of all the TMDs are very low and approximately of the same magnitude in all compared trajectories. The only obvious exception is TMD 2 in the complete trajectory of system 2 where the Cα atoms clearly exhibited heightened mobility. Another difference between the (shorter) simulation including the NIC ECD and the complete trajectory of system 2 was the mobility of the loops connecting the C-terminal TMDs 7, 8, and 9. Upon closer inspection, however, also TMDs 6, 7, 8, and 9 displayed slightly increased dynamics in the complete trajectory of system 2. To put these results into perspective one has to consider the fact that the simulation of system 2 is more than twice as long as the one of system 1 and as has already been discussed, PS-1 undergoes a conformational change including the (relative) rearrangement of several TMDs. Furthermore, TMD 2 is known to be highly mobile, so increased positional fluctuations in this part of the protein are not really surprising. For a more balanced comparison between the shorter and the longer simulation, trajectory 2 has been divided into a 1,000 ns inactive conformation state and a 1,000 ns long active conformation state, while the TMD rearrangements taking place in approx. the middle of the simulation were omitted from the data (these trajectories were exactly the same as those that have been used to generate the additional RMSD plots above). The B-factors corresponding to these new trajectories are shown of **Figure 10C** as green and blue lines, respectively. These split-trajectories lead to the verdict that the mobility of PS-1 TMDs is not affected by the presence or absence of the NIC ECD: The resulting B-factors of the shorter system 2 trajectories fit nicely to the B-factors calculated for the TMDs in the simulation with complete nicastrin. The case of the loop regions is a bit more complex: The data suggested that (i) the active form of PS-1 exhibits lower fluctuations compared to the inactive conformation, (ii) the loop (and adjacent TMD regions) connecting TMDs 2 and 3 seemed to be of greatly reduced mobility in the simulations without the NIC ECD if inactive-active conformational changes are taken out of the picture. Since, however, the evaluation of the complete simulation 2 trajectory showed greatly increased mobility in this exact region, differences in B-factors concerning the region connecting TMDs 2 and 3 are insufficient to be taken as prove for external influences. These aberrations were very likely just of statistical nature and due to the fact that not all evaluation windows used for the respective B-factor calculations caught the same extent of the configurational changes. Altogether, the available data suggest only a small influence of the ECD of NIC on the structure and dynamics of PS-1.

Apart from conformational transitions, one of the questions in the context of intramembrane proteolysis is the availability of a sufficient number of water molecules, not only to facilitate the hydrolysis but also to stabilize putative transition states and the (putative) unwinding of the alpha helical substrate molecule.

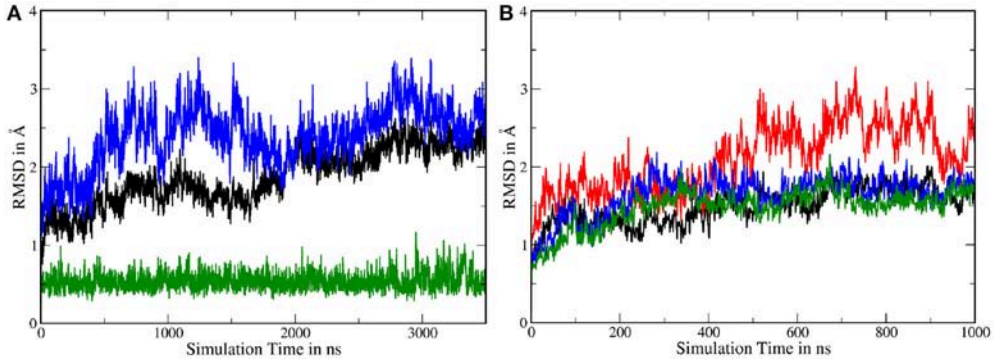

FIGURE 9 | (A) Backbone RMSD with respect to the first frame in the trajectory. Green: nicastrin TMD; black: PS-1 TMDs; blue: all TMDs. **(B)** Backbone RMSDs of the split trajectory. In order to investigate its hydration properties PS-1 has been approximated by a box with a volume of approx. 30,200Å^3. Subsequently, the mean number of water molecules within that cube was calculated by averaging over all 3,500 sampling frames. This evaluation showed that a mean number of 123.2 (with 87 being the lowest count and 167 the highest) water molecules were situated somewhere between the TMDs of PS-1 and with that also inside the membrane. The water distribution, depicted by **Figure 11** is not homogeneous and the number of solvent molecules rapidly diminishes in the vertical center of the protein.

Since the active-site aspartates are situated at the intracellular side of the g-sec complex, the water molecules located in this region can be expected to play a larger role in processing and stabilizing the substrate. Therefore, the number of water molecules residing inside the area around the active site—presumably coinciding with the region where the C-terminal part of a substrate molecule is located, has been ascertained as well. The box chosen to represent the putative binding and processing site was approx. 7,800 Å^3 in size and incorporated a mean value of 34.8 water molecules, ranging from 13 to 73 (see also **Figure 12**).

Intriguingly, if the number of water molecules is plotted against simulation time, an abrupt change is apparent (purple line in **Figure 5A**). This change in number of water molecules coincided with the transition from inactive to active state PS-1. Since the box volume remained constant, a change of water accessibility to the binding region must be responsible for

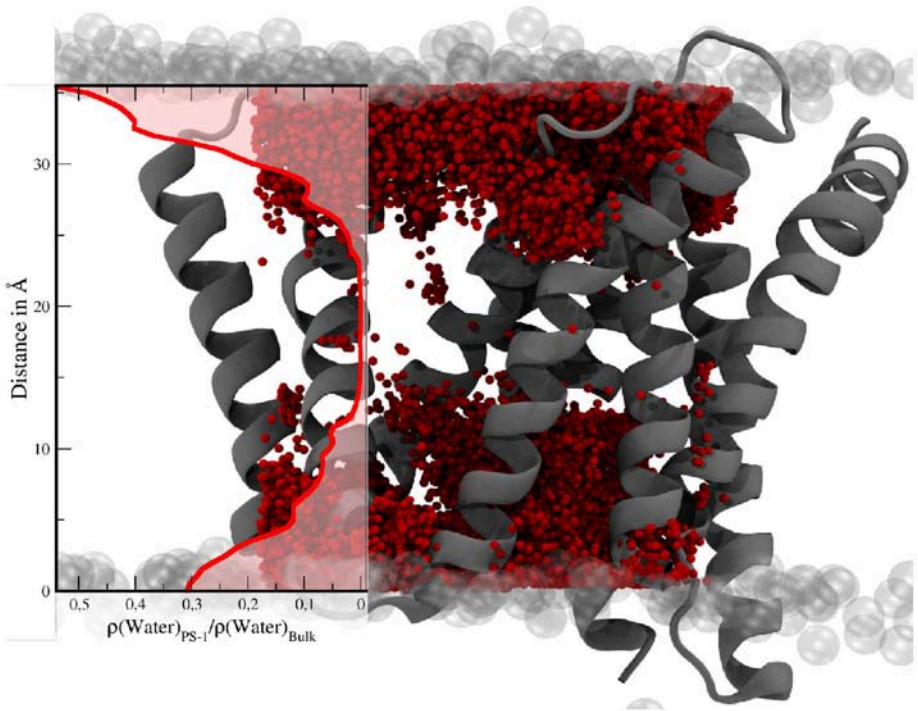

FIGURE 11 | Water molecules within a box of 30 × 28 × 36Å in the TM region of PS-1. The transparent gray spheres indicate the edge of the membrane domain. The red spheres are water molecules. The visualization of the water distribution has been generated by superimposing the positions of all water molecules within the given boundaries at every tenth evaluation frame of the simulation. The graph on the left shows the mean water density (N_{water}/*Volume*) in PS-1, relative to the bulk region.

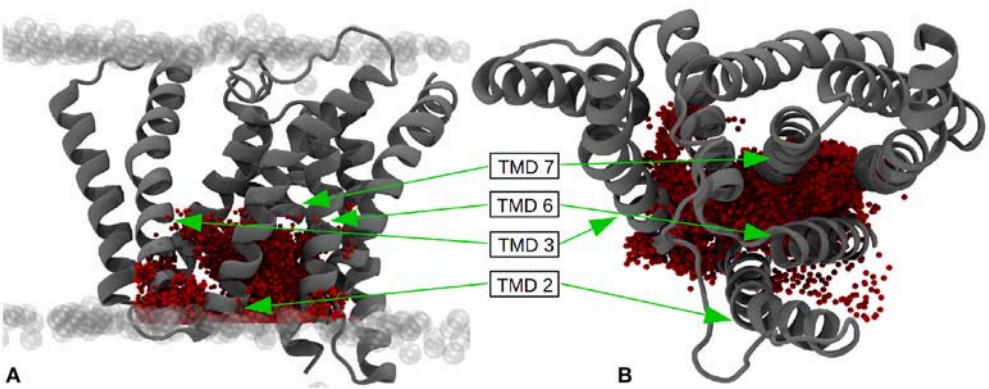

FIGURE 12 | (A) Water molecules within the putative binding region of the substrates (27 × 18 × 16Å) - side view. **(B)** Top view of the putative binding region. The pictures have been generated by superimposing the positions of all water molecules within the given boundaries at every tenth evaluation frame of the simulation. The extracellular side is at the top.

this behavior. This finding can be explained by the proposed contraction of the TMDs during the conformational transition of PS-1 to the active form. The plot also highlights that the fluctuation of the number of water molecules close to the cleavage site was distinctly lower in the active conformation, again suggesting a more rigid conformational state (the standard deviation changes from 4.4 to 3.0). The water molecules directly responsible for the hydrolysis of the substrate are of course those that are very close to both catalytic aspartates. As shown by the blue line in **Figure 5A**, the number of water molecules within 4Å of both D257 and D385, changed from a mean 1.0 (inactive conformation) to 2.6 (active conformation), indicating structural properties more favorable for substrate processing.

One of the open questions regarding g-sec and its processing of single-span TMDs is the location of the substrate binding site(s). In addition to the active site (leading to immediate cleavage), the existence of several exosites responsible for the recognition and recruitment of substrate TMDs has been heavily

indicated by a number of experimental studies (Esler al., 2002; Tian et al., 2002; Kornilova et al., 2005; Fukumori and Steiner, 2016). The identification of such sites could help to elucidate the path along which C99 and other substrates enter the active site of PS-1, thereby enabling the analysis of the role played by many of the known PS-1 FAD mutations. Although fatty acid chains of POPC lipids differ quite substantially from TMD α-helices, their main mode of interaction with transmembrane proteins is similar—namely through dispersion effects in the apolar bilayer region and polar interactions at the lipid-water interface. Simple apolar interactions are rather unspecific (especially when compared to hydrogen bonds or salt bridges) and it can be argued that protein regions that are able to immobilize and bind POPC lipids should also be able to form substantial interactions with transmembrane α-helices. Insight into the number and position of such interaction patches was gained by measuring the mobility of all lipids in the simulation box. The ones that showed a very small deviation from their mean position can be regarded as situated at a protein region favorable for binding hydrophobic species (with polar headgroups). In order to achieve this, all subsequent frames of trajectory 2 have been aligned to the first frame with respect to the Cα atoms of the protein TMDs. Subsequently, the heavy-atom B-factors of all fatty acid chains have been calculated.

The resulting positional deviations indicated that lipid mobility in the system was very diverse. Generally, most POPC molecules were able to freely travel around the bilayer in the simulation box, however, some lipids were evidently held in place by interactions with one ore more of the g-sec subunits. These lipids have been identified by their low B-factor and the immobilization of their fatty acid chains has been confirmed by visual inspection of the trajectory. The left panel on **Figure 13** shows the seventeen lipids that exhibited the lowest B-factors in the simulation. All of the depicted fatty acid chains remained trapped in position and did not diffuse through the bilayer.

The four fatty acids showing the lowest B-factor (157–250Å^2) depicted in cyan, were situated at two different positions: One lipid (consisting of two fatty acid chains) was bound between the TMDs of nicastrin and APH-1a but since this patch is very far away from the active site it is unlikely that a putative substrate entry path starts from there (let alone it being the active site). The second binding site was intriguingly coinciding with the cavity formed by TMD 2, TMD 3, and TMD 5 in which a co-purified helix had been identified by Bai et al. (2015b). This cavity (see also **Figure 13**, right panel) remained stable for the duration of all the conducted simulations and is outlined by many of the known mutations reportedly leading to early onset Alzheimer's disease (cf. www.alzforum.org). These circumstances make a strong case for this region being an important substrate binding site, perhaps even the active site.

Another area often suspected to be involved in substrate adoption consists of TMDs 2, 6, and 9 (Tomita and Iwatsubo, 2013; Fukumori and Steiner, 2016). This suggestion is also supported by the present data as two fatty acids chains belonging to the same lipid were binding to that specific region. However, the color scheme (green: B-factor between 405 and 519 Å^2; purple: B-factor between 785 and 1025 Å^2 in **Figure 13** indicates that the immobilizing effect was lower and one of the two chains was bound with higher affinity than the other. Upon visual inspection of the simulation it became evident that most of the time only one of the two fatty acids was interfacing with the protein, with very few instances where both were able to bind simultaneously. This hints at slightly unfavorable conditions for binding larger entities at this position. Nevertheless, this location is easier to access than the cavity at TMD 2, 3, and 5, as there is a cytosolic loop connecting TMDs 2 and 3, requiring deformation of the substrate helix upon entering. A potential substrate helix bound at either of the two positions would be very close to the active site. Another interesting accumulation of lipids was situated at PEN-2 and PS-1 TMD 4 where a number of immobilized fatty acid could can be found, indicating that this region might play a role as an exosite, capturing potential substrates moving freely in the membrane.

CONCLUSIONS

Two atomistic (1 to 3.5 μs long) simulations of the γ-secretase complex have been conducted. with evaluation trajectories that were up to 3.5 μs in length. To our knowledge these are the longest purely atomistic computer simulations of the complete g-sec complex conducted to date. All simulations exhibited modest positional deviations throughout the sampling phase, indicating that the employed force fields were able to maintain stable conditions and keep the structure of the protein complex close to its native Cryo-EM-deduced structure. The existence of different conformational classes with respect to the distance between the active site aspartates and the relative position of PS-1 and PEN-2, as predicted by experimental means (Bai et al., 2015b), were also observed in the simulations. Additionally, similar tilting motion as exhibited by PEN-2 were also witnessed for APH-1a in agreement with available high resolution Cryo-EM structures.

Evaluation of the dynamical aspects of the complete complex in a POPC bilayer further confirmed the existence of a pronounced "up/down" and "left/right" movement exhibited by the NIC ECD. This sort of relative ecto-TMD movement has previously been suggested by simulations conducted with coarse grained (Aguayo-Ortiz et al., 2017) or elastic network models (Lee et al., 2017) of g-sec.

Since g-sec has been simulated with and without the bulky nicastrin ectodomain it was possible to investigate the influence on the dynamical and structural properties of the catalytic subunit of the complex. On the time scale of the present simulations no significant effect of the ectodomain on the structure and dynamics of presenilin-1 has been observed.

In one of the simulations a conformational change leading from catalytically inactive PS-1 to the active conformation has been sampled and the associated distinct motions characterizing the transition have been identified: A reduction of the distance between TMD 6 and 7 by an inward movement on the part of TMD 6, as well as a rotation of the N-terminus of TMD 7, leading D385 to face D257. Also, the observation of an active conformational arrangement over μs time scale indicated that such a state is at least transiently accessible also in the apo state of the enzyme. RMSD, mobility and water hydration data strongly suggested that the active conformation of g-sec is more rigid than the inactive form. It has recently been speculated

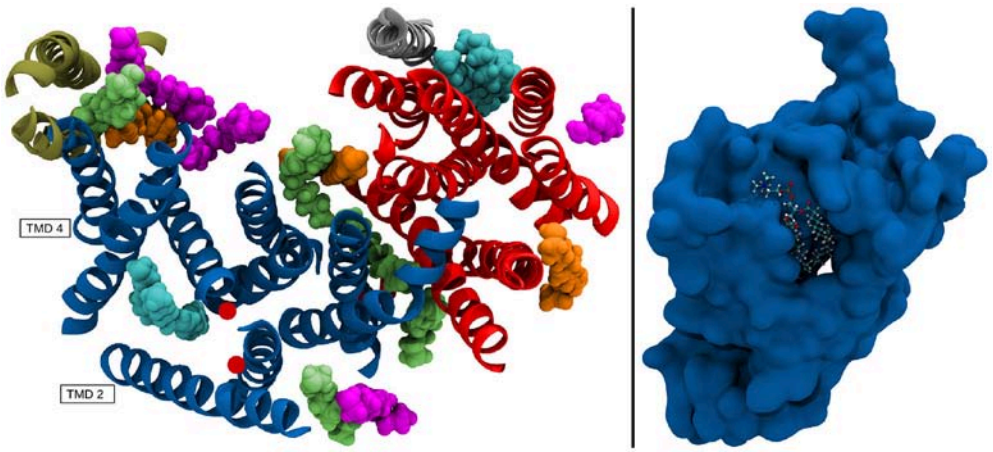

FIGURE 13 | (Left panel) TMDs of γ-secretase with strongly immobilized lipids. The TMDs of PS-1 are colored in dark blue, PEN-2 is depicted in beige, APH-1 in red and nicastin in gray. The lipids are colored according to their B-factor: Cyan: 156 to 250Å^2; orange: 405 to 519Å^2; green: 610 to 732Å^2; purple: 785 to 1026Å^2. The active site residues D257 and D385 are marked by red dots. **(Right panel)** Van der Waals surface depiction of presenilin-1 with the strongly bound POPC molecule in the cavity.

that some FAD mutations may lead to a destabilization of the protein fold which in turn could have an impact on its proteolytic capabilities (Szaruga et al., 2017). The conformational change sampled in this study suggests that even the wildtype of γ-secretase exists in conformational states with differing rigidity. Mutations at neuralgic positions can be expected to shift the balance between these states also in the direction of the state with more loosely associated TMDs. This could have an impact on both, the enzyme-substrate complex stability and the length of the interval between two processing steps (because g-sec is more likely to be in a state where it is not capable to cleave the APP fragment).

The hydration properties of PS-1 have been elucidated by counting the water molecules present at specific locations, leading to the conclusion that there is an ample amount of water molecules present in and around the active site of PS-1. The high number of polar solvent molecules in the putative binding site also hinted at the possible destabilization of a hydrophobic substrate helix, not only in the location of the scissile bond but also further downstream up to the substrate C-terminus.

The prime suspect to be the main substrate binding site is the cavity located between TMDs 3 and 5. Not only has it been stable throughout all simulations, it was large enough to bind a substrate TMD (Bai et al., 2015b), outlined by several FAD mutation sites (cf. www.alzforum.org) and strongly immobilized hydrophobic chains as shown by the lipid mobility computation for system 2. If C99 or other substrates bind in this groove, it would also be very likely that they formed additional interactions with the nicastrin loop extending from residue S241 to C248. What speaks against TMDs 2 and 3 forming the portal to the active site is the presence of a very short loop connecting both helices at the intracellular side, thus forcing a potential (uncleaved) substrate molecule to be kinked in order to fit. On the other hand, the gathered simulation data strongly suggests, that the protein is very flexible in exactly this region. Such high plasticity is of course very beneficial for the hypothetical entry of a sterically demanding substrate molecule. Future simulation studies in the presence of a substrate TM helix may help to elucidate putative substrate binding sites as well as entry pathways to the active site and also provide insight into how the flexibility of γ-secretase is affected by substrate binding.

AUTHOR CONTRIBUTIONS

MH performed research, analyzed data, and wrote the article. MZ designed research and wrote the article.

FUNDING

Financial support by the DFG (German Research Foundation) grant FOR 2290 (project P7) is gratefully acknowledged. Computer resources for this project have been provided by the Gauss Centre for Supercomputing /Leibniz Supercomputing Centre under grant pr27a.

ACKNOWLEDGMENTS

We thank Dieter Langosch, Christina Scharnagl, and Harald Steiner for many helpful discussions.

Single atom catalysts (SACs) are emergent catalytic materials that have the promise of merging the scalability of heterogeneous catalysts with the high activity and atom economy of homogeneous catalysts. Computational, first-principles modeling can provide essential insight into SAC mechanism and active site configuration, where the sub-nm-scale environment can challenge even the highest-resolution experimental spectroscopic techniques. Nevertheless, the very properties that make SACs attractive in catalysis, such as localized *d* electrons of the isolated transition metal center, make them challenging to study with conventional computational modeling using density functional theory (DFT). For example, Fe/N-doped graphitic SACs have exhibited spin-state dependent reactivity that remains poorly understood. However, spin-state ordering in DFT is very sensitive to the nature of the functional approximation chosen. In this work, we develop accurate benchmarks from correlated wavefunction theory (WFT) for relevant octahedral complexes. We use those benchmarks to evaluate optimal DFT functional choice for predicting spin state ordering in small octahedral complexes as well as models of pyridinic and pyrrolic nitrogen environments expected in larger SACs. Using these guidelines, we determine Fe/N-doped graphene SAC model properties and reactivity as well as their sensitivities to DFT functional choice. Finally, we conclude with broad recommendations for computational modeling of open-shell transition metal single-atom catalysts.

Keywords: density functional theory, catalysis, single atom catalysis, spin state crossover, transition metal chemistry

INTRODUCTION

Single atom catalysts (SACs) (Yang et al., 2013) are emergent catalytic materials (Yang et al., 2013; Liang et al., 2015, 2017) that have the promise of merging the scalability of heterogeneous catalysts with the high activity and atom economy of homogeneous catalysts, but the reactivity of SACs is poorly understood (**Figure 1**). Fe/N-doped graphene SACs have been demonstrated for critical transformations such as selective hydrocarbon oxidation (Liu et al., 2017), including ambient methane to methanol conversion (Cui et al., 2018), and as non-Pt oxygen reduction reaction (ORR) electrocatalysts (Li et al., 2016; Chen et al., 2017; Yang et al., 2018). The short-lived, variable

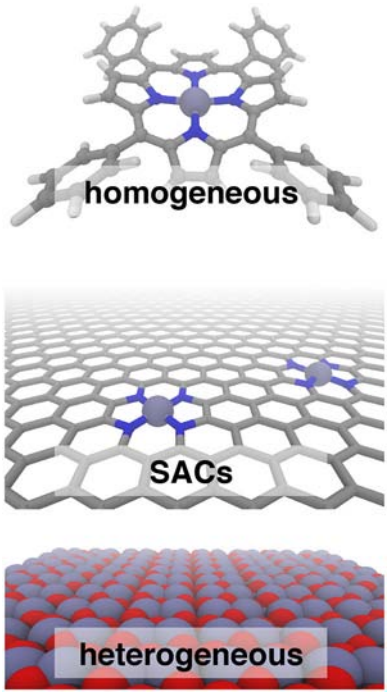

FIGURE 1 | Iron catalysts in three classes: homogeneous tetraphenyl porphyrin **(Top)**, N-doped graphene single atom catalysts (SACs, **Middle**), and heterogeneous hematite **(Bottom)**. In all cases, carbon is shown in gray, nitrogen in blue, iron in purple, and oxygen in red.

SAC active sites that are fundamentally sub-nm-scale challenge the resolution of spectroscopic techniques (Fei et al., 2015; Wang and Zhang, 2016), making first-principles modeling essential to mechanistic study.

For these emerging catalysts, changing synthesis (Liu et al., 2017) or reaction (Li et al., 2016; Zitolo et al., 2017) conditions changes the distribution of SAC coordination geometries, and the most reactive species for key reactions (e.g., ORR or selective partial hydrocarbon oxidation) remain under debate (Zitolo et al., 2015; Zhu et al., 2017; Yang et al., 2018). In selective partial hydrocarbon oxidation, spin-state-dependent reactivity of Fe/N-doped graphene SACs has been observed, with an intermediate, five-coordinate Fe(III)-N-C catalyst more reactive and selective (Liu et al., 2017) than low-spin or high-spin Fe active sites with four- or six-fold coordination. The fundamental source of this spin-state dependent reactivity remains unknown. In SAC electrocatalysts (Fei et al., 2015; Qiu et al., 2015; Zitolo et al., 2015, 2017; Back et al., 2017; Chen et al., 2017; Cheng et al., 2017; Zhang et al., 2017a,b; Zhu et al., 2017; Gao et al., 2018; Jiang et al., 2018; Wang et al., 2018; Zhang et al., 2018), changes in applied potential (e.g., in ORR) have been suggested to change the Fe SAC active site, possibly through a change in spin state (Zitolo et al., 2017).

Although perhaps surprising in the context of heterogeneous catalysis, strong spin-state dependence in reactivity is well-known in homogeneous catalyst (Schröder et al., 2000) analogs. Thus, it follows that paradigms that work in coordination chemistry might apply to SACs as well. The near-octahedral coordination environment around a metal center produces distinct quantum mechanical spin states (i.e., local metal magnetic moments) that are determined by the ligand-field strength as well as oxidation state and metal identity (Tsuchida, 1938). Different spin states often have distinct reaction barriers (Schröder et al., 2000; Schwarz, 2017) in a paradigm known as two-state reactivity (TSR) (Shaik et al., 1995; Schröder et al., 2000; Schwarz, 2017). TSR was first identified for Fe^+ ions, where oxidation of H_2 or CH_4 to H_2O or CH_3OH, respectively, is limited by spin inversion from a steep ground state, high spin (HS) surface to a more reactive but excited state low spin (LS) surface. For cases such as iron-oxo porphyrin systems that have nearly degenerate spin states, different pathways can indeed lead to distinct products (Kamachi and Yoshizawa, 2003; Ji et al., 2015).

In minimal model single-site catalysts, we recently demonstrated (Gani and Kulik, 2018) that bond elongation or compression has an effect similar to modulating ligand field strength, which could also alter ground state spin and reactivity in an interconnected manner. Most Fe(II)/N complexes have near degenerate HS and LS states because nitrogen ligands are of intermediate field strength, but small changes in the N-N separation of bidentate ligands that make up the octahedral complex are known to tune the experimental ground state of the material (Phan et al., 2017). In metal-doped graphene, strain has been predicted to change the ground state spin (Huang et al., 2011). Even changes in orientation of ligands (i.e., one equatorial swapped with one axial) have been experimentally observed to change the favored ground state spin of related molecular complexes (Andris et al., 2016).

The confined nature of metal *d* states and interactions with localized *p* orbitals from organic ligand atoms impart properties to open-shell SACs in a manner more closely resembling the chemical bonding of homogeneous catalysts than bulk metal counterparts. These very features, i.e., quantum size effects (Yang et al., 2013) at an open shell, high-valent metal atom, that make SACs reactive for essential catalytic transformations (Qiao et al., 2011; Yang et al., 2013; Zitolo et al., 2015, 2017; Zhang et al., 2018) also make conventional computational tools used in heterogeneous catalysis (i.e., plane wave, semi-local density functional theory, or DFT) ill-suited to predictive SAC study. Well-localized electrons are disproportionately affected by self-interaction error in approximate DFT (Cohen et al., 2011; Kulik, 2015), leading to an imbalanced treatment of differing spin and oxidation states (Ganzenmüller et al., 2005; Kulik et al., 2006; Droghetti et al., 2012; Ioannidis and Kulik, 2015, 2017; Mortensen and Kepp, 2015; Gani and Kulik, 2017).

Despite evidence of the importance of spin in homogeneous (Abram et al., 2014; Zhu et al., 2016; Schwarz, 2017) and SAC catalysts (Liu et al., 2017), most first-principles studies of SACs (Chu et al., 2015; Ma et al., 2016; Xu et al., 2018) have avoided directly quantifying the role of metal center spin in reactivity, with few exceptions (Impeng et al., 2014; Fong et al., 2018; Sirijaraensre and Limtrakul, 2018). In most studies, the magnetic moment is calculated with a semi-local DFT functional known to produce erroneous magnetic moments (Kulik, 2015; Ioannidis and Kulik, 2017; Janet et al., 2017; Wilbraham et al.,

2017) and the magnetization is often allowed to vary along the reaction coordinate (Xu et al., 2018). However, in confined metal centers, spin states are well defined and transitions between spin states occur with low probability because they are quantum mechanically forbidden. Spin state transitions can become kinetically limiting (Shaik et al., 1995; Schröder et al., 2000; Schwarz, 2017), explaining unexpected experimental reactivity (Andris et al., 2016). Within the homogeneous catalysis community (Harvey, 2014; Hernández-Ortega et al., 2015), significant effort has been made to develop tools to assess whether spin crossover is kinetically limiting, but this is not the case in SACs.

Unfortunately, given the importance of spin in predicting reactivity, spin state ordering is highly sensitive to the exchange-correlation functional employed in approximate DFT (Ganzenmüller et al., 2005; Kulik et al., 2006; Droghetti et al., 2012; Ioannidis and Kulik, 2015, 2017; Mortensen and Kepp, 2015). Semi-local (e.g., generalized gradient approximation, GGA) DFT functionals widely employed for their good cost/accuracy balance for many properties consistently stabilize overly-delocalized, covalent states (Autschbach and Srebro, 2014). GGAs thus favor the increased bonding in low-spin over high-spin states (Kulik, 2015; Gani and Kulik, 2017; Ioannidis and Kulik, 2017; Janet et al., 2017; Wilbraham et al., 2017). Hybrid functionals, which incorporate an admixture of HF exchange, are employed in organic chemistry to correct delocalization errors (Kümmel and Kronik, 2008). In transition metal catalysis, the fraction of HF exchange required, as judged by comparison to experiment or accurate correlated wavefunction theory (WFT) reference, is strongly system dependent (Bruschi et al., 2004; Ganzenmüller et al., 2005; Smith et al., 2005; Bowman and Jakubikova, 2012; Droghetti et al., 2012; Ioannidis and Kulik, 2015; Verma et al., 2017).

Thus, in this work, we carry out highly accurate correlated wavefunction theory calculations to develop benchmarks for transition metal complex spin state ordering with ligands that model the environment observed in single atom catalysts. Using these benchmarks, we identify trends in DFT functional performance, and then we evaluate how these observations influence predictions of the stability, reactivity, and ground state identity in models of Fe(II)/N-doped graphene SACs. Finally we provide our conclusions and outlook, including recommendations for computational modeling in this emergent space of single atom catalysis.

COMPUTATIONAL DETAILS

Octahedral Transition Metal Complexes

Initial structures of octahedral transition metal (TM) complexes with H_2O, NH_3, pyridine, and pyrrole ligands were built with the molSimplify toolkit (Ioannidis et al., 2016) with both ligand force-field pre-optimization and trained metal-ligand bond length features enabled. For the hexa-aqua and hexa-ammine complexes, M(II) Ti-Ni and M(III) V-Cu ions were studied, but the pyrrole and pyridine ligands were only studied in complex with Fe(II) or Fe(III). The formal charges assigned to the ligands were neutral in all cases except for pyrrole, which was deprotonated and given a −1 charge. High-spin (HS)-low-spin (LS) states studied in this work were defined as: triplet-singlet for d^2 Ti(II)/V(III) and d^8 Ni(II)/Cu(III), quartet-doublet for d^3 V(II)/Cr(III) and d^7 Co(II)/Ni(III), quintet-singlet for d^4 Cr(II)/Mn(III) and d^6 Fe(II)/Co(III), and sextet-doublet for d^5 Mn(II)/Fe(III). Intermediate-spin (IS) states were also studied: triplet d^4 Cr(II)/Mn(III) or d^6 Fe(II)/Co(III) and quartet d^5 Mn(II)/Fe(III).

Fe/N-Doped Graphene SAC Finite Models

Two possible Fe(II) coordination environments in finite graphitic SAC models were investigated with DFT, and in both the metal is coordinated by four nitrogen atoms substituted in the graphene structure. In both cases, we employed a hydrogen-atom-terminated graphene flake to avoid increasing computational cost in accordance with prior SAC computational studies that used finite models (Xu et al., 2018). First, a FeN_4C_{10} compound (chemical formula: $C_{36}N_4H_{16}Fe$) was studied in which all coordinating nitrogen atoms were in six-membered rings (i.e., pyridinic N). This structure is formed by removing two adjacent C atoms from $C_{42}H_{16}$ and replacing the four C atoms surrounding the vacancy with N atoms. This active site would correspond to two adjacent point defects in graphene, as has been observed experimentally (Banhart et al., 2011). A second compound, FeN_4C_{12} (chemical formula: $C_{40}N_4H_{16}Fe$), was also studied in which all coordinating nitrogen atoms were in five-membered rings (i.e., pyrrolic N). This structure was formed by removing two C atoms from a $C_{46}H_{16}$ structure, which contains two seven-membered rings in the center surrounded by four five-membered rings. Thus, this structure would require vacancy migration that has also been experimentally observed (Banhart et al., 2011). The two C atoms were removed from where the seven membered rings are joined, and the four inward-facing C atoms that are part of the five-membered rings were replaced with N atoms. All initial coordinates were generated by drawing the 2D structures with ChemDraw and converting the xml structures to 3D coordinates with the molSimplify (Ioannidis et al., 2016) interface to OpenBabel (O'Boyle et al., 2011) followed by force field optimization with the universal force field (Rappé et al., 1992). Singlet, triplet, and quintet spin states were studied, and all simulations had zero net charge.

Fe/N-Doped Graphene SAC Periodic Models

Periodic analogs to the flake models were studied starting from a 4×4 supercell of graphene at its experimental lattice parameter (Trucano and Chen, 1975). A smaller supercell than suggested (i.e., 7×7) in previous work (Krasheninnikov et al., 2009) was used for computational efficiency, and future work should focus on the effect of supercell size on dopant properties. The pyridinic (chemical formula: FeN_4C_{18}) SAC model was created following the same vacancy/N-atom replacement approach as in the finite case. For the pyrrolic (chemical formula: FeN_4C_{20}) SAC model, we started from the pyridinic case, inserting C atoms into the five-membered FeN_2C_2 ring. Next, we adjusted the adjacent six-membered rings into five-membered rings to create pyrrolic N atoms. In this small supercell, an eight-membered C ring was

then formed next to the five membered rings. Neutral systems were studied by spin polarized, fixed magnetization periodic calculations in singlet, triplet, and quintet states.

Localized Basis Set DFT Calculations

Transition Metal Complexes

All LS, IS, and HS complexes were geometry optimized with DFT using the PBE0 (default 25% exchange) global hybrid GGA functional (Adamo and Barone, 1999) with the def2-TZVP basis set (Weigend and Ahlrichs, 2005) in ORCA v.4.0 (Neese, 2018). Singlet states were calculated in a restricted formalism, whereas all remaining calculations were open shell and required level shifting (Saunders and Hillier, 1973) in select cases to aid self-consistent field convergence typically with a value of 1.0 eV but as large as 100.0 eV in one case ($[Mn(NH_3)_6]^{2+}$). The optimizations were carried out using the BFGS algorithm in redundant internal coordinates implemented to the default tolerances of 3×10^{-4} hartree/bohr for the maximum gradient and 5×10^{-6} hartree for the change in self-consistent field (SCF) energy between steps. All calculations at other levels of theory or with differing functional definitions were obtained as single point energies on these optimized geometries. The effect of Hartree-Fock (HF) exchange fraction choice on spin-state energetics within DFT was investigated by altering the fraction in a modified form of the PBE0 global hybrid. The HF exchange fraction was varied from as low as 0% [i.e., a pure PBE GGA (Perdew et al., 1996)] to as high as 100% HF exchange in increments of 10–20%, as indicated in the text, again using the def2-TZVP basis set. In previous work (Gani and Kulik, 2016), we found tuning range-separation parameters in range-corrected hybrids to have a comparable effect on density and energetics of transition metal complexes to global exchange tuning, and therefore we focus on only global exchange tuning in this work.

Fe/N-Doped Graphene Flake Models

Geometry optimizations and single-point energy calculations were performed with ORCA v4.0. All DFT methodology was kept the same as for transition metal complexes, including geometry optimizing at PBE0 (25% exchange) and carrying out single points at modified exchange fractions in PBE0 in 10% increments in conjunction with the def2-TZVP basis set, except as noted below. All singlet, triplet, and quintet calculations were carried out in an unrestricted formalism. All calculations employed the resolution of the identity (RI) (Baerends et al., 1973; Whitten, 1973; Dunlap et al., 1979; Eichkorn et al., 1995, 1997; Kendall and Fruchtl, 1997) and the chain-of-sphere (COSX)(Neese et al., 2009) approximations with the auxiliary basis set def2/J (Weigend, 2006) and def2-TZVP/C (Hellweg et al., 2007) for all atoms to accelerate the calculations while introducing marginal errors (Kossmann and Neese, 2009). Molecular structures and orbitals were visualized and plotted with VESTA (Momma and Izumi, 2011).

Periodic DFT Calculations

All systems were calculated with both the PBE (Perdew et al., 1996) semi-local GGA functional and the HSE06 (Heyd et al., 2003, 2006) local, range-separated GGA hybrid using the plane wave, periodic boundary condition Quantum-ESPRESSO (Paolo et al., 2009) code. Norm-conserving pseudopotentials for C, N, and Fe were generated with OPIUM (Rappe et al., 1990). The wavefunction and charge density cutoffs employed were 50 Ry and 200 Ry, respectively. A Monkhorst-Pack k-point grid of 8 $\times$ 8 $\times$ 1 was used for efficiency after confirming convergence of total energies with k-point mesh size. Total energies were converged to 0.1 meV and forces were converged to 1 meV/Å. Quantum-ESPRESSO post-processing tools were employed to visualize the spin density and projected density of states. Variable cell relaxation was employed to obtain final lattice parameters with PBE GGA for the pyridinic (result: 8.34 Å $\times$ 7.55 Å) and pyrrolic (result: 8.35 Å) models. A vacuum between each SAC layer of 10 Å was included along with a dipole correction to limit periodic image effects (Bengtsson, 1999). The HSE06 calculations were obtained as single point energies applied to these structures.

Correlated WFT

Complete active-space second-order perturbation theory (CASPT2) (Andersson et al., 1992) calculations were performed with OpenMolcas[1] (Aquilante et al., 2016) on M(II)/M(III) hexa-aqua and hexa-ammine octahedral complexes. Calculations were carried out with two active space definitions: the standard active space and an extended active space. For the standard active space, we followed literature recommendations for TM complexes (Pierloot, 2003; Veryazov et al., 2011) to include five orbitals with TM 3*d* character, two σ bonding orbitals describing covalent metal-ligand bonding, and five double-shell *d* orbitals for mid-row and later transition metals [i.e., Mn(II/III) and later]. For n 3*d* electrons, the standard active space is (n + 4, 7) (i.e., for Sc-Cr) or (n + 4, 12) (i.e., for Mn-Cu). In the extended active space, we followed additional literature recommendations (Wilbraham et al., 2017) to include the metal 3*s* orbital and an unoccupied counterpart, giving an active space of (n + 6, 9) (i.e., for Sc-Cr) or (n + 6, 14) (i.e., for Mn-Ni). Relativistic atomic natural orbital (ANO-rcc) basis sets (Roos et al., 2004, 2005) contracted to [7s6p5d3f2g1h] for the metal center, [4s3p2d1f] for O and N, and [3s1p] for H were used together with the scalar relativistic Douglas-Kroll Hamiltonian (Douglas and Kroll, 1974; Hess, 1986). The 10 core orbitals were frozen in all calculations. An imaginary level shift (Forsberg and Malmqvist, 1997) of 0.1 was used, and a zeroth-order Hamiltonian empirical correction, i.e., the IPEA shift (Ghigo et al., 2004), was set as 0.5 a.u. or varied as described in the main text to identify the effect on spin state energetics. For difficult to converge complete active space self-consistent field iterations, a level shift was applied to the Hamiltonian with shift value 1.0.

RESULTS AND DISCUSSION

Spin State Ordering in Model Complexes

Correlated WFT Results

We first conducted correlated wavefunction theory (WFT) calculations to generate reference spin-splitting energies of model

[1]OpenMolcas. Available online at: https://gitlab.com/Molcas/OpenMolcas.git (accessed June 6, 2018).

first row octahedral transition metal complexes. Our focus is on weak field hexa-aqua and hexa-ammine complexes that are small (i.e., 19–25 atoms in size) and of comparable ligand field strength to the coordination environment in SACs. Although CASPT2 is often the method of choice for predicting spin state energetics for molecules that are either too large or multireference in character to be comfortably treated with CCSD(T) (Pierloot et al., 2017), a number of calculation parameters can strongly influence the CASPT2 predictions. Specifically, spin state energetics can be influenced by the active space choice and the formulation of the zeroth-order Hamiltonian, i.e., the value of the IPEA shift (Ghigo et al., 2004). Here, we investigate the effects of both of these factors and then select reference results for DFT calculations.

Several studies (Kepenekian et al., 2009; Lawson Daku et al., 2012; Vela et al., 2016; Pierloot et al., 2017) have shown that the standard IPEA shift of 0.25 a.u. in CASPT2 overstabilizes high spin states. However, there is no universal agreement about the best solution to this problem. Some (Kepenekian et al., 2009; Lawson Daku et al., 2012; Vela et al., 2016) have recommended increasing the IPEA shift to 0.5–0.7 a.u. based on comparison with experimental or MRCI results, whereas others (Pierloot et al., 2017) recommend the standard IPEA value because increased IPEA can reduce the high spin bias but only at the expense of deteriorating the CASPT2 description of valence correlation. To understand the effect of IPEA shift, we obtained CASPT2 spin-splitting energies with IPEA shifts of 0.0, 0.50, and 1.5 a.u. and standard active spaces (**Figure 2** and see Computational Details). For all complexes, increasing IPEA shifts the high-spin/low-spin splitting toward more positive values, reducing high spin stabilization. The range of energetics calculated with different IPEA values for each complex provides a measure of IPEA sensitivity of each transition metal complex's spin-splitting energy (**Figure 2**). The IPEA sensitivity is consistently largest for cases where the high spin state has four more unpaired electrons than the low spin state (i.e., Cr^{2+} through Co^{3+}).

To focus only on spin state definitions in which the high spin state has two more unpaired electrons, we compare the high spin/low spin splitting, ΔE_{H-L}, for early and late TMs with the high spin/intermediate spin splitting, ΔE_{H-I}, for mid-row TMs. For these two electron differences, we observe similar sensitivities, with a ca. 10–20 kcal/mol positive shift when the IPEA is changed from 0.0 to 1.5 a.u. (**Figure 2**). This observation excludes only very early or late TM complexes that have smaller sensitivities. In comparison, the 4 electron-difference cases have higher sensitivities of around 30 kcal/mol or more (**Figure 2**). Overall, most early- and mid-row complexes remain high spin regardless of the IPEA shift (i.e., below the zero axis in **Figure 2**). The smaller energetic differences between states in later TM complexes [e.g., hexa-aqua Ni(III)] mean that the IPEA shift can change the ground state from high spin to low spin for very large IPEA shifts. For subsequent calculations, we selected the 0.5 a.u. IPEA shift but note that variation across the commonly employed range of 0.0–0.5 a.u. can shift the predicted ΔE_{H-L} (ΔE_{H-I}) spin-splitting for mid-row [e.g., Fe(II/III)] complexes by around 10 (3) kcal/mol (**Figure 2**).

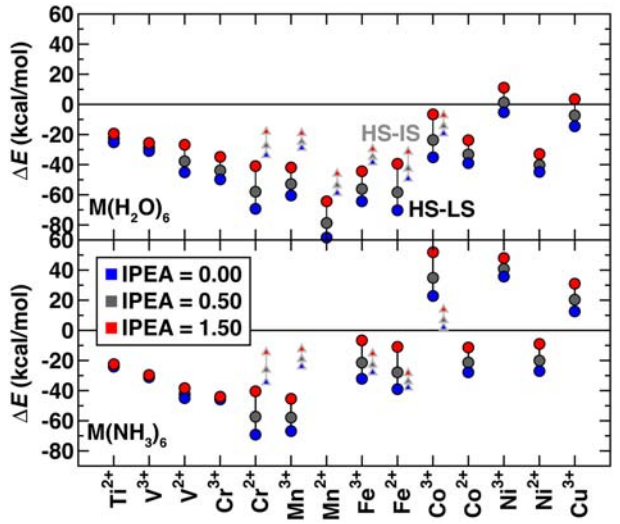

FIGURE 2 | CASPT2 spin splitting energetics in kcal/mol for ΔE_{H-L} (circles) and ΔE_{H-I} (triangles), as indicated in inset, of hexa-aqua (top) and hexa-ammine (bottom) transition metal complexes. Results are shown for 3 IPEA shifts: 0.00 (blue symbols), 0.50 (dark gray symbols), and 1.50 (red symbols) a.u.. Both M(II) and M(III) complexes are shown sorted by the number of 3*d* electrons, from Ti^{2+} to Cu^{3+}.

We next investigated the effect of use of a standard active space vs. a more extended active space in the CASPT2 calculations of ΔE_{H-L} and ΔE_{H-I} using the 0.5 a.u. IPEA shift (**Supplementary Table 1**). For most complexes, the energetic difference due to active space change is on the order of a few kcal/mol, which suggests that the calculation is converged with respect to active space size, as motivated in previous work (Wilbraham et al., 2017). The major outlier identified is $[Mn(NH_3)_6]^{2+}$, which is strongly low-spin in the standard active space but becomes high-spin like hexa-aqua Mn(II) with the extended active space, exhibiting greater active space dependence than had been observed in Mn(II) porphyrins (Yang et al., 2016) (**Supplementary Table 1**). This discrepancy is likely caused by orbital rotation of some active orbitals into the inactive metal 3*s*/4*s* orbitals, as suggested in recent work (Radoń and Drabik, 2018) on aqua complexes. After removing this outlier, the mean absolute difference between the standard and extended active space results for all ΔE_{H-L} and ΔE_{H-I} combinations is 3.3 kcal/mol for the hexa-aqua and 5.9 kcal/mol for the hexa-ammine complexes. The mean signed error is near zero for the hexa-aqua cases, and weakly negative (ca. −3 kcal/mol) for the hexa-ammines (**Supplementary Table 1**). Generally, discrepancies are smallest for the hexa-aqua complexes throughout and especially small for the early or late TMs (e.g., Ti^{2+}-V^{2+} and Ni^{3+}-Cu^{3+}), typically as little as 0–2 kcal/mol (**Supplementary Table 1**). In mid-row cases, there is no universal preference as to whether ΔE_{H-L} or ΔE_{H-I} has more active space dependence.

Given the small size of the studied octahedral complexes, we selected the extended active space calculations as reference values for comparison to DFT. Use of the larger active space changed some ground state spin assignments. When calculated

with the extended active space, almost all hexa-aqua complexes are high spin, excluding only weakly low spin $[Ni(H_2O)_6]^{3+}$ with a ΔE_{H-L} of 0.49 kcal/mol. The slightly stronger ligand field in the hexa-ammine complexes produces some additional LS late-TM complexes [e.g., Co(III) and Cu(III)] along with the analogous Ni(III) complex. Examining isoelectronic metals generally reveals that the later, more oxidized metal has only a weak high-spin-stabilizing effect that is smaller than the ligand-field effect in cases where the two metals converge to similar electronic states (**Figure 2** and **Supplementary Table 1**).

DFT Functional Performance

Despite the high accuracy of CASPT2 for treating spin state energetics in TM complexes, the high computational cost and sensitivity to active space definition and parameters limit its application on SACs. We thus sought to identify the extent to which DFT functionals can be selected or tuned to reproduce the spin-splitting energetics obtained with CASPT2. We focused on the exchange fraction within the global hybrid PBE0 (Adamo and Barone, 1999), motivated by previous observations of comparable behavior in tuning range-separated hybrids (Gani and Kulik, 2016), global hybrids with a different correlation functional (Ioannidis and Kulik, 2015), or those that incorporate meta-GGA exchange (Ioannidis and Kulik, 2017).

From all complexes studied with CASPT2, we narrowed our focus to those containing nominally 3–7 3*d* electrons (i.e., V^{2+} to Ni^{3+}) that are most likely to be good candidates for understanding spin-state dependent single atom catalysis. We determined the effect of varying PBE0 exchange fraction on both ΔE_{H-L} and ΔE_{H-I} for the relevant subset (i.e., 4–6 3*d* electrons). In accordance with prior work (Droghetti et al., 2012; Ioannidis and Kulik, 2015), we anticipated the sensitivity of these quantities to exchange fraction and the optimal exchange fraction to minimize error with respect to CASPT2 to be chemistry dependent. However, we aimed to identify if these trends can be readily rationalized (Gani and Kulik, 2017) or learned (Janet and Kulik, 2017) for use in SAC modeling.

As expected (Droghetti et al., 2012; Ioannidis and Kulik, 2015; Zhao and Kulik, 2018), spin-state energetics vary linearly with exchange fraction over a wide range (i.e., 0–50%) and high-spin states are stabilized with increasing exchange fraction for all transition metal complexes studied (**Supplementary Tables 2–3**). We quantified the exchange sensitivity of the spin-splitting energetics (Ioannidis and Kulik, 2015) by an approximate linear fit:

$$\frac{\partial \Delta E_{H\text{-}L/I}}{\partial a_{HF}} \approx \frac{\Delta \Delta E_{H\text{-}L/I}}{\Delta a_{HF}} \quad (1)$$

We use the unit notation HFX corresponding to the variation from 0 to 100% exchange. To maximize correspondence in quantities compared, we evaluate exchange sensitivity of all spin states that differ by two paired electrons: ΔE_{H-L} for V(II)/Cr(III) and Co(II)/Ni(III) and ΔE_{H-I} for the remaining complexes (ΔE_{H-L} values are also tabulated in **Supplementary Table 3**). The exchange sensitivity of two-electron-difference spin-state ordering for $[M(H_2O)_6]^{2+}$ complexes is relatively invariant to

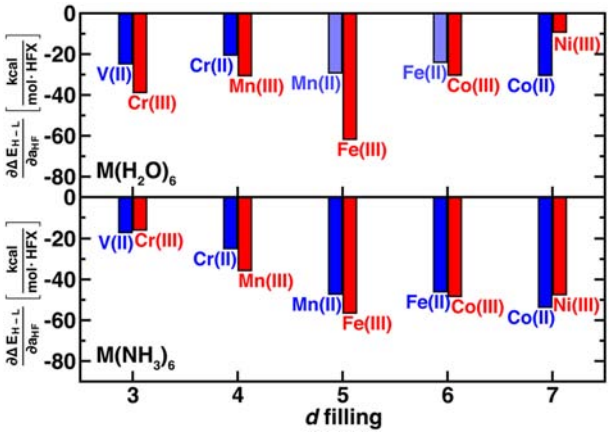

FIGURE 3 | Sensitivity of spin-state splitting with respect to HF exchange (i.e., $\partial \Delta E_{H-L}/\partial a_{HF}$, in kcal/mol·HFX) for hexa-aqua (top) and hexa-ammine (bottom) transition metal complexes. Both M(II) and M(III) complexes are shown grouped by their nominal *d* filling from 3 to 7 3*d* electrons for V(II) to Ni(III). For the 4, 5, and 6 *d*-electron cases, the energy gap corresponds to high-spin/intermediate-spin rather than high-spin/low-spin. Shaded bars indicate that spin contamination could not be eliminated for both spin states and sensitivity may not be reliable.

3*d* filling (i.e., varying only 2–4 kcal/(mol·HFX), see **Figure 3**). Conversely, hexa-ammine Mn(II), Fe(II), and Co(II) complexes have increased spin-splitting exchange sensitivity over the earlier TM complexes (**Figure 3**). For both ligand fields, the M(III) complexes are even more varied, with the least exchange sensitivity being observed in either late or early transition metal complexes (**Figure 3**). These observations are consistent with the fact that these complexes should have the least difference in electron delocalization between the two spin states, reducing exchange sensitivity (Gani and Kulik, 2017). Although M(III) complexes are more variable, isoelectronic +2/+3 complexes do have somewhat comparable exchange sensitivity (**Figure 3**). In comparing ΔE_{H-L} for all complexes, exchange sensitivity is universally higher for these mid-row cases due to the enhanced sensitivity of the four-electron difference energetics (e.g., $[M(H_2O)_6]^{2+}$: −57 kcal/(mol·HFX) for Mn vs. −25 kcal/(mol·HFX) for V, see **Supplementary Figure 1**).

The remaining question is whether the exchange fraction can be appropriately tuned within a modified form of PBE0 to obtain ΔE_{H-L} and ΔE_{H-I} values that match CASPT2 results. Comparing the range of spin-splitting energies obtained from 0 to 100% exchange to the CASPT2 extended active space values generally reveals that high exchange fractions (c.a. 40%) are required to reproduce CASPT2 results (**Figure 4** and ΔE_{H-L}-only results shown in **Supplementary Figure 2**). With the exception of Ni(III) or V(II)/Cr(III) hexa-ammines, pure PBE GGA ΔE values are much more positive (i.e., low-spin biased) than the WFT results (**Figure 4**). Increasing exchange thus in most cases improves agreement with WFT, but the optimal exchange fraction for reproducing the CASPT2 result varies significantly for the different complexes (**Figure 4**). For five of the cases [e.g., midrow $Mn(II)(H_2O)_6$, $Fe(II)(NH_3)_6$, and $Co(II)(H_2O)_6$], the optimal exchange fraction is larger than

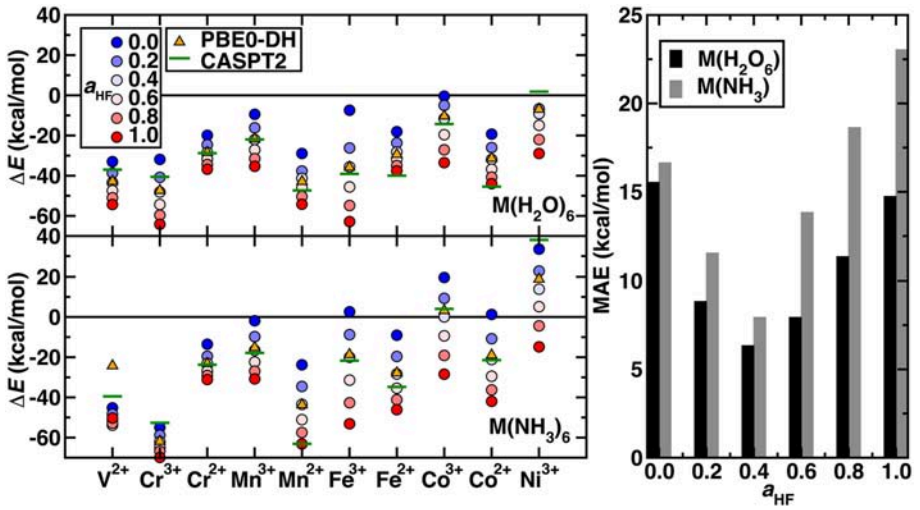

FIGURE 4 | (Left) Spin-splitting energetics (in kcal/mol) corresponding to ΔE_{H-l} for Cr^{2+}-Co^{3+} and ΔE_{H-L} for all other cases shown for hexa-aqua **(Top)** and hexa-ammine **(Bottom)** complexes. Modified PBE0 GGA hybrid results are shown as circles. The exchange fraction, a_{HF}, is colored from blue for 0.0 (pure GGA) to red for 1.0 (full HF exchange), according to the inset legend. Reference CASPT2 results with the extended active space and IPEA shift of 0.5 a.u. are shown as green horizontal lines. The PBE0-DH results are shown as orange triangles. **(Right)** MAE (in kcal/mol) at several exchange fractions for the hexa-aqua and hexa-ammine complexes indicated at left.

0.4, whereas the majority of the remaining complexes would require exchange fractions of 0.0-0.4 to recover the CASPT2 value (**Figure 4**). Only three complexes [i.e., V(II)$(H_2O)_6$, Cr(III)$(H_2O)_6$, and Ni(III)$(H_2O)_6$] have an optimal exchange fraction corresponding to typically applied (Ioannidis and Kulik, 2015) values of around 10–30%.

Considering overall performance on the 20 TM complexes, incorporating any exact exchange reduces the mean absolute error (MAE) of spin-splitting energies with respect to WFT. From PBE to 20% to 40% exchange, the MAE decreases monotonically from 17 to 12 to 8 kcal/mol for hexa-ammines and comparably (i.e., 16 to 9 to 6 kcal/mol) for hexa-aquas (**Figure 4**). Increasing HF exchange higher than 40% increases the MAE again for both ligand fields. For these two weak ligand fields, the optimal exchange fraction is more metal dependent than ligand field dependent, producing comparable optimal exchange values for fixed metal and oxidation state (**Figure 4**). Recent work (Wilbraham et al., 2018) has suggested double hybrids (DH, i.e., with MP2 long-range correlation) could improve predictions of spin-state ordering. We selected the PBE0-DH, which contains 50% global HF exchange for comparison to GGA global hybrid results (**Figure 4**). The PBE0-DH results are comparable to those obtained with a modified PBE0 global hybrid GGA with 40% exchange (i.e., MAE of 8 kcal/mol for hexa-ammine complexes and 6 kcal/mol for hexa-aqua complexes, see **Supplementary Table 4**). Given the higher computational cost and scaling of the double hybrids, tuned GGA hybrids would remain a preferable choice for modeling larger systems.

Comparison of Nitrogen-Containing Ligands

So far, we have studied model complexes and confirmed the importance of incorporating exact exchange in DFT functionals to reproduce correlated WFT reference spin-splitting energetics. We next considered the transferability of exchange sensitivity of DFT spin-splitting energetics to octahedral transition metal complexes that contain coordination environments similar to Fe/N-doped graphene SAC models. The two ligands we used to represent these environments were pyridine (py) in which the coordinating nitrogen is in a six membered carbon-containing ring and pyrrole (pyr) in which the coordinating nitrogen is in a five membered carbon-containing ring (**Figure 5** inset and see Computational Details). With a pure PBE GGA, all complexes except for hexa-pyr Fe(II) are low spin, whereas exchange fractions above ∼15% instead result in all ground states being assigned as high spin (**Figure 5**). The trend with exchange is again linear as in the hexa-ammine complexes, although the linearity is slightly reduced for Fe(II) vs. Fe(III) complexes (**Figure 5**).

The ΔE_{H-L} values are within ∼7 kcal/mol for all complexes of the same oxidation state across the full range of exchange due to the relatively similar ligand field strengths of the N-containing ligands and comparable metal-ligand bond lengths (**Supplementary Table 5**). However, the hexa-ammines are generally the most low-spin-favoring, whereas the SAC-like nitrogen complexes have a slightly increased high-spin bias. In analogy to ligand field arguments for ΔE_{H-L}, exchange sensitivities, $\frac{\partial \Delta E_{H-L}}{\partial a_{HF}}$, of spin splitting are also comparable for ammonia, pyridine and pyrrole complexes (**Figure 5**). For $\frac{\partial \Delta E_{H-L}}{\partial a_{HF}}$, NH_3 and pyrrole are very similar in both Fe(II) [−72 and −77 kcal/(mol·HFX)] and Fe(III) [−88 and −85 kcal/(mol·HFX)], whereas pyridine has slightly larger slope of −92 kcal/(mol·HFX) in both oxidation states. These observations are consistent with the previously observed greater sensitivity to the ligand identity than to oxidation state for Fe(II)/Fe(III) (Ioannidis and Kulik, 2015). Due to the similar spin-splitting

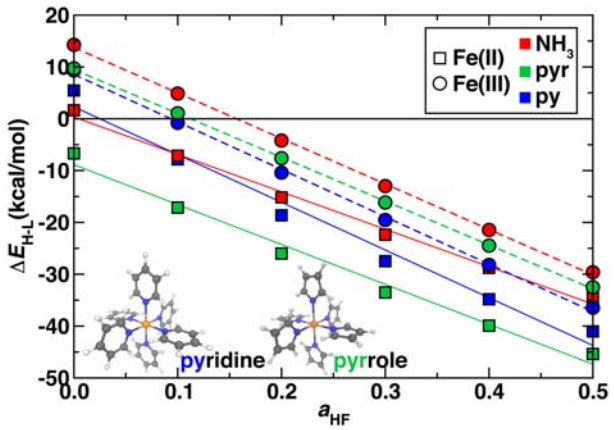

FIGURE 5 | Sensitivity to HF exchange fraction (a_{HF}) of high-spin/low-spin splitting (ΔE_{H-L}, in kcal/mol) for Fe(II) (squares) and Fe(III) (circles) homoleptic octahedral transition metal complexes with NH_3 (red symbols), pyridine (blue symbols), and pyrrole (green symbols) ligands. The structures of pyridine and pyrrole compounds are shown in inset in ball and stick (gray carbon, blue nitrogen, white hydrogen, and orange for iron). A zero axis is shown that indicates change in favored ground state spin.

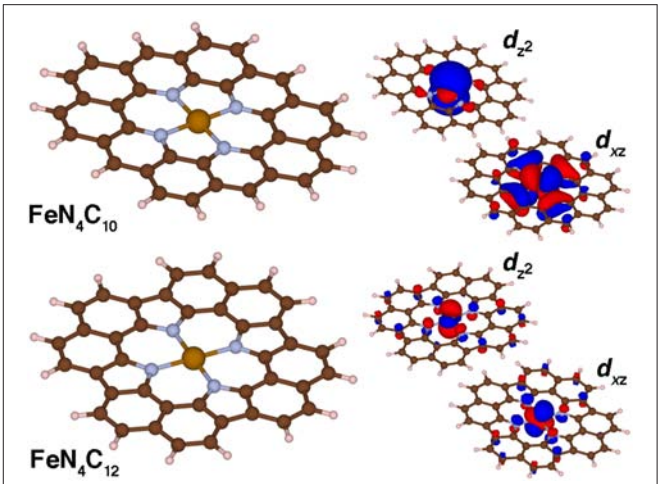

FIGURE 6 | Molecular structures (left) and singly occupied d_{xz} and $d_z{}^2$ spin-up molecular orbitals (right) for FeN_4C_{10} and FeN_4C_{12} graphene flake SAC models in the triplet state. The positive and negative phases of the wavefunction are shown in red and blue, respectively. An isosurface of 0.01 e/Bohr^3 was used for the orbitals of FeN_4C_{10} and of 0.03 e/Bohr^3 for those of FeN_4C_{12} for clarity. All structures are shown in ball and stick representation with carbon in brown, hydrogen in white, nitrogen in light blue, and iron in orange.

energetics and sensitivities to exchange, we expect that our observations on hexa-ammine complexes are applicable to pyridinic and pyrrolic nitrogen-containing complexes and materials as well. Thus, for larger SAC models, we recommend either typical exchange fractions for qualitative ground state spin assignment (i.e., high spin) or higher exchange fractions (ca. 40–50%) that were needed in the hexa-ammine cases to reproduce WFT results quantitatively.

Graphene Flake Models of SACs

Fe/N-doped graphitic SACs are expected on the basis of experimental spectroscopic characterization (Zitolo et al., 2015; Chen et al., 2017; Liu et al., 2017) to consist of Fe metal centers coordinated by pyridinic or pyrrolic nitrogen atoms. These experimental observations come from a combination of aberration corrected scanning tunneling electron microscopy to confirm well-isolated metal sites as well as numerous spectroscopic techniques (e.g., X-ray absorption spectroscopy) to confirm the metal coordination (Zitolo et al., 2015; Chen et al., 2017; Liu et al., 2017). Although the most reactive SAC active site remains an open question, we consider in this work two limits in finite graphene flake SAC models that contain either four pyridinic (FeN_4C_{10}) or pyrrolic (FeN_4C_{12}) N atoms (**Figure 6**). Due to the rigidity of the graphene flakes, singlet Fe(II) pyridinic (py) and pyrrolic (pyr) Fe-N bond lengths are shorter than the corresponding py or pyr octahedral complexes (py: 1.90 vs. 2.08 Å or pyr: 1.97 Å vs. 2.11 Å, see **Supplementary Tables 5–6**). This rigidity in the SAC models without any displacement of iron from the plane that has been observed in porphyrins (Sahoo et al., 2015) also leads to average Fe-N distances being invariant to spin state. There is a marginal (ca 0.01 Å) increase from singlet to quintet spin states for the FeN_4C_{10} SAC in comparison to large (ca. 0.16–0.20 Å) bond length increases from singlet to quintet in the $Fe(II)(py)_6$ complex (**Supplementary Tables 5–6**). The Fe-N distances are shorter in pyridinic FeN_4C_{10} than in pyrrolic FeN_4C_{12} (i.e., 1.90 Å vs. 1.96 Å) due to smaller N-N separations (FeN_4C_{10}: 2.61 Å and 2.75 Å, FeN_4C_{12}: 2.75 Å). Despite this difference in N-N separation, which has previously been noted to influence experimental spin state ordering (Phan et al., 2017), the PBE0 ground state spin is triplet in both models (**Supplementary Table 7**).

The two singly occupied orbitals in both triplet SAC models correspond to the d_{xz} and $d_z{}^2$ orbitals consistent with expectations for square-planar coordinated triplet Fe(II) (**Figure 6**). Small differences are observed in the orbital character due to the lower symmetry for the pyridinic FeN_4C_{10} flake: in this case, d_{xz} and d_{yz} degeneracy is broken (**Figure 6**). The longer N-N separation along the x-axis leads to a pure d_{xz} orbital vs. d_{xz} and d_{yz} mixing for the case of pyrrolic FeN_4C_{12} (**Figure 6**). In both cases, weak coupling is observed between the metal-centered orbitals and p-orbitals of both the N and C atoms in the graphene flake (**Figure 6**).

For both SAC models at the PBE0 level of theory, singlet and quintet states reside ∼4–6 kcal/mol and 12 kcal/mol above the triplet ground state, respectively, and thus singlet-quintet ΔE_{H-L} is around +6–8 kcal/mol (**Supplementary Table 7**). These observations contrast with the octahedral models: ΔE_{H-L} for $Fe(II)(py)_6$ is −15 kcal/mol and is −30 kcal/mol for $Fe(II)(pyr)_6$ (**Supplementary Table 4**). These differences can be traced to several factors, including the coordination number (4 vs. 6) in the models as well as rigidity of the graphene flakes that compress Fe-N bonds to values more commensurate with equilibrium low-spin geometries. Finally, examining the electronic structure of the SAC models reveals distribution

of spin not just on the metal but also on the flake in the high spin states, particularly for the pyrrolic FeN_4C_{12} models (**Supplementary Tables 8, 9**). Even in the triplet ground state this is apparent with a magnetic moment of 2.2 μ_B, close to that expected (i.e., 2 μ_B) for FeN_4C_{10}, but with a larger 2.7 μ_B on Fe for FeN_4C_{12} (**Supplementary Tables 8, 9**). The singlet FeN_4C_{12} is also open shell with a 1.4–2.0 μ_B magnetic moment on Fe (**Supplementary Table 9**). In contrast with the molecular complexes, the quintets are particularly poorly described by a localized metal spin, with a reduced Fe moment vs. the triplet state of around 2.4 μ_B on Fe for FeN_4C_{12} and a comparable one of 2.2 μ_B on Fe for FeN_4C_{10}. Although spin contamination can be expected with increasing HF exchange fraction, comparison of these moments across 0–50% exchange does not ever produce a pure 4 μ_B moment on Fe for the quintet FeN_4C_{12} (**Supplementary Table 9**). This observation could be due to low-lying unoccupied states on graphene that are populated instead of the metal states, especially in these models and at this level of theory, as is known to occur in porphyrins as well (Fujii, 2002).

Beyond PBE0 (25%) results on the graphene SAC models, we considered properties over a range that spans from typical values in periodic catalysis modeling (i.e., 0%) to larger values (40%) motivated by our octahedral complex studies (see section Spin State Ordering in Model Complexes). Over this 0–40% range of exchange fractions, singlet and triplet states become destabilized with respect to high-spin quintet states (**Figure 7**). The reduced dependence of spin-state ordering observed here on exchange fraction in comparison to the octahedral complexes is due to differences in coordination number and rigidity of the SAC models. Intermediate Fe spin states were observed experimentally (Liu et al., 2017) for N-doped graphitic SACs using Mössbauer spectroscopy. Although high HF exchange fractions favoring quintet states for both SAC models would suggest inconsistencies with experiment, it is important to recall that the magnetic moments of the Fe metal are intermediate in both triplet and quintet states. Therefore, high HF exchange fractions are in fact stabilizing the simultaneous presence of spin on the graphene coupled to an intermediate Fe center (**Supplementary Tables 8, 9**). In both FeN_4C_{12} at low exchange fractions and FeN_4C_{10} over a larger range of 0-100% exchange, higher order than typically linear sensitivities are observed to % exchange (**Supplementary Figure 3**). For FeN_4C_{12}, the anti-ferromagnetically coupled metal spin on Fe varies significantly (i.e., 0.6 μ_B) and discontinuously, leading to less smooth energetic variations (**Figure 7**). For the FeN_4C_{10} model where spin states are more well defined, the variations are instead linear over the expected range of HF exchange (Droghetti et al., 2012; Ioannidis and Kulik, 2015; Zhao and Kulik, 2018).

High-valent Fe(IV)=O intermediates are expected to be essential for catalytic transformations at N-doped graphitic SACs (Liu et al., 2017). Thus, we examined the spin-state-, model-, and exchange-fraction-dependence of reaction energetics for Fe(IV)=O formation. Here, we employed N_2O as a model oxidant, but results are comparable when assuming the oxygen atom comes from triplet O_2 (**Figure 8** and **Supplementary Figures 4–6**). Overall, pyridinic SACs form more stable oxo species across the range of HF exchange and spin states than pyrrolic SACs (**Figure 8**). Although activation energies would be needed to make firmer statements about relative active site model reactivity, the endothermic reaction energies for the intermediate spin FeN_4C_{12} above 20% exchange (ca. +10 kcal/mol at 40% exchange) suggest that the pyrrolic model could potentially be unreactive with N_2O oxidant (**Figure 8**). Regardless of spin state or model, increasing exchange fraction makes formation of oxo intermediates less favorable due to the penalty for delocalization (Gani and Kulik, 2017).

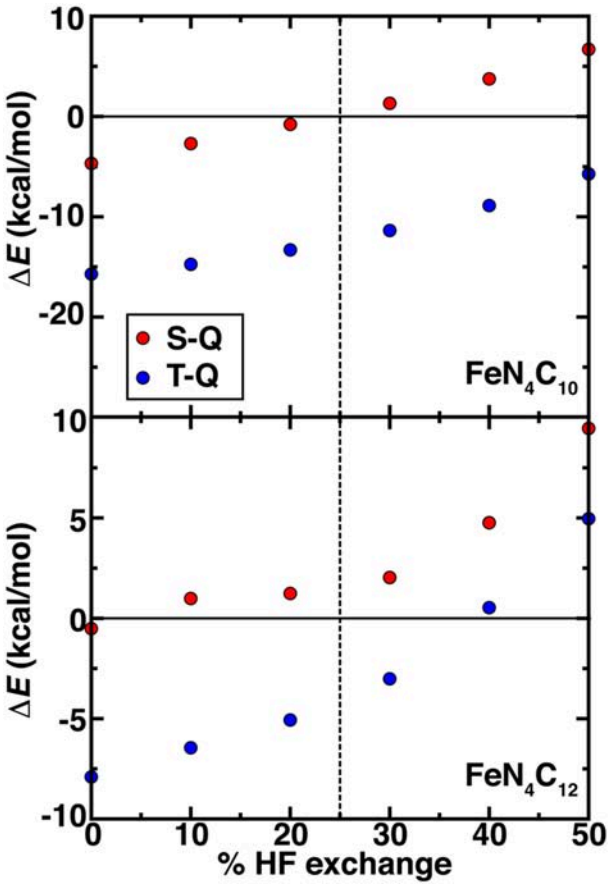

FIGURE 7 | Spin-splitting energetics (in kcal/mol) for singlet-quintet (S-Q, red circles) or triplet-quintet (T-Q, blue circles) spin states vs. % HF exchange for pyridinic (FeN_4C_{10}, top) and pyrrolic (FeN_4C_{12}, bottom) SAC models. The 25% exchange in standard PBE0 is indicated as a vertical dashed line.

Determination of ground state spin from DFT of the pristine Fe(II)/N SAC model and the Fe(IV)=O intermediate should be carried out with caution, noting that spin (ca. 0.5–1.0 μ_B) arises on the O atom in triplet and quintet states of both Fe(IV)=O SAC models but not in the singlet states (**Supplementary Tables 8, 9**). Although spin on the oxo species can be expected and even linked to catalytic efficiency (Liu et al., 2009; Quesne et al., 2014), these states cannot readily be described within a single Kohn-Sham determinant in DFT (Koch and Holthausen, 2015). Overall, spin state ordering of the bare Fe(II) SAC is largely preserved in the Fe(IV)=O intermediate, with singlet and triplet Fe(IV)=O states being weakly stabilized

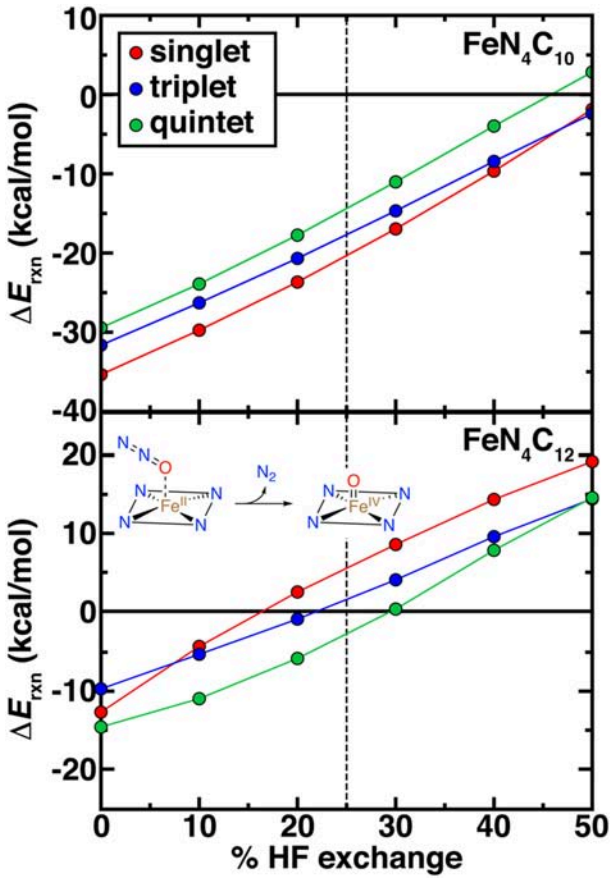

FIGURE 8 | Reaction energetics (ΔE_{rxn}, in kcal/mol) for oxo formation from N_2O oxidant vs. % HF exchange for pyridinic (FeN_4C_{10}, top) and pyrrolic (FeN_4C_{12}, bottom) SAC models. The reaction is shown in inset. In each case, singlet (red circles), triplet (blue circles), and quintet (green circles) oxo formation energies are shown. The 25% exchange in standard PBE0 is indicated as a vertical dashed line.

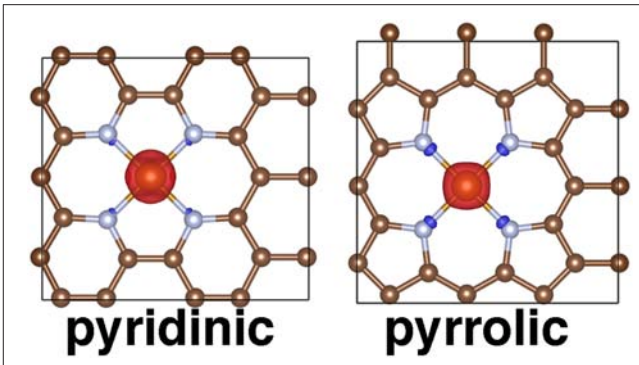

FIGURE 9 | Periodic structures for pyridinic and pyrrolic periodic SAC models in the triplet state with spin density shown. Positive spin density is shown in red and negative spin density is shown in blue, with an isosurface value of 0.03 e/Bohr^3. All structures are shown in ball and stick representation with carbon in brown, nitrogen in light blue, and iron in orange.

by around 3–5 kcal/mol with respect to the bare Fe(II) case for the pyridinic SACs (**Supplementary Figure 4**). In the pyrrolic case, the opposite occurs, potentially due to the loss of spin on the ring in triplet pyrrolic Fe(IV)=O (**Supplementary Table 9** and **Figure 4**). Nevertheless, further investigation of kinetic barriers is merited in future work, as close spin state ordering of both the Fe(IV)=O and pristine Fe(II) intermediates combined with comparable differences of around 5–10 kcal/mol between reaction energetics in each spin state could give rise to spin-state dependent reactivity with distinct product formation (Kamachi and Yoshizawa, 2003; Ji et al., 2015). Finally, it is noteworthy that at 0% exchange (i.e., pure PBE), singlet FeN_4C_{12} is predicted to produce a slightly more stable Fe(IV)=O than the triplet, the same ordering that is observed for FeN_4C_{10} albeit at −10 to −15 kcal/mol in the former case vs. −30 to −35 kcal/mol in the latter case (**Figure 8**). At the 40% exchange motivated by our careful CASPT2 characterization of Fe-N bonds (see section Comparison of Nitrogen-Containing Ligands), or even at the 25% exchange fraction motivated in stronger ligand field cases (Ioannidis and Kulik, 2017), conclusions are different. Namely, at these higher exchange fractions: (i) the triplet oxo is more stable for pyrrolic SACs than the singlet, whereas the ordering remains the same for the pyridinic case, and (ii) neither form exothermically for the pyrrolic case at these exchange fractions.

Periodic Modeling of SACs

We validated our choice of finite SAC flakes by comparing to periodic models of both pyridinic and pyrrolic SAC active sites (**Figure 9**). We focused on the triplet intermediate spin state favored both in our finite models and in experiment (Liu et al., 2017). Shorter Fe-N 1.91 Å vs. 1.97 Å Fe-N bond lengths are observed for the pyridinic model than for the pyrrolic models, consistent with the finite models. It is more straightforward to localize the magnetic moment to the metal in these periodic systems than was observed for the molecular models (**Supplementary Table 10** and **Supplementary Figure 7**). For the triplet cases, spin density is nearly exclusively observed on the metal center (**Figure 9**). In both pyridinic and pyrrolic periodic models, use of the hybrid functional leads to less electron density on the Fe center than when a GGA is employed, consistent with prior observations (Gani and Kulik, 2016; Zhao and Kulik, 2018) (**Supplementary Table 10**).

We compared the electronic structure of the pyridinic and pyrrolic SAC active site models by determining the projected density of states (PDOS) decomposed by N 2*p*, C 2*p*, and Fe 3*d* contributions with the HSE06 hybrid functional (**Figure 10**). Qualitatively, the occupied orbitals and symmetries confirm observations made on the finite graphene flake models with PBE0, which may be expected if short range effects dominate as HSE06 and PBE0 both incorporate 25% exchange in the short range mixed with pure PBE exchange. That is, the pyridinic system again has singly occupied d_z^2 and d_{xz} orbitals and no occupation of the d_{xy} state. The pyrrolic system also differs from the pyridinic by having degenerate d_{xz} and d_{yz} states, consistent with the molecular flakes (**Figure 10**). Generally, agreement is more variable for other spin states, where convergence of the magnetic state is sensitive to starting conditions in the periodic calculation (**Supplementary Figures 8–9**). In the pyridinic case,

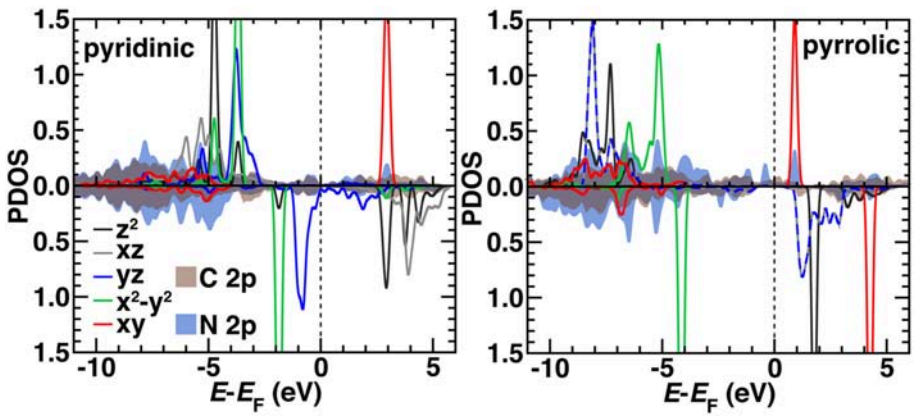

FIGURE 10 | The HSE06 projected density of states (PDOS) for spin up **(Top)** and down (**Bottom**, reflected curves) triplet pyridinic **(Left)** and pyrrolic **(Right)** SAC models. The 3*d* Fe orbital PDOS are shown as indicated in inset legends as solid curves except for *yz* and *xz* in the pyrrolic case, which are shown as dashed lines due to their degeneracy. The average PDOS for a 2*p* orbital from C (brown) or N (dark blue) are shown as translucent shaded regions. All energy levels (in eV) are aligned to the Fermi level (E_F), which is shown as a vertical dashed line. Some *d* levels have been truncated by the *y*-axis range to be able to compare to the broader C 2*p* and N 2*p* features.

d_{yz} states span the Fermi level, whereas the 3*d* states are well separated in the pyrrolic SAC (**Figure 10**). The pyrrolic 3*d* states also mix more deeply into the C and N 2*p* bands, whereas in the pyridinic case, most 3*d* states sit at the top of the occupied C/N 2*p* bands (**Figure 10**). Overall, these observations support the use of finite models at higher levels of theory for consistent modeling, due to the unique challenges of modeling periodic systems with such methods (Janet et al., 2017). More analysis in larger supercells with variable graphene defects will be necessary in future work to strengthen this conclusion.

CONCLUSIONS AND OUTLOOK

We have presented an overview of the effect of computational model choice on the properties of octahedral transition metal complexes and emergent single atom catalyst (SAC) materials made from Fe centers in N-doped graphene. The octahedral transition metal complexes chosen mimic the ligand field environment observed in the SAC models but remain tractable for study with multi-reference wavefunction theory. Observations from the hexa-aqua and hexa-ammine complex studies revealed that spin state ordering of mid-row complexes could be sensitive both to the IPEA shift chosen and whether an extended active space was used, whereas late and early transition metals were far less sensitive. Then using these extended active space CASPT2 results as a benchmark, we observed that nearly all transition metal complexes benefitted from increased HF exchange. In fact, errors with respect to exchange fraction chosen monotonically decreased from 0 to 40% but with no improvement for higher exchange fractions. The 40% exchange hybrid results had comparable accuracy to the more computationally demanding double hybrid PBE0-DH.

The HF exchange tuning study confirmed the comparable behavior of Fe(II) complexes with ammonia, pyridine, and pyrrole ligands due to the overriding role of the metal, oxidation state, and ligand connecting atom in determining functional sensitivity. Comparison to CASPT2 results on the hexa-ammine system motivated us to propose higher exchange fractions (ca. 40% rather than 25% in PBE0) to be essential to counteract the low-spin bias in semi-local DFT. Using these benchmarks, we then evaluated the effect of DFT functional tuning on finite graphitic SAC models with pyridine or pyrrole nitrogen atoms. In these square planar SAC geometries, rigid structures compressed the Fe-N bond length, reducing exchange sensitivity of spin state ordering but otherwise confirming the observations in the octahedral complexes (i.e., favoring higher spin configurations and destabilizing singlet states). We observed that at the recommended higher exchange fractions, the formation of an oxo intermediate from N_2O became unfavorable at the pyrrolic SAC active site. We also observed changes in spin state ordering of the most stable oxo intermediates. Thus, incorporation of exchange can alter predictions of reactivity at SAC active sites. Finally, we confirmed that these observations were not sensitive to choice of a finite SAC model by comparing to periodic SAC models where similar electron configurations were observed.

Overall, predictions of reactivity and spin state ordering are highly sensitive to the functional employed. We have shown that this sensitivity is broadly transferable across different ligand environments as long as the metal and direct ligating atom are kept constant. This observation can be leveraged to obtain DFT functional performance on smaller models where correlated WFT is tractable. Additionally, smaller flake models may be amenable to direct WFT calculation with methods not covered in this work. Spin state exchange sensitivity can be expected to be depressed in cases where the SAC is fully rigid and prevents expansion of the metal-ligand bond when the spin state changes. The highly ordered, symmetric cases here are expected to be the limit in this rigidity argument, and more disordered SAC models

or more flexible active sites (e.g., graphitic carbon nitride) are expected to be more sensitive. Still, some outstanding challenges remain in understanding the extent to which spin arising on the graphene itself could be physical and also impart reactivity or whether it arises due to increased static correlation error for hybrid DFT. Furthermore, in periodic simulations with larger supercells than studied in this work it will become essential to employ range-separated hybrids with HF exchange only in the short range, and the comparison to CASPT2 results to range-separated hybrid tuning will be essential here. Overall, modeling in SACs will continue to benefit from this multi-level approach in assessing method accuracy and sensitivity and how method choice impacts predictions of active site geometry and reactivity.

AUTHOR CONTRIBUTIONS

HK designed the research. FL, TY, JY, EX, and AB carried out the research. FL, TY, JY, and HK wrote and revised the manuscript.

FUNDING

The authors acknowledge support by the Department of Energy under grant number DE-SC0018096 for the work on density functional theory and the support of FL and AB. The authors also acknowledge the National Science Foundation under grant number CBET-1704266 for the support of TY. CherryPicker: An Algorithm for the Automated Parametrization of Large Biomolecules for Molecular Simulation

Ivan D. Welsh[1,2] *and Jane R. Allison*[1,2,3,4]*

Molecular simulations allow investigation of the structure, dynamics and thermodynamics of molecules at an atomic level of detail, and as such, are becoming increasingly important across many areas of science. As the range of applications increases, so does the variety of molecules. Simulation of a new type of molecule requires generation of parameters that result in accurate representation of the behavior of that molecule, and, in most cases, are compatible with existing parameter sets. While many automated parametrization methods exist, they are in general not well suited to large and conformationally dynamic molecules. We present here a method for automated assignment of parameters for large, novel biomolecules, and demonstrate its usage for peptides of varying degrees of complexity. Our method uses a graph theoretic representation to facilitate matching of the target molecule to molecular fragments for which reliable parameters are available. It requires minimal user input and creates parameter files compatible with the widely-used GROMACS simulation software.

1. INTRODUCTION

Molecular simulations provide a means to investigate molecular interactions at or near atomistic detail. Such simulations are becoming increasingly important in areas ranging from biomedical to materials science. The accuracy of molecular simulations is in large part dependent on the quality of the parameters used to describe the inter- and intra- molecular interactions; that is, the force field. Within the realm of biomolecular simulations, force fields such as AMBER (Weiner et al., 1984, 1986; Cornell et al., 1995; Duan et al., 2003), CHARMM (Brooks et al., 1983; Reiher, 1985; MacKerell et al., 1998, 2000; Foloppe and MacKerell, 2000) and GROMOS (Schuler et al., 2001; Oostenbrink et al., 2004; Poger et al., 2010; Schmid et al., 2011) are widely used. These contain highly optimized parameters for proteins, and to varying degrees, nucleic acids, lipids and sugars. However, when it comes to simulating novel molecules, such as drug molecules, toxins, non-ribosomal peptides, post-translational modifications to proteins, or certain lipids, parameters are unlikely to be included in a given force field, necessitating parametrization.

Over the decades, a range of automated parametrization methods have been developed, such as MKTOP (Kaminski et al., 2001; Ribeiro et al., 2008), Antechamber (Wang et al., 2004, 2006),

PRODRG (Schüttelkopf and van Aalten, 2004), the ATB (Malde et al., 2011; Canzar et al., 2013; Koziara et al., 2014), Paramfit (Betz and Walker, 2015), GENRTF (Miller et al., 2008), RED (Vanquelef et al., 2011) and LigParGen (Dodda et al., 2017). Such methods generally rely on performing quantum chemical calculations and deriving atomic partial charges and bonded parameters from the resultant electronic information.

As the size of the molecule to be parameterized increases, such quantum chemical based methods become impractical. Firstly, quantum chemical methods scale at least as poorly as N^3, where N is the number of basis functions, with many scaling even more poorly. As such, the required computational effort quickly becomes intractable as molecule size increases. Additionally, it is well known that charge distributions are highly conformationally dependent (Stouch and Williams, 1992, 1993; Urban and Famini, 1993; Koch and Stone, 1996). As a consequence, derivation of reliable force field parameters capable of describing the full conformational space of the molecule requires quantum chemical calculations to be carried out for multiple conformations. This conformational dependence applies to both non-bonded and, to a lesser extent, bonded parameters.

Historically, biomolecule force fields were constructed by careful parametrization of small model chemicals, for example, compounds representative of each amino acid side chain. A similar approach could conceivably be taken to generate parameters for novel molecules. Proteins have a very limited chemical space, comprising just 20 unique amino acids that are joined together in a linear fashion, and which themselves mostly contain an identical "backbone." In comparison, the chemical space available to drug molecules is extremely large. For example, the ZINC15 database (Sterling and Irwin, 2015) contains over 100 million unique molecules. This greatly increased chemical space makes it implausible to define a finite set of model compounds. However drug molecules are typically relatively small, and are often conformationally constrained, making automated parameterisation schemes both tractable and best suited to their parameterisation. Biomolecules besides proteins and other well-studied cases present a different scenario, however. Their chemical space is much more limited, but their size can extend well beyond the reaches of quantum chemical calculations. Additionally, they are likely to undergo significant conformational motion.

We have therefore developed a fragment-based approach, reminiscent of the construction of biomolecular force fields, to parameterisation of novel biomolecules. Our approach utilizes graph theoretic representation and methodology. In contrast to other existing parameterisation methods, our approach avoids the use of expensive quantum chemical calculations. Our implementation is split into two parts: an Athenaeum, a library of molecular fragments, and CherryPicker, an algorithm for parameterisation based on matching portions of a target molecule to fragments in an Athenaeum. The code is written in C++, with Python bindings to enable ease of use provided by pybind11 (Jakob et al., 2017), and is available on GitHub at https://git.io/fp4Fr.

2. ALGORITHM DESCRIPTION

An overview of the procedures carried out in parameterizing a novel molecule using CherryPicker and one or more Athenaeums is provided in **Figure 1**. Parameterizing a novel molecule using CherryPicker proceeds as follows. A target molecule is submitted to CherryPicker and parameters are determined by comparing the target with molecular fragments contained in one or more Athenaeums. We use a graph theoretic framework in which molecules are represented as condensed molecular graphs, and matching between the target molecule and the fragments in the Athenaeum is done using subgraph isomorphism. A default parameterisation scheme is provided where parameters assigned to the target molecule are the mean (point charges) or mode (all other parameters) of the set of parameter values obtained from the pool of matching fragments. The set of assigned parameters is written to file in a format suitable for use in a simulation engine such as GROMACS (Abraham et al., 2015).

Below, we describe the implementation details of the Athenaeum library and CherryPicker algorithm. For clarity, we assume the use of the GROMOS force field and the GROMACS simulation engine. This entails the parameter values for each force field term, such as the parameters of the Lennard-Jones term for atomic centers or harmonic force constants for bonds, being identified by an integer type code. The only exception is the atomic partial charges, for which the actual parameter value is used throughout. The implementation is designed such that adding support for additional force fields or simulation engines is straightforward, however.

2.1. Data Input and Output

We provide a number of file input and output methods for handling chemical structure and parameter data.

To build an Athenaeum, both the chemical structure and the associated parameters of one or more molecules are required. Supported input file formats are the MTB format used by the GROMOS simulation engine (Christen et al., 2005), and the ITP format used by GROMACS (Abraham et al., 2015). It is also possible to supply a PDB file alongside the MTB or IFP file. ITP parsing currently assumes a GROMOS-style force field. As MTB and, in many cases, ITP files use force field type codes rather than specifying the actual parameter values, the force field itself, i.e., the parameter values associated with each force field type code, is also required. Currently only the GROMOS IFP file format is able to be parsed, but a hard-coded implementation of the GROMOS 54A7 force field (Schmid et al., 2011) is also provided.

The chemical structure of the target molecule for parameterisation must be provided in PDB format, including CONECT records. Chemical structures can be output in either PDB or GROMACS GRO formats, and the associated assigned parameters can be output in MTB or IFP format.

2.2. Condensed Molecular Graph

The target molecule and all fragments in the Athenaeum are represented as *molecular graphs* or *condensed molecular graphs*. A *molecular graph* is a labeled graph whose vertices correspond to the atoms of a molecule and edges correspond to the chemical

bonds. Generally, vertices are labeled with the element type of the atom, and edges are labeled with the type of the bond, i.e., its bond order. Such graphs often contain a large number of leaves, which can cause combinatorial explosion of search algorithms. This is particularly true of the subgraph isomorphism mappings used here. To alleviate this problem we introduce the concept of a *condensed molecular graph*.

A condensed molecular graph is a molecular graph where leaves are removed and the label of the leaf's parent vertex modified to indicate the absence. A leaf is only removed if its corresponding atom has a formal charge of 0, is either hydrogen or a halogen, and the edge that would be removed is labeled with a bond order of one. In this way, we ensure that any potentially important chemical information is explicitly maintained while reducing the computational cost.

Another reason for the use of condensed molecular graphs is their increased information density. Bit manipulation is utilized to compress multiple pieces of information into a single integer value for labeling both the vertices and edges. Doing so means that when performing subgraph isomorphism matching, the comparison between two potentially matching vertices or edges can be executed in a single CPU instruction.

2.2.1. Vertex Labels

The vertices of the condensed molecular graph carry ten distinct pieces of information. Bit manipulation means that each vertex label requires just 32 bits, as shown in **Figure 2** and detailed below.

$2^0 \rightarrow 2^6$

These seven bits represent the atomic number, in binary form, of the element associated with the vertex. Currently, there are 118 elements in the periodic table, meaning they can all be represented by the seven available bits.

$2^7 \rightarrow 2^9$

These three bits give the magnitude of the formal charge on the atom associated with the vertex, again in binary form. The use of

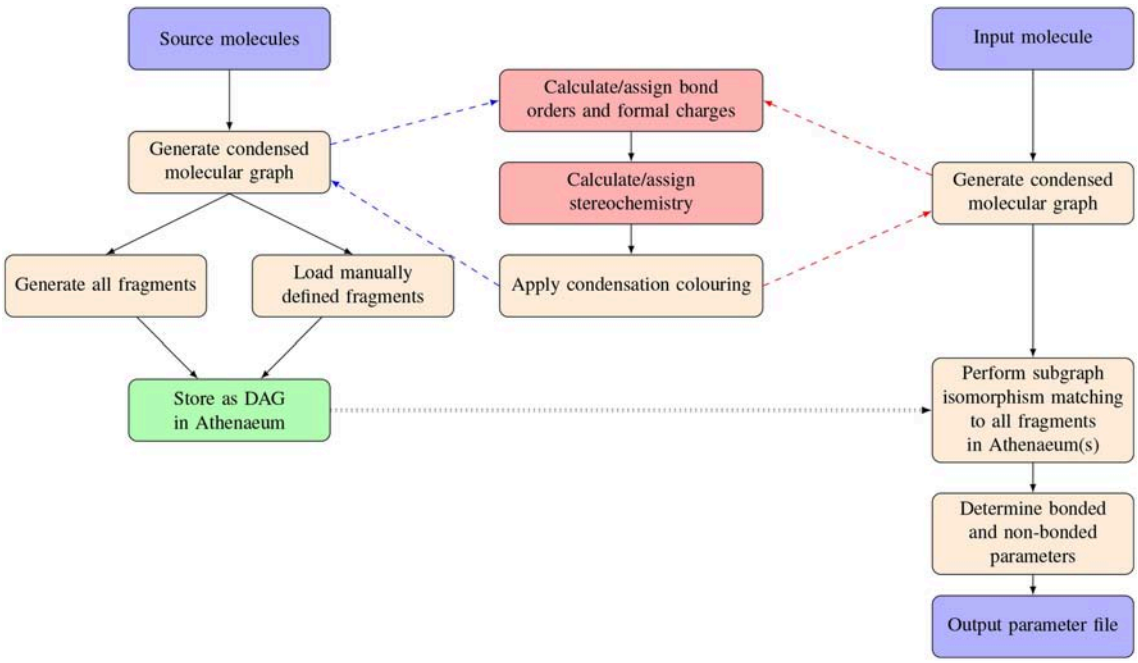

FIGURE 1 | Schematic of the process of automated parameterisation carried out by CherryPicker. The two red boxes indicate procedures described elsewhere (Welsh and Allison, 2019).

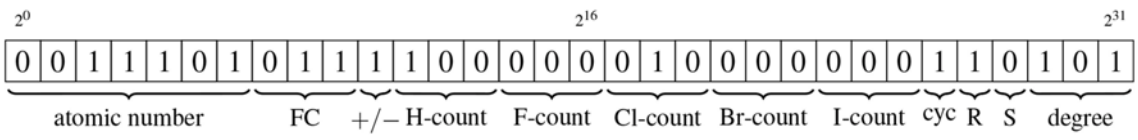

FIGURE 2 | Schematic illustrating how bit manipulation allows all information associated with a vertex to be stored using just 32 bits. The types of information are, from left to right: atomic number of the element associated with the vertex; magnitude of the formal charge of the atom associated with the vertex; sign of the formal charge; the counts of each of the five different elements that can be condensed into a vertex; whether the vertex is part of a cycle of size up to eight; the chirality (R/S) of the vertex; the degree of the vertex. All items are stored by converting the positive numeric values to binary format, other than the sign of the formal charge and the cycle and chirality indicators, for which the binary encodings are described in the text.

three bits allows for formal charge magnitudes of between zero and seven, which covers all formal charge values likely to occur in the context of molecular simulation. An automated means of determining formal charge, such as that previously described by us (Welsh and Allison, 2019), can be utilized.

2^{10}
This bit gives the sign of the formal charge. It is set to `0` if the formal charge is zero or positive and `1` if it is negative.

$2^{11} \rightarrow 2^{13}$, $2^{14} \rightarrow 2^{16}$, $2^{17} \rightarrow 2^{19}$, $2^{20} \rightarrow 2^{22}$, $2^{23} \rightarrow 2^{25}$
These five groups of three bits represent the counts of each of the five different elements that could be condensed into a vertex in the transition from a molecular graph to a condensed molecular graph, which are limited to hydrogen or halogen atoms. While in most molecular contexts, no more than three vertices of the same element would be condensed into the same parent vertex, we allow three bits per element rather than just two so as to allow for cases such as methane where there are four condensed vertices. The value of each bit is the binary value of the integer count of that element, with the first group being for condensed hydrogen atoms, the second for condensed fluorine and so forth down the halogen column of the periodic table.

2^{26}
This bit is set if the vertex is part of a cycle of size up to eight.

$2^{27} \rightarrow 2^{28}$
These two bits are used to represent any chirality associated with the atom represented by a vertex. Bit 2^{27} is set when the atom has *R* chirality, and bit 2^{28} is set when the atom has *S* chirality.

$2^{29} \rightarrow 2^{31}$
These final three bits represent the degree, in binary representation, of the vertex within the molecular graph.

2.2.2. Edge Labels

Edge labels utilize 12 bits to store four distinct pieces of information, again making use of bit manipulation, as shown in **Figure 3** and detailed below.

$2^{0} \rightarrow 2^{2}$
These three bits contain the bond order of the associated bond, with each value matching the integer value of the bond order, so that single to quadruple bonds carry values of $1 - 4$, an aromatic bond has a value of 5, a one-and-a-half bond has a value of 6 and a two-and-a-half bond has a value of 7.

$2^{3} \rightarrow 2^{4}$
These two bits are used to represent any stereochemistry associated with the bond represented by an edge. Bit 2^{3} is set when the bond is the central bond of an *E* isomer, and 2^{4} is set when the bond is the central bond of a *Z* isomer.

2^{5}
This bit is set if the edge is part of a cycle with a size of up to eight.

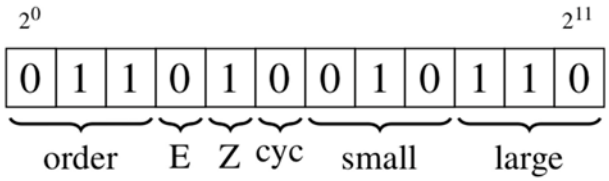

FIGURE 3 | Schematic showing the edge information, which is stored using 12 bits. The types of information are, from left to right: bond order of the associated bond; stereochemistry (E/Z) of the associated bond; whether the edge is part of a cycle with a size of up to eight; the smallest and largest degree of the vertices on either side of the edge. The numeric values of the bond order and degree are converted to binary format; the binary encodings of the stereochemistry and cycle indicators are described in the text.

$2^{6} \rightarrow 2^{8}$, $2^{9} \rightarrow 2^{11}$
These two groups contain the degree of the vertices on either side of the edge, with the first group containing the lowest degree value, and the second the highest. The three bits in each group are set to match the binary value of the integer degree.

2.3. Athenaeum

The CherryPicker algorithm utilisers one or more Athenaeums, each of which is a collection of already-parameterized molecules and the fragments derived from them. Fragmentation can be user-directed or fully automated, as outlined below.

An Athenaeum can be marked as *self-consistent*. This label is intended for use in Athenaeums constructed from fragment sources, such as the amino acids, for which the parameter values assigned to a given functional group are consistent. Being labeled as such indicates that all matching fragments that the CherryPicker algorithm finds within the Athenaeum will carry the same parameter values. If any cases where this is not the case are discovered, an error will be thrown.

2.3.1. Fragments

A fragment is a connected induced subgraph of a condensed molecular graph, consisting of two regions defined by non-intersecting vertex sets. The first region is the *core region*, from which parameters will be extracted. The vertex set of this region must also induce a connected subgraph of the overall condensed molecular graph. The second region is the *overlap region*. The overlap region does not contribute parameters; rather, it is used to ensure that the core region of a fragment and the portion of the target to which it matches have similar chemical environments. See the **Supplementary Materials** for a discussion on choosing the overlap size.

Fragments are stored within an Athenaeum in a tree like structure on a per molecule basis. A fragment is a vertex superset of another (smaller) fragment if the set of vertices in the smaller fragment are a subset of those in the larger fragment. Each fragment stores a reference to each of its immediate vertex supersets. However if multiple fragments are vertex subsets of another larger fragment, the larger fragment is only referenced by the first such smaller fragment.

2.3.2. User-Specified Fragment Generation

User-specified fragment generation involves providing a molecule, and a list of the core and overlap atoms that will form a fragment. The fragment specification file format allows for the user to specify any number of fragments to generate from a given molecule. Examples are provided in the GitHub repository. The only restriction on user-specified fragments is that the core atoms and core + overlap atoms must form induced subgraphs of the molecule's condensed molecular graph. Unlike automatically generated fragments, the overlap regions of each fragment are specified individually, and may contain different numbers of atoms.

2.3.3. Fully Automated Fragment Generation

For fully automated fragment generation, the only input required is a molecule. The overlap size is a property of the Athenaeum to which the fragments formed from this molecule will be added. Fragments of all possible sizes are generated. The user has the option to specify minimum and/or maximum fragment sizes, as well as choose which Athenaeum(s) to match against, when running CherryPicker.

For each provided molecule, all connected induced subgraphs $G' = (V', E')$ of the molecule's condensed molecular graph, $G = (V, E)$, are generated and tested against the three criteria outlined below to determine whether they are valid fragments, with each subgraph forming the core region of a fragment. The overlap region is then all vertices of the subgraph G' within a path length k of the core region, where k is the overlap length. Each Athenaeum generated fully automatically has a separate value of k.

The three criteria used to determine if a fragment is valid are:

1. Given a subgraph $G' = (V', E')$ of G, and edge $e = (u, v)$ incident on G', that is, $(u \in V \wedge v \in V') \vee (u \in V' \wedge v \in V)$, e must be labeled as representing a bond of order one or aromatic. Allowing aromatic bonds here enables fused cyclic systems to be fragmented.
2. Any edge $e = (u, v)$ incident on G' must have at least one of its vertices labeled as being carbon.
3. Let the subgraph $G'' = (V'', E'')$ be the induced subgraph of G containing the union of the core region vertex set and overlap region vertex set. Every leaf of G'' that belongs to the overlap region vertex set must have a path length of at least k to all vertices of the core region.

The user can choose which of these rules to activate when generating an Athenaeum, and the implementation also makes it straightforward to add additional rules as desired.

2.4. CherryPicker

The CherryPicker algorithm assigns parameters to a target molecule by iterating through a list of Athenaeums. The user can determine the minimum and/or maximum size of the core region of the fragments to test, defaulting to a minimum size of four and no maximum size. At each iteration, all fragments within the current Athenaeum are checked for subgraph isomorphism with the target condensed molecular graph. If the fragment is found to match a portion of the target molecule, the values of the fragment's atom, bond, angle and dihedral parameters are tallied against the corresponding vertices and edges of the target condensed molecular graph. This process is repeated until all Athenaeums have been exhausted, or the target molecule has a parameter pool for all its terms. The resulting *target molecule parameter pool* is then returned.

CherryPicker allows the concept of *dangling* bonded parameters. This refers to the case where, when a fragment is matched to a target molecule, at least half of the atoms involved in a given bond, angle or dihedral term are within the core region of the fragment, and the remainder are in the overlap region. Parameters can be assigned from the dangling bonded term, effectively enabling the core region be to edge terminated rather than vertex terminated. The criteria for allowing a bonded term to dangle is that one of the two atoms defining a bond, two of the atoms defining an angle, or two neighboring atoms defining a dihedral must be in the core region.

Being NP-complete, the subgraph isomorphism problem is inherently difficult. A number of heuristic methods have been developed for solving this problem. Here, we have implemented and tested two algorithms for subgraph isomorphism: the VF2 algorithm (Cordella et al., 2004), as implemented in the Boost Graph Library (Siek et al., 2002), and the RI algorithm (Bonnici et al., 2013). The latter is the default setting as it is more efficient. Both algorithms allow for labeled vertices and edges of graphs. As the labels used here are single integer values, a *mask* is created prior to performing the subgraph isomorphism search that dictates the pieces of information in the label to consider. For example, vertex matches could be based upon only the element and formal charge components of the label without having to modify the label, and thus the Athenaeum, itself. Additionally, to further speed up the parameterisation time, we exploit the tree-like way in which fragments are stored in an Athenaeum. The smaller fragments are tested for subgraph isomorphism first. If a small fragment does not match the target molecule, all larger fragments of which the small fragment is a subgraph will also not match, and therefore do not need to be tested.

Athenaeums are searched in a first-in first-out manner. Ideally they are provided in an order running from most to least reliable. Once all fragments within an Athenaeum have been compared to the target molecule, all components of the target molecule which mapped to a fragment are marked. These regions are excluded from any subsequent searches through additional Athenaeums, thus ensuring that the most reliable parameters identified from the early-stage Athenaeums are not replaced by less reliable parameters from later Athenaeums. Additionally, if an Athenaeum is marked as self-consistent, once all fragments in that Athenaeum have been tested, the mapped parameters are checked to ensure that they are indeed self-consistent. If they are not, CherryPicker ceases execution and the user is alerted.

The target molecule parameter pool is a distinct representation of a molecule containing all parameter values mapped to it during the subgraph isomorphism searches through an Athenaeum. For atoms, the parameter pool consists of counts of the type of each mapped atom, and the list of partial atomic charges of each mapped atom. For bonds, angles and dihedrals

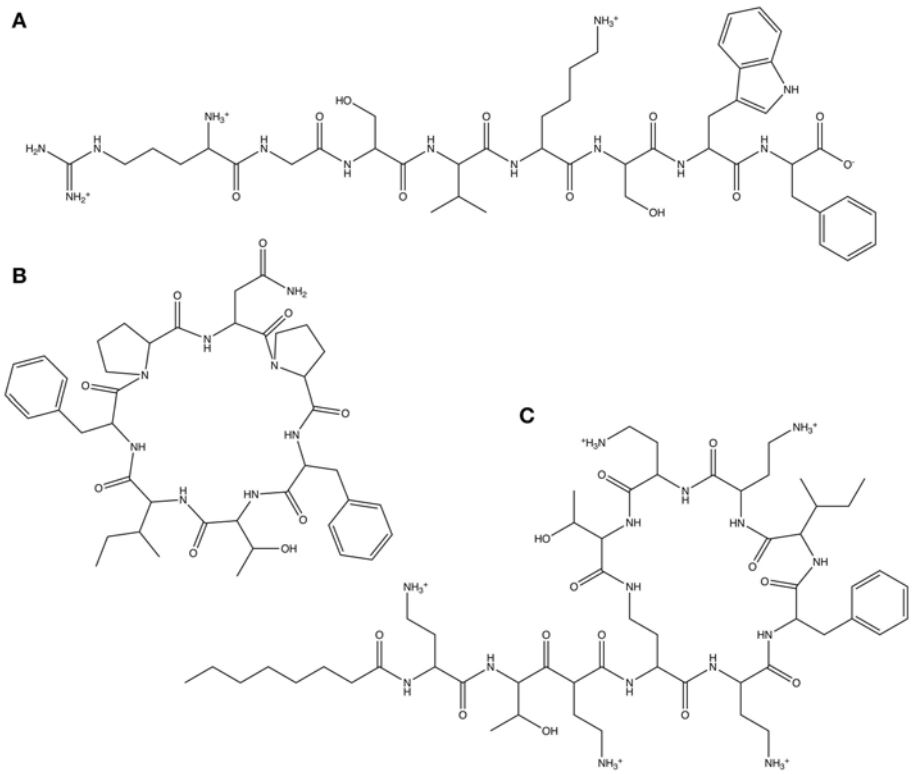

FIGURE 4 | The three peptides used to illustrate the performance of CherryPicker using user-specified and automatically-generated Athenaeums. **(A)** The randomly generated amino acid sequence Arg-Gly-Ser-Val-Lys-Ser-Trp-Phe, **(B)** the cyclic peptide Axinellin A, which has the amino acid sequence cyclo(Asn-Pro-Phe-Thr-Ile-Phe-Pro), **(C)** the non-ribosomal cyclic lipopeptide Polymyxin B3, which has the amino acid sequence octanoyl-Dab-Thr-Dab-Dab(1)-Dab-D-Phe-Leu-Dab-Dab-Thr-(1).

the parameter pool consists of counts of the corresponding mapped types.

Once each Athenaeum has been searched, the target molecule parameter pool is distilled down to a set of *assigned parameter values* for the marked components of the target molecule. Partial charges for atoms are set to the mean of the distribution of mapped partial charges. Preliminary tests revealed that for fragments with an overlap size of at least two atoms, the partial charges are approximately normally distributed, thus the mean is appropriate (see **Figures S1**, **S2**). All other parameter values are set to the mode of the mapped types.

Once all Athenaeum's have been searched, the partial charges are checked. Adding the means of partial atomic charges from matched fragments is likely to result in a non-integer total charge on the target molecule. We therefore implement a simple scheme to avoid this physically unreasonable situation. We assume that the difference between the expected total charge of the target molecule and that obtained with CherryPicker is small. As such, the difference between the assigned and expected charge is added to the atom with the most negative (assigned charge $>$ expected charge) or positive (assigned charge $<$ expected charge) partial charge. Atoms whose parameters were determined by mapping to a self-consistent Athenaeum are excluded from charge adjustment.

CherryPicker outputs both the assigned parameter values and the entire molecule parameter pool. The latter given as comments so that the provided MTB or ITP files could be used without further modification. Providing the entire molecule parameter pool allows the user to check and, if desired, adjust the assigned parameters, as well as gain a deeper understanding of the performance of the CherryPicker algorithm and suitability of the Athenaeums.

3. ALGORITHM TESTING

To illustrate the effectiveness of this fragment based method for parameterisation we present a few simple test molecules, focusing on the well studied peptide space. In future work we will explore much larger and more diverse chemical spaces.

As our first test, we use a linear octapeptide with the randomly generated amino acid sequence Arg-Gly-Ser-Val-Lys-Ser-Trp-Phe (**Figure 4A**). The second test molecule is the cyclic peptide *Axinellin A*, a bioactive cyclic heptapeptide isolated from the marine sponge *Axinella carteri* (Randazzo et al., 1998), which has been chemically synthesized (Fairweather et al., 2010) and has the amino acid sequence *cyclo*(Asn-Pro-Phe-Thr-Ile-Phe-Pro) (**Figure 4B**). Finally, we look at the non-ribosomal peptide *Polymyxin B3* (Zavascki et al., 2007), a lipopeptide antibiotic

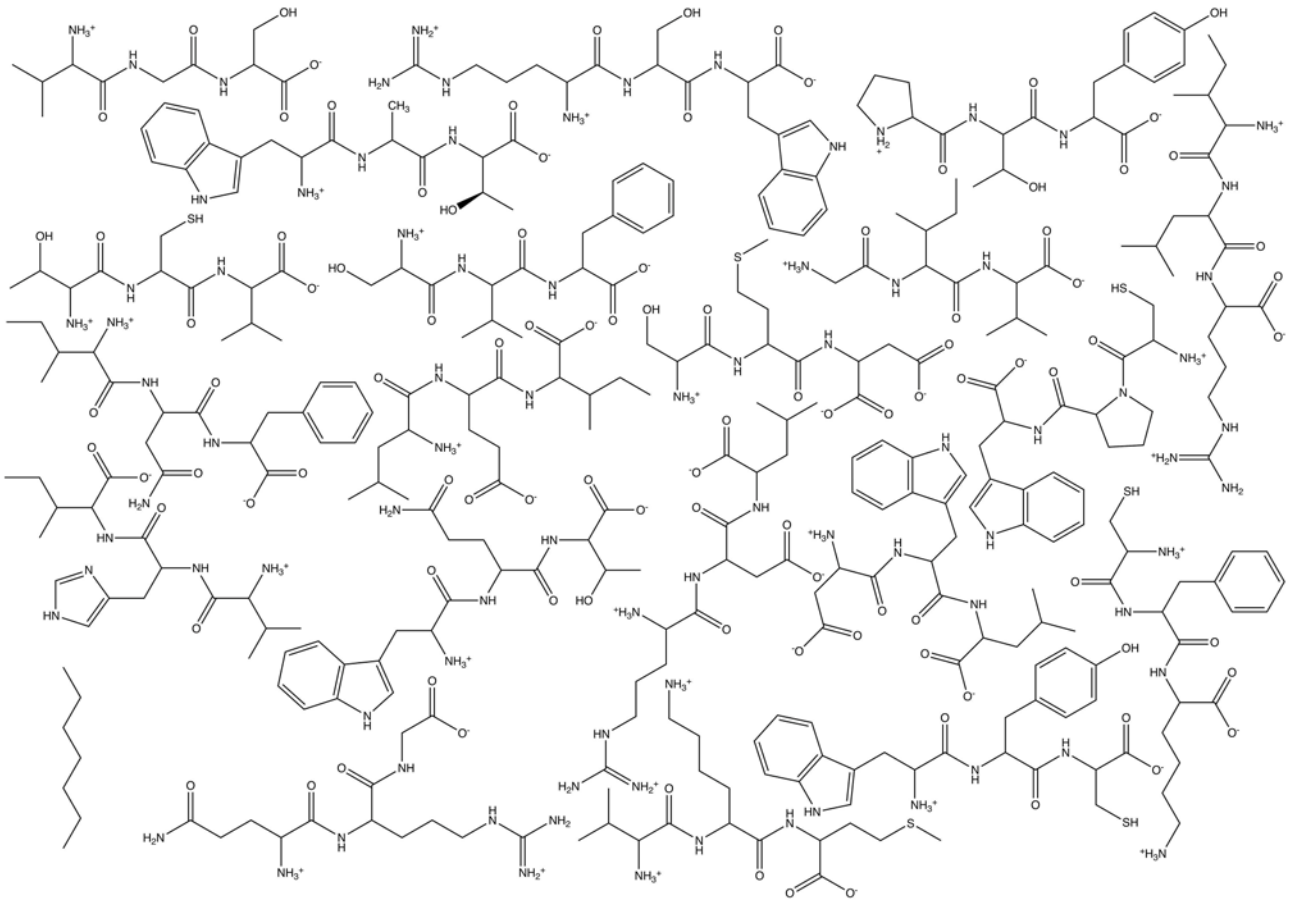

FIGURE 5 | Chemical structures of the molecules used to generate the two Athenaeums used here: 20 tripeptides plus heptane.

isolated from *Bacillus polymyxa*. Polymyxin B3 comprises a cyclic polypeptide with a tripeptide side chain and a fatty acid tail and has the amino acid sequence octanoyl-Dab-Thr-Dab-Dab(1)-Dab-D-Phe-Leu-Dab-Dab-Thr-(1) (**Figure 4C**). The parameters obtained for each test molecule using CherryPicker are provided in the **Supplementary Material**.

The CherryPicker algorithm was run with masked vertex and edge labels. Vertices were masked such that only the element type, formal charge, condensed vertices, and degree were used for matching. Edge labels were masked such that only bond order, and the source/target degree were used. For the automatically generated Athenaeums, the minimum fragment size, that is, the size of the core region in a fragment graph, was two.

3.1. Athenaeums

For these tests, we utilized simple Athenaeums to better illustrate the effects of Athenaeum content and the choices that a user can make in fragment generation and in running CherryPicker. Two different Athenaeums were generated from a set of 21 small molecules. For each of the 21 natural amino acids, a tripeptide was generated, with charged N- and C- termini and the amino acid flanked by two random amino acids. Generating these 20 random molecules resulted in the following sequences: Val-Gly-Ser, Trp-Ala-Thr, Arg-Ser-Trp, Pro-Thr-Tyr, Thr-Cys-Val, Ser-Val-Phe, Ile-Leu-Arg, Gly-Ile-Val, Ser-Met-Asp, Cys-Pro-Trp, Cys-Phe-Lys, Trp-Tyr-Cys, Asp-Trp-Leu, Leu-Glu-Ile, Ile-Asn-Phe, Trp-Gln-Thr, Val-His-Ile, Val-Lys-Met, and Gln-Arg-Gly. Of note is that the amino acids Asp and Glu were in their deprotonated, negatively charged state, Lys and Arg were in their protonated, positively charge state, and His was neutral and protonated at the NE2 position. The final molecule was heptane. Structures of the molecules used for Athenaeum generation are given in **Figure 5**. All molecules were in GROMOS united-atom format and parameterized using the standard GROMOS 54A7 force field (Schmid et al., 2011).

The first Athenaeum was built from a simple set of user-specified fragments. For each of the 20 random peptides, the central amino was defined as the core region of a fragment, and each instance of a terminal amino acid was also defined as the core region of a fragment. In all cases, the overlap region comprised the neighboring amine and/or carboxo group. This resulted in 44 fragments. **Figure 6** shows an example of one such fragment from one of the peptides. From heptane, two fragments were defined. The core of the first fragment comprises the three carbon atoms from a methyl terminal, and

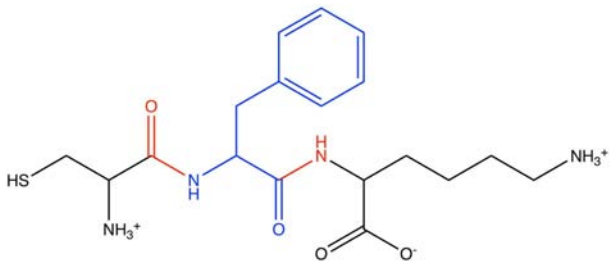

FIGURE 6 | Example of a fragment in the user-specified Athenaeum: the phenylalanine-centered tripeptide Cys-Phe-Lys, showing (blue) the core atoms of the phenylalamine fragment and (red) the overlap regions.

its overlap region is the next carbon in the chain. The core of the second fragment comprises the three carbon atoms in the center of the heptane molecule, with the overlap region comprising a single carbon atom on either side. This Athenaeum was marked as being self-consistent. While this Athenaeum is sufficient for the test cases presented here, we note that it will not be able to parameterize all possible linear proteins/peptides containing only the natural 20 amino acids as, for example, not all protonation states of side chains are present. However, this is easily resolved by adding more source molecules. On the flip side, a user-specified Athenaeum has the advantage of allowing prior knowledge, such as which functional groups or connections between functional groups are most transferable, to be included.

The second Athenaeum was automatically generated. The 21 molecules listed above were passed through the fully-automated fragment generation method (see above) using an overlap length of $k = 1$, which gave rise to an Athenaeum containing 134799 fragments. It is not marked as being self-consistent, as not all fragments created in this way will provide the same parameters to a given functional group.

3.2. Linear Octapeptide

Parameterisation of linear peptides/proteins is already well supported by all molecular dynamics simulation engines. We use this example to illustrate that CherryPicker produces the same results as existing methods, such as the GROMACS (Abraham et al., 2015) tool *pdb2gmx*, which generates parameter files for proteins from a coordinate (PDB) file. Using only the user-specified Athenaeum, CherryPicker exactly reproduces the parameters that *pdb2gmx* provides for the linear octapeptide using the GROMOS 54A7 force field. While it would generally be ill-advised to use CherryPicker in such a manner, as existing tools are more than capable of performing the same task, CherryPicker does have some advantages. For example, *pdb2gmx* uses a database to identify amino acids based on the amino acid names in the input coordinate file. If any of the amino acids are misnamed, *pdb2gmx* is unable to determine which parameters to assign. As CherryPicker uses a chemical structure-matching algorithm, it does not require the input amino acids to be correctly named.

3.3. Axinellin A

Axinellin A is a cyclic peptide, parameterisation of which is not explicitly supported by *pdb2gmx*. While it is relatively simple to generate parameters for the corresponding linear peptide and then manually modify the resultant parameter file to create a cyclic peptide, this requires detailed understanding of both the parameter file format and the correct parameters to select. CherryPicker, in contrast, handles cyclic and linear systems equivalently.

Using only the user-specified Athenaeum, CherryPicker is unable to completely parameterize *axinellin A*. Specifically, it fails to parameterize the two residues that precede proline residues, that is, the asparagine residue and the penultimate phenylalanine residue. This is not unexpected, as the cyclic nature of the proline side chain means that its backbone amine group is tertiary as opposed to secondary as it is for all the other residues. The simple user-specified Athenaeum does not contain fragments for all the different amino acids preceding a proline, and is thus unable to parameterize all Xxx-Pro combinations.

This failure of the user-specified Athenaeum provides an opportunity to showcase the use of an automatically-generated Athenaeum. From the molecules used to generate the Athenaeums (**Figure 5**), it is clear that parameters for the two unparameterized residues are available, but the necessary fragments are not included in the user-specified Athenaeum. Adding the automatically-generated Athenaeum, which is searched only after the user-specified Athenaeum and so only used to parameterize regions of the target molecule not parameterized by the user-specified Athenaeum, does result in complete parameterisation of *axinellin A*. The automatically-generated Athenaeum also results in self-consistent parameters in this instance, which are consistent with those generated by manually cyclising a parameter file for a linear version of Axinellin A generated using *pdb2gmx*.

3.4. Polymyxin B3

Our final test case is *polymyxin B3*, a peptide that is both cyclic and branched, which makes it difficult to handle with a tool like *pdb2gmx*. Additionally, it contains non-natural amino acids and a lipidated amino acid, parameters for which are not included in the standard force field parameter files provided with molecular dynamics engines and searched by tools like *pdb2gmx*. It is therefore an ideal case for illustration of the functionality of CherryPicker.

For this molecule we ignore the stereochemistry of the C_α backbone carbon, i.e., both L- and D-amino acids are considered equivalent. This is easily adjusted by the user after parameter generation, but can also be solved by generating an Athenaeum that includes L- and D-amino acids and using a mask that includes stereochemistry matching.

With the user-directed Athenaeum, CherryPicker is only able to extract parameters for the naturally occurring amino acids, threonine, phenylalanine, and leucine, as expected given the nature of this Athenaeum. It also extracts parameters for the majority of the fatty acid, excluding the peptide bond that joints it to the remainder of the polymyxin. The natural amino acids are

correctly identified, and the presence of heptane fragments allows for the identification of straight chain alkane fragments.

After exhausting the fragments in the manual Athenaeum, the remaining unparametrized portions of *polymyxin B3* are mainly the diaminobutyric acid residues. Structurally, these are similar to lysine residues, except with a shorter carbon chain length. As such, an Athenaeum containing fragments of lysine would be expected to be able to parameterize the diaminobutyric acid residues. This is what is observed when using the automatically-generated Athenaeum. All atoms, bonds and angles, except those involving the carboxy group joining the fatty acid tail to the peptide chain, are assigned consistent parameters.

The unmatched atoms, bonds and angles involving the carboxy group of the fatty acid indicate a deficiency of the Athenaeum, rather than a deficiency of the matching algorithm. This can easily be overcome by building additional Athenaeums that incorporate a wider range of already-parameterized molecules, such as lipids. Our purpose here, however, was to illustrate how much can be achieved with even a very simple Athenaeum that requires only molecules already available in standard biomolecular force fields.

Parameters were also not assigned to the dihedral terms for rotation about the central bond of the diaminobutyric acid side chains. This is because the fragments that matched to these side chains had a maximum (core plus overlap) size of three, whereas a core+overlap size of four is required for dihedral terms to be included in a fragment, even utilizing dangling bonds. Again, this would be alleviated by using a broader Athenaeum that covered more chemical groups.

In the current implementation of CherryPicker, placeholder parameters are inserted in the output parameter file when parameters are not assigned after parsing all available Athenaeums, giving the user a clear indication that parameters were not assigned from the Athenaeum. In the future, it will be possible to automatically identify unmatched regions and extract them as separate molecules, capped as necessary to maintain appropriate chemistry, for parameterisation by other means. As these regions are likely to be individually fairly small, parameterisation using automated web servers that carry out quantum chemical calculations will be possible. Once parameterized, these molecules will then be able to be added to the Athenaeum, thus plugging its gaps and broadening the scope of molecules that can be parameterized.

3.5. Limitations

As with all automated parameterisation schemes, there are limitations to the approach presented here. Firstly, the quality of parameters obtained for the target molecule is highly dependent on the nature and parameters of the source molecules from which fragments are generated. If molecular dynamics simulations of the source molecules give incorrect emergent properties, simulations of target molecules parameterized by CherryPicker will likely also give incorrect properties. Additionally, deficiencies in the Athenaeum, i.e., Athenaeums that do not provide fragments to cover all regions of a target molecule, will become apparent, as was shown with the parameterisation of *polymyxin B3* discussed above. Finally, the choice of overlap size will have a potentially pronounced effect on the parameters attained, especially in the fully automated use case. A smaller overlap will lead to more of a target molecule being parameterized, but risks loss of the chemical environment selectivity that a larger overlap region enables, and thus poorer quality parameters.

4. CONCLUSIONS

The CherryPicker algorithm, combined with one or more Athenaeums, provides a simple to use yet widely applicable method for rapidly generating parameters for novel biomolecules. By assembling parameters derived from fragments of molecules that are already parameterized according to a particular biomolecular force field, we ensure that the resultant parameter set for the novel molecule is by design compatible with an existing force field. The user is able to specify the nature and number of Athenaeums used, including how the already-parameterized molecules are fragmented. This provides control over, for instance, the reliability and consistency of the parameters that are assigned to the target molecule. In demonstrating the application of CherryPicker to a series of peptides of varying degrees of complexity, we illustrate how even very simple Athenaeums are able to parameterize a wider range of molecules than would be possible with existing parameter generation tools. Target molecules are input to CherryPicker in the standard and commonly-used PDB format, and coordinate and parameter files are output in the formats required for the popular GROMACS simulation software, making it straightforward to integrate CherryPicker into established simulation pipelines. This will in turn act to facilitate the use of molecular simulations across a broad range of scientific fields.

AUTHOR CONTRIBUTIONS

IW co-designed, coded, and tested the software and co-wrote the manuscript. JA co-designed the software and tests, and co-wrote the paper.

FUNDING

JA is supported by a Rutherford Discovery Fellowship (15-MAU-001). IW was supported by a Marsden Fast Start grant to JA (13-MAU-039) and by Massey University Doctoral Completion and Dissemination grants.

ACKNOWLEDGMENTS

The authors are extremely grateful for inspiration and advice from Prof. Alan Mark, Dr Alpesh Malde, Dr Martin Stroet, and Bertrand Caron, University of Queensland.

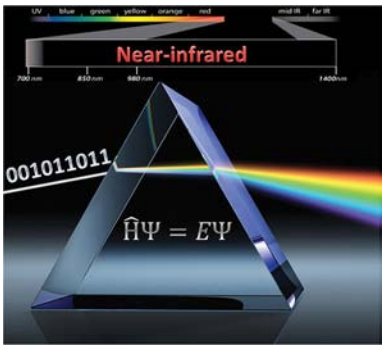
Beć KB and Huck CW (2019) Breakthrough Potential in Near-Infrared Spectroscopy: Spectra Simulation. A Review of Recent Developments. Front. Chem. 7:48. doi: 10.3389/fchem.2019.00048

Near-infrared (12,500–4,000 cm^{-1}; 800–2,500 nm) spectroscopy is the hallmark for one of the most rapidly advancing analytical techniques over the last few decades. Although it is mainly recognized as an analytical tool, near-infrared spectroscopy has also contributed significantly to physical chemistry, e.g., by delivering invaluable data on the anharmonic nature of molecular vibrations or peculiarities of intermolecular interactions. In all these contexts, a major barrier in the form of an intrinsic complexity of near-infrared spectra has been encountered. A large number of overlapping vibrational contributions influenced by anharmonic effects create complex patterns of spectral dependencies, in many cases hindering our comprehension of near-infrared spectra. Quantum mechanical calculations commonly serve as a major support to infrared and Raman studies; conversely, near-infrared spectroscopy has long been hindered in this regard due to practical limitations. Advances in anharmonic theories in hyphenation with ever-growing computer technology have enabled feasible theoretical near-infrared spectroscopy in recent times. Accordingly, a growing number of quantum mechanical investigations aimed at near-infrared region has been witnessed. The present review article summarizes these most recent accomplishments in the emerging field. Applications of generalized approaches, such as vibrational self-consistent field and vibrational second order perturbation theories as well as their derivatives, and dense grid-based studies of vibrational potential, are overviewed. Basic and applied studies are discussed, with special attention paid to the ones which aim at improving analytical spectroscopy. A remarkable potential arises from the growing applicability of anharmonic computations to solving the problems which arise in both basic and analytical near-infrared spectroscopy. This review highlights an increased value of quantum mechanical calculations to near-infrared spectroscopy in relation to other kinds of vibrational spectroscopy.

Keywords: near-infrared, NIRS, spectra simulation, theoretical spectroscopy, anharmonic methods



Graphical Abstract | The properties of near-infrared spectroscopy create unique synergy with quantum mechanical spectra simulations.

INTRODUCTION

Near-infrared spectroscopy (commonly abbreviated as NIRS) has distinguished itself by a remarkable evolution from an undervalued section of vibrational spectroscopy to one of the presently most widespread modern analytical techniques with strong prospects for further expansion (Ciurczak and Drennen, 2002; Siesler et al., 2002; Cozzolino, 2014; Huck, 2014, 2016a; Ozaki et al., 2017). The second major application field taking advantage of the potential embodied in NIRS is hyperspectral imaging (Ozaki et al., 2017; Türker-Kaya and Huck, 2017; Dorrepaal and Gowen, 2018; He et al., 2018), which enjoys a rapidly growing interest in the biomedical applications (He et al., 2015; Türker-Kaya and Huck, 2017) and is a subject of focused development nowadays (He et al., 2015; Sun et al., 2017; Wong et al., 2019). As will be discussed further on, most of the distinctiveness of NIRS results from the specificity of the corresponding spectral region located between visible and infrared (near-infrared or NIR; 800–2,500 nm; 12,500–4,000 cm^{-1}). From the point of view of the present review, the foremost aspect worth emphasizing is the molecular mechanisms standing behind the absorption of electromagnetic radiation in NIR, which involves excitations of non-fundamental vibrations, overtones and combination modes. The primary parameters of the resulting bands, wavenumbers and intensities are ruled by anharmonic effects with inter-mode anharmonicity playing the most substantial role. In this sense, NIRS distinctively sets itself apart from the other kinds of vibrational spectroscopy (mid-infrared, MIR; far-infrared, FIR; Mantsch and Naumann, 2010[1] and Raman) in which the major chemical information originates from fundamental vibrational transitions. Unlike these latter ones, which put the harmonic approximation into good use, theoretical NIRS unequivocally requires computationally intensive anharmonic approaches. Hence, NIR spectral simulations have remained rather rare in literature until the recent advances in theory and computer technology made such studies feasible for the molecules extending beyond a few atoms in complexity. It can be stated that this is an emerging field, as the entirety of literature reporting on theoretical NIR simulations of the molecules relevant for applied studies has emerged in the current decade.

The aim of the present review is to provide a comprehensive introduction to theoretical NIRS and to expound its distinctiveness and exceptional significance for the contemporary progress of applied spectroscopy (**Graphical Abstract**). In order to fully apprehend a remarkable synergy arising between the theoretical and experimental NIRS, far outweighing the analogous relation existing in the other kinds of vibrational spectroscopy, the present article includes brief information on the specificity of basic and analytical NIRS. Throughout the following sections, the underlying phenomena and key correspondences are thoroughly explained, together with a brief history sketch reaching the most recent accomplishments and future prospects, outlining a complete overview of the highly promising and boundary-crossing development currently taking place in the field of NIRS.

NEAR-INFRARED SPECTROSCOPY. THE TALE OF AN UGLY DUCKLING

Early Developments

Near-infrared light has been the first kind of non-visible electromagnetic radiation discovered as early as in year 1800 in the famous experiment of Herschel. Although this happened by observing that NIR light is absorbed by matter, it may be considered a peculiar plot twist of scientific history that the actual development of NIR spectroscopy has lagged behind the techniques resorting to other spectral regions, e.g., ultra-violet (UV), visible (VIS) or MIR. By the time these other kinds of optical spectroscopy have reached reasonable levels of maturity (ca. 1950–1960s), instrumentation capable of working in the NIR region was still being used only as an add-on unit to the major optical devices. The potential of NIR region remained not recognized at that time for several reasons. First, in basic research the lack of stimulus resulted primarily from the competition from MIR spectroscopy. The chemical information derived from the fundamental bands has always seemed more specific and readily available. The absorption occurring in the NIR region of the vast majority of both organic and inorganic matter is relatively weak. An example of a common and relatively strongly absorbing medium is liquid water, whose NIR absorption coefficient values remain at least two orders of magnitude lower than in the MIR region (**Figure 1**). At that time, before the era of Fourier-transform (FT) optical spectrometers, the relatively primitive dispersive devices have, by design, been less potent in capturing weaker signals. Both the registered peak positions and absorption intensity values have been rather unreliable because of the imperative instrument calibration and also due to analog electronics (Davies, 2011). The spectra collection was a time-consuming and manpower-intensive process. Additionally, weak and broad structures resulting from multiple overlaying bands are typically found in this spectral region. Hence, NIR absorption

[1]This includes terahertz (THz) spectroscopy; despite differences in the instrumentation, FIR and THz spectroscopy both elucidate the same information from the analyzed sample (Mantsch and Naumann, 2010).

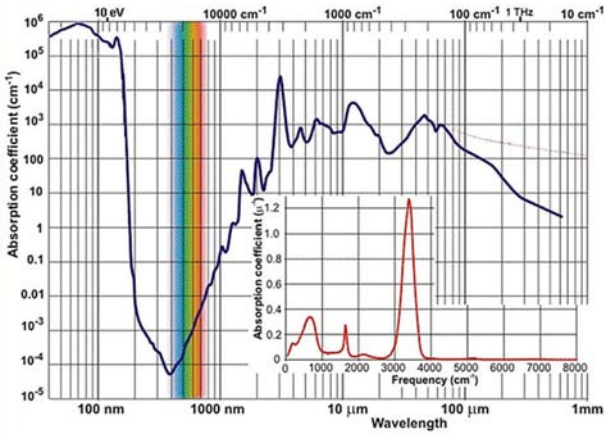


FIGURE 1 | The spectrum of absorption coefficient of liquid water[2].

was troublesome in measurement and analysis and its potential has long remained undervalued (Davies, 2011).

In this context, the fact that analytical chemistry first reached to the unique favors of NIR spectroscopy may be unexpected. Briefly during the 1950s, the NIR region attracted limited attention in measurements of moisture in hazardous materials, where MIR spectroscopy found limited applicability due to strong absorption of water (**Figure 1**). However, other emerging analytical techniques (e.g., chromatography) proved to be even more superior for such a task and soon took over. Much has changed when an engineer K. Norris working for the United States Department of Agriculture re-invoked NIR spectroscopy for the analysis of moisture in grains and oilseeds (Davies, 2011). This required the designing of an instrument featuring a very high light efficiency. Over the next years, Norris and collaborators further developed early analytical NIRS, often facing scientific and engineering challenges, as well as straight opposition from some part of the spectroscopic community. Although early instrumentation has initially been troublesome and barely reliable enough for analytical applications, the unique advantages of applied NIR spectroscopy have been recognized and this activity marked the beginning of the evolution path leading to the present state-of-the-art NIRS (Davies, 2011).

Analytical NIRS Today

Nowadays NIRS is being widely used in modern analytical applications due to a uniquely synergistic combination of qualities. Its universality, wide applicability, uncomplicated instrumentation, low time-to-result and low cost factors are prominent advantages from the point of view of qualitative and quantitative analysis (Ciurczak and Drennen, 2002; Siesler et al., 2002; Cozzolino, 2014; Huck, 2014, 2016a; Ozaki et al., 2017). It enables the non-invasive, non-destructible analysis of a variety of samples while maintaining a good balance between its cost, time, and analytical performance. The mentioned typical low absorptivity in NIR (**Figure 1**) results in the ability of examining a bulk sample in high volume with no limitation to the sample surface, as often encountered in optical spectroscopy. NIRS has found its way to quality control laboratories dealing with, e.g., food (Smyth and Cozzolino, 2013; Henn et al., 2016; Ringsted et al., 2017; Chapman et al., 2018) and natural products (Pezzei et al., 2017a), agriculture-related items (Pezzei et al., 2017b), pharmaceuticals (Kirchler et al., 2017a; Yan and Siesler, 2018a), phytopharmaceuticals (Stecher et al., 2003) and phytoanalysis in general (Huck, 2017a), polymers (Huck, 2016b; Unger et al., 2016; Yan and Siesler, 2018b) fuel (Lutz et al., 2014a), cosmetics (Blanco et al., 2007), biomedical applications (Jue and Masuda, 2013), general industry (Huck, 2017b) and environmental studies (Altinpinarn et al., 2013; Roberts and Cozzolino, 2016, 2017), among others (Ciurczak and Drennen, 2002; Siesler et al., 2002; Iwamoto, 2009; Cozzolino, 2014; Huck, 2014, 2016a; Ozaki et al., 2017; Power et al., 2018; Yan and Siesler, 2018c). In response to strong demand from the industry the instrumentation has been undergoing continuous development. One of the most recent milestones in this evolution path was the introduction of portable spectrometers (Herberholz et al., 2010; O'Brien et al., 2012; Alcalà et al., 2013), which marked the beginning of truly on-site capability of NIRS analysis (Wiedemair et al., 2018). Within the next decade, strong prospects exist for this technique to ultimately achieve wide-spread use even at consumer level due to the development of inexpensive mobile phone-attachable spectrometers and highly autonomous software for data analysis (Klakegg et al., 2016; Watanabe et al., 2016). The cost factor should not be underestimated, as it is a crucial factor for wide utilization; this is a subject of focused development (Saranwong et al., 2013). It may be reasonably envisioned that the next major breakthrough will be accomplished by the successful design and implementation of single-chip *in-silicon* spectrometers; the era of such devices in MIR spectroscopy is approaching (Wang et al., 2013; Ribessi et al., 2016; Sieger and Mizaikoff, 2016) and similar evolution in NIRS should be anticipated.

Analytical NIRS relies extensively on various methods of statistical analysis, which are commonly grouped under the well-established term of chemometrics (Beebe et al., 1998; Marini, 2013). These methods may be roughly divided into three classes. (1) Exploratory Data Analysis (EDA) includes techniques of data mining (e.g., Cluster Analysis, PCA-Principal Component Analysis) which are used for gaining deeper insights into high-volume complex data such as a large set of NIR spectra. (2) Regression analysis groups the methods used for the prediction/quantification of chemical content (predictive models); it finds extensive use in detection and quantification of selected chemical components. The most utilized techniques include Multiple Linear Regression (MLR), Principal Component Regression (PCR) and Partial Least Squares Regression (PLSR). (3) Classification techniques are used for the separation and sorting as well as grouping of samples with regard to a selected property. Classification approaches include supervised (e.g., SIMCA, Soft Independent Modeling of Class Analogy; LDA, Linear Discriminant Analysis; PLS-DA, Partial Least Squares Discriminant Analysis or SVMC, Support Vector Machine

Classification) and unsupervised approaches (e.g., K-mean and K-median methods, Hierarchical Cluster Analysis or PCA, this time in its classification role). Classification methods allow e.g., group samples in accordance with their source of origin, level of authenticity, or even the region or conditions of cultivation in the case of agricultural products. Within the set content rule, the classification methods may be used, for example, for the separation of contaminated samples from the pure ones.

At present, analytical NIRS is an active research field with a considerably wide scientific and professional community involved, as evidenced by the narrowly scoped and highly attended international conferences (to list only the few: meetings of International Council for Near-Infrared Spectroscopy [ICNIRS]; International Diffuse Reflectance Conference [IDRC]; Asian NIR Symposia [ANS]), and scientific journals (e.g., *Journal of Near Infrared Spectroscopy*; *NIR News*). The development of the data analytical/statistical methods (i.e., chemometrics Burns and Ciurczak, 2007), which are essential in analytical NIRS, has grown to become another largely independent field of research (e.g., *Journal of Chemometrics*; *Chemometrics and Intelligent Laboratory Systems*; *Journal of Multivariate Analysis*). On the other hand, a rapid expansion of applied NIRS has resulted in its detachment from basic spectroscopy, physical chemistry, and molecular science. This fact, in turn, creates hindrances in the further advancement of this field, as will be explained in detail below.

The stimulated development of applied NIRS created focus on relatively narrow, short-reaching goals suiting specific analytical applications. This pragmatic demeanor has led to a detachment of analytical NIRS from its physicochemical background. Basic NIR investigations of the chemical structure, molecular vibrations, and intra- and inter-molecular interactions remain limited in relation to the exceedingly active field of applied studies (Huck, 2014). Due to an intrinsic complexity of NIR spectra, reflecting the anharmonic nature of molecular vibrations (Huck, 2014; Ozaki et al., 2017) the observed spectral outline typically emerges from multiple overlapping contributions. The resulting broad and non-homogeneous bands create significant difficulties in the comprehensive association of the observed spectral variability and physicochemical background. For this reason, in NIR analytical routines, spectral data is often used without any attempt to interpret the chemical information embodied within. Chemometrics allows the correlation of subtle spectral variability with the sample composition and thus yields effective chemical content detection and quantification. However, it lacks in providing a physicochemical interpretation for the information it delivers. In this context, the analytical NIRS is often effectively limited to a "black-box tool."

NIRS in Physical Chemistry

The value of NIRS to basic research stems from specific physicochemical features differing from those of the fundamental region (IR, Raman) (Czarnecki et al., 2015). NIR spectra remain the most natural and rich source of information on the anharmonicity of molecular vibrations. The absorptivity of NIR transitions gradually decreases toward the higher tones and higher order combinations. The co-existence of various bands (e.g., first, second, and third overtones Gonjo et al., 2011; Futami et al., 2012; Chen et al., 2014) within the same spectra is a key advantage here. Low band intensities enable systematic studies of the molecules in solution with a widely spread concentration range. This provides the possibility of a comprehensive investigation of intermolecular interactions, association mechanisms, solvent effects, molecular self-organization, and the structure of liquid phase (Czarnecki et al., 2015; Wrzeszcz et al., 2016a,b). In the NIR region, the bands originating from X-H (e.g., C-H, O-H, N-H) vibrations are strongly articulated. These chemical groups are most commonly responsible for the formation of hydrogen bonding. This enhances the potential of exploring the nature of hydrogen bonding and molecular interactions (Czarnecki et al., 2015). In the NIR region, particular types of bands are being enhanced in their intensity. The bands due to non-associated species usually are much more intense than those of aggregated molecules (Czarnecki et al., 2015). The NIR band heights often carry valuable information on themselves. For example, the prominence of the first overtone band of C=O stretching mode (5,260–5,130 cm^{-1}) varies strongly among different molecular systems (Czarnecki et al., 2015). On the other hand, the second overtone of C=C stretching mode is not commonly observed in NIR spectra. One can conclude on this mode by investigating the spectral shift of its first overtone band or the combination band with the modes of a C-H group connected directly to the C=C moiety. Another relevant example may be provided in the form of the first overtone of C≡N stretching mode, or the second overtone of C=N mode. Contrary to the respective fundamentals, these transitions have very low absorptivity and have not yet been identified in the NIR region.

The specificity of such vibrational effects in NIR, different from those observed in MIR spectra, create a large amount of independent spectral information of high value for physical chemistry. However, NIR spectral analysis remains prone to ambiguities due to overlapping, anharmonicity, and the omni-presence of coexisting effects, which translate to convoluted spectral changes. Similar reasons have also been forming a hindrance in analytical NIRS. The intrinsic complexity of the spectra has forced the extensive usage of spectral pretreatment methods and advanced data analysis, for example, two-dimensional correlation spectroscopy (2D-COS) (Noda, 1989; Noda et al., 1995; Noda and Ozaki, 2004). The 2D-COS technique allows the expanding of the spectral information onto two-dimensions, basically elucidating the correlations in the spectral variations and visualizing straightforwardly the complex dependencies which would be otherwise difficult to trace in linear NIR spectra. It finds an extreme value in the analysis of spectral variations, as not only the changes are illuminated, but their direction and sequence can also be elucidated. 2D-COS also gains a better resolution through the simplification of the spectral data, the possibility of a more distinct assignment of bands, and exploration of the sequential order of changes occurring in the sample. Therefore, the different inter- and intramolecular behavior of samples can be investigated through the peaks visible in the synchronous (*syn*) and asynchronous (*asyn*) spectra, which are obtained by spreading spectral information as a function of

two independent wavenumber axes over the second dimension (Noda and Ozaki, 2004).

A brief note on NIRS in biophysical chemistry should be made here as well (Huck, 2016a). In addition to the advantages outlined above, low absorptivity of NIR radiation also promotes its value when applied for the purpose of hyper spectral imaging (Huck, 2016a; Ozaki et al., 2017; Türker-Kaya and Huck, 2017; He et al., 2018). The resulting relatively deep penetration of NIR light plays a key role here, allowing an effective in-depth probing of the sample, a fact which finds an exceptional applicability in biophysical and biomedical studies (Huck, 2016a; Sun et al., 2017; Türker-Kaya and Huck, 2017). This currently remains a strongly developing area (He et al., 2015; Dorrepaal and Gowen, 2018; Wong et al., 2019), ultimately aiming at multi-modal imaging (He et al., 2018), which gives rise to an intriguing question of how in the nearest future this may be hyphenated with a similarly rapidly growing theoretical NIRS. This review will also include a short exploration of this topic.

THEORETICAL NEAR-INFRARED SPECTROSCOPY–AN OVERVIEW OF THE EMERGING FIELD

Fundamentals of Theoretical NIRS

As mentioned earlier, the simplistic harmonic approximation of molecular vibration brings substantial practical advantages from the point-of-view of computational complexity. The Newton equations of molecular oscillation lead to a matrix eigenvalue equation in which the harmonic vibrational frequencies are obtained through diagonalization of the matrix of mass-weighted second derivatives of the potential energy (mass-weighted Hessian). Consequently, the transition intensity is calculated from the derivative of dipole moment over the normal coordinates. Since Hessian is given as a straightforward output of the geometry optimization procedure, harmonic frequencies are calculated with a relatively minor additional cost. A commonplace overestimation of harmonic frequencies is being routinely addressed with a simple empirical scaling, thus yielding cost-effective theoretical MIR or Raman spectra (Wilson et al., 1955). However, NIR modes unequivocally require to step beyond harmonic approximation. While di-atomic anharmonicity remains relatively easy to account for, the problem arises in complexity for polyatomic molecules, mostly due to mode-mode couplings. A variety of anharmonic approaches has been proposed in the literature. However, in practical terms these methods have been prohibitively expensive and thus, until recently, have not been employed for the prediction of NIR spectra of reasonably complex molecules. The computational affordability is the primary factor from the point of view of applied spectroscopy. The anharmonic approaches may thus be categorized by their accuracy vs. cost ratio. In this sense, variational methods may be omitted due to extreme expense. This holds, in spite of their capability to yield an exact solution, limited only by the quality of potential energy evaluation. Variational methods are practically applicable to the simplest systems only (Polyansky et al., 2003). In contrast, applied spectroscopy relies on reasonably efficient anharmonic methods with the ability to treat complex molecules at a controlled penalty of a less accurate description of certain non-essential factors. For example, the Vibrational Self-Consistent Field (VSCF) method, which has fairly often been used for anharmonic simulation of MIR spectra (Gerber et al., 2005; Lutz et al., 2014b), assumes full factorizability of vibrational wavefunction into a set of normal mode wavefunctions. However, the VSCF scheme requires reasonably accurate probing of the vibrational potential; it is commonly based on a 16-point grid. The key economical feature here is the approximate treatment of inter-modal anharmonicity, effectively in which any given mode feels an averaged effect resulting from all other modes. This approximation has often been too severe; a number of refinements in the approach appeared, in which the cost-accuracy balance has frequently been skewed toward accuracy. For example, an improved variant, perturbation-corrected VSCF (PT2-VSCF) uses the second-order perturbation theory to correct the VSCF level couplings, yielding a higher certainty (Jung and Gerber, 1996). Concurrently, a number of reported attempts have been aimed at increasing the method's affordability, e.g., by reducing the grid-density for potential evaluations (Lutz et al., 2014c) or by employing more efficient ways for the determination of the electronic structure underlying the layer of anharmonic vibrational analysis [e.g., the resolution of the identity (RI) approximation in connection with the Moller-Plesset second order perturbation, i.e., RI-MP2; (Lutz et al., 2015)]. Interestingly, the precision penalty of basic VSCF decreases as the molecule complexity increases. This occurs due to a more effective averaging with the increasing numbers of modes within the VSCF mean-field approximation and has been exploited, for example, in biomolecule studies (Pele and Benny Gerber, 2010).

Another class of anharmonic methods is based on the vibrational second-order perturbation theory (VPT2) (Nielsen, 1951; Clabo et al., 1988). In principle, these include the anharmonic correction of vibrational potential in the form of cubic and quartic force constants yielded through the numerical differentiation of the harmonic Hessian at molecular geometries only slightly displaced from the equilibrium; very few energy evaluations are needed in this case. VPT2 methods are known for being computationally cost-effective; this is particularly evident if only bi-modal correlations are included in the calculations. However, the applicability of these methods has typically been hindered by their tendency to produce meaningless results in case of tightly-coupled modes (close degeneracies, i.e., vibrational resonances). The appearance of such singularities does not follow any consecutive pattern. Instead, their presence depends on a particular molecule; consequently, customized solutions have typically been needed almost each time. This fact severely restricted VPT2 usage in applied spectroscopy. Attempts have been made to develop an automated treatment of close degeneracies (Barone, 2005). For example, deperturbed (DVPT2) and generalized (GVPT2) schemes have appeared recently. These methods identify and remove close degeneracies from the perturbative treatment (in DVPT2 scheme) and reintroduce the removed terms through the variational approach (only in GVPT2 approach) (Barone,

2005). Essential for applied spectroscopy, these methods are suitable for any general molecule, effectively creating a robust and generally applicable tool for anharmonic calculations of even fairly complex molecules. Investigations into the solution phase often find a useful addition of computationally affordable implicit solvation model. Several different approaches may be found in recent literature, e.g., Polarizable Continuum Model (PCM) and derivatives; conductor-like polarizable continuum model (CPCM) or integral equation formalism variant (IEF-PCM); these approximate description of solvation allow for efficient increase in the quality of simulations performed in solution phase (Beć et al., 2016a, 2017).

Other anharmonic methods may also be mentioned, e.g., vibrational configuration interaction (VCI) (Whitehead and Handy, 1975) and vibrational coupled-cluster (VCC) (Christiansen, 2004) methods. These computationally highly expensive approaches are rarely found in the literature being used for the simulation of MIR spectra of simple molecules, particularly in cases where certain vibrational intricacies cannot be omitted (Oschetzki et al., 2013). Ongoing development in high-power computing may result in an increased application of these methods in the future. A final remark may be aimed at anharmonic calculations of macromolecules and biomolecules. As is known, anharmonic effects are sometimes substantial in those cases; certain biomolecules, e.g., proteins or nucleic acids, exhibit strong anharmonicity expressed in low-barrier bond torsions, low-energy vibrations in the THz region, ring modes in large ring systems, or hydrogen-bonded complexes (Hamm and Hochstrasser, 2001; Walther et al., 2002). In these applications, even a basic account for anharmonicity may yield significant gains. Due to the complexity of such molecules, the computational cost factor remains the center of attention. A number of efficiency-oriented methodological studies aimed at large molecular systems has emerged; this challenging research area meets strong stimulus from various fields and remains very active (Levy et al., 1984; Pele and Benny Gerber, 2010; Schlick, 2010; Krasnoshchekov and Stepanov, 2015).

Recent times have seen a progressing amount of quantum mechanical (QM) simulations of NIR spectra. Such studies, so far, have mostly utilized either VSCF or VPT2 routes, as those possess the required balance between accuracy and computing cost, essential in applied spectroscopy. Various examples of such studies will be overviewed beneath.

Basic Molecules

A number of QM studies on NIR spectra of basic molecules have been reported over the last few years (Beć et al., 2016a, 2018a; Grabska et al., 2017a,b). Vibrational studies of these systems are relatively important for our understanding of the general spectra-structure correlations (Czarnecki et al., 2000; Wojtków and Czarnecki, 2006; Michniewicz et al., 2007, 2008; Haufa and Czarnecki, 2010) and the role of conformational isomerism (Czarnecki et al., 2006; Wojtków and Czarnecki, 2006), structure and dynamics of hydrogen-bonding, self-association mechanisms and intermolecular interactions (Czarnecki and Ozaki, 1999; Czarnecki et al., 2000, 2010; Czarnecki, 2003; Czarnecki and Wojtków, 2004; Michniewicz et al., 2007; Haufa and Czarnecki, 2010), in particular the interactions with solvent molecules (e.g., water, nonpolar solvents) (Gonjo et al., 2011; Tomza and Czarnecki, 2015), or chiral discrimination (Czarnecki, 2003); the temperature influence on the above effects was often also examined (Czarnecki and Ozaki, 1999; Iwahashi et al., 2000; Šašić et al., 2002; Wojtków and Czarnecki, 2005, 2006, 2007; Grabska et al., 2017a). In the above contexts, alcohol molecules have remained among those investigated most frequently in physicochemical NIRS; often, the lack of QM spectra simulations hindered full comprehension therein. Beć et al. recently investigated basic alcohols; methanol, ethanol and 1-propanol by experimental and theoretical NIRS, demonstrating the potential of such approach in gaining a deep understanding of these spectra (Beć et al., 2016a). A good agreement between the experimental (solution; 3 10^{-5} M in CCl_4) and calculated spectra has been achieved, including the reproduction of finer bands (**Figures 2**–**3**) and the manifestation of conformational isomerism. This demonstrated well the potential of QM spectra simulation in explaining the spectra-forming factors in NIR (**Figure 2**) far surpass that achievable by classical spectroscopic methods even for an elementary molecule such as methanol (Weyer and Lo, 2002). Ethanol and 1-propanol feature more vibrational bands, and additionally, have conformational isomers which results in distinct spectral signatures (**Figure 3**). Beć et al. have shown that with QM simulations it is possible to unambiguously follow the contributions from conformational isomers in the NIR region (Beć et al., 2016a). They also reproduced the bandshape details of the 2νOH band, a major peak in NIR spectra of alcohols. A homogenous structure of methanol is clearly set apart from ethanol and 1-propanol, accounting for their conformational flexibility. The simulation reflected well an increasing complexity of 2νOH bandshape due to the separation of the contributions stemming from different conformers (Beć et al., 2016a).

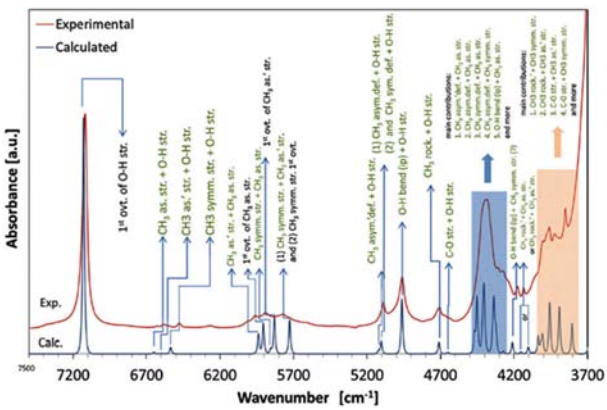

FIGURE 2 | NIR spectra of diluted methanol; experimental (5 10^{-3} M CCl_4) and simulated by the use of anharmonic calculations (GVPT2 scheme on DFT-B2PLYP/SNST level of electronic theory and CPCM solvation model of CCl_4) (Beć et al., 2016a). Reproduced by permission of the PCCP Owner Societies.

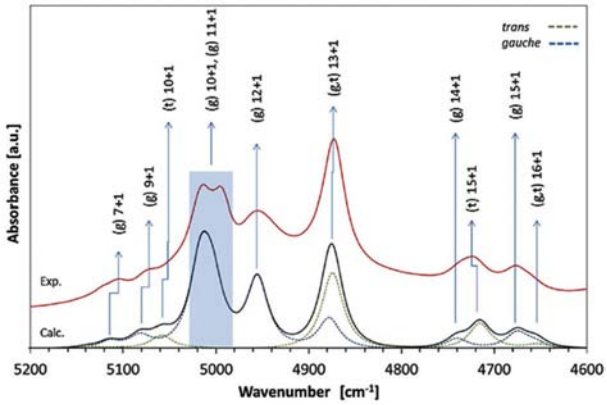

FIGURE 3 | Band assignments in the experimental and calculated NIR spectra of low concentration (5 10^{-3} M CCl_4) ethanol. The calculated NIR spectrum is based on the CPCM-B2PLYP-D/SNST level of theory. Details of the 5,200–4,600 cm^{-1} region (Beć et al., 2016a). Reproduced by permission of the PCCP Owner Societies.

TABLE 1 | An exemplary comparison of total computational time for methanol molecule (including geometry optimization, harmonic calculations and VPT2 treatment).

Method	Solvent model	CPU time[a] [s]	Wall time[a] [s]	Wall time relative ratio
B3LYP/6-31G(d,p)	–	117	353	1
B3LYP/6-31G(d,p)	CPCM	135	375	1.1
B3LYP/6-31G(d,p)	IEF-PCM	147	409	1.2
B3LYP/6-31G(d,p)	SMD	151	422	1.2
B3LYP/N07D	–	157	466	1.3

In the study of simple alcohol molecules, the deperturbed/generalized vibrational second-order perturbation theory (DVPT2/GVPT2) has been used at several levels of electronic theory (Beć et al., 2016a). A number of basis sets have been considered, as well as a selection of three different solvation models within self-consistent reaction field (SCRF) formalism. This allowed for an effective method validation accounting to their feasibility in accurate reflection of NIR modes; similar comparisons assembled for fundamental (IR) modes are frequent in literature yet remain very rare for non-fundamentals. Beć et al. concluded that the density functional theory (DFT) should be prioritized in applied spectroscopic studies. DFT offers a good cost-precision balance, this being a primary factor since anharmonic vibrational analysis is notably expensive in itself (**Table 1**). Post Hartree-Fock approaches, e.g., the Møller-Plesset second order perturbation (MP2) method may find limited use due to unfavorable accuracy/computing time factor. DFT with a carefully selected density functional, matching the complexity of the calculated molecule, may be considered the best choice here. For the treatment of molecules in solution, B3LYP and B2PLYP functionals are recommended, even more with the addition of empirical correction for dispersion improving the description of non-covalent and long-range interactions at a moderate cost. The conclusion was that double-hybrid functionals, e.g., B2PLYP, offer better consistency of NIR frequencies albeit when short-time of the simulation is prioritized, single-hybrid B3LYP is sufficiently good. A more detailed evaluation of the computational demands of different electronic approaches used inVPT2 calculation has been reported by the same authors (Beć et al., 2016b). Calculations employing the B2PLYP functional were roughly twice as expensive as those with B3LYP; a triple-ζ SNST basis set versus a small double-ζ N07D basis increases the computing time by a factor of two, at least in the case of methanol molecule. Contrarily, an addition of the empirical dispersion correction and implicit solvation model (CPCM, IEF-PCM or SMD) introduce only a meager overhead (**Table 1**). Therefore, including these two supplementary calculation steps may be recommended; the former is applicable in general, while the latter is applicable to molecules in the solution phase (Beć et al., 2016a).

The influence of temperature on the structure and association mechanisms of alcohols and similar molecules has always been a primary scientific problem studied in physicochemical NIRS. It has been well-known that in diluted alcohols the 2νOH band undergoes a temperature-induced spectral shift and intensity variation. Additionally, bandshape changes have been closely monitored by second derivation and two-dimensional correlation analyses (2D-COS); the latter technique has proven to be particularly powerful in these studies. In this context, examinations of butyl alcohols were helpful due to the differences among these isomeric molecules (Maeda et al., 1999; Czarnecki et al., 2015). A change of the 2νOH bandshape and a peakshift is observed in the case of 1-butanol, 2-butanol, and *iso*-butanol; however, *tert*-butanol spectrum features only a peak shift. Accordingly, 1-butanol, 2-butanol and *iso*-butanol feature conformational flexibility; on the contrary, *tert*-butyl alcohol is inflexible. These observations suggested that conformational isomerism should be responsible for the respective temperature-dependent NIR spectra inconsistency; yet, no decisive explanations could be provided at that time (Maeda et al., 1999). This problem has recently been reinvestigated by Grabska et al. this time

with the solid support of QM simulations (Grabska et al., 2017a). Their attempt to theoretically reproduce the temperature induced spectral variations in the NIR region of butanols was successful. To improve the accuracy/cost balance in the anharmonic treatment of these larger molecules, they applied a hybrid approach in vibrational analysis; the harmonic and anharmonic steps were performed on different levels of electronic theory (B2PLYP/def2-TZVP and B3LYP/SNST; respectively), maximizing the efficiency of the calculation. The obtained simulated NIR spectra have resembled the experimental ones remarkably well (**Figure 4**), including the reproduction of subtle effects, e.g., minor bands between 5,200 and 4,500 cm^{-1} for all four butyl alcohols (**Figure 4**). Detailed and reliable band assignment and full comprehension of the NIR spectra of diluted butanols was achieved (Grabska et al., 2017a). In the next step, Grabska et al. investigated the temperature dependence of the conformational population of butyl alcohols (Grabska et al., 2017a). By calculating the Boltzmann coefficients corresponding to all conformational isomers of 1-butanol, 2-butanol and *iso*-butanol and subsequent use of these values in spectra simulation, including theoretical 2D-COS plots, they have succeeded in reproducing the temperature-dependent spectral shift and bandshape changes observed experimentally. This comparison has confirmed that the relative changes in the conformational populations contribute, at least partially, to the observed spectral variability. Hence, the background for the experimental observations was decisively explained and the old and never fully explained scientific problem was solved. Grabska et al. has adequately demonstrated the usefulness of QM simulations in bringing definite answers to the problems which have often been difficult to become unequivocally resolved by means of classical NIR spectroscopy (Grabska et al., 2017a).

A number of open questions related to NIR spectroscopy and physical chemistry of alcohols still remain. In example, Beć, Grabska and Czarnecki examined 1-hexanol, cyclohexanol, and phenol (Beć et al., 2018a). They focused on the spectra-structure correlations in NIR due to the vibrations of an OH group attached to a molecular skeleton of three different kinds; linear and cyclic aliphatic, and aromatic ring. It is well known that the bands due to X-H modes and particularly OH vibration, are enhanced in NIR spectra. Hence, OH vibrations belong to the primary spectra-forming factors; in this context, investigating how a molecular structure affects the NIR spectrum brings long-awaited answers (Beć et al., 2018a). Those three molecules manifest remarkable dissimilarity in NIR spectra; 1-hexanol remains similar to shorter chain linear alcohols. However, cyclohexanol, and even more phenol, had substantial differences (**Figure 5**). Detailed band assignments and the elucidation of distinct trends in NIR spectra could be carried out with the aid of

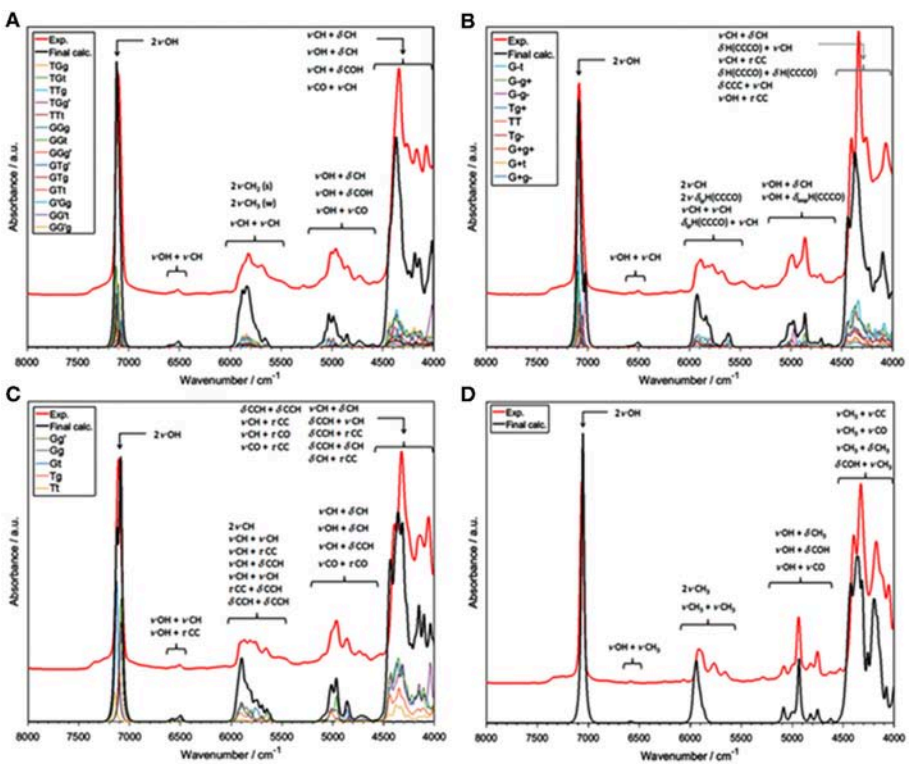

FIGURE 4 | Experimental and simulated (harmonic: B2PLYP/def2-TZVP; VPT2: B3LYP/SNST; CPCM) NIR spectra of butyl alcohols; **(A)** 1-butanol; **(B)** 2-butanol; **(C)** *iso*-butanol; **(D)** *tert*-butyl alcohol. QM simulations. The peculiarities of combination bands of νOH mode could be noted. This mode couples strongly to a number of other modes and gives a distinct spectral signature between 5,500 and 4,000 cm^{-1} (**Figure 5**). The specificity of phenol ring modes was also concluded. Good separation of the fundamental bands in the MIR region translates into NIR features with well-resolved sharp peaks appearing throughout lower wavenumbers (5,500–4,000 cm^{-1}). This should be considered an uncommon observation in NIR spectra and also in elementary molecules e.g., methanol rather manifest broadened bands (**Figure 2**). The established signature allows to discriminate easily between different kinds of alcohols (aliphatic, aromatic) and to identify an OH group attached to an aromatic ring (Beć et al., 2018a). It should be noted that the accuracy of VPT2 simulation is lower for the 2νOH peak in general, but in the case of cyclohexanol it was by far inadequate (**Figure 5A**). The reasons for this are well-understood and will be discussed in detail in the present review.

Investigations of Intermolecular Interactions

NIRS manifests unique suitability for investigating intermolecular interactions, e.g., hydrogen-bonding. Not without reason, this aspect is strongly focused in physicochemical NIRS (Czarnecki and Ozaki, 1999; Czarnecki et al., 2000, 2010; Czarnecki, 2003; Czarnecki and Wojtków, 2004; Michniewicz et al., 2007; Gonjo et al., 2011; Tomza and Czarnecki, 2015). The potential of QM simulations has long been utilized in MIR and Raman studies. On the contrary, NIRS lacked such powerful support due to practical limitations, as explained earlier. The cyclic dimer of carboxylic acids, e.g., formic acid or acetic acid, has frequently been considered a prototypic system of the hydrogen bonded complex. Beć et al. have recently presented a combined experimental and computational NIRS study of acetic acid in a CCl_4 solution (Beć et al., 2016c). The focus was on the spectroscopic properties of the cyclic dimer, which is strongly stabilized and persist as the major form throughout a widely variable concentration. The QM simulation has reproduced the majority of experimental NIR bands; however, a distinct exception was observed. The binary combination bands involving the stretching and bending of OH modes had a very strong calculated intensity, resulting in the appearance of two sharp and well-resolved peaks in the simulated spectrum. In contrast these are clearly absent in the experimental NIR lineshape. However, prominent elevation of the baseline is apparent in the NIR spectrum of soluted acetic acid, visible between 6,500 and 4,000 cm^{-1} and extending below. The following hypothesis was proposed in the article; the aforementioned combination bands undergo a spectral shift and broadening as a hydrogen-bonding effect; similar effects are well-known in MIR spectra. These two particular simulated combination bands were then fitted to the experimental spectrum to reflect the baseline contribution. Such treatment significantly improved the agreement with the experimental NIR spectrum (**Figure 6**). This investigation focused attention on the possibility of hydrogen bonding being manifested in the NIR spectrum through the baseline elevation (Beć et al., 2016c); such spectral feature is frequently observed in the NIR spectra of complex samples.

The basic study of acetic acid yielded a good understanding of NIR properties of simple carboxylic acids, which was helpful

in the further exploration of fatty acids. These fundamental biomolecules can be grouped into short- (SCFAs), medium- (MCFAs) and long-chain fatty acids (LCFAs). Fatty acids manifest various properties interesting from the point of view of physical chemistry, e.g., association mechanisms and hydrogen bonding properties (Iwahashi et al., 1995a,b; Matsuzawa et al., 2013). These systems are also extremely important in applied NIR studies involving any kind of biological samples, e.g., in hyperspectral imaging and analytical applications (Ishigaki et al., 2016a,b; Puangchit et al., 2017). For these reasons, SCFAs and MCFAs were examined by Grabska et al. in their two following studies (Grabska et al., 2017c,d). The former one focused on five SCFAs; saturated: propionic and butyric acid; and unsaturated ones: acrylic, crotonic and vinylacetic acid (Grabska et al., 2017c). These carboxylic acids are reasonably more complex than acetic acid, and are thus appropriate test subjects for verifying if the conclusions on acetic acids can be generalized onto larger carboxylic acids. Additionally, their complexity and mutual differences in the structure are perfect for investigating the NIR manifestations of the aliphatic chain structure and the existence of C=C bonds (Grabska et al., 2017c). Grabska et al. have selected these objects to capture the principle structural features of FAs (**Figure 7**). Those included: the difference between saturated and unsaturated SCFAs, impact of the location of C=C bond (medium-chain: crotonic acid; terminal: acrylic and vinylacetic acid), exclusive existence of either of the three following structural features: methyl (crotonic acid), sp^3 or sp^2 (terminal; acrylic acid, vinylacetic acid), methylene group (Grabska et al., 2017c).

The DVPT2 anharmonic vibrational analysis performed at the B3LYP/SNST+CPCM level of electronic theory involved full conformational analysis for each of SCFAs in the spectra simulation procedure (Grabska et al., 2017c). The final agreement between the simulated and experimental spectra as measured in the solution phase (0.05 M; CCl_4) was of high quality (**Figure 9**). The SCFAs case confirmed the previous observation; a baseline elevation phenomenon similar to that observed for acetic acid was clearly noticed (Beć et al., 2016c). Specific combination bands had higher intensities by orders of magnitude than those of the other NIR bands. Those combinations ($a + b$ and $a + c$) result from the following modes: (a) out-of-phase (or opposite phase) stretching and (b) in-plane bending modes, each time combined with (c) in-phase stretching mode of hydrogen-bonded OH groups. Through a band-fitting procedure analogous to that performed for acetic acid, a much better reproduction of the experimental spectra was accomplished. The stimulus for attempting the band fitting resulted from an undoubtful absence of any intensive sharp peaks in the experimental spectra, which were suspected to form the baseline elevation through band broadening. Grabska et al. also observed consecutive trends throughout several NIR subregions of SCFAs. Specific disparities in overtone and combination intensities were observed; the elucidated contribution of the CH_3 group was found to be fully consistent with experimental studies found in the literature. Unsaturated SCFAs revealed a specific impact on the NIR spectrum of the localization of C=C bond; e.g., terminal C=C imposing an appearance of sp^2 CH_2 group leads yields extremely specific, well-defined and intense NIR bands, observed at 6,172/6,131, 4,746/4,734, and 4,483/4,489 cm^{-1} for acrylic/vinylacetic acids, respectively. It was concluded that these bands are excellent structural markers because of high intensity and positioning in wavenumber regions where the bands of other structures remain absent (Grabska et al., 2017c).

A continuation of the above overviewed study was published soon after, in which the NIR features of two MCFAs, saturated hexanoic and unsaturated sorbic acid, were examined (Grabska et al., 2017d). Those molecules exhibit distinct differences in the NIR region observable from a very high dilution (minimal self-association) to a more concentrated solution (with the domination of the spectral bands from cyclic dimers; **Figure 7**). For both cases, accurate spectra simulation yielded a comprehensive explanation of the observed features. Evidence showed that the shape of NIR spectra is similar through a widely varying concentration; this holds even in neat liquid (hexanoic acid) and powder (sorbic acid) (Grabska et al., 2017d). These findings were consistent with previous ones, as reported for acetic acid and SCFAs (Beć et al., 2016c; Grabska et al., 2017c). The three discussed studies (Beć et al., 2016c; Grabska et al., 2017c,d) indicated that theoretical NIR biospectroscopy may become

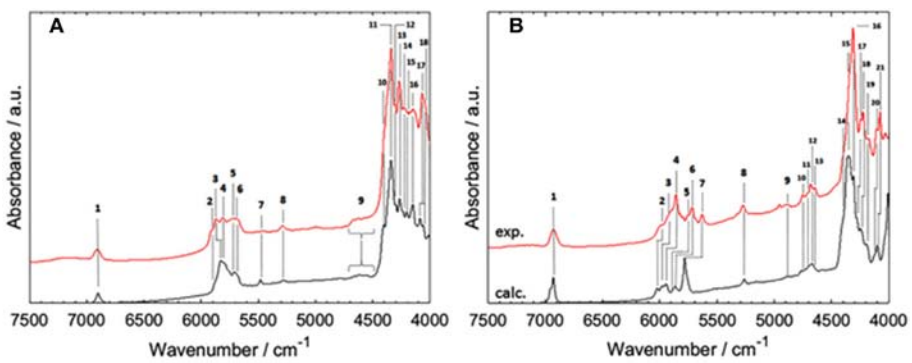

FIGURE 7 | Band assignments proposed for NIR spectra of MCFAs in medium to high concentration (CCl_4); **(A)** hexanoic acid, **(B)** sorbic acid. Reprinted with permission from Elsevier (Grabska et al., 2017d).

feasible as small and medium-sized biomolecules are within the potential for accurate NIR simulations. Further expansion onto more complex objects (e.g., LCFAs, lipids, proteins, nucleic acids) may be anticipated in the foreseeable future. So far, the reported accomplishments in theoretical NIRS of small biomolecules were successfully employed for the interpretation of NIR images of biosamples (Puangchit et al., 2017).

Other Examples of NIR Simulations in Physical Chemistry

Isotopic substitution has definitely been a key phenomenon remaining in the center of attention of vibrational spectroscopy. It gives a prominent spectral signature; primarily significant spectral shifts (Jaffe, 1987; Davis et al., 1996; Workman and Weyer, 2007). For this reason, it has been one of the most potent tools of classical spectroscopy used for band assignments. One can relatively easily follow the spectral changes resulting from specifically arranged isotopic substitutions, e.g., through the deuteration of an OH or other functional groups in simple molecules. In this way, the corresponding spectral variability may be comprehended relatively easily even in the NIR region. However, an imperfect partial substitution (e.g., the existence of CX_3 groups, where X=H,D are distributed randomly) resulting from a spontaneous isotope equilibration or faulty synthesis leads to significant difficulties in interpreting an NIR spectrum. Such random forms are impossible to be isolated from the sample, and thus, no reference spectrum of any of such forms can be recorded. In this case, spectra simulation is an extremely potent tool, as recently demonstrated by Grabska et al. In their comprehensive study of methanol and its deuterated derivatives, they examined all isotopomers of methanol molecule by simulating their NIR spectra (**Figure 8**; Grabska et al., 2017b). Through this, they successfully identified randomly substituted species found in two commercial samples of CH_3OD, and they directly monitored different levels of contamination by random isotopomers of methanol molecule in NIR spectra. Such an achievement would be out of reach in classical spectroscopy. Additionally, the anharmonic QM simulation yielded comprehensive band assignments in the NIR spectra of the four major methanol isotopomers, CH_3OH, CH_3OD, CD_3OH, and CD_3OD. These compounds have routinely been employed in physicochemical NIRS. Grabska et al. also included vibrational transitions up to three quanta in their computational study. The resulting simulated spectra included first and second overtones as well as binary and ternary combinations (Grabska et al., 2017b). This move gave an opportunity to confirm an earlier assumed non-essential loss of spectral information in NIR spectra modeling when only first overtones and binary combinations are considered. The conclusion that a practical restriction of the simulation to two quanta transitions (first overtones, binary combinations) could earlier been only assumed, e.g., such simplification in the simulated spectra of butanols did not prevent an excellent agreement with the experimental bands (**Figure 4**). On this occasion, the study of methanol and deuterated derivatives confirmed that the loss of up to ca. 20% of spectral information may be anticipated. This estimation

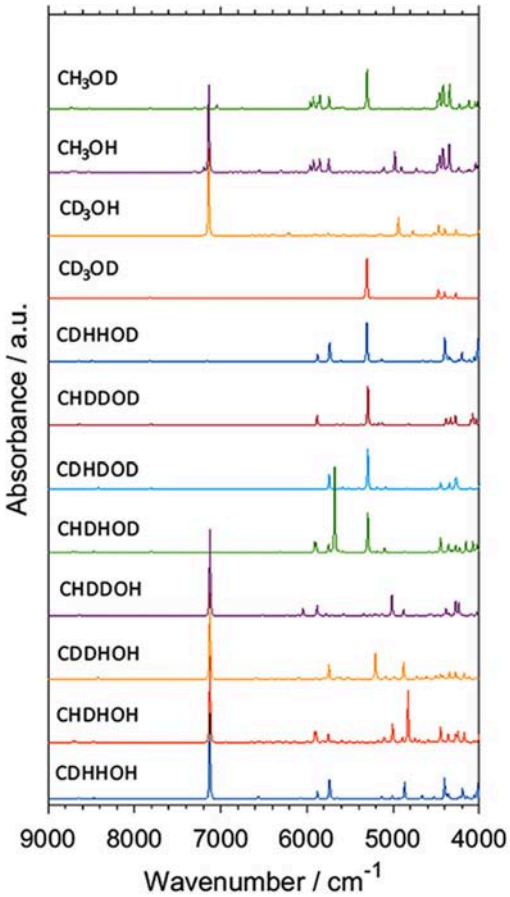

FIGURE 8 | Simulated NIR spectra of CXXXOX (X = H, D) molecules. Reprinted with permission from Grabska et al. (2017b). Copyright 2017 American Chemical Society.

was based on the relationship between the summed integral intensity of the calculated bands. The lost (or omitted) calculated spectral information is distributed among multiple yet weak bands and remains effectively "diffused" over the wavenumber axis. Hence, second overtones and ternary combinations are not essential for NIR spectra comprehension. This approximation holds unless ones would want to examine the upper NIR region, over 7,000 cm^{-1}. These wavenumbers have typically been rather rarely focused on in both physicochemical and analytical NIRS. However, upper NIR is the working region of some new miniaturized NIR instruments (Kirchler et al., 2017b). Thus, an additional ability to model second overtones and ternary combinations should be of increasing importance in the upcoming studies.

Worth emphasizing is the fact that QM calculations deliver a clear image of the intrinsically complex nature of NIR spectra. Although it has long been known, nowadays simulated spectra reproduce it accurately and visualize it straightforwardly. A good example of the NIR band overlay was provided by Grabska et al. in the case of vinylacetic acid (**Figure 9**; Grabska et al., 2017c). A common intensity scale of all bands depicted in **Figure 9**

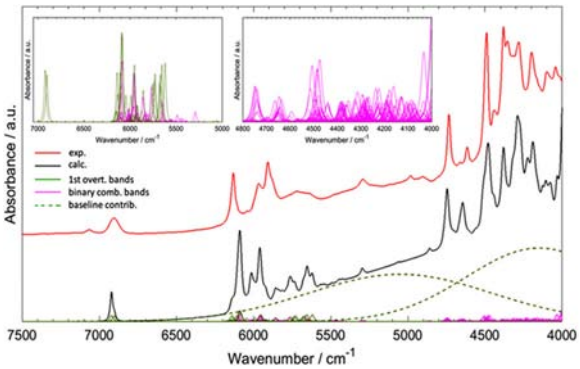

FIGURE 9 | Convolution of NIR bands on the example of spectra simulation for vinylacetic acid. All bands are presented in common intensity, note an extensive band overlay. Reprinted with permission from Grabska et al. (2017c). Copyright 2017 American Chemical Society.

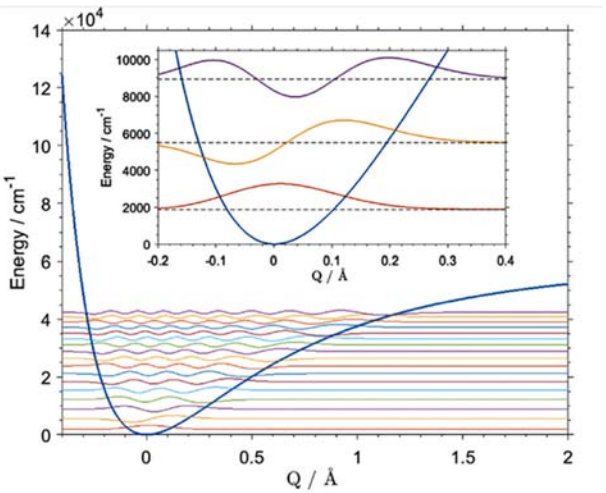

FIGURE 10 | Vibrational potential and vibrational states [B3LYP/6-311G(d,p)] of the OH stretching mode of the main (equatorial-gauche) conformer of cyclohexanol. Reprinted with permission from Elsevier (Beć et al., 2018a).

adequately demonstrates the extensity of band overlapping. Despite the complexity of that and similar NIR spectra, QM simulation reproduced it accurately including very complex region of 5,000–4,000 cm^{-1}, where the maximum overlay occurs due to appearance of the majority of binary combinations therein (Grabska et al., 2017c).

Highly Accurate Modeling of Single-Mode Anharmonicity

Generally applicable anharmonic computational schemes, e.g., VPT2 or VSCF, through simplifications are affordable enough to be used for the calculation of a large number of transitions, e.g., first overtones and binary combinations of all modes (Beć et al., 2017). The general methods are highly useful in the simulation of an entire NIR spectra as overlapping of the manifold bands in this region would make it extremely difficult to rely on any arbitrary selection of particular modes. Exceptions can be found though, e.g., 2νOH band most often appears as a single peak at least in the absence of molecular association (Czarnecki et al., 2015; Beć et al., 2016a). At the same time, as a highly anharmonic mode it is frequently described inadequately by VSCF or VPT2 approaches. These methods acquire their efficiency by approximating the anharmonic potential on a possibly lowest number of energy evaluations. Thus, effectively they "capture" a limited amount of anharmonicity, which may be enough in most cases, but not necessarily, e.g., when the mode deviates from the harmonic oscillator to a certain degree (Beć et al., 2017). Several attempts to improve accuracy have been made e.g., by transformation of the vibrational coordinates; this remains an active field of research (Yagi et al., 2012; Thomsen et al., 2014). The application of VSCF or VPT2 calculations to highly anharmonic modes may yield unreliable results. Particularly troublesome cases may be addressed through a detailed study of the single-mode anharmonicity through multi-point energy evaluations, and solving the corresponding time-independent Schrödinger equation. With an adequately large number of evaluation points, the vibrational levels can be derived with very high accuracy (Gonjo et al., 2011; Yagi, 2016; Schuler et al., 2017).

A number of approaches to the described vibrational problem exist. The differences between them often results from various numerical methods being employed for solving the matrix differential equation in the eigenvalue problem (Schuler et al., 2017). These computations are often used in NIR physicochemical studies, where the precision of the calculation of a certain mode is essential. For example, Beć et al. recently showcased the potential of improving the quality of simulation of cyclohexanol in NIR (**Figure 10**; Beć et al., 2018a). In that case, the VPT2 method erroneously reproduced the 2νOH band, yielding a very high error on the wavenumber of the equatorial-*trans* form, the major conformer of the molecule. Consequently, a splitting of the 2νOH band appeared in simulation while it is absent in the experimental spectrum (Beć et al., 2018a). Dense grid-point probing [B3LYP/6-311G(d,p)+CPCM(CCl_4)] of the vibrational potential along the OH stretching normal coordinate was carried out for the two leading conformers of cyclohexanol (Beć et al., 2018a). The generalized matrix Numerov method was used in solving the time-independent Schrödinger equation. By capturing the majority of anharmonicity, the vibrational levels were obtained with effectively absolute accuracy (<1 cm^{-1}). This means that vibrational analysis was not a source of any meaningful error in itself. A reduction in the anharmonic vibrational analysis imprecision is essential, as it is sometimes a source of significant error (Schuler et al., 2017). However, the final inaccuracy vs. the experimental value is still affected by a number of other unavoidable factors, e.g., error on electronic energy or simplification of the molecular model such as single molecule calculations, implicit solvent models, etc. (Schuler et al., 2017). Luckily, that kind of error is frequently equal between similar molecules, e.g., the two cyclohexanol conformers. Effectively, high accuracy in relative sense in comparative studies is possible due to precise reproduction of the wavenumber differences existing between those systems.

Beć et al. evidenced this circumstance well as they obtained an exact match of the splitting between 2νOH among the two conformers of cyclohexanol (calculated 30 cm^{-1}, experimental 27 cm^{-1}). By contrast, that value was predicted erroneously by VPT2 as 260 cm^{-1} (Beć et al., 2018a). Obviously, such quality of prediction requires large computing expense. The grid density may, however, be flexibly adjusted, which would allow for e.g., the affordable examination of larger molecules.

A highly accurate determination of vibrational states and transition intensities was performed e.g., in systematic examinations of subtle spectral variations due to certain substituents (Takahashi and Yabushita, 2013) or solvent effects (Futami et al., 2011, 2012; Gonjo et al., 2011) in NIR and MIR. For example, Gonjo et al. studied solvent effects in vibrational spectra of phenol and 2,6-dihalogenated derivatives (Gonjo et al., 2011). In this particular case, a high environmental sensitivity of the OH stretching mode delivered valuable spectral information; however, because of a high anharmonicity, this information is difficult for elucidation and accurate computations are essential. They examined fundamental, first-, second-, and third overtones by including broad spectral region, VIS, NIR, and MIR (15,600–2,500 cm^{-1}). Such a wide aim necessarily required an accurate solution, particularly for the higher overtones. Therefore, the νOH vibrational potential was probed with a dense step (0.02 q_0; −0.7 to 1.0 q_0) using a relatively high level of electronic theory [B3LYP/6-311++G(3df,3pd)] for accurate energy evaluations; the vibrational problem was solved through Johnson's approach (Johnson, 1977). Implicit solvation by means of the Isodensity Polarizable Continuum Model (IPCM) allowed the reproduction of the experimental effects observable for phenol, 2,6-difluorophenol, 2,6-dichlorophenol, and 2,6-dibromophenol in different solvents (*n*-hexane, CCl_4, $CHCl_3$, CH_2Cl_2). Gonjo et al. concluded a "parity" in relative intensities over the sequences of transitions and they suggested that an intermolecular OH...Cl hydrogen bond between phenols and the solvent is responsible for that phenomenon (Gonjo et al., 2011). A similar problem was further investigated by Futami et al. for pyrrole (Futami et al., 2011). An accurate modeling of single-mode anharmonicity also enabled studies on the influence of the solvent's dielectric constant on X-H stretching mode in the solution phase, as reported by Futami et al. on the example of HF as a prototypic polar molecule (Futami et al., 2012). The computations [B3LYP/6-311++G(3df,3pd) and CCSD/aug-cc-pVQZ levels; IPCM solvent approximation] elucidated the potential and dipole moment function variations in response to the changing solvent's dielectric constant. The investigation of the solvent effect in NIR and IR was continued by Chen et al. (2014); in this case, C=O stretching vibrations in acetone and 2-hexanone were examined.

The formation of X-H...B hydrogen bonding induces significant changes to the potential curve, vibrational states and transition intensities of the stretching X-H vibration. Due to the high anharmonicity of this mode, accurate theoretical methods as discussed in this section are essential. This was demonstrated by Futami et al. on the example of the pyrrole, pyridine, and pyrrole–pyridine complexes (Futami et al., 2009). The experimental observation of non-bonded pyrrole reveals a well-resolved 2νNH peak at 6,856 cm^{-1}; yet, the band is absent in the pyrrole–pyridine complex. A computational study explained that, in the complex the transition dipole moment is remarkably reduced for the first overtone mode of the hydrogen-bonded NH group (Futami et al., 2009). Continued further by Futami et al., other complexes featuring NH...π hydrogen bonding, e.g., pyrol-ethylene and pyrrole-acetylene systems, were evidenced to follow the above pattern (Futami et al., 2014).

Toward Feasible Modeling of NIR Spectra of Complex Systems and Biomolecules

Biomolecules feature a largely increasing importance in current spectroscopy in response to the strong stimulus for boundary-crossing research e.g., with focus on medicinal applications Jue and Masuda (2013). This also holds for NIRS, which is useful for investigations of biomaterial owing to its capability of studying moist samples. As it was well-explained throughout this review so far, biomolecules are complex systems which prove to be a particular challenge for theoretical NIRS. It is, therefore, of high importance to advance toward efficient NIR simulations of biomolecules. Because of this, recently matured VPT2 routines (DVPT2/GVPT2) seem to be the most promising due to their favorable cost-to-accuracy ratio (see section Fundamentals of Theoretical NIRS). Among the major kinds of biomolecules, long-chain fatty acids (LCFAs) have the advantage of forming better-defined structures, due to the tendency of carboxyl groups to form cyclic dimers strongly stabilized through dual hydrogen-bond (see section Investigations of Intermolecular Interactions). LCFAs feature protracted aliphatic chains (13–22 carbons); those most commonly appearing (e.g., oleic acid or palmitic acid) have chains with 15 to 22 carbons. They exist in all kinds of biological matter, either as the constituents of lipids or as free fatty acids (FFAs). They are the second energy source of the animal body and are also part of the chemical composition of several vegetable oils (Zielinska, 2014). They also suit a wide range of industrial applications, thus remaining the focus of NIRS in pharmaceutical (Ahmad, 2017), cosmetics (Białek et al., 2016), and food industries (Wood et al., 2003). For these reasons, the relevancy of these biomolecules in the context of NIRS is very high. Hence, LCFA molecules suited as perfect objects for the breakthrough study as reported recently by Grabska et al. (2018). A selection of six compounds, saturated (palmitic, stearic, arachidic) and unsaturated (linolenic, linoleic, oleic) acids, was investigated by experimental/theoretical NIRS. These examinations were aimed at providing an in-depth explanation of the spectral origins, their relationships to the chemical structure, in particular the impact of alkyl chain's saturation, as well as deeper insights into anharmonicity of the most important vibrational modes in these molecules (Grabska et al., 2018). Two separate computational approaches were used in this study. The first one, DVPT2, was an effective way to reproduce the entire NIR spectra and proved that the cost-effectiveness of the method is adequate even for biomolecular studies (Ozaki et al., 2017). The accurate reproduction of

the NIR lineshapes proved that the approximation of inter-modal anharmonicity, i.e., coupling between vibrational modes, in DVPT2 retains adequate quality even for the molecular systems with an overwhelming number of such couplings; the number of binary combinations surpassed 66,000 for the dimeric molecules of LCFAs (Beć and Grabska, 2018; Grabska et al., 2018). This fact also reflects the exponentially increasing complexity of the NIR spectra with the size of a molecule. The resulting combination band overlay creates substantial difficulty in elucidating certain spectra-forming factors and comparing specific features, e.g., the impact of the saturation of LCFAs. For this reason, Grabska et al. presented a clearer and more accessible illustration of the spectral contributions in the form of heatmap (**Figure 11**). These maps reflect the level-of-influence of selected modes of interest, arbitrarily grouped in such a way that the important factors could be easily assessed. The quality of simulation allowed for unambiguous assignment of all NIR bands and also to differentiate clearly between saturated and unsaturated LCFAs. Further progress in this field is strongly promoted as it finds immediate application in NIR biospectroscopy and imaging (Grabska et al., 2017c,d; Puangchit et al., 2017).

Theoretical NIRS in Aid of Analytical Applications

Bio-significant molecules remain near the center of attention of applied NIRS. Qualitative and quantitative analysis of natural products (e.g., raw biomaterials, intermediate and final products) is a strongly developing field of applications (Huck, 2014, 2016a); this fact focuses attention on biomolecules. NIRS in hyphenation with chemometrics (multivariate analysis; MVA) uses rich chemical information entangled in the NIR spectrum of complex samples and correlates it with the chosen property of sample (Ozaki et al., 2006). Despite practical effectiveness, the procedure is performed in black-box from the point of view of physical chemistry. Molecular and vibrational background phenomena remain transparent in this routine. It has been a necessity for analytical NIRS to evolve despite such hindrance. The concept of incorporating chemical band assignments into chemometrics appeared in literature (Westad et al., 2008) with the aim to improve the analytical performance of NIRS. However, this idea has not been truly employed further. The lack of readily available high-resolution deconvolution of the spectra, which would additionally offer an ability to assign the resolved contributions was the major problem here. QM simulation of NIR spectra bears a strong potential to finally reactivate this extremely promising line of research. Recent time has seen attempts to adopt theoretical NIRS for the benefit of analytical studies (Schmutzler et al., 2013; Lutz et al., 2014a; Kirchler et al., 2017a; Kirchler et al., 2017b).

The first of such an example appeared in 2014 as Schmutzler et al. reported their design of an analytical pathway which employs NIRS/MVA for the effective quality control of apples (Schmutzler et al., 2013). This contribution had a substantial impact on the quality control of food/agricultural products, as it proposed entirely automatic, non-destructive

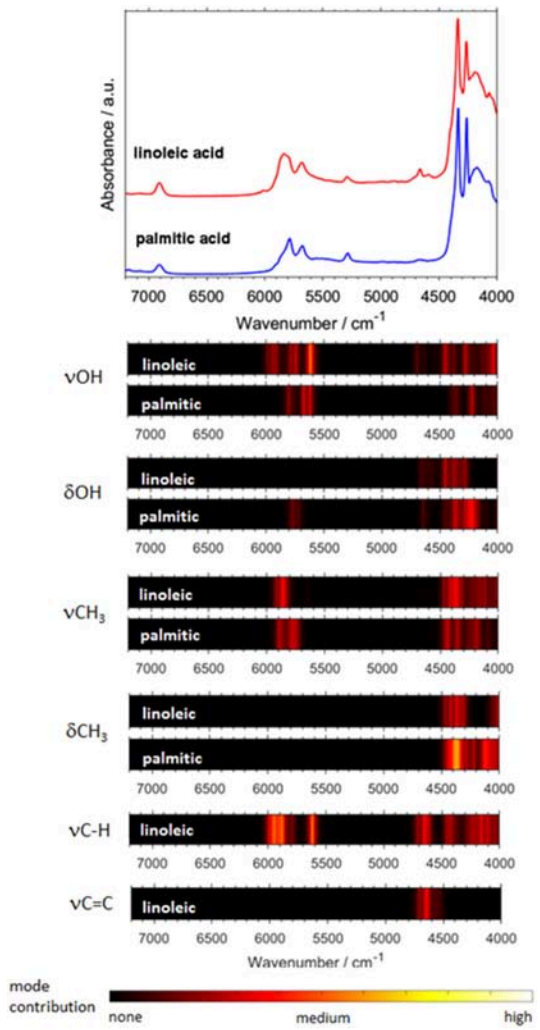

FIGURE 11 | Generalized contributions into NIR spectra of the selected types of modes involved in the binary combinations as uncovered by quantum mechanical spectra simulation of linoleic and palmitic acid. NIRS instrumentation for the analysis of apples. It utilized the principle of surface scanning in order to average the sample's surface inhomogeneity and a fiber probe for the convenient arrangement of the analytical instrumentation. From the point of view of the present review, it should be emphasized that this work also employed QM spectra simulation in the procedure, resulting in a first attempt of creating a computer-aided NIRS analytical spectroscopy. In this study, the point of interest was put on malic acid, a dicarboxylic acid existing on apple surface, which is a highly informative marker of the fruit's general condition (Schmutzler et al., 2013).

For the anharmonic vibrational analysis of malic acid, Schmutzler et al. used PT2-VSCF, a second-order perturbation corrected VSCF scheme, which features an improved quality of prediction of inter-modal anharmonicity (Schmutzler et al.,

2013). The electronic structure was determined at the Møller-Plesset MP2 level of theory with a 6-31G(d,p) basis set; an implicit approximation of aqueous solution through CPCM solvation model of water was included. L- and D- chiral isomers of malic underwent anharmonic treatment and theoretical bands up to three quanta, second overtones and ternary combinations, were obtained. Simulated bands compared to the experimental NIR spectrum are presented in **Figure 12**. The experimental features were reflected in the simulation qualitatively, correctly yielding comprehensive band assignments. According to the authors, the assumed simplifications i.e., quartic force field approximation, relatively simple basis set, implicit solvation model, could decrease the accuracy of their simulation. They also concluded that the PT2-VSCF approach involves only moderate computational efficiency which is further lowered by unfavorable scaling with molecule size. As they pointed out, this considerably hinders the feasibility of studying larger molecules using similar methods (Schmutzler et al., 2013). Notwithstanding this, simpler molecules such as malic acid may successfully undergo PT2-VSCF treatment in aid of analytical NIRS. Accordingly, Lutz et al. applied a similar computations scheme in their development of miniaturized NIRS for gasoline content analysis and quantification (Lutz et al., 2014a). Several kinds of compounds were needed to be considered, in order to represent the chemical residents in gasoline. Consequently, they examined ethanol (oxygenated fuel additive), *n*-octane (linear alkane representative), toluene (aromatic and branched/alkyl-substituted aromatic hydrocarbons) and ethyl *tert*-butyl ether (ethers and branched/alkyl-substituted aliphatic hydrocarbons and also oxygenated fuel additive). These systems retain relative simplicity and are suitable for PT2-VSCF anharmonic analysis without an apparent need for simplifications. This even allowed for the employment of the post-Hartree-Fock method for the determination of electronic energy, as the MP2 method together with TZVP basis set were used. Thus, the level of electronic theory was considerably higher than in the study of malic acid. In this case, Lutz et al. succeeded in inserting QM simulation into their analytical study, and the benefits included comprehensive band assignments, vastly improving the qualitative discrimination of the gasoline residents (Lutz et al., 2014a).

Phytoanalysis is one of the fields in which analytical NIRS becomes the tool-of-choice in qualitative and quantitative analysis (Huck, 2014, 2016a). The phytopharmaceutical industry requires highly robust methods of analysis as natural products are complex and susceptible to content variation. Hence, an independent insight from the NIR simulation brings in a substantial value, e.g., by allowing the qualitative evaluation of analyzed data or the comprehension of chemical factors influencing chemometric analysis. Recently, Kirchler et al. showcased the potential of combined theoretical/analytical NIRS in two of their subsequent feasibility studies on the analytical performances of miniaturized NIRS in quantifying rosmarinic acid (RA) in *Rosmarini folium* (Kirchler et al., 2017a,b). In various traditional plant medicines, RA is the primary active compound with therapeutic and antioxidant properties. As a relatively complex molecule (42 atoms; 188 electrons), it is somewhat expensive to obtain the anharmonic force field. For a similar reason, the resulting NIR spectrum involves numerous convoluted bands. This stems from a high number of binary combinations (7,140 in total), and naturally, a similarly substantial amount of intermodal couplings required to simulate the NIR spectrum of RA. To achieve the best cost/accuracy balance, the DVPT2 approach at the B3LYP/N07D level of electronic theory were employed for this task (**Figure 13**). This selection offers good efficiency without any essential accuracy compromise. As showcased in the case of RA, it delivered a qualitatively correct result and may be useful in simulating large molecules. A simplified treatment of the RA molecule in a vacuum did not reduce the quality of simulation exceedingly; manifestations of intermolecular interactions e.g., 2νOH band broadenings could be easily identified in the experimental spectrum with the availability of a clear image resolved from QM simulation. Additionally, the

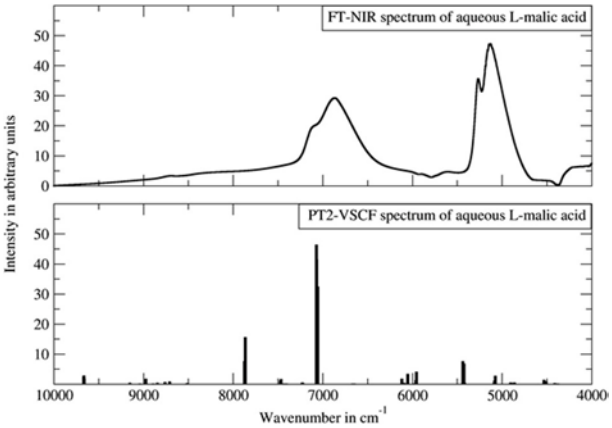

FIGURE 12 | The experimental FT-NIR spectrum of aqueous malic acid in comparison with the PT2-VSCF derived line spectrum. Reprinted from Schmutzler et al. (2013). Reprinted with permission from Nova Science Publishers, Inc.].

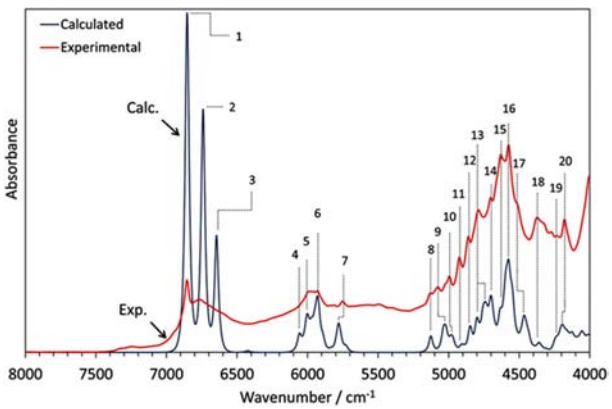

FIGURE 13 | The experimental (powder) and theoretical NIR spectrum of rosmarinic acid obtained in anharmonic GVPT2//DFT-B3LYP/N07D simulation (Kirchler et al., 2017b). Reproduced by permission of The Royal Society of Chemistry.

baseline elevation effects could also be understood, much like the effects observed previously for carboxylic acids (Grabska et al., 2017c,d). These accomplishments yielded full comprehension of the NIR spectrum of RA, leading to detailed band assignments (**Figure 13** and **Table 2**). These findings could then be used by Kirchler et al. for gaining a better understanding of the variability of PLS regression coefficients vectors assembled for the data originating from different NIR spectrometers with particular attention paid to miniaturized devices (Kirchler et al., 2017b). Different instruments yield different calibration curves, and different wavenumber regions manifest varying levels of influence in the regression. Kirchler et al. presented a state-of-the-art multi-method approach combining QM simulations, chemometrics (involving wavenumber discriminant methods, e.g., Moving-Window PLSR, MW-PLSR), and advanced methods of spectral analysis (Two Dimensional Correlation, 2D-COS; in particular, heterocorrelation elucidating spectral differences due to instrumental factors), indicating how modern analytical NIRS may be evolving in the foreseeable future (Kirchler et al., 2017b).

A more recent study confirmed the feasibility of the concept outlined above and went a step further in exploring how QM spectra simulations can be used to obtain new insight and physicochemical interpretation of the predictive models benefitting analytical applications (Beć et al., 2018b). Beć et al. investigated NIR properties of thymol with a handful of highly informative findings which would be otherwise unobtainable without accurate NIR simulation. Thymol is a phenolic constituent commonly found in a number of herbal plants, e.g., in a traditional plant medicine Thymi herba. Thymol strongly contributes to the general therapeutic properties of these herbs; e.g., by its anti-oxidant, anti-inflammatory, antiseptic (antifungal and antibacterial), antispasmodic, and immunomodulatory properties. Beyond its pharmaceutical significance, thymol is also an interesting molecule for spectroscopic investigations because of its vibrational features. The side groups attached to an aromatic ring may provide plentiful information on the spectra-structure correlations. An OH group commonly manifests a strong tendency to interact with the chemical neighborhood,

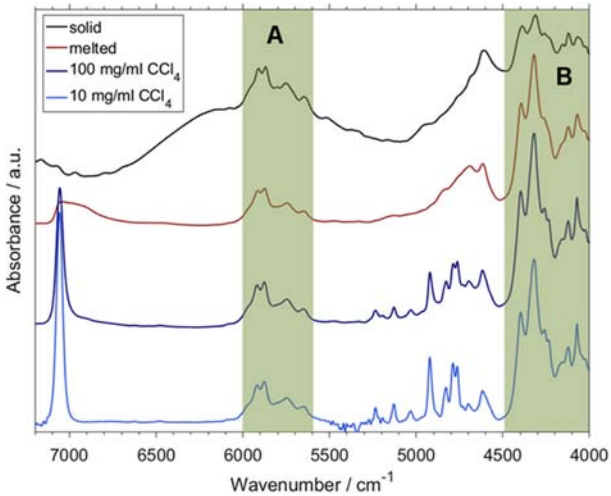

FIGURE 14 | A set of the experimental NIR spectra of thymol; solid state and melted (neat liquid, 333 K) as well as diluted in CCl_4 (100 and 10 mg mL^{-1} CCl_4). Highlighted are the wavenumber regions qualitatively independent of sample phase and concentration; **(A)** 6,000–5,600 cm^{-1}; **(B)** 4,490–4,000 cm^{-1} (Reprinted with permission from Beć et al., 2018b).

TABLE 2 | Band assignments in NIR spectrum of rosmarinic acid, based on GVPT2//DFT-B3LYP/N07D calculation.

	Wavenumber/cm^{-1}		Major contributions
	Exp.	Calc.	
1	6854.9	6,853	2νOH (ar)
2	6767.2	6,741	2νOH (ar)
3	~6680	6,645	2νOH (carboxyl)
4	~6044	6,056	2νCH (ar, aliph, in-phase)
5	5986.5	6,001	2νCH (ar, aliph, opp.-phase); 2νCH (ar)

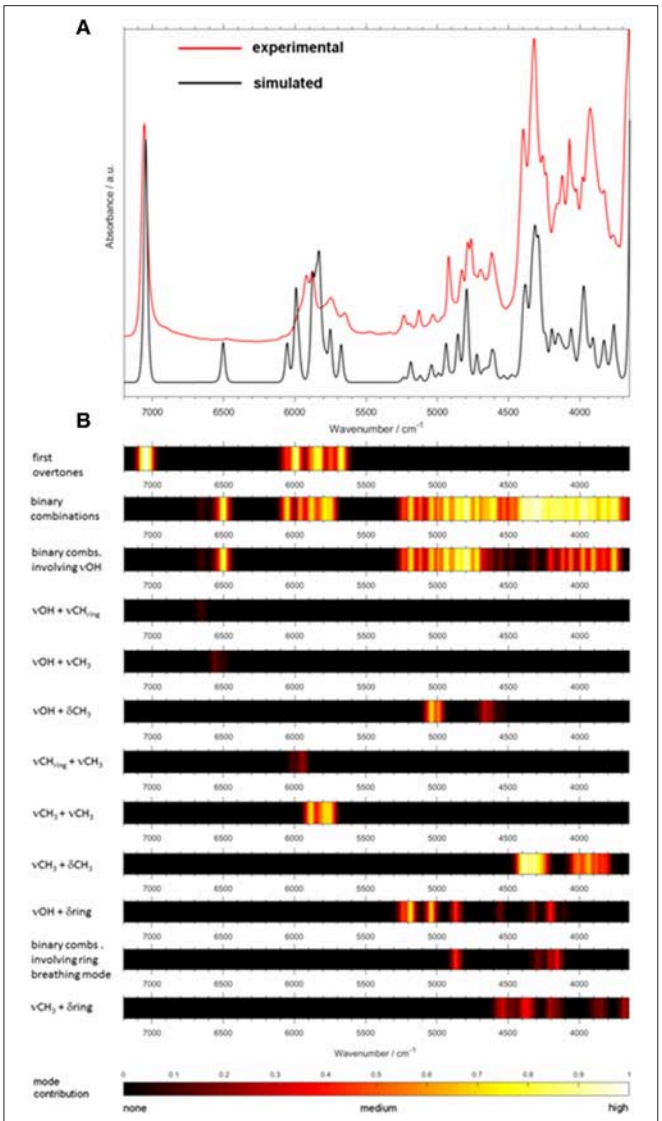

FIGURE 15 | The analysis of mode contribution into NIR spectrum of thymol (solution; 100 mg mL^{--1} CCl_4) based on the simulated data (DVPT2//DFT-B3LYP/SNST+CPCM). **(A)** Experimental and simulated outlines. **(B)** Contributions of selected modes as described on the figure (Reprinted with permission from Beć et al., 2018b).

e.g., to form a hydrogen-bond network. Due to this fact, and also because of the high anharmonicity of its vibrations, the existence of an OH group is a major spectrum-forming factor in NIR. For these reasons, the OH group has frequently been in the center of attention of NIR physicochemical as found in the literature (Czarnecki et al., 2015). The examination by Beć et al. elucidated a pattern of spectral variability following the sample state (solid and melted, neat liquid) and concentration (neat liquid and diluted in an inert solvent; CCl_4). Certain spectral regions in NIR manifested strong insensitivity to those properties of the sample (**Figure 14**; regions highlighted as A and B), while some others were observed to be clearly affected (**Figure 14**; all bands outside regions A and B). By QM simulations, the modes which stand behind that consecutive pattern could be fully identified (**Figure 15**). It was then observed that there exists a clear division between the highly relevant factors from the point of view of NIRS. Vibrations which are the most essential in shaping the NIR spectrum, and also sensitive to the changes in the sample property, were found to be consecutively discriminated by the PLS regression while quantifying the thymol content in a natural sample. Upon confronting these influential wavenumbers with the major features in the PLSR coefficients vector, it was found that the entirety of the spectral features identified as decisive in the PLSR model (5,860, 5,760; falling into the region A; **Figure 14** and 4,476, 4,418, 4,392, 4,368, 4,220, 4,128, and 4,092; cm^{-1}; belonging in the region B; **Figure 14**) originate from two insensitive to the concentration and sample state NIR sub-regions of thymol. These "invariant" regions contain CH_3 and aromatic CH bands. Surprisingly, the νOH mode, which is otherwise the most influential spectrum-forming factor (**Figure 15**), was largely omitted in the chemometric model. It was suggested that the sensitivity of the νOH mode to intermolecular interactions, manifested in NIR through significant band broadening, may be one of the responsible factors (Beć et al., 2018b). That promising study demonstrated well the need to further explore through a systematic investigation the underdeveloped area which appears at the connection between physical chemistry, theoretical NIRS and applied spectroscopy.

Other Applications, Arising Possibilities, and Remaining Challenges

As explored so far in the present review, the advent of feasible NIR spectra simulations has brought substantial gains to physical and analytical chemistry, both in basic and applied studies. The benefits for biomedical applications, e.g., NIR hyperspectral imaging (mapping) of biosamples could be evidenced as well (e.g., Huck, 2016a; Ozaki et al., 2017; Türker-Kaya and Huck, 2017). Deep penetration of the sample by NIR light, a consequence of the typically low absorptivity in this spectral region (see section Near-Infrared Spectroscopy. The Tale of an Ugly Duckling), forms a perfectly synergistic effect with the other values of NIRS (e.g., non-invasive character, low cost factor, wide applicability, superior time-to-result ratio), creating a strong stimulus for further development at the foundations of this technique (He et al., 2018; Wong et al., 2019). A question may arise on how in the nearest future theoretical and computational methods may become useful in these developments.

Several topics of the highest importance for spectral imaging presently remain a subject of intensive research, with the ultimate goal of introducing a feasible multi-modal imaging technique (He et al., 2018). A good example is the recent development of NIR radiation sources (He et al., 2015; Sun et al., 2017; Wong et al., 2019), with aim of being used in NIR fluorescence imaging, as thoroughly reviewed by He et al. (2018). The development studies for novel sources utilizing small-molecule fluorophores by Sun et al. (2017), high-efficiency NIR emitting materials coming from Wong et al. (2019), or ultralow-intensity NIR radiation source for drug delivery using upconverting particles

by He et al. (2015), could potentially see substantial gains from readily available theoretical and computational approaches. The new radiation sources which yield their superior capabilities from novel applications of bioinorganic chemistry, e.g., heavy transition metal and lanthanide complexes, could potentially benefit from computational simulations of the vibrational and electronic properties of such materials. At present, this remains a challenge, due to the complex electronic structure of transition metal atoms. Anharmonic simulations of vibrational spectra of such materials are prohibitively expensive; the computational expense associated with solving the vibrational problem in anharmonic approximation of advanced materials requires well-thought simplifications applied at several potential levels, ranging from the vibrational analysis itself (e.g., through reducing the grid density for total energy evaluations; Lutz et al., 2014c) to ingenious approaches to the electronic structure itself (e.g., Messner et al., 2014; Lutz et al., 2015). Vibrational spectra simulations of the metaloorganic complexes involving lighter metal ions can be found in recent literature.

As a good example, Lutz et al. have succeeded in the accurate reproduction of vibrational properties of the bioinorganic complex, trans-bis(glycinato)copper(II) (*cis* and *trans* isomers), in an aqueous solution (Lutz et al., 2013). They conducted quantum mechanical charge field molecular dynamics (QMCF-MD) studies, reporting the first QM simulations of organometallic complexes by this method. In hyphenation with experimental MIR spectroscopic data, they yielded accurate structural details of the investigated isomers as well as novel dynamic data, which has successfully been confirmed and extended by subsequent mid-infrared measurements. Although still being limited to a scaled harmonic approximation, according to Lutz et al. (2013), the spectroscopic results, critically assessed by adjacent multivariate data analysis (chemometrics), indicated an isomeric stability at ambient conditions, vanishing at elevated temperatures. Chemical systems containing metal ion significantly increase the computational complexity of the simulation procedure. Often, while maintaining careful error control, simplifications in the determination of the electronic structure may bring substantial gains in this regard. As recently demonstrated by Messner et al. in their investigation of the hydration of immobilized Fe(III), complexes of Fe(III) with methyl substituted iminodiacetate ($[Fe(MSIDA)(H_2O)_3]+$), as well as with methyl substituted nitrilotriacetate ($[Fe(MSNTA)(H_2O)_2]$) in aqueous solutions (Messner et al., 2014) by QMCF-MD, ingenious balancing between the cost-accuracy of the applied electronic method brings notable advantages, e.g., allowing to expand the parameters of molecular dynamics in return. By choosing a relatively fundamental Hartree-Fock (HF) approach, even over a much more robust MP2 method, Messner et al. accomplished essential progress in our understanding of the hydration structure and dynamics of metaloorganic complexes. Their effort has also been aimed at vibrational properties, while MIR spectroscopic data has been used as the reference. The understanding of the dynamics of metal cations and metaloorganic complexes in aqueous solution progressed further with ongoing studies continued within the same research group, e.g., as reported by Tirler et al. (2015) who once again applied, with high success, the quantum dynamic QMCF-MD simulation for the exploration of the stability of aqueous hexacyanoferrate(II) ion, in isolation as well as in the presence of potassium counterions. Further progress has been achieved in understanding the structure and dynamics of solvated metaloorganic complexes, when Tirler and Hofer investigated [MgEDTA]2– and [CaEDTA]2– systems (Tirler and Hofer, 2015). Furthermore, even more sophisticated systems, such as the aqueous 18-crown-6 (18C6) and strontium(II)-18-crown-6 (18C6–Sr) have been proven (Canaval et al., 2015) to be applicable to QMCF-MD treatment.

So far, simulation studies have repeatedly been evidenced to be of high value to metaloorganic chemistry, by delivering unique and highly desired information on the structure, vibrational features, dynamics, solvation, interactions, and stability of these important constituents of novel materials. It may be anticipated that these accomplishments will result in further progress in the computer-aided material design, which could find immediate application in the development of novel chromophores and enhancing NIR spectral imaging. On the other hand, the evolution toward anharmonic approximation may bring feasible studies of the properties of such materials in the NIR region. Currently, this remains hindered by the computational complexity introduced through anharmonic approximation, which indirectly also makes it difficult to fully incorporate a number of other effects, (e.g., relativistic effects Kondo et al., 2018; Madhu Trivikram et al., 2018), spin-orbit interaction (Gans et al., 2013), or vibronic coupling (Bloino et al., 2016). On the other hand, the exploration of the possible ways to increase the affordability of the relevant computational approaches (e.g., Lutz et al., 2014c, 2015; Messner et al., 2014) is ongoing, as explained above, and substantial advancements may be anticipated to occur in the near future.

FINAL REMARKS AND FUTURE PROSPECTS

Analytical NIRS relies on correlating the spectral variability with sample properties. The tools used for this purpose do not provide any understanding of these correlations, e.g., the parameters of the chemometric models have no immediately available physical interpretation. This creates a serious hindrance for applied NIRS from a conceptual, but also from a practical, point of view. For example, it has been shown that the structure of the PLS regression coefficients vector changes, e.g., between different spectrometers. Sensitivity to a multitude of different factors makes it difficult to elucidate the vibrational background of the analyzed spectral variability and the role of anharmonic effects. Theoretical spectroscopy offers substantial aid in answering the principle questions, which would be beneficial for both basic NIRS in the physicochemical context and in applied analytical spectroscopy.

Theoretical NIRS currently stands in a unique spot, where its usefulness to applied spectroscopy is far superior than the analogous relationships present in other kinds of vibrational spectroscopy. Nowadays, theoretical NIRS is still at a relatively early stage of development. It is an emerging field, which only

recently became more explored as the associated computational complexity had long been prohibitive. It was the current decade which witnessed advances in anharmonic theories, aided by ever-growing computer technology, which has enabled the feasible theoretical NIRS in connection with applied spectroscopy. As the number of studies in this area develops, the link between analytical and theoretical NIRS is being further strengthened; a clear trend in this evolution path is marking the anticipated further advancement. Focus of applied spectroscopy is on complex samples in which molecules remain under constant influence of the chemical neighborhood througha variety of intermolecular interactions, e.g., as in the discussed case of malic acid-water complex (Schmutzler et al., 2013). One should anticipate that in the near future research will be oriented to this direction, with more complex and interacting molecular systems, large biological systems and direct applications of theoretical NIRS in analytical routines. An even more coherent growth of theoretical near-infrared spectroscopy in close connection to analytical applications may be envisioned.

Advances in Sustainable Catalysis: A Computational Perspective

Matthew G. Quesne, Fabrizio Silveri, Nora H. de Leeuw and C. Richard A. Catlow*

School of Chemistry, Cardiff University, Cardiff, United Kingdom

The enormous challenge of moving our societies to a more sustainable future offers several exciting opportunities for computational chemists. The first principles approach to "catalysis by design" will enable new and much greener chemical routes to produce vital fuels and fine chemicals. This prospective outlines a wide variety of case studies to underscore how the use of theoretical techniques, from QM/MM to unrestricted DFT and periodic boundary conditions, can be applied to biocatalysis and to both homogeneous and heterogenous catalysts of all sizes and morphologies to provide invaluable insights into the reaction mechanisms they catalyze.

Keywords: green chemistry, computational chemistry, density functional theory, QM/MM, homogeneous catalysis, heterogeneous catalysis

INTRODUCTION

The challenge of moving toward a greener and more sustainable society will inevitably require the drastic transformation of many aspects of modern culture and economy, with all areas of resource management and production needing radical overhaul (Liu et al., 2015; Little et al., 2016; Bakshi et al., 2018). From a green chemistry standpoint this means the reengineering of chemical pathways that: (i) make the most efficient use of natural resources (Hellweg and Canals, 2014; Bakshi et al., 2015, 2018; Jaramillo and Destouni, 2015), (ii) reduce the volume of hazardous/polluting reagents and solvents (Clark et al., 2015; Clarke et al., 2018), and (iii) promote the substitution of fossil fuel resources with renewable alternatives (Gallezot, 2012; Wettstein et al., 2012; Sheldon, 2014, 2016; Den et al., 2018; Talebian-Kiakalaieh et al., 2018). Achieving all these goals will require the design of novel and efficient catalysts that are active under mild conditions and can be produced sustainably without leading to unacceptably high levels of toxic pollutants (Beletskaya and Kustov, 2010; Polshettiwar and Varma, 2010; Chua and Pumera, 2015; Egorova and Ananikov, 2016). However, before any of these new catalysts can be developed a fundamental understanding of the properties of the currently most efficient and environmentally sustainable options has to be obtained, in order to enable the design of their replacement (Campbell et al., 2016; Hutchings et al., 2016; Pelletier and Basset, 2016; Friend and Xu, 2017; Chen et al., 2018; Kornienko et al., 2018; Caddell Haatveit et al., 2019). Computational models have proved to be one of the most efficient and least resource heavy ways of obtaining such information and have now become an invaluable component in the field as a whole (Nørskov et al., 2009; Hansgen et al., 2010; Medford et al., 2015; Sutton and Vlachos, 2015; Greeley, 2016; Grajciar et al., 2018). In recent years, joint experimental and theoretical catalytic studies have become routine and have proven crucial to any fundamental understanding of catalysis at the molecular level, which will be underscored in detail in the proceeding example sections of this perspective (Hirunsit et al., 2015; Van Speybroeck et al., 2015; Yu et al., 2017; Kulkarni et al., 2018; Zhu et al., 2018).

Quantum Mechanical/Molecular Mechanics

Computational chemistry really came of age during the 1960s, with the advent of mainframe computers; however, early breakthroughs in approximating the wavefunction of many electron systems date back almost 30 years earlier with the development of the Møller-Plesset second-order perturbation wavefunction theory (MP2) (Møller and Plesset, 1934). One major and much more recent development was the applicability of density functional theory (DFT), especially after the incorporation of the gradient approximations into the exchange correlation function (Becke, 1993). However, not all DFT functionals are created equally and at the turn of the millennium John Perdew proposed a climbing scale coined the "Jacob's ladder" with pure GGA functional near the bottom and hybrid functionals close to the top (Perdew and Schmidt, 2001; Sousa et al., 2007). In practice, this often means that *in silico* homogenous catalytic systems, which are often modeled with hybrid functionals (Green et al., 2014; Wójcik et al., 2016; Wojdyła and Borowski, 2016; Delarmelina et al., 2017; Dabral et al., 2018), produce results that are closer to experimental values then those obtained when modeling heterogenous catalysts, where pure GGA are frequently the only efficient functionals to be implemented periodically (Hammond et al., 2012; Zhao et al., 2015; Ishikawa et al., 2017; Kunkel et al., 2018; Morales-Gar et al., 2018; Fang et al., 2019; Wang et al., 2019). Unfortunately, there is no universal functional and the most appropriate exchange–correlation term must be assessed on a system specific basis by benchmarking theoretically obtained electronic or catalytic properties to those observed experimentally (Laurent and Jacquemin, 2013; de Visser et al., 2014; Hickey and Rowley, 2014; Cantú Reinhard et al., 2016); additionally, the amount of Hartree–Fock component included in the exchange component of the most commonly used hybrid functionals can be modified to produce a better match between experimental and *in silico* values (Reiher et al., 2001; Walker et al., 2013). Increasingly, the importance of systematically benchmarking the functional of choice to experimentally determined properties of heterogenous catalysts is also becoming widely understood (Janthon et al., 2013, 2014; Quesne et al., 2018; Zhang et al., 2018). Implementing such well-benchmarked quantum mechanical techniques, has led to an explosion in studies that highlight fundamental aspects of the reaction mechanisms catalyzed by (i) enzymatic biocatalysts (Meunier et al., 2004; Li et al., 2012; Quesne et al., 2013; Blomberg et al., 2014; de Visser et al., 2014), (ii) homogenous catalysts (Kumar et al., 2010; Prokop et al., 2011; Neu et al., 2014; Sahu et al., 2014; Yang et al., 2016), and (iii) heterogenous catalytic materials (Alfredsson and Catlow, 2002; Sun and Liu, 2011; Cadi-Essadek et al., 2015, 2016; Quesne et al., 2018; Schilling and Luber, 2018; Silveri et al., 2019). Moreover, when such techniques are combined with classical molecular mechanics or dynamics, hybrid QM/MM cluster models can be constructed that act as relatively computationally inexpensive methods for studying large catalysts from microporous and mesoporous materials (O'Malley et al., 2016; Catlow et al., 2017b; Nastase et al., 2019) to heterogenous nanocatalysts (Xie et al., 2017; Lu et al., 2019) and are often especially useful during the study of enzymatic reaction mechanisms (Gao and Truhlar, 2002; Senn and Thiel, 2007, 2009; van der Kamp and Mulholland, 2013). Indeed, one of the initial motivations for the development of the QM/MM method in the 1970s was to investigate such biocatalyzed reaction (Warshel and Levitt, 1976); although, despite the techniques early development, it was not until much later that the methodology really came into its own and the technique started to become widely applied (Field et al., 1990; Rothlisberger et al., 2000). As previously mentioned, QM/MM methods are now being increasingly used to model heterogenous catalysts, for example in modeling catalytic process in zeolites (Nastase et al., 2019) and supported nano-catalysts (Xie et al., 2017; Lu et al., 2019). An illustrative example of one such ionic catalyst is shown in **Figure 1**, where a QM region with a circumference of 10 Å has been applied to a slab of magnesium oxide.

Most QM/MM studies begin with a crystal structure that is often deposited and stored online, whereby database of everything from zeolites (Baerlocher and McCusker, 2010) to enzymes (Berman et al., 2000) as well as the primitive cells of ionic material (Hellenbrandt, 2014) are available to researchers. Heterogeneous catalysts tend to be very ordered with relatively small primitive cells that can be optimized using a 3D periodic scheme (Ghorbanpour et al., 2014); as incorporated in codes such as VASP (Kresse and Furthmüller, 1996a), CASTEP (Clark et al., 2005), and CRYSTAL (Dovesi et al., 2014), prior to the preparation of a larger supercell for QM/MM treatment. However, even with heterogenous catalysts, there may be a need for some post-optimization modification of the crystal structure to introduce defects and active sites; as is often the case with zeolites whereby Brønsted acid sites need to be included, which involves substitution of silicon atoms by aluminum and charge compensation by protons (Sastre et al., 2002; O'Malley et al., 2016; Nastase et al., 2019). Conversely, large catalysts with disordered tertiary structures often require a far more extensive preparation protocol, which is especially true for enzymatic catalysts, since it is often impossible to crystallize an active enzyme/substrate complex and heavy atom positions need to be modified to create reactant starting structures (Quesne et al., 2014). Additionally, all residues need to be protonated because hydrogen atoms do not have enough electron density to be resolved accurately; which is typically done to a specific pH value with a PROPKA server (Dolinsky et al., 2007). Finally, since most crystallization techniques reduce the water content inside the protein core, a detailed molecular dynamics protocol needs to be run to solvate the model using one of the biomolecular force fields designed specifically for proteins (Oostenbrink et al., 2004; Wang et al., 2004; Brooks et al., 2009).

Once a working model of the catalyst and substrate is obtained, the large system needs to be split into a minimum of two regions. Typically, the much smaller region contains all the atoms that need to be describe quantum mechanically (QM region) and the other much larger region contains all the remaining atoms (MM region); which are described at a much lower level of theory, often with classical molecular mechanics. Since creating these regions may necessitate the breaking of either covalent or ionic bonds, an accurate description of the

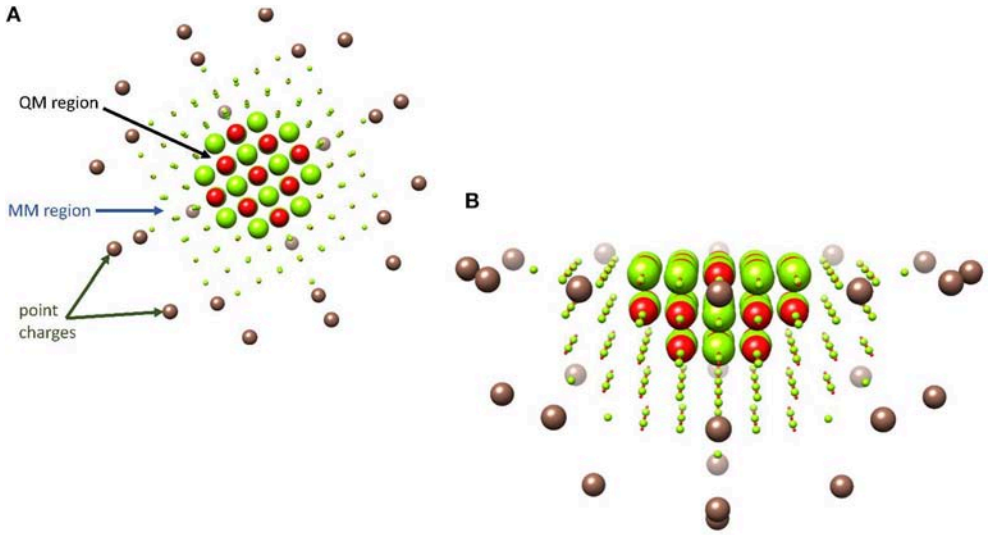

FIGURE 1 | Illustrative representation of a typical QM/MM set-up of an example metal–oxide, MgO. A QM region with a circumference of 10 Å is shown with large red and green spheres, with point charges colored brown. **(A)** Top–view from above the slab, **(B)** side–on from the slab edge.

interactions between different regions is critical for the correct electronic structure of the QM region. Currently the most common method for dealing with the valence issue in covalent systems, such as zeolites and biocatalysts, requires capping boundary atoms with hydrogen linkers (Senn and Thiel, 2009; Catlow et al., 2017a). When modeling ionic catalysts, interatomic potentials are often used to describe the MM region and an electrostatic embedding protocol is used to provide a countering polarizing environment to the ions at the border of the QM region (Bredow et al., 1996; Sokol et al., 2004).

Although, electrostatic embedding is also commonly applied to QM/MM models of covalent catalysts (Field et al., 1990) there is also the possibility of using a reduced mechanical embedding approach (Maseras and Morokuma, 1995). Both techniques model electrostatic interactions between atoms either side of the QM/MM boundary; however, MM charges are only included in the QM Hamiltonian with electrostatic embedding, which makes it the only appropriate methodology for ionic catalysts. In mechanical embedding protocols, electrostatic interaction between the two regions are assigned classically and so changes in the polarization of QM atoms due to electron transport (i.e., during a chemical reaction) is unaccounted for by changes in charge distribution (Chung et al., 2015). Importantly, the use of an electrostatic embedding protocol often produces results that are very sensitive to the choice of a given QM region, with convergence studies reporting that the absolute mean deviation between 40 different QM regions increased from 1.7 kcal mol^{-1} to ∼5 kcal mol^{-1} when moving from a mechanical to an electrostatic embedding protocol (Hu et al., 2011). Therefore, the use of an electrostatic embedding protocol may lead to less accurate results for the study of covalent catalysts in cases where the boundaries of the QM/MM regions are chosen poorly. This problem is negated in for example QM/MM case study reported here, where ChemShell was used as a platform to create quickly create several different QM regions for benchmarking and the boundary regions were very carefully chosen to only cut through sp^3 hybridized C–C bonds (Sherwood et al., 2003; Lu et al., 2019).

After a model of the catalyst is created, there are two major schemes for calculating the reaction landscape. Subtractive protocols are very commonly used in the study of reaction landscapes catalyzed by covalent catalysts, such as zeolites (Namuangruk et al., 2004; Vreven and Morokuma, 2006) and enzymes (Quesne et al., 2014; Wojdyla and Borowski, 2018). In two-layer subtractive protocols, only the QM region is capped with linker atoms because the whole system is also calculated at the MM level of theory, which would means that the MM energy of the QM region needs to be subtracted [$E_{MM}(\mathrm{QM_{region}})$] from the total energy to avoid double counting (see Equation 1). The QM/MM case study presented in this perspective utilizes the alternative additive approach, shown in Equation (2), whereby, only the MM region is calculated at the MM level of theory (E_{MM}). This negates the need for a subtraction step but requires the addition of a specific coupling term to describe the QM/MM border region (E_{border}), which includes bonding, electrostatic and Van der Waals interactions between the two regions (Sherwood et al., 2003). Importantly, when calculating using a mechanical embedding approach to calculate energy landscapes for covalent catalysts, it has been reported that both protocols should provide identical results (Cao and Ryde, 2018).

$$E^{total}_{QM/MM} = E^{whole}_{MM} + E_{QM}\left(QM_{region}\right) - E_{MM}\left(QM_{region}\right) \quad (1)$$

$$E^{total}_{QM/MM} = E_{MM} + E_{QM}\left(QM_{region}\right) + E_{border} \quad (2)$$

Other Computational Techniques

One of the main alternatives to the QM/MM technique for the study of reaction mechanisms catalyzed by enzymes involves the use of QM cluster models that focus on the biocatalyst's active site region and immediate surroundings. The models can consist of dozens to hundreds of atoms, which are all treated with a highly accurate level of computational theory. Generally, the majority of the substrate binding pocket is included with priority given to charged hydrophylic residues that form strong hydrogen bonds or π-staking interactions with either the substrate or co-factors, which inevitably are also included (Siegbahn and Crabtree, 1997; Borowski et al., 2004; Hernández-Ortega et al., 2014, 2015; Miłaczewska et al., 2018). Thus, these models should faithfully mimic substrate position as well as the enzyme's catalytic activity; however, the need to add geometric constraints to these models can sometime restrict substrate mobility. Of course there are many advantages and disadvantages to both techniques, which have been well discussed elsewhere (Blomberg et al., 2014; de Visser et al., 2014; Borowski et al., 2015; Quesne et al., 2016a). Molecular cluster approaches have also been used successfully to calculate adsorbate energies and simulate frequencies for many heterogenous catalysts (Haase and Sauer, 1994; Pelmenschikov et al., 1995, 1998; Zygmunt et al., 1998; Dangi et al., 2010); however, the neglecting of long-range Coulomb interactions as well as the lack of realistic steric constraints can reduce the effectiveness of such techniques for calculating reaction pathways. Dynamical approaches such as metadynamics (Barducci et al., 2011; Qian, 2012), umbrella sampling (Kästner, 2011), transition path sampling (Bolhuis et al., 2002) as well as many others (Meliá et al., 2012; Roca et al., 2012), can also be applied to catalyst reactivity, where they can be very advantageous in the study of free energy landscapes and rare-events, which is especially true for large systems where there are many degrees of freedom to be considered along with many energetically close "representative" transition states (Tsai et al., 2002). Metadynamics aims to sample the three–dimensional free energy surface of a reaction landscape using one of several "collective" variable associated with the transfer atom(s) (Laio and Parrinello, 2002; Iannuzzi et al., 2003; Ensing et al., 2005; Laio et al., 2005) and has been extensively applied to zeolite (Moors et al., 2013; Van Der Mynsbrugge et al., 2014; Dewispelaere et al., 2015; Hajek et al., 2016; Cnudde et al., 2017) and enzyme (Petersen et al., 2009; McGeagh et al., 2011; Lira-Navarrete et al., 2014; Raich et al., 2016; O'Hagan et al., 2019) catalyzed reaction. Such techniques work best when a reaction coordinate can be assigned to a simple set of collective variables that apply to distinct groups inside the reactant(s); however, in cases where the reaction path is uncertain more degrees of freedom can be explored using a transition path sampling protocol. Such methods incorporate Monte Carlo techniques into a molecular dynamical algorithm to locate a number of potential transition states connecting different minima (Bolhuis et al., 2002; Petersen et al., 2009) and have also been extensively applied to both enzyme (Swiderek et al., 2014; Althorpe et al., 2016) and zeolite (Lo et al., 2005; Bucko et al., 2009) catalyzed reaction pathways. Of course, the holy-grail of modeling is to drive the first-principles design of these very large macro-catalysts from the ground up using knowledge about their functional building blocks and related existing catalysts to predict the three-dimensional structure of the whole *in silico*. Exciting developments in this field are being developed for both microporous (Wells and Sartbaeva, 2015; Nearchou et al., 2018) and biological catalysts (Zanghellini et al., 2006; Kiss et al., 2013) and aim to explore a much larger structural space than exists in the naturally occurring catalysts, opening up the potential for novel route toward sustainable chemical reactions (Muñoz Robles et al., 2015; Rodríguez-Guerra et al., 2018).

Neither QM/MM methods nor large restricted cluster model techniques are required for small homogenous catalysts, where a reasonable gas phase system can often be created using all of the catalyst and substrate atoms (Draksharapu et al., 2015; Sahoo et al., 2015; Greer et al., 2019). However, this is often not the case for the computational study of heterogenous catalysts, which are most commonly investigated using a periodic treatment to enable proper description of the band structure of a solid (Blöchl et al., 1994; Kresse and Furthmüller, 1996a,b). Notwithstanding the increased use of many of the advanced techniques as mentioned above, for these materials it is still extremely common to use periodic boundary conditions to simulate an infinite solid surface (Grau-Crespo et al., 2003, 2006; Janthon et al., 2013). It is also important to note that QM/MM approaches can be especially unsuitable for calculating metallic catalysts that have extended states that are not localized to and extend beyond the QM boundary. Examples of such systems are discussed in the final section of this perspective, whereby, the electronic properties and catalytic activity of various transition metal carbides are modeled in reciprocal rather the real space. The only cases where an unrestricted, molecular, DFT type protocol may be warranted is either when the number of atoms in the solid state catalyst are too few for banding to occur (Abuelela et al., 2012; Liu and Lee, 2012; Feng et al., 2018; Zheng et al., 2018), or when a specific geometric feature such as an edge site in a strongly ionic or covalent catalyst is under investigation (Pelmenschikov et al., 1996; Chieregato et al., 2014; Pasini et al., 2014; Geng et al., 2018). The example sections that follow, provide case studies where all these techniques have been applied to a wide range of different catalysts and work to highlight the potential for improving the sustainability of various chemical protocols by computationally led "catalysis by design."

APPLICATIONS OF QUANTUM MECHANICS/MOLECULAR MECHANICS (QM/MM)

Green Biocatalysis of Terminal Olefins From Fatty Acids

It is widely recognized that there is an urgent need for the development of sustainable replacements to crude oil (Kerr, 2007; Shafiee and Topal, 2009; Murray and King, 2012). Sustainable generation of bio-fuels utilizing biocatalytic pathways from fatty acid feedstocks has been identified as a promising area of research (Stephanopoulos, 2007; Kung et al., 2012; Peralta-Yahya et al., 2012; Straathof, 2014). However, much of these biosynthetic

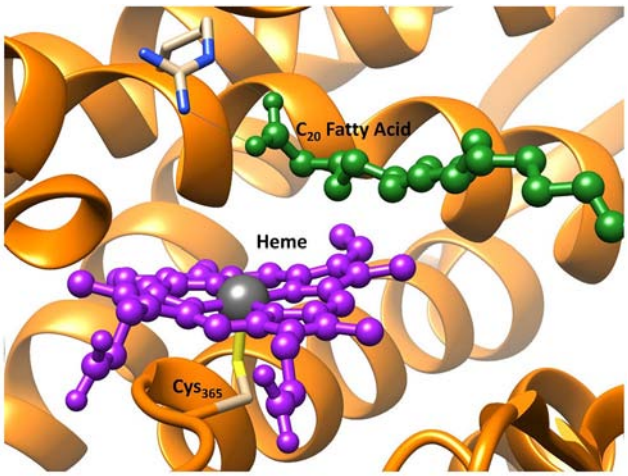

FIGURE 2 | Active site region of P450 OleT, from PDB 4L40 (Belcher et al., 2014) with heme in purple and the fatty acid substrate in dark green. Figure modified using atomic coordinate reported previously (Ji et al., 2015; Faponle et al., 2016).

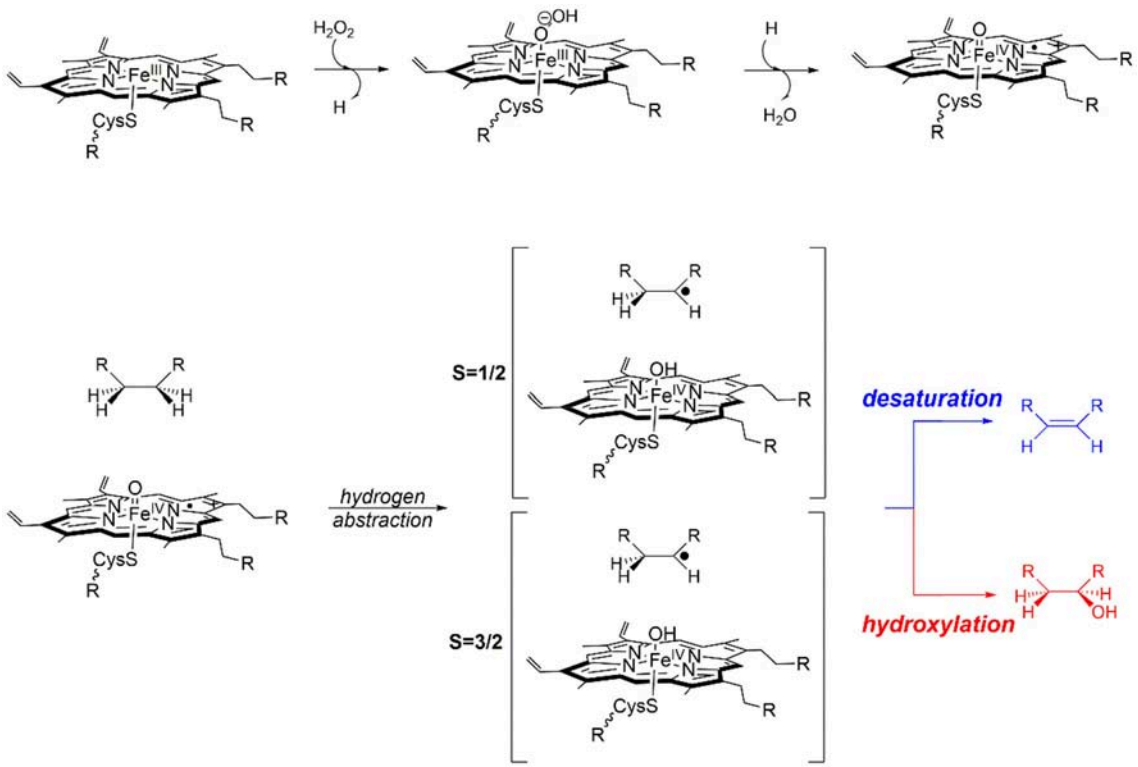
processes require whole cell techniques that reduce efficiency. Many of the alternative chemical synthesis protocols, used to transform fatty acids into terminal alkenes, are very far from green and require palladium catalysts and high temperatures (Gooßen and Rodríguez, 2004; Liu et al., 2014). In recent years, it has been reported that the bacterial P450 peroxygenases $OleT_{JE}$ is able to catalyze the conversion of fatty acids to olefins without the need for additional cellular electron transfer machinery, since H_2O_2 and not O_2 is used as the oxidant (Rude et al., 2011; Wang et al., 2014; Dennig et al., 2015; Grant et al., 2015). These medium-chain terminal olefins make excellent feedstocks for biofuels because they can be substituted for diesel without major engine modification and have improved temperature tolerance as well as a high energy content (Peralta-Yahya et al., 2012; Lennen and Pfleger, 2013). However, whilst such research does offer the possibility of an environmentally friendly route for the production of bio-fuels, at present, industrial application are limited by the abundance of side-products (alcohols). Therefore, before industrial applications can proceed there needs to be a more fundamental understanding into the origin of the bifurcation of the olefin and alcohol pathways. Two combined DFT and QM/MM studies have recently been published that investigate this bifurcation in depth, with the aim of steering bio-engineering of $OLeT_{JE}$ to improve product selectivity (Ji et al., 2015; Faponle et al., 2016), and these studies will be discussed in our first example section.

As mentioned above $OleT_{JE}$ is a cytochrome P450, a family of enzymes that are ubiquitous and highly conserved throughout nature (Groves, 2003; Meunier et al., 2004; Ortiz de Montellano, 2004; Denisov et al., 2005; de Montellano, 2010; Kadish et al., 2010). Importantly, this enzyme family exhibits an extreme functional diversity in the reaction mechanisms they catalyze: from the metabolism of harmful drug molecules in the liver (Ji et al., 2015), to hormone biosynthesis (Guengerich, 2001; Posner and O'Neill, 2004; Munro et al., 2007) and they have also been commercially implemented in the cosmetics industry (Reinhard and de Visser, 2017). The active site region of OleT is depicted in **Figure 2**, and highlights the conserved thiolate linkage (Cys_{365}) coordinated to an iron center of the heme co-factor, which are common features of all P450s (Poulos et al., 1985; Schlichting et al., 2000; Auclair et al., 2001). This resting state is primed to activate hydrogen peroxide via a hydrogen atom isomerization to form, the highly active iron(IV)-oxo heme cation radical species, Compound I (Cpd I) (de Visser et al., 2003; Shaik et al., 2005; Rittle and Green, 2010). Whilst there is significant structural homogeneity amongst the P450s, they often diverge in the residues close to their active sites; in general those enzyme that possess relatively tight binding pockets such as $P450_{cam}$ oxidizing smaller substrate and those who incorporate more open active regions such as $P450_{BM3}$ catalyzing larger substrate, like fatty acids (Gelb et al., 1982; Atkins and Sligar, 1987; Ruettinger et al., 1989; Davydov et al., 1999). In addition to the reduction in energy and toxic material consumption, many P450 isozymes demonstrate improved product regioselectivity over more conventional catalysts; therefore, their industrial application could lead to a reduced volume of wasteful side-products and therefore the biotechnological approach can be considered superior in terms of environmental sustainability (Grogan, 2011; O'Reilly et al., 2011). The question then concerns which aspects of $OleT_{JE}$ causes its atypical product infidelity and can an in-depth computational investigation of its activity drive future bio-engineering of this enzyme toward selective bio-fuel production.

Biofuel Production: What Drives Enzymatic Regioselective Toward the Olefin

The bifurcated reaction mechanism proposed in **Scheme 1**, has been previously validated by computational models that predict the initial formation of a Cpd I species that exhibits spin-state selective product distribution (de Visser et al., 2001; Kamachi and Yoshizawa, 2003; Kumar et al., 2004b; Shaik et al., 2005; Quesne et al., 2016b). Computational studies that modeled only the first coordination sphere of Cpd I are in very good agreement with experimental observations (Rettie et al., 1987; Loch et al., 1995; Forkert and Lee, 1997; Sadeque et al., 1997; Lee et al., 1998; Wen et al., 2001; Gunes et al., 2007), whereby in general these models showed that Cpd I in the doublet spin state predominantly catalysis alcohol formation via small hydroxyl rebound barriers, whilst the quartet species can destabilize the radical intermediate and catalyze a broader range of products (de Visser et al., 2001, 2013). However, in order to confirm the veracity of this proposed mechanism for $OleT_{JE}$ and to provide a deeper understanding of the effect of the protein environment on product specificity a combination of DFT and QM/MM techniques were required (Ji et al., 2015; Faponle et al., 2016).

These studies initially relied on small DFT models in order to evaluate the extent to which product specificity was driven by substrate properties, since *in vitro* experiments had shown that a member of this enzyme family catalyzes the exclusive



SCHEME 1 | Proposed hydroxylation and desaturation pathways, as catalyzed by P450 OleT.

hydroxylation of ethane (ET) to ethanol and the desaturation of dihydroanthracene (DHA), whilst valpronic acid (VA) can go through either pathway (Groves and McClusky, 1976). However, whilst the minimal DFT models did manage to predict the exclusive production of ethanol from ET, both DHA and VA showed similar reaction profiles, whereby, the doublet spin state catalyzed a combination of products via barrierless reaction mechanisms, whilst the quartet spin state catalyzed only the alcohol production via much lower hydroxyl rebound barriers. Therefore, the kinetic control exhibited by this active site model has proven insufficient for the understanding the different product selectivity reported for DHA and VA (Groves and McClusky, 1976). Importantly, this observation indicates that such a minimal model system may also be insufficient for the study of regioselectivity in product formation, as catalyzed by $OleT_{JE}$. Excitingly, if product selectivity in these cases can be assigned to environmental factors remote from the first coordination sphere of the co-factor, then it may be possible to modify product selectivity through bio-engineering of $OleT_{JE}$.

Therefore, to investigate the origin of the lack of fidelity in product regioselectivity vis-a-vis desaturation vs. α-hydroxylation of long chain fatty acids, as catalyzed by $OleT_{JE}$, a detailed QM/MM protocol was initiated. The QM/MM model was designed starting from the crystal structure coordinates of the enzyme/substrate complex (see **Figure 2**) (Belcher et al., 2014). These crystal coordinates represent the enzymes resting state and therefore were modified to approximate the heavy atoms of the Cpd I active species, in a manner previously reported (Porro et al., 2009; Postils et al., 2018). Finally, the active enzyme/substrate reactant species was solvated, protonated, equilibrated and split into QM and MM regions before the reaction coordinates could be followed, using a well-established protocol (Kumar et al., 2011; Quesne et al., 2014). The QM/MM calculations employ a combination of the CHARMM27 force field (Brooks et al., 2009), as implemented in DL_POLY (Smith et al., 2002) and UB3LYP/SV(P) method as implemented in TURBOMOLE (Ahlrichs et al., 1989) with a solvent sphere of 35Å placed around the whole enzyme/substrate complex. All calculations were performed using the ChemShell code (Sherwood et al., 2003) as a platform to run an electrostatically embedded, additive QM/MM scheme. As hoped, this model did show that the presence of the protein environment had a major impact on product selectivity; whereby the ground state switched from the doublet, found in the small DFT model, to a quartet. More importantly, the product selectivity also flips with the decarboxylation barrier reduced from 17.8 to 5.1 kcal mol^{-1}, which is below the 6.6 kcal mol^{-1} found for the hydroxyl rebound step. Thus, the ordering of the two barriers is reversed from that seen with the DFT model, where the alcohol production was favored by >10 kcal mol^{-1}. A more detailed study found that this reversal in the barrier ordering was strongly dependent on the position of the hydrogen atom that was to be abstracted (Faponle et al., 2016). The energy

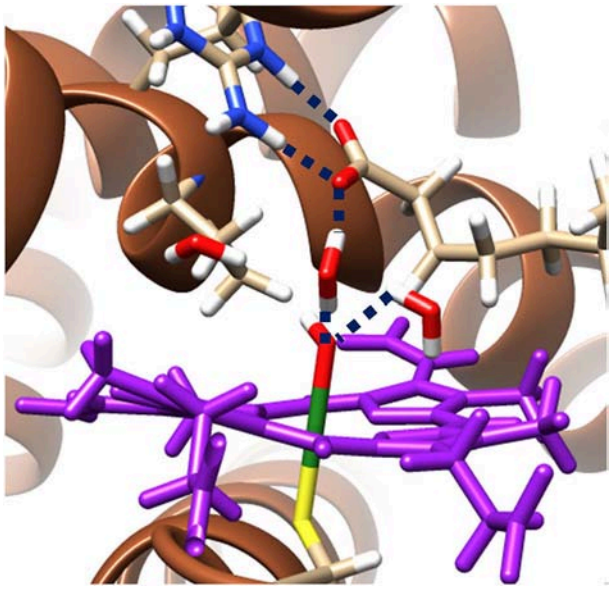


FIGURE 3 | QM/MM model of the ground state radical intermediate of hydrogen atom abstraction catalyzed by $OleT_{JE}$. Hydrogen bonding networks are linked with blue dashed lines and the heme co–enzyme is colored purple. The MM region is shown as brown secondary structure alpha–helices and beta–sheets; whilst, all atoms specifically highlighted are included in the QM region. Figure modified using atomic coordinate reported previously (Ji et al., 2015; Faponle et al., 2016).

barriers for hydrogen atom abstraction from the beta carbon of the fatty acid was very slightly lower than that seen with the alpha carbon. Importantly, hydrogen abstraction at the alpha position favored the alcohol production, whilst olefin production was dominant in the slightly more favorable beta radical intermediate. Intriguingly, while olefin production is favored using the QM/MM methodology, the two barriers are within the margin of error of the theory, which could help explain the mix product distribution seen experimentally (Rude et al., 2011; Wang et al., 2014,Dennig et al., 2015; Grant et al., 2015).

The hydrogen bonding networks present in the ground state radical hydroxyl-intermediate are highlighted in **Figure 3** and provide an insight into the origin of the reversal of product selectivity seen between the two methods. Often the use of a well-designed QM/MM protocol is the only way faithfully to replicate the local solvation environment surrounding an enzymes active region (Borowski et al., 2015; Quesne et al., 2016a). This phenomenon is evident here, with water networks surrounding the iron(IV)-hydroxo of the radical intermediate forming a bridge to a guanidine group of Arg_{245}, which in turn increases the energy required for the rotation of the hydroxyl group, which is required to position the correct orbital overlap to initiate a rebound of the hydroxyl-group toward the substrate radical. Importantly, $OleT_{JE}$ has an especially large binding pocket, allowing greater solvation of its active site. The effect of this is obvious when comparing the active site region of $OleT_{JE}$ to other P450s such as $P450_{cam}$, which tend to exclude much of the water from their active site (Poulos et al., 1987; Auclair et al., 2001). Thus, these results indicate that $OleT_{JE}$ is able to effectively elevate the hydroxyl rebound barrier for radical recombination and therefore enable the pathway toward olefin production to become competitive. These results taken together are very encouraging with regard to the potential of directed bioengineering of a OleT based isoenzymes that is able to sustainably and selectively produce biofuels from terminal olefins, without the need for harsh reaction conditions or wasteful redox partners.

ACTIVE SITE CLUSTER MODELS

The Promise of Sustainable Routes for the Catalysis of Spin Forbidden O_2 Activation

Activating molecular oxygen in its triplet ground state is a very important step in many industrial processes (Wang et al., 2001; Liang et al., 2011; Suntivich et al., 2011). However, currently harsh conditions are generally required along with the use of a precious metal cofactor, which are in low-earth abundance and whose extraction has high environmental cost (Murthi et al., 2004; Zhang et al., 2007; Kotobuki et al., 2009; Widmann and Behm, 2014). This is due to the high stability and low reactivity of triplet O_2, whose oxidation of substrates is often spin forbidden. Therefore, it is important to look at nature in order to develop more sustainable chemical pathway for oxygen reduction, which also drastically reduces the heavy metal component of the catalyst (Solomon and Stahl, 2018). However, most biocatalysts not only require metal cofactors but also organic co-enzymes, which in turn require the use of whole cell cultures to be regenerated, and these limitations reduce the utility of such enzymes in industrial processes (Solomon et al., 2000; Bugg and Ramaswamy, 2008; Quesne et al., 2015; de Visser, 2018). There is however, a small subgroup of these dioxygenases that are able to direct the spin-forbidden triplet to singlet conversion of molecular oxygen without the need of either a redox active metal co-factor or a sacrificial organic co-enzyme (Fetzner and Steiner, 2010). One of the few examples of this type of enzyme is the (1H)-3-hydroxy-4-oxoquinaldine 2,4-dioxygenase (HOD), which catalyzes dioxygenation of (1*H*)-3 hydroxy-4-oxoquinaldine (QND), leading to cleavage of the *N*-heteroaromatic ring (Bauer et al., 1996). Therefore, in our second example section, HOD was chosen as the subject of a couple of detailed studies (Hernández-Ortega et al., 2014, 2015), based on the DFT cluster model approach, into the basis of co-factor and flavin free activation of O_2. It is anticipated that a detailed first-principles understanding of the origin of this activity could help direct the future design of industrial catalysts that can more environmentally perform spin-forbidden oxygenation reactions.

Biocatalytic Activity of Metal-Independent Dioxygenases

These studies employed variable sized DFT models, shown in **Figure 4**, where enzyme thermodynamics and kinetics were determined by models of only the substrate and molecular oxygen (highlighted in red). Of the two larger active site cluster

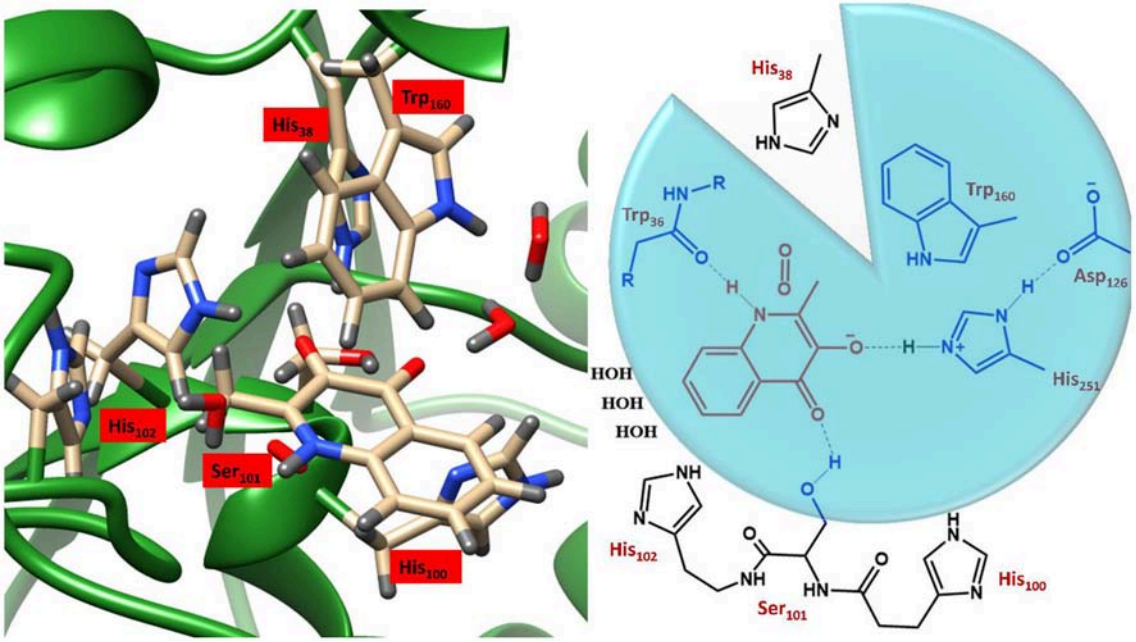

FIGURE 4 | Illustration of the active site region of HOD and a schematic representation of the three DFT cluster models. Model A (red) simply contains the substrate and O_2, Model B (blue circle) also the residues in blue, and Model B includes all residues depicted. Figure modified using atomic coordinate reported previously (Hernández-Ortega et al., 2014, 2015).

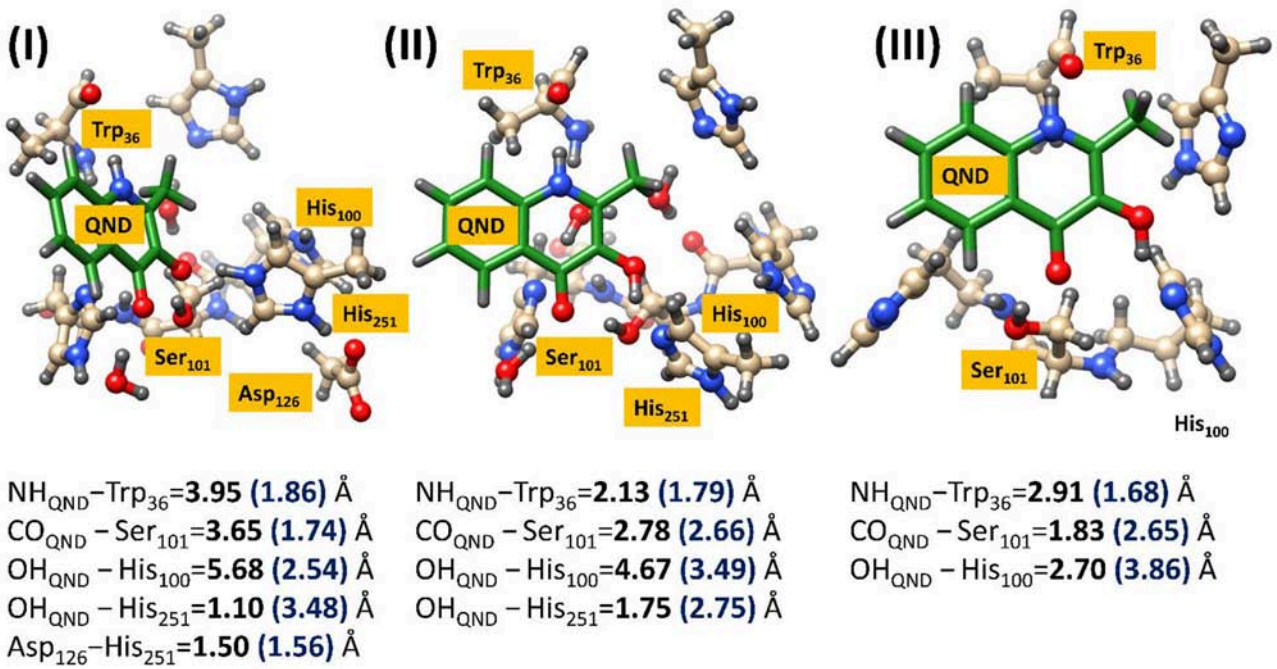

FIGURE 5 | Comparison of the geometric changes between the initial QM/MM optimized structures and those obtained using a DFT cluster model, for three HOD variants. **(I)** Wild type HOD, **(II)** D126A, and **(III)** H251A. All systems were optimized at B3LYP/6-31+G*/Cluster//QMMM level of theory with important atomic distances from DFT (left) and QMMM (right) optimization given in Å. Figure modified using atomic coordinate reported previously (Hernández-Ortega et al., 2014, 2015).

models, the smaller one incorporated only the atoms in the blue circle, whereby, truncated versions of His_{251}, Asp_{126}, Ser_{101}, and Trp_{160} and the backbone of Trp_{36} were added. The largest cluster model included all the atoms of the smaller ones as well as three water molecules and three additional imidazole groups, representing His_{38}, His_{100}, and His_{102} (black). Since the initial study focused purely on the formation of a substrate anion by a proton abstraction (Hernández-Ortega et al., 2014), oxygen was only present in the cluster models of the second study into the rate-limiting spin-forbidden activation of triplet oxygen, by the activated QND (Hernández-Ortega et al., 2015). The protocol for setting up the cluster models was very similar to that discussed in the previous section, whereby, the crystal structure was initially protonated, solvated, equilibrated and optimized. The crystal structure of the wild type enzyme was taken from the protein data bank (PDB) file 2WJ4 (Steiner et al., 2010), whilst the mutant variants were prepared *in silico* by modifying either a carboxylate or an imidazole group. As is shown in **Figure 4**, the QM regions of the two mutants lacked atoms for either a carboxylate or a carboxylate and imidazole group, for D126A and H251A, respectively. These structures were then equilibrated and optimized in the same manner described for $OleT_{JE}$ (above), whereby a solvent sphere of 35 Å was placed around the whole system and the functional UB3LYP (Lee et al., 1988; Becke, 1993) in combination with the 6–31G(3d,p) basis set was used for the QM region. Therefore, whilst for this example QM/MM was not employed to investigate the kinetics of QND oxidation by HOD, it was used to obtain cluster model starting structures that represented protonated, solvated and optimized coordinates.

This approach was required to obtain reasonable starting structures for the cluster models, which were also calculated using the same UB3LYP/6–31G(3d,p) methodology, only this time implemented in the Gaussian software package (Frisch et al., 2009). However, after the large cluster models were excised and optimized it became evident that the two technique gave radically different geometries, as can be seen in **Figure 5**. Much of these effects can be attributed to changes in substrate orientation that might to some extent be constrained by residues remote from the active site region. The precise position of the substrate seems to be significantly model dependent, although, there does appear to be a general migration away from hydrogen bonding networks with Trp_{36} and Ser_{101}, in all models. Even though it could be argued that either increasing the cluster size or putting more constraints on the substrate might increase the match between the reactant geometries obtained by the two techniques, it was decided that such techniques would be too costly and could lead to unphysically high barriers along the reaction path. It is also important to note that the initial QM/MM optimized starting structures show there to be barely any effect of residue modification on substrate positioning, which may indicate that the QM/MM models are too inflexible to accurately simulate point-mutations. Alternatively, it is very possible that these two point-mutations would not be expected to produce a large amount of tertiary structure changes, and even if they did would require much more intensive molecular dynamics simulations to replicate *in silico*. In either case, as demonstrated below, it was shown that the cluster models were sufficient to provide important electronic insights into the origin of the experimentally observed differences in catalytic activity between the different variants.

TABLE 1 | QND deprotonation by His residues, using active site models of different HOD variants and minimal models of the His/Asp dyad.

	$\Delta E + ZPE$	ΔG
WT	−0.9	−0.8
D126A	13.1	14.0
H251A	28.0	27.8
His251-H	13.4	13.3
His251-Asp126	1.8	1.8

All Zero point (ZPE) and Gibbs free energies for QND deprotonation were obtained at UB3LYP/6–31G(3d,p) level of theory. All energies are given in kcal mol^{-1} and relate the deprotonated QND to reactant species.

The first study used a combined experimental and theoretical (cluster model) approach in order to investigate the preliminary proton abstraction step, which forms the active substrate anion. This combination technique underscored the importance of the histidine/aspartate dyad, since on its own His_{251} is not basic enough to abstract a proton from QND. Therefore, a strong hydrogen bond with Asp_{126} is required to catalyze QND deprotonation, which is evident by the >13 kcal mol^{-1} endothermicity of the smallest model shown in **Table 1**. These findings were replicated experimentally with the production of two mutant variants D126A and H251A, which each targeted one of the dyad residues with a point-mutation to an alanine. Each mutation caused a substantial drop in enzyme activity. Stop-flow experiments assessed deprotonation rate constants (k_H) that were 5- to 40-fold lower in D126A and too low to measure in the H251A variant. Importantly, initial optimizations with both cluster and QM/MM models of wild-type HOD showed spontaneous proton transfer from the substrate; whilst, a stable hydrogenated QND species was found in both mutant clusters. The driving force for these different initial states is validated by the theoretical models, whereby, the wild-type models were the only ones to show exothermic deprotonation steps, with the thermodynamics of the D126A and H251A models pointing the equilibrium toward (QND)–OH (see **Table 1**). These substrate deprotonation energies report the bond formation energy of the $His_{(x)}$–H, where His_{100} substitutes His_{251} in the H251A variant, minus the bond dissociation energy of the (QND)-H bond that is broken. As shown in **Table 1**, when these energies are calculated the slightly exothermic nature of the wild-type cluster model is set against endothermic energies of >10 kcal mol $^{-1}$ for D126A and $\sim$30 kcal mol $^{-1}$ for H251A. Finally, it was determined that the origin of the loss in proton abstraction ability seen in the D126A variant was an increase in the proton affinity of His_{251} by 12 kcal mol $^{-1}$ upon coordination with Asp_{126}.

At the time of publication, the computational results of the second study were somewhat controversial (Thierbach et al., 2014; Silva, 2016). This study focused on the spin-forbidden

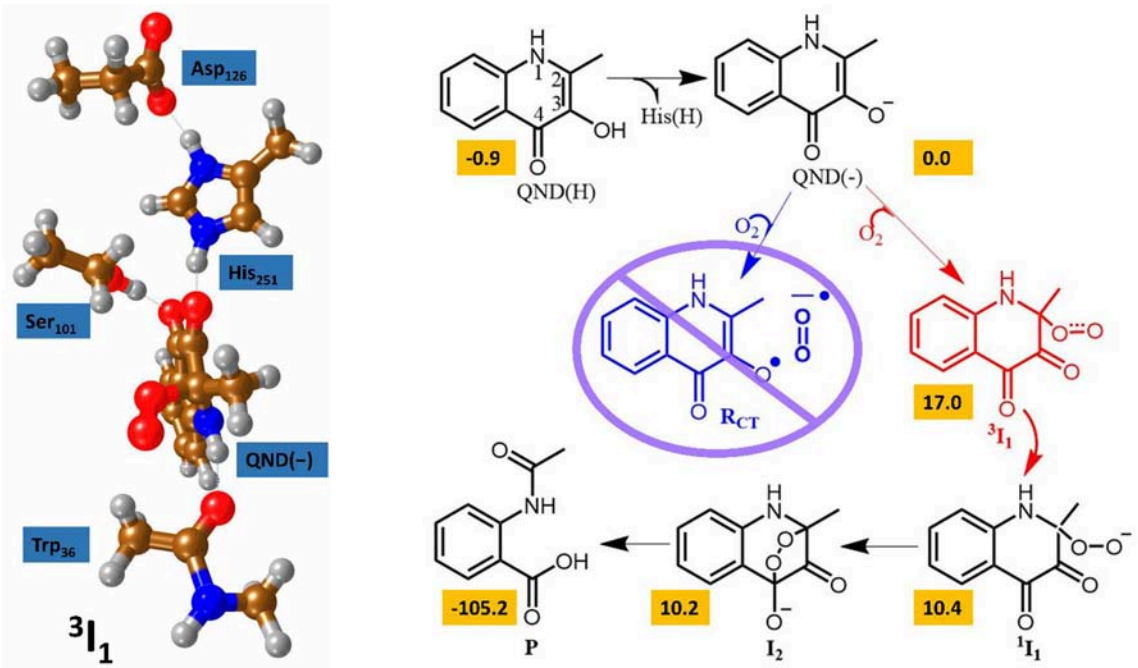

FIGURE 6 | The two calculated reaction mechanisms for the oxidation of QND. The proposed pathway (blue) was assessed as less favorable than the alternative (red). A graphical representation of the alternative triplet intermediate is also shown (left). Figure modified using atomic coordinate reported previously (Hernández-Ortega et al., 2014, 2015).

incorporation of triplet oxygen into the singlet product, the mechanism of which has wide implications for green chemistry. In this study the authors concluded that the rate-limiting oxygen activation step proceeded via an initial short lived oxygen bond triplet intermediate (Hernández-Ortega et al., 2015). Spin trapping experiments had been used to propose an alternative mechanism, whereby an initial long range electron transfer created a superoxo radical species that was then able to recombine with the substrate radical (see **Figure 6**) (Müller et al., 1987; Thierbach et al., 2014; Kralj et al., 2015). However, the authors of this theoretical study determined that their calculations indicated the experimentally observed radical could be more correctly assigned to the radical rearrangement that transformed the QND(−) substrate into the $^3\mathbf{I_1}$ intermediate with the aid of an elongation of the C2–C3 bond and the rehybridization of these two carbon centers from sp^2 to sp^3. The theoretical findings were additionally strengthened by transient state stop-flow experiments, which were completely unable to detect any signature that could have been assigned to the proposed $\mathbf{R}_{CT}$ intermediate. These studies provided a greater fundamental knowledge of this novel class of dioxygenases that could have important implications for future development of novel green catalytic routes to spin forbidden oxygen activation. These results indicate that the stabilization of a short-lived triplet intermediate, which last long enough for spin state crossing, could be key to future catalyst design.

HOMOGENOUS CATALYSTS MODELED WITH UNRESTRICTED DFT

Oxidation of Methane to Methanol

Using density functional theory (DFT) methodology to characterize and rationally tune bioinorganic, earth-abundant and environmentally compatible homogenous catalysts, is a major field of combined computational and experimental research (Kumar et al., 2010; Prokop et al., 2011; Neu et al., 2014; Sahu et al., 2014; Yang et al., 2016). DFT techniques have been used to study the selective halogenation (Quesne and de Visser, 2012), nitrogenation (Timmins et al., 2018), and oxygenation (Jastrzebski et al., 2014) abilities of many such catalysts. Indeed, work on the selective dioxygenation of catechol by tris(2-pyridylmethyl)amine (TPA) has shown promise for the potential of a sustainable, green-catalytic route for nylon production via dimethyl adipate (Jastrzebski et al., 2013, 2014). Homogenous catalysts are often able to catalyze reaction mechanisms selectively at far lower temperatures and pressures then conventional routes. Indeed, selectivity can be one of the most important environmental benefits of choosing homogenous catalysts because of the increased yields and lower side-products. However, it is important to consider the potential of homogeneous catalysts increasing the volumes of contamination and waste, as well as the excess energy required for product separation and catalyst recycling, which is often

greater than observed using heterogenous catalysts (Lam et al., 2010; Tan et al., 2013). Therefore, it is crucial to consider to what extent there could be an overall environmental benefit to using homogenous catalysis over the more conventional heterogenous routes (Corma and García, 2003; Astruc, 2007; Baroi and Dalai, 2015). The example catalyst presented here, is very novel for possessing the ability of converting methane to methanol at low temperatures and ambient pressures (Kudrik and Sorokin, 2008; Sorokin et al., 2008, 2010; Isci et al., 2009; Kudrik et al., 2012). Whilst the reactivity of this bio-mimetic catalyst has been well characterized, the origin of its efficiency was poorly understood. Therefore, a detailed an in-depth computational study was undertaken to understand the aspects of its catalysis that enabled such high activity toward methane hydroxylation, so that such a fundamental understanding of reactivity could be used to further improve the activity of this or related catalysts (Quesne et al., 2016b).

As discussed in the olefin production section, the P450 super family of enzymes are amongst the most efficient and powerful catalysts for oxidizing C-H bonds. However, despite the extreme amount of substrate diversity, there is no natural pathway that utilized a P450 isoenzyme and is also powerful enough to activate the 104.9 kcal mol $^{-1}$ strong C–H bond of methane. In fact, under guest/host activation conditions, methane was the only short chain alkane that $P450_{BM3}$ was unable to oxidize (Kawakami et al., 2011, 2013; Zilly et al., 2011). Bioengineering does a little better than nature with CYP_{153A6} actually showing some oxidation activity toward methane, although, with an extremely slow turnover frequency of 0.02–0.05 (Chen et al., 2012). These observations are in stark contrast with the μ-nitrido-bridged diiron-oxo porphyrin catalyst discussed in this section, which has demonstrated high oxidative activity toward methane and is based on a dimer of two of the co-enzymes found in P450s (Kudrik and Sorokin, 2008; Sorokin et al., 2008, 2010; Isci et al., 2009; Kudrik et al., 2012). The active site of P450 enzymes consists of thiolate linked iron-oxo porphyrin (see **Figure 1**). Importantly, the observation that the use of perfluoro-carboxylic acid to enable alkane activation by $P450_{BM3}$ proved insufficient for methane oxidation provides evidence against a mechanism whereby the lack of P450 activity is simply due to the absence of a isoenzyme that is able to accommodate methane in its active site (Kawakami et al., 2011, 2013). An alternative explanation for the inferior activity, toward the oxidation of methane, demonstrated by P450s over the diiron porphyrin catalysts is seen in the numerous studies into the effect of different axial ligands in the catalytic activity of iron-porphyrins (Gross and Nimri, 1994; Czarnecki et al., 1996; Song et al., 2005; Takahashi et al., 2012). Regardless of the relative importance of either of these affects, the origin of the massive improvement seen in the diiron porphyrin dimer above the mono-porphyrin bio-catalyst is of crucial important for the future design of the next generation of powerful oxidants for sustainable methanol production.

Origin of the Catalytic Activity of Diion(IV)oxo Porphyrinod

Over the years, a minimum model of Compound I (see **1**, **Figure 7**) has been extensively tested and proved to be sufficient for explaining the first coordination sphere P450s (Yoshizawa et al., 2001; de Visser et al., 2004; Shaik et al., 2005), which is the same model ([FeIV(O) (Por^+) −SH]) that was mentioned in our first example section and consisted of an iron-porphyrin coordinated by an oxo group *trans* to an SH, representing the axial cysteine. The μ-nitrido-bridged diiron-oxo porphyrin model (see **2**, **Figure 7**) replaces the SH group for a nitrogen, which became a linker for a second iron-porphyrin. The DFT calculations were performed without any geometric restrictions on any of the atoms in the model systems and full optimizations were undertaken for each minima using UB3LYP (Lee et al., 1988; Becke, 1993), in combination with the initial double-ζ basis set 6–31G (Ditchfield et al., 1971) on all atoms except for Fe where LACVP with a Neon core potential was implemented (BS1). Subsequently, single point gas-phase and solvent corrected calculation were run using the same functional in combination with the polarizable and defuse triple-ζ basis sets 6–311+G(d,p) and LACV3P+ (BS2). Free energy values were calculated at 298.15K and 1 atmosphere of pressure, with such a protocol being well benchmarked previously (de Visser, 2010).

Figure 7 shows the free energy landscapes for the methane to methanol reaction as catalyzed by both model catalysts. Since the energy barriers associated with the hydrogen atom transfer (HAT) on both the doublet and quartet spin state surfaces are the same to the first decimal place for catalyst **1**, the energy landscapes of both are considered. This spin state derived bifurcation in the pathways catalyzed by CpdI is in excellent agreement with multiple different studies (de Visser et al., 2003, 2014; Kumar et al., 2004a,b) and stands in sharp contrast to the diiron porphyrin dimer catalyst (**2**), which exhibits a doublet ground state with a rate-limiting step that is well separated (by >40 kcal mol $^{-1}$) from the hydrogen atom abstraction barrier on the quartet energy landscape. Such a dominant doublet ground state is also in excellent agreement with previous work on **2** (Silaghi-Dumitrescu et al., 2011; Ansari et al., 2015; Işci et al., 2015). Therefore, only the low spin state surface of **2** is included in **Figure 7**. The reaction mechanism for both catalysts proceeds via a rate-limiting hydrogen atom abstraction transition state ($\mathbf{TS}_{HA}$) leading to a radical hydroxyl intermediate ($\mathbf{I}_H$), which is capable of forming methanol ($\mathbf{P}_{OH}$) through radical recombination with the methyl radical following a hydroxyl rebound barrier ($\mathbf{TS}_{OH}$). The decrease in the free energy barrier for $\mathbf{TS}_{HA}$ of 13.6 kcal mol $^{-1}$ for **2** over **1** corresponds to a rate enhancement of $\sim 10^{10}$. Indeed, such a low barrier would imply that **2** was able to catalyze the oxidation of methane at room temperature, which has been observed experimentally (Sorokin et al., 2008). The bond length shown in **Figure 7** show that the high energy $\mathbf{TS}_{HA}$ seen in **1** is considerably more product like with a shorter O-H and a longer C-H distance than is the case for $\mathbf{2TS}_{HA}$. Notwithstanding these differences, both transition states are generally product like, which was expected and is a consistent trend in methane

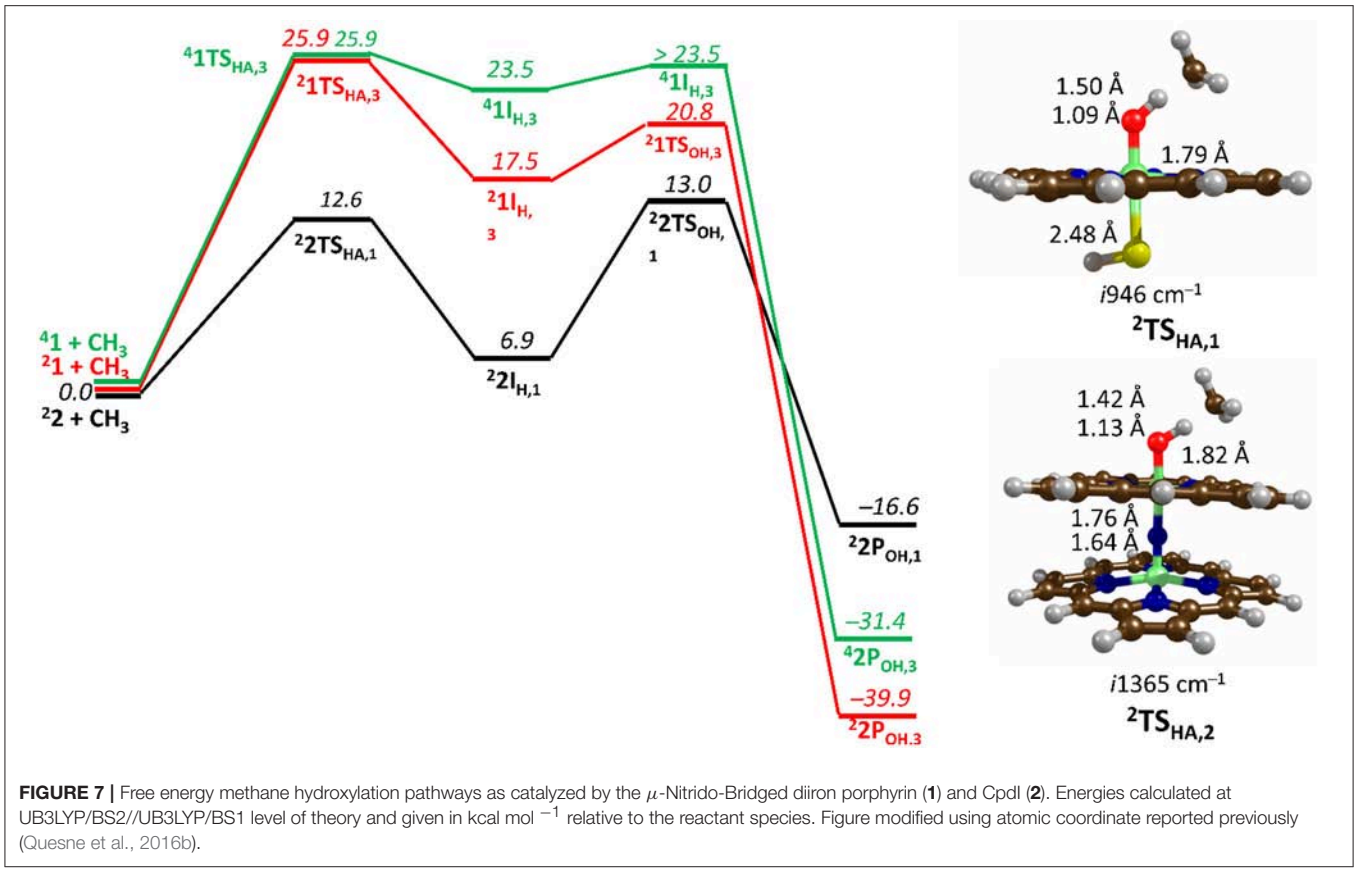

FIGURE 7 | Free energy methane hydroxylation pathways as catalyzed by the μ-Nitrido-Bridged diiron porphyrin (**1**) and CpdI (**2**). Energies calculated at UB3LYP/BS2//UB3LYP/BS1 level of theory and given in kcal mol $^{-1}$ relative to the reactant species. Figure modified using atomic coordinate reported previously (Quesne et al., 2016b).

hydroxylation barriers (Yoshizawa et al., 2001; de Visser et al., 2004; Shaik et al., 2008).

The divergence in the performance of these two catalysts can be explained by differences in the electronic structure with regard to the location of valence electrons, as shown in **Figure 8**. The valence electrons for CpdI (**1**) are shown on the left and have an occupancy of π^2_{xz}, π^2_{yz}, π^{*1}_{xz}, π^{*1}_{yz} dominated by the Fe(IV)oxo combined with a singly occupied a^1_{2u} on the heme cation radical. Therefore, CpdI has a ground state with a total of three unpaired electrons and the close lying doublet and quartet spin state only diverge electronically by either anti-ferromagnetically or ferromagnetically coupled heme and FeO orbitals (de Visser et al., 2003; Porro et al., 2009). In **2** the eight valence electrons of an axial Fe(IV)-nitrido mix with the seven of the Fe(IV)oxo and the energy of the a_{2u} orbitals of both porphyrins are lowered to give an occupancy of π^2_{x1}, π^2_{y1}, π^2_{x2}, π^2_{y2}, $a^2_{2u,1}$, $a^2_{2u,2}$, π^{*2}_{x3}, π^{*1}_{y3}. For simplicity only the two occupied anti-bonding π– orbitals as well as the highest lying a_{2u} orbital is included in **Figure 8**. In retrospect such a change is not unexpected since it has been determined that mixing between the $3P_Z$ orbital on the axial Sulfur atom, which is absent in **2**, and the a_{2u} porphyrin orbital raises the latter's energy above that of the π FeO orbitals and leads to the porphyrin radical in **1** (Ogliaro et al., 2001). However, the degree to which this change affects the electron and proton affinities of **2** is somewhat more surprising, since research has indicated that the kinetics of HAT reactions is usually correlated to the thermodynamics of hydrogen atom binding ($\mathbf{BDE_{OH}}$) (Friedrich, 1983; Bordwell and Cheng, 1991; Mayer, 1998). **Figure 9** breaks down the $\mathbf{BDE_{OH}}$ of both catalysts into electron (**EA**) and proton ($\mathbf{\Delta_{acid}}$) affinity components. Therefore, for each catalyst $\mathbf{BDE_{OH}} = \mathbf{\Delta_{acid}} - \mathbf{EA} - \mathbf{IE_H}$, whereby ($\mathbf{IE_H}$) describes the ionization energy of a hydrogen atom. It is clear from **Figure 9** that whilst the electron affinity of the FeO is greater by ∼ 29 kcal mol^{-1} in the CpdI mimic this is more than compensated by the >35 kcal mol^{-1} increase basicity of the anionic species of **2**, which is consistent with other studies that show the dominance of $\mathbf{\Delta_{acid}}$ in $\mathbf{BDE_{OH}}$ (Green et al., 2004; Parsell et al., 2009). Therefore, it is the increase basicity of the μ-nitrido-bridged diiron-oxo porphyrin that is the origin of its increased activity and any attempt to further design this powerful oxidant will have to consider carefully the consequences of attempting to improve the election affinity by addition of axial ligands, which could lead to a loss in the orbital reorganization that is critical to increasing $\mathbf{\Delta_{acid}}$.

HETEROGENOUS CATALYSIS MODELED WITH PERIODIC BOUNDARY CONDITIONS

Catalytic Activity of Transition Metal Carbides

Transition metal carbides (TMCs) are a class of material known for their catalytic activity since 1973 (Levy and Boudart, 1973).

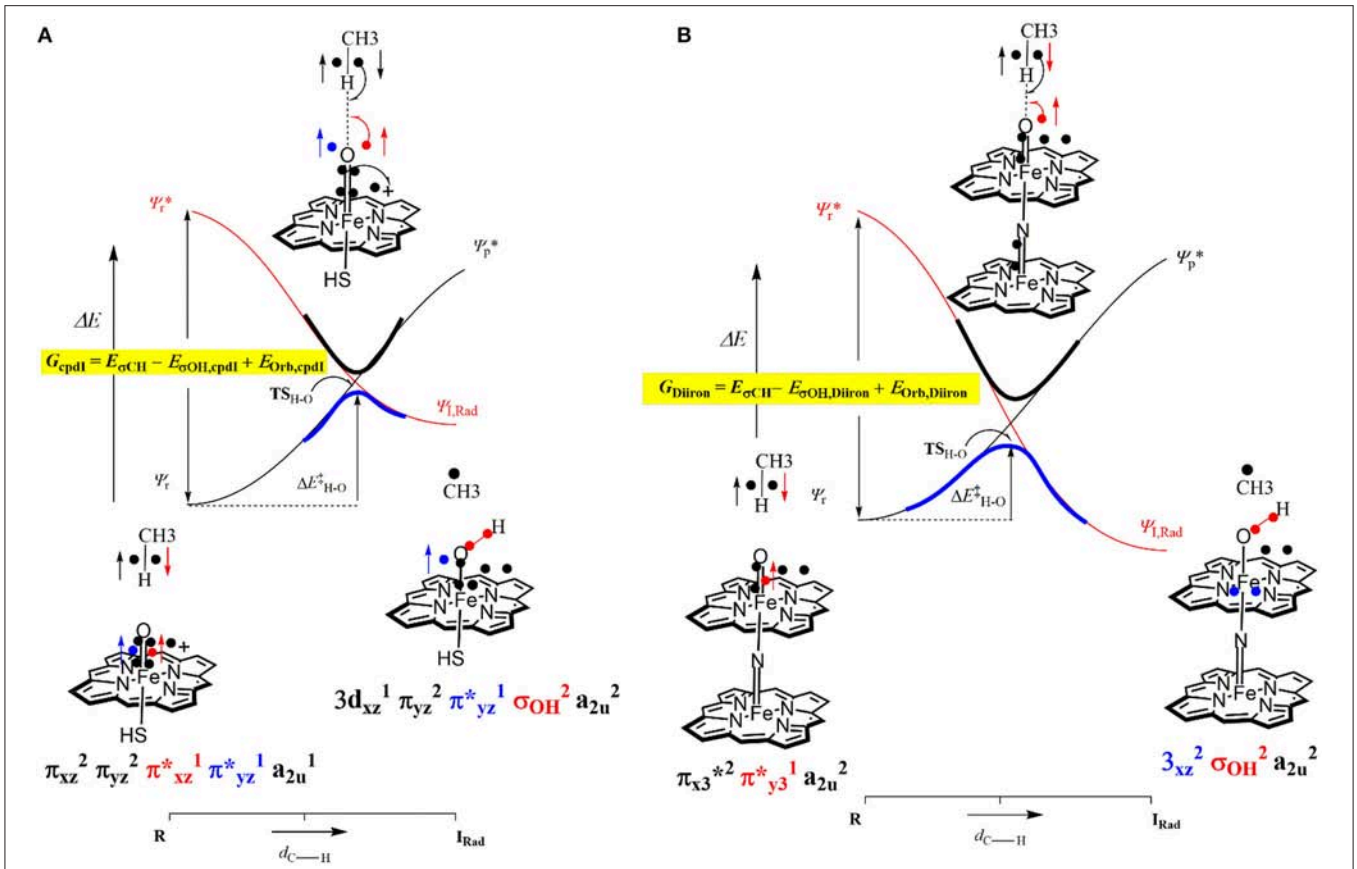

FIGURE 8 | Valence bond diagram of methane hydroxylation by models of P450 CpdI **(A)** and the Diiron porphyrin catalyst **(B)**.

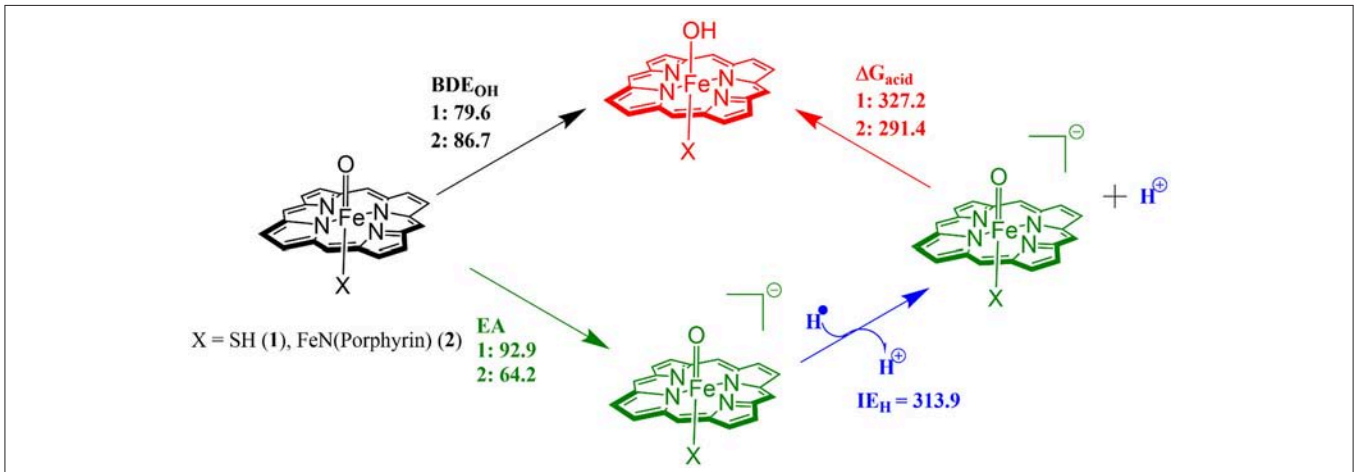

FIGURE 9 | Theoretically determined free energy values for the hydrogenation of catalysts **1** and **2**. All solvent corrected free energies were obtained at UB3LYP/BS2//UB3LYP/BS1 level of theory and are given in kcal mol^{-1}.

These materials present different stoichiometries and structures depending on the position of the metal in the periodic table: Ti and Zr, on the left-hand side of the d-series, form stable and non-defective monocarbides, while metals toward the center of the periodic table present a lower carbon content, as seen in the widely studied case of Fe_3C (Häglund et al., 1993; Oyama, 2008). All these materials, however, are considered valuable for industrial applications because of their relatively low cost, high durability and melting points as well as their catalytic activity (Hwu and Chen, 2005; Qi et al., 2013). TMCs have been tested for

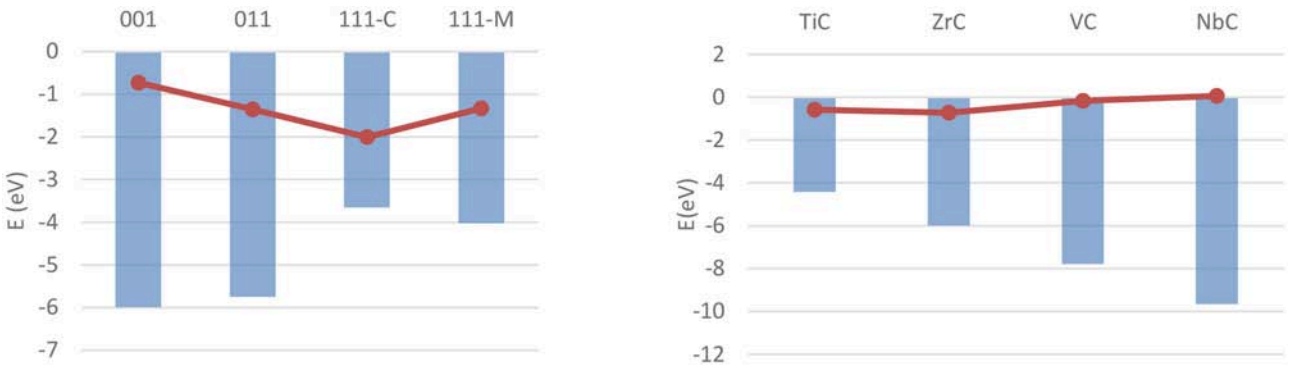

FIGURE 10 | Correlation between ΔE_{ads} of a single hydrogen molecule (red dots) and the d-band centers (blue columns) on different carbides and surfaces. **(Left)** Shows the values for ZrC over the four investigated surfaces, **(Right)** shows the values for (001) surfaces over the four carbides.

a wide variety of catalytic reactions, especially hydrogenation and dehydrogenation reactions for which their activity has proved to be qualitatively similar to that of Pt (Levy and Boudart, 1973; Delannoy et al., 2000). One such avenue of research, that exploits TMCs as catalysts for the hydrogen evolution reaction (HER), is particularly relevant to environmentally sustainable chemistry, as it is considered to be a key element in the transition from a fossil fuel-based to a hydrogen-based economy. The HER is the focus of a large amount of research interest worldwide for its role in alkaline water electrolysis, which produces highly pure H_2, and in hydrogen fuel cells; both these applications make use of Pt as a catalyst to lower the overpotential required to perform the reaction down to appropriately 0.2 eV, but the cost and scarcity of the element (Yang, 2009), as well as the questionable environmental sustainability of Pt mining (Maboeta et al., 2006; Saurat and Bringezu, 2008; Glaister and Mudd, 2010) have driven the research toward catalysts composed of more earth-abundant elements such as TMCs. A related application, is the catalytic reduction of CO_2 with H_2, which usually aims at the production of CO or CH_3OH, often requiring a surface-mediated proton transfer to transform CO_2 into COOH (Posada-Pérez et al., 2017a).

The bulk and surface properties of TMCs have been well characterized in the past few years (Vines et al., 2005; Quesne et al., 2018), but fewer computational studies have been performed on their catalytic activity. Adsorption and activation studies have been performed for both H_2 and CO_2 for a wide range of early- and mid-series TMCs, with all of these studies modeling low-index surfaces of the catalysts using periodic boundary conditions. The (001) surfaces of MoC and Mo_2C, the latter being either Mo- or C-terminated, have been the focus of a work from Posada-Pérez et al. on hydrogen adsorption (Posada-Pérez et al., 2017b), which found stable, dissociative adsorption of H_2 on all three materials with no activation barrier when dispersion interaction correction is taken into account. The adsorption is found to occur primarily on top of surface carbon atoms on both materials, with adsorption energies calculated with the Perdew–Burke–Ernzerhof (PBE) (Perdew et al., 1996) functional in the −1 to −2.5 eV range, whilst consistently higher on the metal-rich carbide. Similarly, a study from Silveri et al. (2019) investigated the adsorption of H_2 on TiC, VC, ZrC, and NbC, using a combination of periodic boundary conditions and the PBE functional, found adsorption to be exothermic on these systems' (001) surfaces as well. Unlike the former, however, this study was extended to the (011) and (111) surfaces as well, in order to obtain a more complete picture of the reactivity of the material. These data highlighted how the stability of the (001) surface is correlated with a lower reactivity on all carbides. More generally, all monocarbides show similar geometric and electronic properties of the adsorption, with the only major difference between the carbides being the strength of the adsorption in most cases. The exceptions are the carbon termination of the (111) surfaces of TiC and VC, which are found to be unstable in presence of hydrogen. However, the availability of adsorption energy data for all low-index surfaces across four carbides allowed these to be correlated with surface properties such as work function and *d*-band center position, as shown for the latter in **Figure 10**.

Higher coverage states have also been investigated, observing a decrease in the adsorption energy per atom as well as a similar, although not linear, decrease in work function, attributable to the electron transfer from the adsorbed hydrogens to the metallic slab. The coverage states of each surface of the four carbides were also predicted at a wide range of temperatures and pressures, and correlated with the tendency of the hydrogen either to adsorb on or desorb from the surface. As a result, it was shown how the strength of the C–H and M–H bonds on the (011) and (111) surfaces is predicted to hinder the feasibility of catalytic reactions such as HER on all higher-index surfaces. Conversely, the (001) surface - previously shown to be the lowest energy termination, shows a rapidly changing coverage state, suggesting its potential as an active termination for catalytic reactions involving a surface mediated hydrogenation and further elucidating the mechanistic details of the catalytic activity of the carbides. **Figure 11** shows the hydrogen coverage states as a function of the H_2 chemical potential for the TiC (001) surface.

MoC and Mo_2C have also been studied computationally for their capability to adsorb CO_2 and dissociate it to CO (Posada-Pérez et al., 2014). These studies show how both materials effectively activate carbon dioxide and in the case of the far more

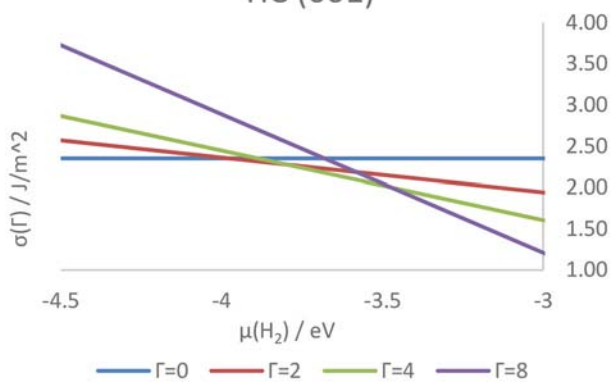

FIGURE 11 | Surface free energies of surfaces in different hydrogenation states as a function of the chemical potential of gaseous hydrogen above the TiC (001) surface. The letter Γ indicates the number of atoms on the surface of the catalyst, with $\Gamma = 0$ and $\Gamma = 8$ corresponding, respectively to a coverage of 0 ML and 1 ML.

active Mo_2C material, it is also possible to observe spontaneous dissociation. These studies, albeit not elucidating the catalytic behavior of early- and mid-series transition metal carbides completely, provide a powerful basis for further theoretical and experimental work on the catalytic activity of these materials for reactions such as HER, CO_2 reduction and inverse water-gas shift and demonstrate the power of the periodic DFT approach to highlight fundamental properties of heterogenous catalyst. The elucidations of the mechanistic aspects of such reactions will help greatly in the development of the sustainable generation of fuels and chemicals as well as guiding the future design of the catalytic component of the hydrogen fuel cell—a challenge for which innovative catalysis is of paramount importance.

SUMMARY AND CONCLUSIONS

The urgent need for society to move toward a greener and more sustainable future presents a very exciting opportunity for catalytic chemists. Many of the necessary changes in resource management and increased energy efficiency will be propelled by the directed design of new catalysts, for which a detailed theoretical understanding of the activity of current catalysts is a crucial part. Many very different computational techniques are being applied to the characterization of novel catalysts as a preliminary step to the engineering of new and much greener chemical route to important products. The implementation of a QM/MM protocol to the challenge of bioengineering the enzyme $OleT_{JE}$, in order to increase its selectivity toward olefin production is explored in the first case study. This study indicates that the enzyme was able to effectively elevate a hydroxyl radical recombination barrier which leads to the alternative olefin pathway becoming competitive. This process is modulated by changes in the local solvation environment so there could be the potential to bioengineer an OleT isoenzyme to selectivity produce olefin for a sustainable route to bio-fuel production. The next case study used restricted cluster model calculations to investigate the ability of HOD to catalyze spin-forbidden oxygen activation. Interestingly, this study did not confirm the experimentally proposed reaction mechanism, but instead offered the potential for a novel green catalytic route for the activation of molecular oxygen via the stabilization of a triplet intermediate dioxygen species. The third case study explored the reactivity of a novel μ-nitrido-bridged diiron-oxo porphyrin that was able to catalyze the methane to methanol reaction under very mild conditions. This study used unrestricted DFT methods to determine that the acidity of the FeO anion was mostly responsible for its increased activity over the related mono-oxygen porphyrin catalysts. These results indicated that any improvement of the catalyst could not be made by sacrificing the novel orbital mixing along the Z-axis. Therefore, simply increasing the electron affinity of the FeO by binding a strong electron withdrawing group in the axial position is likely to be counterproductive. Finally, we consider several periodic DFT studies into the electronic properties and catalytic abilities of the low-index facets of early transition metal carbides. These studies point to the possibility of green catalytic routes toward the production of fuels and useful chemicals from the utilization of the green-house gas carbon dioxide; as well as the potential for these materials to be used as catalysts in hydrogen fuel cells.

AUTHOR CONTRIBUTIONS

All authors listed have made a substantial, direct and intellectual contribution to the work, and approved it for publication.

FUNDING

This work was funded by both Cardiff University and an EPSRC under the Low Carbon Fuels initiative.

ACKNOWLEDGMENTS

The authors thank Stefan Nastase for his help and expertise in the area of Zeolite computational chemistry.

Advantages of publishing in Frontiers

OPEN ACCESS
Articles are free to read for greatest visibility and readership

FAST PUBLICATION
Around 90 days from submission to decision

HIGH QUALITY PEER-REVIEW
Rigorous, collaborative, and constructive peer-review

TRANSPARENT PEER-REVIEW
Editors and reviewers acknowledged by name on published articles

Frontiers
Avenue du Tribunal-Fédéral 34
1005 Lausanne | Switzerland
