About Frontiers

Frontiers is more than just an open-access publisher of scholarly articles: it is a pioneering approach to the world of academia, radically improving the way scholarly research is managed. The grand vision of Frontiers is a world where all people have an equal opportunity to seek, share and generate knowledge. Frontiers provides immediate and permanent online open access to all its publications, but this alone is not enough to realize our grand goals.

Frontiers Journal Series

The Frontiers Journal Series is a multi-tier and interdisciplinary set of open-access, online journals, promising a paradigm shift from the current review, selection and dissemination processes in academic publishing. All Frontiers journals are driven by researchers for researchers; therefore, they constitute a service to the scholarly community. At the same time, the Frontiers Journal Series operates on a revolutionary invention, the tiered publishing system, initially addressing specific communities of scholars, and gradually climbing up to broader public understanding, thus serving the interests of the lay society, too.

Dedication to Quality

Each Frontiers article is a landmark of the highest quality, thanks to genuinely collaborative interactions between authors and review editors, who include some of the world's best academicians. Research must be certified by peers before entering a stream of knowledge that may eventually reach the public - and shape society; therefore, Frontiers only applies the most rigorous and unbiased reviews.
Frontiers revolutionizes research publishing by freely delivering the most outstanding research, evaluated with no bias from both the academic and social point of view. By applying the most advanced information technologies, Frontiers is catapulting scholarly publishing into a new generation.

What are Frontiers Research Topics?

Frontiers Research Topics are very popular trademarks of the Frontiers Journals Series: they are collections of at least ten articles, all centered on a particular subject. With their unique mix of varied contributions from Original Research to Review Articles, Frontiers Research Topics unify the most influential researchers, the latest key findings and historical advances in a hot research area! Find out more on how to host your own Frontiers Research Topic or contribute to one as an author by contacting the Frontiers Editorial Office: researchtopics@frontiersin.org

FRONTIERS IN CHEMISTRY: RISING STARS

Topic Editors:
Steve Suib, University of Connecticut, United States
Huangxian Ju, Nanjing University, China
Serge Cosnier, UMR5250 Département de Chimie Moléculaire (DCM), France
Bunsho Ohtani, Hokkaido University, Japan
John D. Wade, University of Melbourne, Australia
Gil Garnier, Bioresource Processing Institute of Australia (BioPRIA), Australia
Nosang Vincent Myung, University of California, Riverside, United States
Luís D. Carlos, University of Aveiro, Portugal
Michael Kassiou, University of Sydney, Australia
Fan Zhang, Fudan University, China
Iwao Ojima, Stony Brook University, United States
Pellegrino Musto, Italian National Research Council, Italy
Tony D. James, University of Bath, United Kingdom
Thomas S. Hofer, University of Innsbruck, Austria
Sam P. De Visser, University of Manchester, United Kingdom

The *Frontiers in Chemistry* Editorial Office team are delighted to present the inaugural "Frontiers in Chemistry: Rising Stars" article collection, showcasing the high-quality work of internationally recognized researchers in the early stages of their independent careers.

All Rising Star researchers featured within this collection were individually nominated by the Journal's Chief Editors in recognition of their potential to influence the future directions in their respective fields. The work presented here highlights the diversity of research performed across the entire breadth of the chemical sciences, and presents advances in theory, experiment and methodology with applications to compelling problems.

This Editorial features the corresponding author(s) of each paper published within this important collection, ordered by section alphabetically, highlighting them as the great researchers of the future.

The *Frontiers in Chemistry* Editorial Office team would like to thank each researcher who contributed their work to this collection. We would also like to personally thank our Chief Editors for their exemplary leadership of this article collection; their strong support and passion for this important, community-driven collection has ensured its success and global impact.

Laurent Mathey, PhD
Journal Development Manager

P., eds. (2020). Frontiers in Chemistry: Rising Stars. Lausanne: Frontiers Media SA. doi: 10.3389/978-2-88963-580-1

Table of Contents

ANALYTICAL CHEMISTRY

14 ***Influence of Fixation and Permeabilization on the Mass Density of Single Cells: A Surface Plasmon Resonance Imaging Study***
Ruoyu Cheng, Feng Zhang, Meng Li, Xiang Wo, Yu-Wen Su and Wei Wang

21 ***ctDNA Detection Based on DNA Clutch Probes and Strand Exchange Mechanism***
Huan Chang, Yiyi Zhang, Fan Yang, Changtao Wang and Haifeng Dong

28 ***Biological Applications of Organic Electrochemical Transistors: Electrochemical Biosensors and Electrophysiology Recording***
Liming Bai, Cristina García Elósegui, Weiqi Li, Ping Yu, Junjie Fei and Lanqun Mao

44 ***An Allosteric-Probe for Detection of Alkaline Phosphatase Activity and its Application in Immunoassay***
Jingjing Guo, Mingxuan Gao, Yanling Song, Li Lin, Kaifeng Zhao, Tian Tian, Dan Liu, Zhi Zhu and Chaoyong James Yang

53 ***Substrate-Assisted Visualization of Surfactant Micelles via Transmission Electron Microscopy***
Zekun Zhang, Kaitao Li, Rui Tian and Chao Lu

61 ***A Threshold-Limited Fluorescence Probe for Viscosity***
Zuhai Lei, Kai Xin, Shaobing Qiu, Liling Hou, Xiangming Meng and Youjun Yang

68 ***Phosphate Assay Kit in One Cell for Electrochemical Detection of Intracellular Phosphate Ions at Single Cells***
Haiyan Xu, Dandan Yang, Dechen Jiang and Hong-Yuan Chen

CATALYSIS AND PHOTOCATALYSIS

77 ***Efficient Light-Driven Hydrogen Evolution Using a Thiosemicarbazone-Nickel (II) Complex***
Stylianos Panagiotakis, Georgios Landrou, Vasilis Nikolaou, Anisa Putri, Renaud Hardré, Julien Massin, Georgios Charalambidis, Athanassios G. Coutsolelos and Maylis Orio

85 ***Highly Active Ni- and Co-Based Bimetallic Catalysts for Hydrogen Production From Ammonia-Borane***
Shinya Furukawa, Genki Nishimura, Tomoaki Takayama and Takayuki Komatsu

92 ***Harnessing Plasmon-Induced Hot Carriers at the Interfaces With Ferroelectrics***
Vineet Kumar, Shaun C. O'Donnell, Daniel L. Sang, Paul A. Maggard and Gufeng Wang

111 ***A Holistic Approach to Model the Kinetics of Photocatalytic Reactions***
Jonathan Z. Bloh

124 ***Flavin Conjugated Polydopamine Nanoparticles Displaying Light-Driven Monooxygenase Activity***
Leander Crocker and Ljiljana Fruk

CHEMICAL AND PROCESS ENGINEERING (FORMERLY CHEMICAL ENGINEERING)

139 ***Porous Boron Nitride Materials: Influence of Structure, Chemistry and Stability on the Adsorption of Organics***
Sofia Marchesini, Xiyu Wang and Camille Petit

148 ***Structural Changes in Polymeric Gel Scaffolds Around the Overlap Concentration***
Han Zhang, Matthew D. Wehrman and Kelly M. Schultz

158 ***Preparation of Renewable Epoxy-Amine Resins With Tunable Thermo-Mechanical Properties, Wettability and Degradation Abilities From Lignocellulose- and Plant Oils-Derived Components***
Louis Hollande, Izia Do Marcolino, Patrick Balaguer, Sandra Domenek, Richard A. Gross and Florent Allais

169 ***Nanocellulose Xerogels With High Porosities and Large Specific Surface Areas***
Shunsuke Yamasaki, Wataru Sakuma, Hiroaki Yasui, Kazuho Daicho, Tsuguyuki Saito, Shuji Fujisawa, Akira Isogai and Kazuyoshi Kanamori

CHEMICAL BIOLOGY

180 ***N,N-Dimethylaminoxy Carbonyl, a Polar Protecting Group for Efficient Peptide Synthesis***
Ryo Okamoto, Emiko Ono, Masayuki Izumi and Yasuhiro Kajihara

186 ***Lighting-Up Tumor for Assisting Resection via Spraying NIR Fluorescent Probe of γ-Glutamyltranspeptidas***
Haidong Li, Qichao Yao, Feng Xu, Ning Xu, Wen Sun, Saran Long, Jianjun Du, Jiangli Fan, Jingyun Wang and Xiaojun Peng

201 ***Imaging of Formaldehyde in Live Cells and* Daphnia magna *via Aza-Cope Reaction Utilizing Fluorescence Probe With Large Stokes Shifts***
Mingwang Yang, Jiangli Fan, Jianjun Du, Saran Long, Jia Wang and Xiaojun Peng

211 ***Near-Infrared Aggregation-Induced Emission-Active Probe Enables* in situ *and Long-Term Tracking of Endogenous ß-Galactosidase Activity***
Wei Fu, Chenxu Yan, Yutao Zhang, Yiyu Ma, Zhiqian Guo and Wei-Hong Zhu

222 ***Chemical Biology Gateways to Mapping Location, Association, and Pathway Responsivity***
Marcus J. C. Long, Xuyu Liu and Yimon Aye

243 ***Elucidating the Lipid Binding Properties of Membrane-Active Peptides Using Cyclised Nanodiscs***
Alan H. Zhang, Ingrid A. Edwards, Biswa P. Mishra, Gagan Sharma, Michael D. Healy, Alysha G. Elliott, Mark A. T. Blaskovich, Matthew A. Cooper, Brett M. Collins, Xinying Jia and Mehdi Mobli

ELECTROCHEMISTRY

261 ***Photochemically Induced Phase Change in Monolayer Molybdenum Disulfide***
Peter Byrley, Ming Liu and Ruoxue Yan

270 ***Low-Loading of Pt Nanoparticles on 3D Carbon Foam Support for Highly Active and Stable Hydrogen Production***
Abdulsattar H. Ghanim, Jonathan G. Koonce, Bjorn Hasa, Alan M. Rassoolkhani, Wei Cheng, David W. Peate, Joun Lee and Syed Mubeen

279 ***Lithium Sulfide–Carbon Composites via Aerosol Spray Pyrolysis as Cathode Materials for Lithium–Sulfur Batteries***
Noam Hart, Jiayan Shi, Jian Zhang, Chengyin Fu and Juchen Guo

286 ***Effect of Surface and Bulk Properties of Mesoporous Carbons on the Electrochemical Behavior of GOx-Nanocomposites***
Tsai Garcia-Perez, Shouzhen Hu, Youngho Wee, Louis Scudiero, Conrad Hoffstater, Jungbae Kim and Su Ha

298 ***The Influence of Interfacial Chemistry on Magnesium Electrodeposition in Non-nucleophilic Electrolytes Using Sulfone-Ether Mixtures***
Laura C. Merrill and Jennifer L. Schaefer

308 ***Localization of Ion Concentration Gradients for Logic Operation***
Nikolay V. Ryzhkov, Pavel Nesterov, Natalia A. Mamchik, Stanislav O. Yurchenko and Ekaterina V. Skorb

317 ***A Review on the Electroless Deposition of Functional Materials in Ionic Liquids for Batteries and Catalysis***
Abhishek Lahiri, Giridhar Pulletikurthi and Frank Endres

GREEN AND SUSTAINABLE CHEMISTRY

333 ***Bioinspired Slippery Lubricant-Infused Surfaces With External Stimuli Responsive Wettability: A Mini Review***
Xian Yang, Yu Huang, Yan Zhao, Xiaoyu Zhang, Jinhua Wang, Ei Ei Sann, Khin Hla Mon, Xiaoding Lou and Fan Xia

340 ***Quantifying the Stability of the Hydronium Ion in Organic Solvents With Molecular Dynamics Simulations***
Alex K. Chew and Reid C. Van Lehn

354 ***A Strategy for Prompt Phase Transfer of Upconverting Nanoparticles Through Surface Oleate-Mediated Supramolecular Assembly of Amino-ß-Cyclodextrin***
Xindong Wang and Guanying Chen

363 ***Membrane-Modified Metal Triazole Complexes for the Electrocatalytic Reduction of Oxygen and Carbon Dioxide***
Skye N. Supakul and Christopher J. Barile

371 ***Photoelectrochemical Gas–Electrolyte–Solid Phase Boundary for Hydrogen Production From Water Vapor***
Fumiaki Amano, Ayami Shintani, Hyosuke Mukohara, Young-Min Hwang and Kenyou Tsurui

381 ***Templated Growth of Crystalline Mesoporous Materials: From Soft/Hard Templates to Colloidal Templates***
Lei Zhang, Lei Jin, Ben Liu and Jie He

INORGANIC CHEMISTRY

399 ***Coordination-Driven Self-Assembly of Silver(I) and Gold(I) Rings: Synthesis, Characterization, and Photophysical Studies***
Cressa Ria P. Fulong, Sewon Kim, Alan E. Friedman and Timothy R. Cook

412 ***Understanding the Role of Yb^{3+} in the Nd/Yb Coupled 808-nm-Responsive Upconversion***
Nan Song, Bo Zhou, Long Yan, Jinshu Huang and Qinyuan Zhang

420 ***Mapping Temperature Distribution Generated by Photothermal Conversion in Graphene Film Using Er,Yb:$NaYF_4$ Nanoparticles Prepared by Microwave-Assisted Solvothermal Method***
Oleksandr A. Savchuk, Joan J. Carvajal, Yolanda Cesteros, Pilar Salagre, Huu Dat Nguyen, Airan Rodenas, Jaume Massons, Magdalena Aguiló and Franscesc Díaz

431 ***Revisiting the Growth of Black Phosphorus in Sn-I Assisted Reactions***
Dongya Wang, Peng Yi, Lin Wang, Lu Zhang, Hai Li, Min Lu, Xiaoji Xie, Ling Huang and Wei Huang

440 ***Upconversion Nanocomposite Materials With Designed Thermal Response for Optoelectronic Devices***
Eduardo D. Martínez, Carlos D. S. Brites, Luís D. Carlos, Ricardo R. Urbano and Carlos Rettori

451 ***Luminescent Schiff-Base Lanthanide Single-Molecule Magnets: The Association Between Optical and Magnetic Properties***

Analytical Chemistry

Wei Wang

Wei Wang received his BSc and MSc degree from the ESE Department of Nanjing University in 1997 and 2000, respectively. He received a PhD degree from the ECE department of the National University of Singapore (NUS) in 2008. He joined the Computer Science and Technology Department of Nanjing University in 2012. Before that, he worked at Microsoft Research Asia (MSRA) as an associate researcher in 2009. His research interests are focused in the areas of wireless networking, including Device-free Sensing, Software Defined Radio, and Mobile Cellular Networks.

Haifeng Dong

Dr Haifeng Dong received his PhD degree from Nanjing University in 2011. He then joined the University of Science & Technology Beijing (USTB) in the same year. He pursued his research as a postdoctoral researcher at the University of Pittsburgh from October 2012 to September 2013. Afterwards, he joined USTB as a Professor. He worked as a visiting Professor at Kyoto University from July 2015 to October 2015. His research interests include the application of functional nanoprobes in DNA biosensors and imaging analysis of intracellular microRNA as well as nanomedicine. His achievements have led to three published books and 70 SCI papers published in Chem. Rev., Angew. Chem. Int. Ed., Adv. Mater., Nano lett., ACS nano, Adv. Funct. Mater., Chem. Sci. and Biomaterials, etc. These papers have been cited over 3,000 times and the most cited paper has been cited 527 times.

Ping Yu

Ping Yu is currently a Professor at the Key Laboratory of Analytical Chemistry for Living Biosystems of the Institute of Chemistry, at the Chinese Academy of Sciences (ICCAS). She received her PhD in Chemistry from ICCAS in 2007 and then joined ICCAS as a faculty member. She was a recipient of the "LU JIAXI Award for Junior Scientists" awarded by the Chinese Academy of Sciences (2014) and the "National Excellent Young Scholars" awarded by National Natural Science Foundation of China (2013). Her ongoing work focuses on ion transport, electrochemistry, chem/(bio)sensors, and *in vivo* analysis.

Zhi Zhu

Prof. Zhi Zhu received her Bachelor's degree in chemistry from Peking University, China in 2006 and her PhD in analytical chemistry from the University of Florida, USA in 2011. She joined Xiamen University, China as an Assistant Professor in 2011 and was promoted to Associate Professor in 2012 and Professor in 2015. She won the Chinese National Excellent Young Investigator Award in 2014 and the Youth in Chemistry Award from the Chinese Chemical Society in 2016. Her current research is focused particularly on molecular recognition, microfluidics, and point-of-care testing.

Chao Lu

Chao Lu received his PhD degree in Materials Science from the Chinese Academy of Sciences. He is currently a full Professor at the State Key Laboratory of Chemical Resource Engineering, Beijing University of Chemical Technology. In 2011, he was selected to participate in the New Century Outstanding Talent scheme of the Ministry of Education. His research interests focus on the design, synthesis, and functional study of luminescent molecules and composites. He is responsible for national and international research projects and has published more than 80 papers in international peer-reviewed journals.

Rui Tian

Rui Tian received her PhD degree at the College of Science, Beijing University of Chemical and Technology under the supervision of Prof. Dr Xue Duan. She now works in the State Key Laboratory of Chemical Resource Engineering, Beijing University of Chemical Technology. Her research interests are focused on the structural design, assembly, and functional study of inorganic-organic composite materials. She is responsible for national research projects and has published more than 20 papers in national and international journals.

Youjun Yang

Youjun Yang is a Professor of pharmacy at the East China University of Science and Technology since 2010. He was trained as a physical organic chemist and a supramolecular chemist in the groups of Robert M. Strongin (PhD, LSU, 2002-2007) and Eric V. Anslyn (Postdoc, UT Austin, 2007-2010). His research interests broadly fall within the field of synthetic dye chemistry, spectroscopy, photochemistry, bioimaging, and redox homeostasis. He developed high-performance deep-NIR absorbing/emitting dyes, Hill-type pH probes, Photo-triggered photo-calibrated NO/CO donors, Covalent-Assembly type molecular probes, and antibacterial hits. He won the Czarnik Emerging Investigator award, and the Excellent Young Scholar of NSFC.

Dechen Jiang

Dr Dechen Jiang is currently a Professor at the School of Chemistry and Chemical Engineering at Nanjing University. He obtained his BSc, MSc and PhD degrees from Nanjing University in 2000, Fudan University in 2003, and the Case Western Reserve University in 2008, respectively. After 3 years of postdoctoral training at UNC-Chapel Hill, Dr Jiang joined Nanjing University to start his independent research. Dr Jiang has authored and co-authored over 50 research publications in journals such as PNAS, JACS, Angew Chem and Anal. Chem. His research focuses on the development of methodology and is instrumental for single cell analysis.

Fixation and permeabilization of cells and tissues are essential processes in biological techniques like immunofluorescence and immunohistochemistry for cell biology studies. In typical procedures, the biological samples are treated by paraformaldehyde and Triton X-100 to achieve cellular fixation and permeabilization, respectively, prior to the incubation with specific antibodies. While it is well-known that the integrity of cell membrane has been broken during these processes, quantitative studies on the loss of cellular mass density and the enhancement of molecular accessibility at single cell level are still rare. In this study, we employed the surface plasmon resonance (SPR) imaging technique to monitor the mass density change of single cells during sequential fixation and permeabilization processes. We further utilize the osmotic responses of single cells to sugar molecules as an indicator to evaluate the integrity of cell membranes. It was found that, while fixation initially destructed the integrity of cell membranes and increased the permeability of intra- and extra-cellular molecules, it was permeabilization process that substantially induced significant loss in cellular mass density.

Keywords: surface plasmon resonance imaging, fixation, permeabilization, immunofluorescence, osmotic pressure

INTRODUCTION

Immunofluorescence is a powerful technique to visualize the distribution of specific biomolecules within biological samples such as cells and tissues (Joshi and Yu, 2017). In typical cell-based immunofluorescent assays, adherent cells were incubated with fluorescent antibody to enable specific recognition and binding between the antibody and the target molecule in the cells. After thorough rinse, the sample was placed under fluorescence microscope to obtain a fluorescence image, from which the distribution of target molecules was reported by the fluorescent tags. In order to facilitate the accessibility of antibody to the target molecules and to inhibit the inherent cellular activity, the samples were often fixed and permeabilized prior to the staining procedures. They were particularly necessary when the target molecules were located within the cytoplasm. Among many types of reagents, paraformaldehyde (PFA) and Triton X-100 are probably the most widely used ones for fixation and permeabilization, respectively.

Depolymerization of PFA produced formaldehyde molecules to create covalent chemical bonds between proteins in the sample. The mechanism of the action relied on the activation of one of the amino acid residuals lysine. PFA also dissolved some lipids in cellular membranes which slightly damaged the cell membrane integrity (Fox et al., 1985; Thavarajah et al., 2012; Kiernan, 2018). Triton X-100, as an effective non-ionic detergent, could dissolve lipids from cell membranes, so that the cell membrane became more permeable to the fluorescent antibody. The permeabilization step removed more cellular membrane lipids due to its uncharged, hydrophilic head groups that consist of polyoxyethylene moieties to allow large molecules like antibodies to get inside the cell (Jamur and Oliver, 2010; Koley and Bard, 2010). A schematic illustration of cell fixation and permeabilization process is shown in **Figure 1D**. Despite of the fact that fixation and permeabilization have become routine procedures in immunofluorescence and immunohistochemistry, pretty rare efforts have been made to quantitatively clarify their influences on the membrane integrity and cellular mass density at single cell level.

Surface plasmon resonance (SPR) has been a popular and powerful technique to determine the binding kinetics between a pair of molecules since its invention in 1980s (Liedberg et al., 1983; Cullen et al., 1987). This is attributed to its remarkable advantages, including real-time quantitative kinetic measurement with high temporal resolutions, compatibility with expanded devices, and most importantly, its intrinsic feature of label-free (Rothenhäusler and Knoll, 1988; Phillips and Cheng, 2007; Homola, 2008; Abadian et al., 2014; Méjard et al., 2014; Yanase et al., 2014; Su and Wang, 2018). Early applications mostly focused on characterizing and quantifying biomolecular interactions by immobilizing purified molecules onto SPR sensing substrates (gold-coated glass slides). Such *ex situ* studies not only required the labor-intensive purification procedures, but also led to results that may not reflect the natural interaction in living beings (Phillips and Cheng, 2007; Homola, 2008). Driven by both the technical advancement in various SPR imaging (SPRi) systems and the scientific motivation in single cell imaging and analysis, both prism and objective-based SPRi techniques have been employed to image the mass distribution of single living cells without the need of labeling (Wang et al., 2010, 2012a; Yanase et al., 2010; Yang et al., 2015; Zhang et al., 2015). Each one has its own merits. The latter has a higher spatial resolutions and the former has a better sensitivity. By monitoring the time-lapsed SPR images of single living cells during various types of physiological and biological stimulations, important spatial and dynamic information regarding the cell-substrate interactions (Giebel et al., 1999), cell migrations (Smith et al., 2004), osmotic responses (Wang et al., 2012a), ligand-receptor binding kinetics (Wang et al., 2012b, 2014), signaling pathways (Deng et al., 2016), protein activation dynamics (Peng et al., 2018), and living cancer cell drug responses (Wang et al., 2018) have been obtained. For instances, existing studies have clearly demonstrated that SPRi techniques were capable for mapping the mass density as well as the membrane integrity at single cell level (Yanase et al., 2010; Wang et al., 2012b; Yang et al., 2015). The image contrast of SPRi came from the subcellular distribution of refractive index, which was roughly determined by the local mass density. Binding of specific antibodies onto the cell membrane that expressed the corresponding antigens, or stimulating the living cells with particular chemicals, was found to alter the mass density of single cells in a heterogeneous and dynamic manner (Wang et al., 2012a,b). Exposure of single living cells to hypertonic solutions was found to induce the contraction of cells, indicating the excellent integrity of cell membranes (Wang et al., 2012a). However, how the fixation and permeabilization treatments would affect the SPR images of single cells remains unclear.

In the present work, we employed a home-built SPRi system to continuously record the time-lapsed SPR images of tens of single living cells when the cells were successively treated by 4% PFA solution and 1% Triton X-100 solution. The mass density of single cells was determined by the averaged SPRi signal. The membrane integrity was evaluated by exposing the cells to hypertonic solution. It was found that, in addition to the slightly reduced mass density by <10%, PFA treatment significantly destructed the cell integrity as indicated by the loss of osmotic response upon the exposure of sugar molecules. Subsequent treatment by Triton X-100, however, significantly reduced the mass density by another 20%, suggesting the severe destruction to the membrane integrity.

MATERIALS AND METHODS

Materials

Dulbecco's phosphate buffered saline (PBS, Gibco), Sucrose (Sinopharm Chemical Reagent Co., Ltd), Triton X-100 (Aladdin), Paraformaldehyde (Shanghai Lingfeng Chemical Reagent Co., Ltd). All of the reagents were dissolved in PBS.

Cell Culture

BT-474 cells were cultured at 37°C with 5% CO_2 and 70% relative humidity in Dubelco's Modified Eagle's Medium (DMEM, Invitrogen) with 10% fetal bovine serum (FBS, Invitrogen), 100 units/mL penicillin and 100 μg/mL streptomycin (Invitrogen). Cells was passed when they were 70–80% confluent by treating with 0.25% trypsin solution (Gibco).

Prism-Based SPR Imaging Setups

A schematic diagram and a photo of the SPRi system are presented in **Figures 1A,B**. The SPRi apparatus is mainly composed of three parts: light source, optical components and camera.

- Light source: A 670 nm light-emitting diode (L7868-01, Hamamatsu, Japan) and a temperature-controlled mounting socket (LDM21, Thorlabs, Newton, USA).
- Optical components (Edmund Optics, USA): A triangle SF-11 prism with a sensor chip on (No. 1 BK7 glass from Fisherbrand), a converging lens, a polarizer, and a tunable lens.
- Camera: Charge-coupled device camera (Pike F032B, Allied Vision Technology, Newburyport, USA).

The p-polarized light hits the bottom of the gold-coated glass slide through the prism directly and the camera captures the

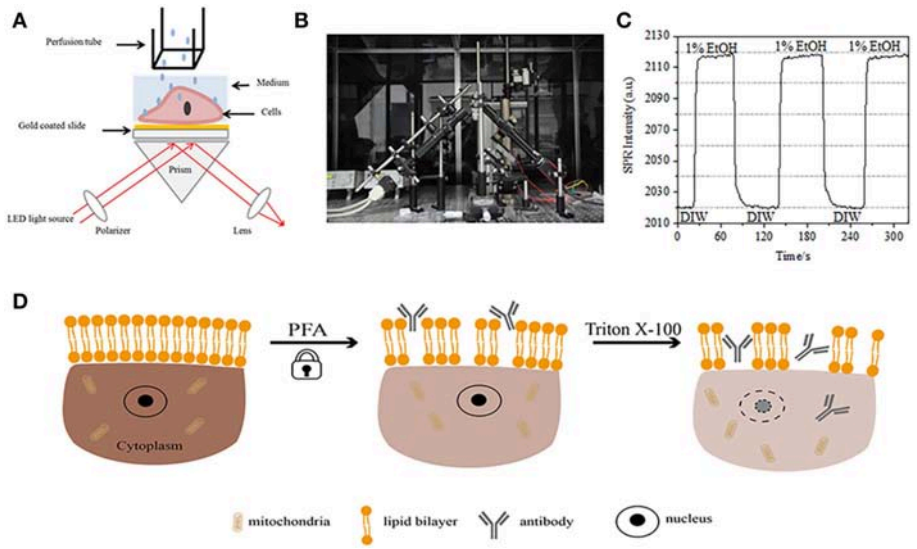

FIGURE 1 | Prism-based SPR imaging setups. **(A)** Schematic illustration of the experimental set-up. **(B)** A photograph of the apparatus. **(C)** Sensitivity calibration curve. **(D)** Schematic illustration of cell fixation and permeabilization.

reflected beam to generate SPR images at a rate of 0.828 Frame per second (fps). When choosing 4X magnification in a tunable lens, the field of view was $\sim 2 \times 2$ mm^2.

Sensor Chip Preparation

Each chip was washed with 75% ethanol and deionized water (DIW), followed by UV exposure for 30 min to remove the surface contamination and sterilize them before each experiment. A Flexi-Perm silicon chamber (Greiner Bio-One) was placed on top of the gold chip to serve as a cell culture well. To achieve the surface modification prior to cell seeding, a 100 μg/mL 150 μL collagen solution was added to the chamber and kept in an incubator for 2 h. The chip was then rinsed with deionized water twice and DMEM twice prior to cell seeding. To make the cells a good shape, the chip was incubated in the growth medium for 36 h. The growth medium was then replaced with PBS buffer solution for 10 min for cells achieving a balance.

Flow System

A gravity driven multichannel drug perfusion system was applied to injection and switch of the solution. The flow rate is 300 μL/min and the solution switching rate around the cells can reach 1–2 s.

Sensitivity Calibration

A sensor chip was prepared as described in preceding part without surface modification and cell seeding. First, DIW flowed over the chip for about 60 s. Then, it was replaced by 1% (v/v) ethanol solution for another 60 s. As one of the most commonly used calibration solution, 1% ethanol is known to increase the SPR angle of DIW by 60 mDeg. Experimental results showed that SPR intensity accordingly increased by 96 I.U. (**Figure 1C**), corresponding to a sensitivity of 1.6 ΔI.U./mDeg.

RESULTS AND DISCUSSION

The cell membrane (also known as cytoplasmic membrane), consisting of a lipid bilayer with embedded proteins, is a semi-permeable membrane that encloses the cytoplasm of a cell. The fixation and permeabilization steps of cells and tissue samples, which could alter the permeability of cell membrane, are crucial procedures that could determine the successes of immunofluorescent or immunohistochemical assays. In addition to this, the antibody quality and the immunoreaction procedure are other key determinants to these kinds of experiments. SPR has the feature that both the resonant angle and the refractive index (RI) near the sensing surface are highly sensitive to the mass density of the surface layer in the medium-metal interface. Therefore, cell's mass density variations taking place on or near the metal film (∼200 nm) could be synchronously recorded by measuring the intensity of the reflected light. By employing surface plasmon resonance imaging technique, we explored dynamic distribution of cellular mass density with high spatial and temporal resolutions and reliable sensitivity in both fixation and permeabilization processes in this study.

Initial Mass Density Loss in Cell Fixation by PFA

The first step to prepare biological samples for immunofluorescent or immunohistochemical analysis is usually fixation. And the most commonly used fixatives for these kinds of assays are crosslinking fixatives like PFA that works by generating covalent chemical bonds between proteins in cells or tissues. We therefore investigated the influence of PFA treatment on cellular mass density. Living BT-474 cells were cultured on coverslip coated by gold film with a thickness of

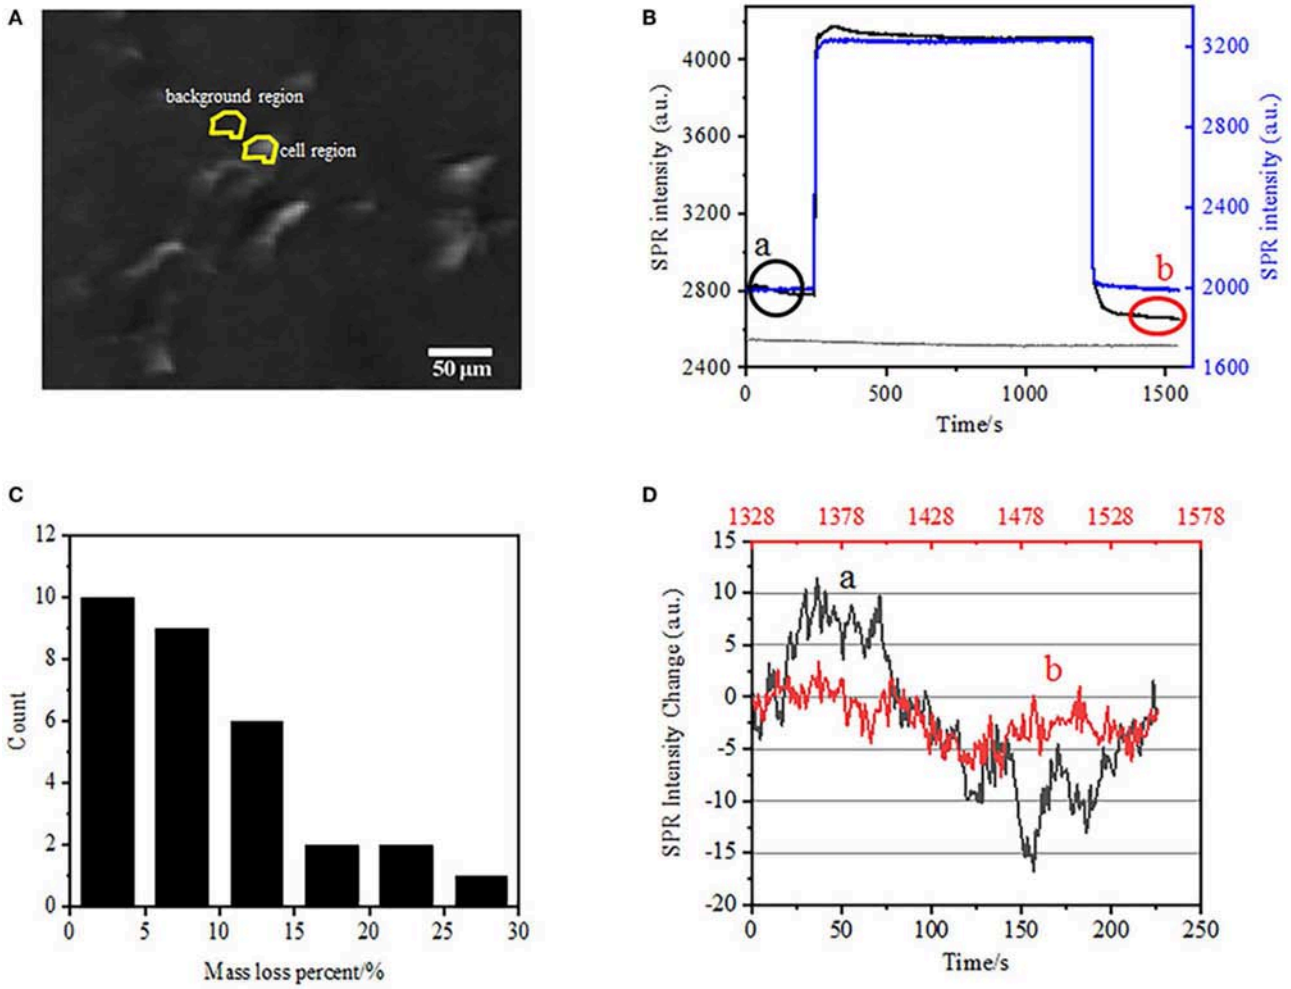

FIGURE 2 | Cell fixation process. **(A)** SPRi image of BT-474 cells. **(B)** SPR signals of single cell (black curve) and background (blue curve) undergoing a solution switching process: PBS buffer to 4% PFA to PBS buffer. 50 nm. A representative SPR image containing single cells is provided in **Figure 2A**. SPR signals of each cell can be obtained by choosing a region-of-interest in the SPR image that matches the morphology of the investigated cell. In a typical experiment, when solution flowed over the cells, SPR sensorgrams of the cells were obtained by analyzing each cell as shown in **Figure 2B** (black curve). In the preceding 242 s, PBS buffer without PFA was flowing over the cells and the baseline was determined by the system stability (light source and mechanical stability) and the inherent micromotion signals generated by the living cells. PFA solution was then introduced at the 242th second, which immediately increased the SPR signal because of the relatively large refractive index of 4% PFA solution (bulk effect). PFA solution ran for another 17 min to achieve sufficient fixation. At the 1237th second, PFA solution was switched back to pure PBS solution. In addition to the reduced bulk effect, a decrease in the SPR intensity of single cells was found when comparing the signals before (0–242) and after (1237–1545) the PFA treatments and the mass loss percent was obtained through dividing the decrease value to the initial value. The SPR sensongrams of the background (an adjacent region without cell adhesion, blue curve) and a single cell treated with PBS during 1,500 s (gray curve) are also shown in **Figure 2B**. Statistical analysis on 30 cells reveals an averaged mass density loss of $10 \pm 5\%$ as shown in **Figure 2C**. It was also found that, after PFA treatment, the baseline fluctuation level in SPR signal was significantly reduced by half or even two third, suggesting the loss of micromotions and fixation of the treated cells as shown in **Figure 2D**. Such micromotion signals were generated by a bunch of dynamic cellular activities from different cell components including skeleton, membranes and organelles. The fixation terminated such biological activities and therefore eliminated the micromotion signals, accompanying with a significantly reduced intensity fluctuation in the SPR sensograms of single cells.

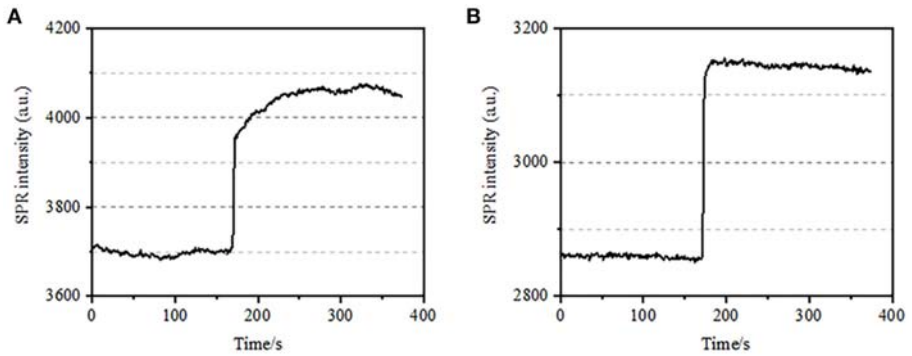

FIGURE 3 | Osmotic pressure responses of cells. **(A)** Response of a living cell to 25 mM sucrose. **(B)** Response of the same cell fixed (10 min) to 25 mM sucrose.

Osmotic Pressure Response in Cell Fixation by PFA

The integrated structure of cell membrane, a semi-permeable membrane, regulates the homeostasis of a cell to reach balance in physiological osmotic pressure. PFA treatment was also found to have the ability in destructing the membrane integrity as shown in **Figure 3**. When the buffer around the target cell changed into 25 mM sucrose solution in <1 s via a drug-perfusion system, a hypertonic cell culture environment was created. For living cells, the exposure to hypertonic solution triggered a series of physiological responses to balance the intracellular and extracellular osmotic pressure, which has been investigated in details in our previous work (Wang et al., 2012a). In this study, a typical SPR sensorgram of single physiological BT-474 cells is provided in **Figure 3A**. Upon the exposure to hypertonic sucrose solution, treated cells firstly underwent a pressing shrink, leading to a gradual increase in SPR intensity until a plateau was reached. It suggested the increased mass density as a result of cell shrink and subcellular components gathering toward the bottom of the gold culture coverslip. The gradual increase in SPR intensity by hypertonic stimulation is a kind of physiological regulation for cellular osmotic pressure, thus indicating the physiological integrity of the cell membrane. When the membrane integrity was destroyed, the introduction of hypertonic sucrose solution was found to immediately increase the SPR intensity in a much shorter time, as shown in **Figure 3B**. It is because the sugar molecules freely penetrated into the cells without resistance from the semi-permeable membrane and increased the local refractive index immediately (bulk effect). It is clear that, while the slow increase in the SPR intensity reflected the physiological osmotic regulation (**Figure 3A**), the rapid jump demonstrated the cell membrane had been damaged to allow for the free entry of small sugar molecules (**Figure 3B**).

Substantial Mass Density Loss in Cell Permeabilization by Triton

In the previous fixation stage, an initial cell mass density decreased just by ∼10% (**Figure 2C**). It is reasonable to speculate that the PFA fixation only slightly destructed the membrane integrity and increased the permeability of small molecules. Majority of the intracellular components should be still harbored within the cytoplasmic membrane. We subsequently studied the influence of a typical permeabilization detergent, 1% Triton X-100, on cells that have been fixed with PFA for 17 min previously. A representative SPR sensorgram of single cells during exposure to 1% Triton X-100 is shown in **Figure 4A**. The introduction of Triton X-100 increased the SPR intensity followed by a gradual decrease. The first increase is a consequence of increase refractive index of bulk solution, and the followed decrease indicated the gradual loss in the mass density due to the cell permeabilization. The reduced mass density was more plentiful when comparing the SPR intensity change before (0-300 s) and after the introduction of detergent (1,300–1,800 s). Analysis on 30 single cells demonstrated that the Triton X-100 treatment created a substantial mass density decrease by another 20 ± 5% after PFA fixation as shown in **Figure 4D** and **Table 1**. It is clear that the detergent Triton X-100 eliminated much more cellular membrane lipids and severely destructed the membrane integrity in this permeabilization stage. This resulted in more intracellular components, especially macromolecules, to release from the cells. And also, this allows large molecules like antibodies to get inside the cell in the next immunoreaction stage. Although SPR intensity of small molecules leaching was detected after PFA fixation, permeabilization by using Triton X-100 detergent clearly solubilized lipids and made the cells much more permeable to the movements of macromolecules in and out of the cell body.

It was found that the loss in mass density is a rather rapid process, which occurred in a few minutes in permeabilization stage (**Figure 4A**). The decrease in mass density roughly followed a monotonic decay within a time period of 126 s. The typical sensorgrams of single cells under 0.5 and 0.1% Triton X-100 are displayed in **Figures 4B,C**, respectively. The permeabilization process became much slower when reducing the concentration of detergent. It took 126, 510, 2,600 s for the three kinds of the treated cells to finish mass loss.

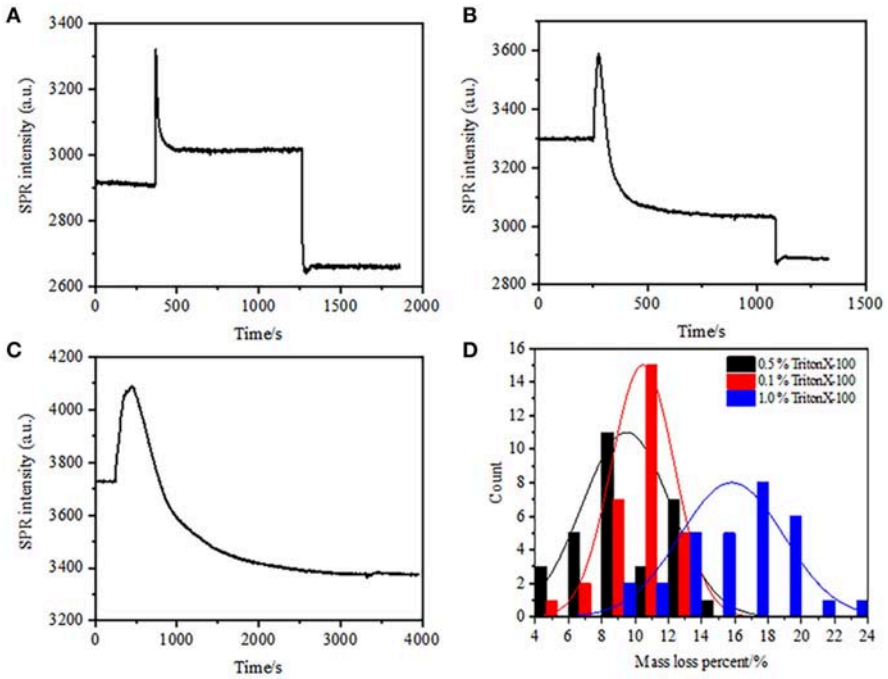

FIGURE 4 | Mass loss curves of cell treated with different concentration solutions **(A)** 1.0%, **(B)** 0.5%, **(C)** 0.1%. **(D)** Mass loss distribution of 30 single cells in different conditions.

Concentrations / Cell counts (30) / Mass loss	1.0 % Triton X-100	0.5 % Triton X-100	0.1 % Triton X-100
4–6%	0	3	1
6–8%	0	5	2
8–10%	2	11	7
10–12%	2	3	15
12–14%	5	7	5
14–16%	5	1	0
16–18%	8	0	0
18–20%	6	0	0
20–22%	1	0	0
22–24%	1	0	0

CONCLUSION

In summary, dynamic redistribution of cellular mass density in both fixation and permeabilization processes have been explored sensitively by using prism-based SPRi setup with high spatial and temporal resolutions. Fixative PFA could initially increase the permeability of cytoplasmic membrane to some extent because its ability of fixing cellular proteins in both membrane and intra-cellular proteins. It was supported by (1) the decreased mass density by ∼10% after a 17-min fixation treatment in 4% PFA solution, and (2) the eliminated cellular response to hypertonic solution, which demonstrated the destruction of cellular integrity to small molecules like sugars. Detergent Triton X-100 is superior to fixative PFA in solubilizing lipids and therefore increasing cell membrane permeability, accompanying with the more substantial loss in the mass density due to the release of not only small molecules but also large molecules and possibly some organelles such as vesicles. Besides, the rate of mass loss is positively correlated with Triton X-100 concentration. These results provided quantitative and dynamic understandings on the influence of fixation and permeabilization on the cellular mass density and membrane integrity, with implications for optimizing the conditions for single cell biological experiments, such as immunofluorescent and immunohistochemical assays.

Circulating tumor DNA (ctDNA), originating directly from the tumor or circulating tumor cells, may reflect the entire tumor genom and has gained considerable attention for its potential clinical diagnosis and prognosis throughout the treatment regimen. However, the reliable and robust ctDNA detection remains a key challenge. Here, this work designs a pair of DNA clutch separation probes and an ideal discrimination probes based on toehold-mediated strand displacement reaction (TSDR) to specifically recognize ctDNA. First, the ctDNAs were denatured to form ssDNAs, the pair of DNA clutch separation probes [one of which modified onto the magnetic nanoparticles (MNPs)] are used to recognize and hybridize with the complemental chains and prevent reassociation of denatured ssDNAs. The complemental chains are removed in magnetic field and left the wild and mutant ssDNA chains in the supernatant. Then, the TSDR specificity recognizes the target mutant sequence to ensure only the mutated strands to be detection. The proposed assay exhibited good sensitivity and selectivity without any signal amplification. The proposed assay displayed a linear range from 2 to100 nM with a limit of detection (LOD) of 0.85 nM, and it was useful for ctDNA biomedical analysis and clinic theranostic.

INTRODUCTION

In recent years, many advanced analytical methods have been established to quantify DNAs and RNAs (Schwarzenbach et al., 2011; Si et al., 2014; Li et al., 2015; Wang et al., 2018), among them, liquid biopsy has increasingly attracted intense attention due to its rapid, cost-effective and non-invasive properties. Circulating tumor DNA (ctDNA), originating directly from the tumor or circulating tumor cells, is an effective diagnostic biomarker existing as a single or double strand in peripheral blood (Zou et al., 2017). It is potential surrogate for the entire tumor genome and has gained considerable attention for cancer diagnosis and prognosis (Das et al., 2016). It is reported that ctDNA levels could reflect the tumor burden, and patients with advanced tumors showed higher concentrations of ctDNA in plasma than that with earlier stage. For example, it was demonstrated that the level of ctDNA was related to the whole body tumor load and ctDNA decreased after complete surgery (Diehl et al., 2008). It was reported that ctDNA was detected in 82 and 47% for patients with stage IV and I disease, respectively (Bettegowda et al., 2014). Additionally, the half-life of ctDNA is very short, and it was promising for monitor the status of the tumor (Bettegowda et al., 2014; Diaz and Bardelli, 2014). Therefore, the detection of specific cancer-related sequences in ctDNA is very important in clinical application.

The detection of the ctDNA is difficult since the special double helix structure and single stranded DNAs (ssDNAs) formed during the annealing process (Noh et al., 2015), which require effective methods to prevent ssDNA from re-annealing for selectively detection of ctDNA (Das et al., 2016). Currently, DNA sequencing and polymerase chain reaction (PCR) are conventional methods for monitoring ctDNA in the blood (Murtaza et al., 2013; Bettegowda et al., 2014; Newman et al., 2014). However, both of them suffer some deficiencies including the biological environment interference, time-consuming, and cost-ineffective (Dewey et al., 2012; Wang et al., 2014). Therefore, the robust, sensitive, and selective detection of ctDNA are still urgently needed.

Two significant prerequisites for ctDNA detection are separation probes effectively preventing ssDNA from re-annealing and discrimination probes specifically recognizing the target ssDNA. The hybridization specificity based on based pairing almost requires the string hybridization condition or chemically complex nucleotide modifications. Toehold-mediated strand displacement reaction (TSDR) is widely applied in the dynamic DNA assembly for biomedical application by regulating the reaction rate (Yurke and Mills, 2003; Zhang and Winfree, 2009). Rationally designed hybridization probes based on strand exchange mechanisms or strand displacement reaction is intriguing since it can effectively and robustly distinguish single-base mutation in the gene fragment in various conditions (Xiao et al., 2005; Wang and Zhou, 2008).

Herein, this work designs a pair of DNA clutch separation probes and an ideal discrimination probes based on TSDR to specifically recognize mutant ctDNA (**Figure 1**). Under annealing, the pair of DNA clutch separation probes clutch 3 and clutch 5 could recognize and hybridize with the complementary chains (red color) and prevent reassociation of denatured ssDNAs. The complementary chains were then removed in magnetic field and the wild and left the mutant ssDNA chains in the supernatant. Finally, the discrimination probes based on TSDR which could specifically recognize the target mutant ssDNA sequence to produce the fluorescence signal for detection. Thus, the specific mutant ctDNA detection has been realized, displaying a good potential in the field of ctDNA biomedical application.

MATERIALS AND METHODS

Reagents and Materials

1-(3-Dimethylaminopropyl)-3-ethylcarbodiimidehydrochloride (EDC), Tris (2-carboxy-ethyl), N-hydro-xysuccinimide (NHS), phosphine (TCEP), were obtained from Sigma-Aldrich (St. Louis, MO). The ultrapure water was from a Millipore water purification system (18 MΩ, Milli-Q, Millipore, USA). Magnetic nanoparticles (MNPs) (20 mg/mL) modified with carboxyl (-COOH) group were obtained from Zhengzhou Innosep Biosciences Co., Ltd. (Zhengzhou, China). All of the DNA sequences were from Sangon Biological Engineering

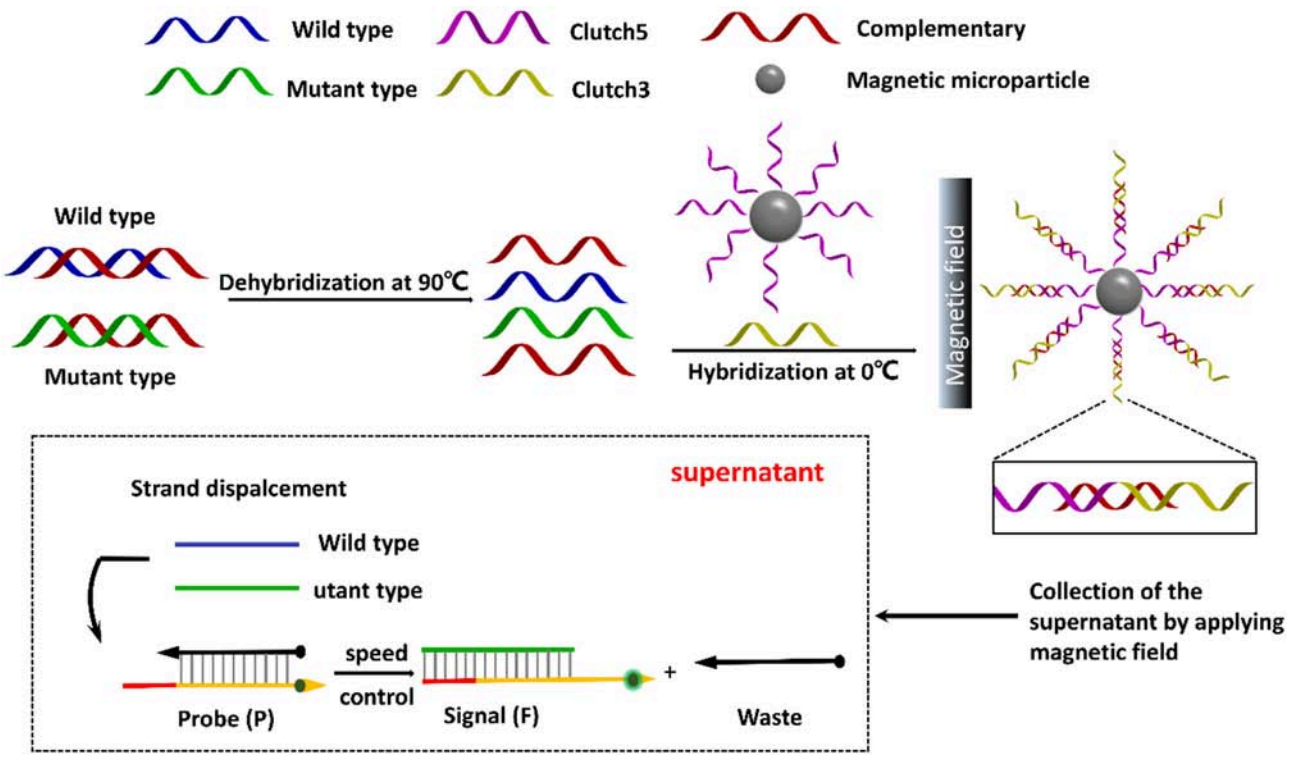

FIGURE 1 | Schematic illustration of direct detection of ctDNA based on DNA clutch separation probes and TSDR reaction.

Technology & Services Co., Ltd. (Shanghai, China) and the detailed information of sequences were presented in **Table 1**. Transmission electron microscopy (TEM; JEM2010F, JEOL, 200 kV) was used to exam the morphology of the MNPs. Dynamic light scattering (DLS) was recorded on a Zetasizer Nano S system (Malvern Instruments, Malvern, U.K.). The UV–vis absorption measurements were performed with a UV-1800 spectrometer (Shimadzu, Kyoto, Japan). All fluorescence measurements were carried out on a F-4500 fluorescence spectrometer (Hitachi, Tokyo, Japan). The agarose gel electrophoresis images were captured with an Alliance Ld2 (Uvitec, Cambridge, U.K.).

DNA 3	/BHQ2/ACGATGTAGCTA
Probe 3	GATTTCACTGTAGCTACATCGT/Cy5/

The base marked red in the table is the mutation site.

Characterization of Carboxylated MNPs

10 mg/mL carboxylated MNPs were diluted into 0.5 mg/mL in phosphate buffer saline (PBS, pH = 5.1, 10 mM) and sufficiently sonicated for 2 h to obtain the dispersed solution, 2 μL of the sample was then dropped on a double networked supporting membrane fixed with small clips and dried using the heating plate for TEM analysis. 0.5 mg/mL MNPs was diluted with distilled water to 1 mL and added to a particle size cell for DLS measurement.

DNA Functionalization of MNPs

30 μL of MNPs (0.5 mg/mL, pH =5.1), 30 μL MNPs probe (100 μM) and 4 mg of EDC were mixed in a centrifugal tube and reacted for 15 min. One milligram of NHS was then injected and the mixture was further reacted for 12 h in PBS solution (10 mM, pH = 7.4). Then the MNPs-DNA were washed with PBS (10 mM, pH = 7.4) for three times and stored in 120 mL of PBS (10 mM, pH = 7.4) for further use.

Electrophoresis Gel Characterization

The hybridization of clutch probes and the ssDNA were performed at 0°C for 1 h, and verified by 4% agarose gel electrophoresis (100 V, 50 mA).

Optimization of Discrimination Probes

The ssDNA (10 μL, 1 μM) labeled with fluorescent FAM firstly hybridized with their complementary ssDNA labeled with quenching groups (BHQ2) at 37°C for 2 h to form duplex helices discrimination probes. The target ssDNA with single nucleotide mutant (10 μL, 1 μM) or its wild type ssDNA (10 μL, 1 μM) was then added to the 100 μL of solution containing discrimination probes and incubated at desired time and temperatures. Afterwards, the fluorescence intensity was detected using a fluorescence spectrometer.

ctDNA Detection

Four microliter ctDNA with different concentrations were heated at 90°C for 2 min, and then added into solution containing 7 μL MNPs probes (20 μM) and 9 μL clutch 3 probe (20 μM) and reacted at 0°C for 60 min. The mixture was separated at a magnetic field and the supernatant was collected for further use. Ten microliter supernatant was added into 4 μL discrimination probes (10 μM) and the mixture was diluted into 200 μL and reacted at 37°C for 10 min. Afterwards, the fluorescence was scanned with a fluorescence spectrometer with excitation wavelength at 488 nm and scanning emission spectra from 505 to 700 nm.

RESULTS AND DISCUSSION

Characterization of MNPs-DNA

As shown in **Figure 2A**, it was obvious that the MNPs displayed uniform spherical and showed a particle size of about 500 nm. The MNP displayed a negative zeta potential of −11.8 mV, and the introduction of negatively charged DNA led to the zeta potential decreased to −22.5 mV (**Figure 2B**). In comparison with the UV-vis spectrum of MNPs, a strong characteristic absorption peak at 258 nm was observed in that of MNPs-DNA, revealing DNA was efficiently modified on MNPs' surface (Zhu et al., 2006; **Figure 2C**). The DLS analysis demonstrated the aqueous size of MNPs was approximately distributed at about 510 nm, in agreement with the TEM analysis, and it increased to 535 nm after the modification of DNA (**Figure 2D**). These results suggested the successful modification of DNA on the surface of MNPs. The electrophoresis experiment was employed to characterize DNA assembly. As shown in **Figure S1**, the lane 1–3 was the complementary sequences (16 bp), clutch probe 3 (35 bp), and clutch probe 5 (44 bp), respectively. From the lanes 4–6 analysis, it indicated the complementary sequences could hybridize with clutch probe 3 (lane 4), clutch probe 5 (lane 5), to form sandwich structure (lane 6).

Toehold Exchange Probes

To obtain an ideal discrimination probes with high specificity, the "toehold exchange" probes were rationally designed. The length of the cohesive ends at the 3′ end of the replacement sequence in the discrimination probes influence significantly the specificity (Chen and Seelig, 2016), which was firstly optimized. Three types of DNA probes consisting of two single sequence labeled with BHQ2 quencher and FAM fluorescent dye, respectively, were employed to investigate the optimized cohesive ends. It was found that the probe 1, probe 2, and probe 3 displayed a

maximum $F/F_0$of 1.15, 1.52, and 4.1, respectively, where the F and F_0 was the fluorescence intensity of probes in response to the mutant-type and wild-type ctDNA (**Figures 3A–C**). Importantly, when the cohesive ends extended to twelve bases (probe 3), the wild-type ctDNA produced similar fluorescence intensity to the control (PBS, pH 7.4, 10 mM) group, which indicated the

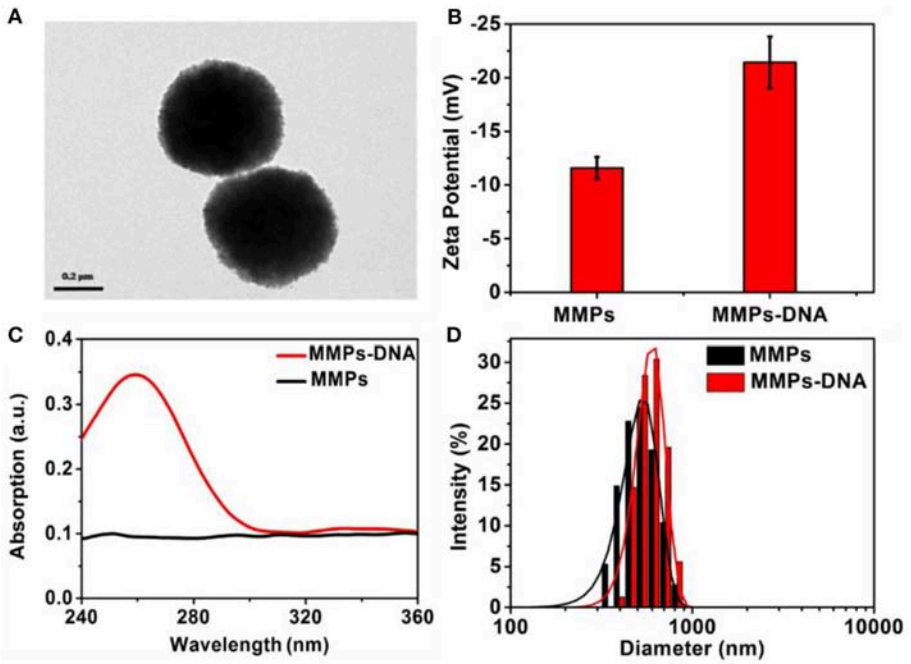

FIGURE 2 | TEM image of **(A)** MNPs, Zeta potential **(B)**, UV-visible spectra **(C),** and **(D)** DLS of MNPs and MNPs-DNA.

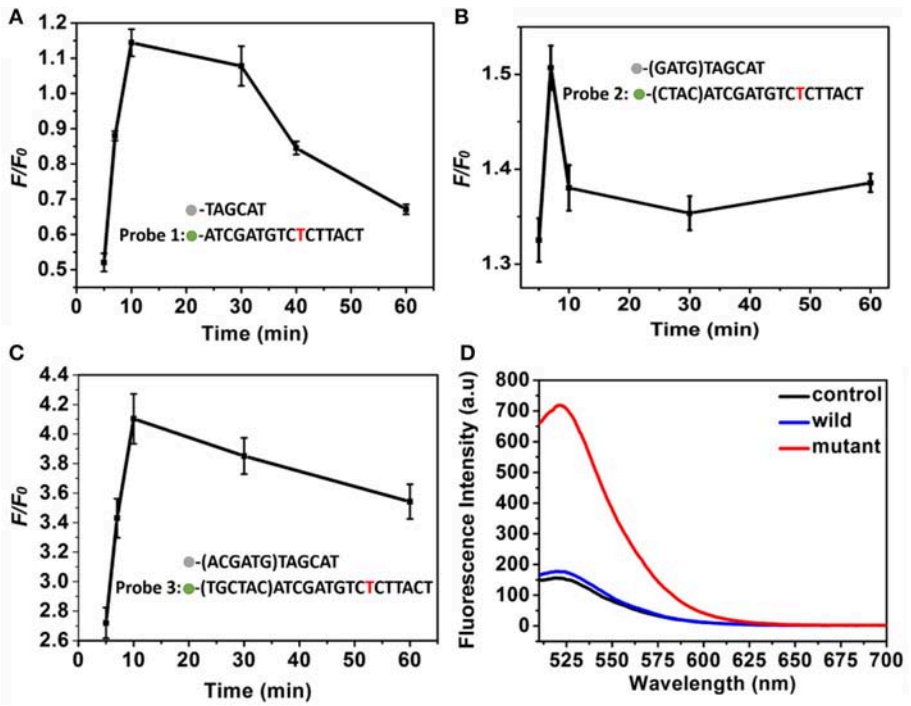

FIGURE 3 | (A–C) The F/F_0 value of **(A)** probe 1, **(B)** probe 2, and **(C)** probe 3 as a function of time. excellent specificity of probe (**Figure 3D**). Therefore, the toehold exchange probe 3 was used in subsequent experiments.

Conditions Optimization

The experimental conditions including the ratio of volume of MNPs and DNA in the PBS (pH 7.4, 10 mM) and strand displacement reaction time were investigated to achieve the optimal signal discriminant validity. The zeta potential analysis was used to optimize the ratio of volume of MNPs and DNA. As shown in **Figure 4A**, the absolute value of zeta potential gradually increased along with the increase of the ratio of volume of MNPs and DNA, and reached to maximum at the ratio of 1:50, which was selected for the followed experiments. The displacement reaction time was a significant factor in the experiment. The short reaction time might induce insufficient displacement reaction, while long reaction time could lead to decrease of the discrimination capability for wild/mutant sequence. As shown in **Figure 4B**, the system showed a sharply increase in the discrimination capability long with the increase of reaction time increased to 10 min, and then decreased when the reaction time further increased. Thus the 10 min was selected as the optimized reaction time.

Sensitivity of the Proposed System Proposed System

Under the optimized conditions, the system was very specific that just produced fluorescence signal toward the mutant-type ctDNA, while no fluorescence signal change was observed even if the concentration of wild-type ctDNA high to 50 nM due to the TSDR probe. Furthermore, the selectivity of the method was detected by using other DNA strands with different sequences. As shown in **Figure S2**, the fluorescent intensity of mutant-type ctDNA was much higher than that produced by other DNA strands, indicating the great selectivity of the detection strategy. Motivated by the intriguing specificity, the sensitivity of the assay was further investigated for mutant-type ctDNA detection. As shown in **Figure 5A**, the fluorescence intensity increased with the increasing mutant ctDNA target concentration, and a good linear relationship between the fluorescence intensity and target concentration ranging from 2 to 50 nM was obtained (**Figure 5B**). The limit of detection

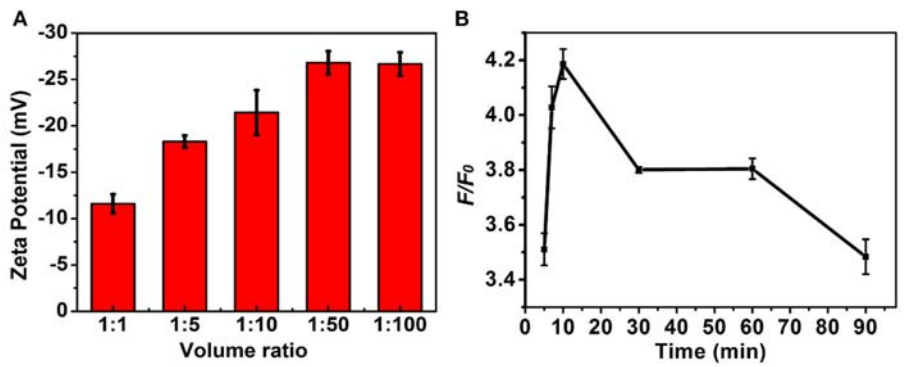

FIGURE 4 | The influence of **(A)** volume ratio of MNPs (0.5 mg/mL) to DNA (1 nM) and **(B)** strand displacement reaction temperature to the F/F_0. The concentration of the mutant type ctDNA and wild ctDNA was 100 nM.

(LOD) was calculated to be 0.85 nM using three times of the standard deviation of the control (Wang et al., 2009). To evaluate the practical application, the serum was chosen as the biological sample to evaluate the performance of the detection system. As demonstrated in **Figure S3**, the mutant ctDNA targets were detected in serum sample solution, implying matrix effects are not a major problem on the reaction system, which indicated the promising potential for clinical application.

CONCLUSIONS

In conclusion, we develop a ctDNA specifical detection method using a pair of DNA clutch separation probes and an ideal discrimination probes based on TSDR. The clutch probes with one of which modified on the MNPs are used to hybridize the mutant ssDNA strand denatured from ctDNA, prevent it reassociation, and separate it in magnetic field to make the other ssDNA strand accessible for hybridization. The discrimination probes were carefully designed and very specific for mutant-type ctDNA, which could efficiently and specifically recognize the mutant-type ctDNA target whereas showed no response to the wild-type ctDNA. Under optimal conditions, the proposed assay displayed a good linear rang and low LOD for target mutant-type ctDNA detection, which was expected to be useful for ctDNA biomedical analysis and clinic theranostic.

AUTHOR CONTRIBUTIONS

HC designed the experiments and performed the optimization of discrimination probes, ctDNA detection, and wrote the manuscript. YZ and FY performed the characterization of carboxylated MNPs and DNA functionalization of MNPs. CW and HD contributed in project design and manuscript preparation. All authors reviewed the manuscript and approved for submission.

Organic electrochemical transistors (OECTs) are recently developed high-efficient transducers not only for electrochemical biosensor but also for cell electrophysiological recording due to the separation of gate electrode from the transistor device. The efficient integration of OECTs with electrochemical gate electrode makes the as-prepared sensors with improved performance, such as sensitivity, limit of detection, and selectivity. We herein reviewed the recent progress of OECTs-based biosensors and cell electrophysiology recording, mainly focusing on the principle and chemical design of gate electrode and the channel. First, the configuration, work principle, semiconductor of OECT are briefly introduced. Then different kinds of sensing modes are reviewed, especially for the biosensing and electrophysiological recording. Finally, the challenges and opportunities of this research field are discussed.

INTRODUCTION

Transistors were invented by William Shockley and his coagent in 1947 for the precluded amplification efficiency and reliability of vacuum tubes. With the discovery of conducting conjugated polymers in the late 1970s, organic conducting polymer-based transistors have been widely investigated. Among of them, organic thin-film transistors have attracted much attention due to their broad range of applications, especially in biological system, which includes two types of transistors, i.e., organic field effect transistors (OFETs) and organic electrochemical transistors (OECTs). OFETs always use small organic molecules and organic conjugated macromolecules as semiconductor, in which the gate voltage is applied across the gate insulator and through field effect doping the gate electrode modulate the channel current. Differently, OECTs use the electrolyte medium between the channel and the gate electrode rather an insulator layer. When applying gate voltages, electrochemical doping or de-doping from the electrolyte modulate the channel current. In this case, the OECTs is easier to be used in biological system since most of biological reaction or species are occurred in an electrolyte medium. More importantly, compared with other kinds of OFETs, OECTs always bear low working voltages (below 1 V), essentially evaluating its potential application in biological system.

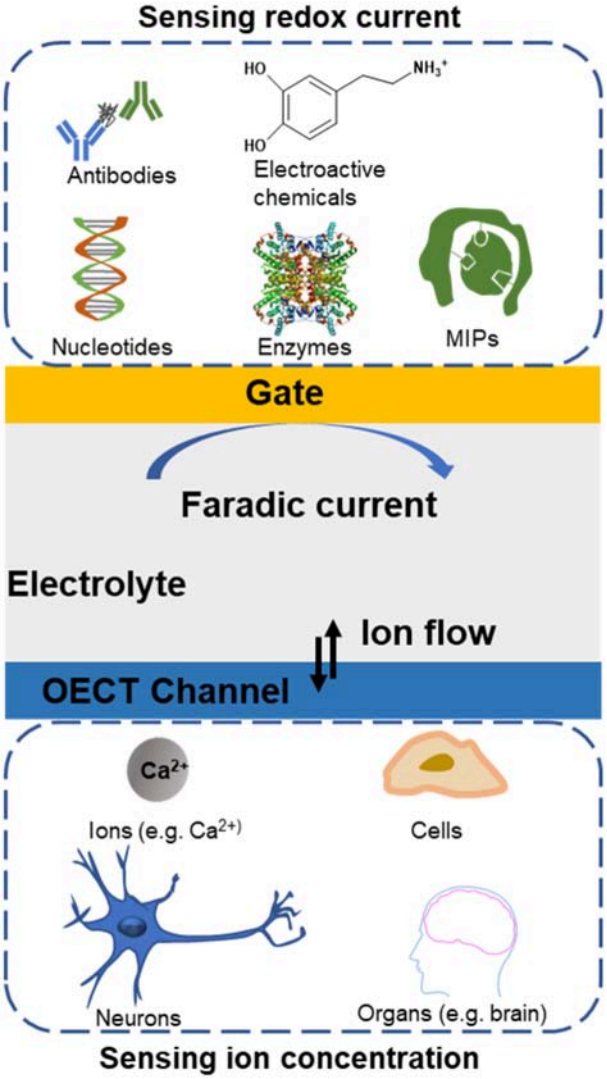

FIGURE 1 | Overview of biological systems applications based on organic electrochemical transistors.

Based on these unique properties of OECTs, various applications have been explored during the last two decades (**Figure 1**), including neural interfaces (Khodagholy et al., 2013a, 2015, 2016; Campana et al., 2014; Yan et al., 2015), chemical and biological sensors (Nakatsuka et al., 2018), printed circuits (Zakhidov et al., 2011; Kim et al., 2013; Lee et al., 2017), neuromorphic devices (Uguz et al., 2016; Gkoupidenis et al., 2017), and clinical or biomedical researches (Berggren and Richter-Dahlfors, 2007; Rivnay et al., 2013; Someya et al., 2016). In electrophysiological signals, OECTs are used both as the recording and stimulation devices (Williamson et al., 2015; Braendlein et al., 2017a). OECTs can also be applied to measure cell coverage (Lin et al., 2010), barrier tissue arrangement and cellular environment for non-electrogenic epithelial cells (Jimison et al., 2012; Yao et al., 2013; Ramuz et al., 2015; Romeo et al., 2015). Assessment protocols have been established, applying white noise at the gate (Rivnay et al., 2015b), showing that OECTs have better performance comparing with impedance sensing (Rivnay et al., 2015b,c). The ability to work in complicated environments, such as blood and milk, paves the way for multi-analyte assay in complex environments (Tria et al., 2014). As for OECT-based biosensors, the detection of metabolites in electrolytes or body fluid are valuable for early prediction of human disease (Zhu et al., 2004; Macaya et al., 2007; Bernards et al., 2008). OECTs were easily to be coupled with various fabrication techniques (ElMahmoudy et al., 2017), resulting in different formative factors with flexible and wearable applications (Fan et al., 2018; Yang et al., 2018). The characteristics of ultrahigh transconductance (Khodagholy et al., 2013b), stability in electrolytes (Lee et al., 2018), cytocompatibility (Inal et al., 2016), and biofunctional modification (Someya et al., 2016; Curto et al., 2017; Pappa et al., 2017) result in their specially appropriate for bioelectronics fabrication. OECTs can also be prepared by conducting polymers compatible with cellular platforms, offering the possibility to modulate the bio-chemical, mechanical, and electrochemical microenvironment of cells and cell health where cells behavior can be concurrently monitored.

Some of previous reviews have summarized the physics and principles of OECTs (Rivnay et al., 2018), and the applications of OECTs on the organic bioelectronics (Simon et al., 2016; Someya et al., 2016), neural monitoring (Yan et al., 2015; Rivnay et al., 2017), and other biological applications (Xenofon et al., 2015). In this review, we mainly emphasize on the recent progress of OECT-based biological applications. Firstly, we would briefly introduce the configuration of OECT, working principle and general conducting polymer for OCET. Then, the biological applications, including biosensors and cell electrophysiological recording, would be discussed in detail. In each part, we will critically demonstrate the working mechanism and evaluate the unique properties for OECTs that facilitate the application progress for special requirements. Finally, challenges and opportunities still exist toward the biofunctional OECTs and the forthcoming studies are envisioned.

BRIEF INTRODUCTION OF OECTS

Typical Configuration of OECTs

The OECTs were firstly built by White et al. (1984), in which they reported a device with a microelectrode array that can work as a transistor to amplify the tiny current when it was immersed in an electrolyte solution (**Figure 2A**). In this work, they for the first time separated the gate electrode and the semiconductor channel with electrolyte, so that both the gate and the channel interfaces can be functionally modified. It is worth to note that the gate electrode was controlled by a traditional three-electrode electrochemical system in White's configuration as shown in **Figure 2A** (White et al., 1984; Nishizawa et al., 1992). In this configuration, the counter and reference electrodes are the essential components and they, respectively, establish the current circuits and ensure the stability of the potential especially for the cyclic potential scanning. If the gate potentials kept at constant value, the gate electrodes could be simplified

into only one electrode because the voltage bias applied on the gate relative to the source electrode is constant, which would not influence the transfer or transconductance curve (Zhu et al., 2004). From then on, various devices based on the configuration of separated gate and channel with electrochemical and biological applications have sprung up. The most typical configuration of OECTs were constructed with one electrode (gate) immersing in the electrolyte and one channel connected by the semiconducting film with two metal electrodes (source and drain), the applied bias on the channel modulates holes or electrons moving in the semiconducting film (**Figure 2B**). In addition to the configuration of gate electrode, the development of the integration and printing technologies with OECTs enable large area computing and integration arrays of OECTs (van de Burgt et al., 2018) (**Figure 2C**).

Principle of OECTs

Bernards and Malliaras (2007) systematically demonstrated the steady-state and transient behavior of OECTs, which provided the initial view of the basic principle of OECTs. The principle was based on the ions in electrolyte transferred into the organic films, then its doping state and accordingly the conductivity of channel were changed. To operating the OECTs, the gate (gate voltage, V_G) and the drain (drain voltage, V_D) are controlled by applying constant voltages, which are referenced to the source electrode (**Figures 3A,B**). The potentials applied on gate electrode are related to the ions injecting into the channel and consequently controlling the doping state (i.e., redox state) of the conducting film. The drain current (I_D), reveals the channel's doping state, which is proportionable to the quantity of mobile holes or electrons in the channel.

To qualitatively describe the working principle of OECT, The Bernards et al. postulates that there are two circuits of the OECTs: an ionic circuit and an electronic circuit, which separately describe the ions flow in the gate/electrolyte/channel system and the charges flow in the source/channel/drain system according to Ohm's law (**Figure 3C**). In the ionic circuit, ions flowing in the electrolyte is regarded as a resistor, and the ions volume in the channel is treated as a capacitor; while the electronic circuit is seen as a resistor. This model provides a prototype of the OECTs working principle, but there are still many significant properties that need to be taken into consideration. In this case, the influences of more factors to the efficiency of OECTs are conducted, such as, the thickness of the channel (Rivnay et al., 2015a), the mixed ion-electron transport (Rivnay et al., 2016; D'Angelo et al., 2018; Berggren et al., 2019; Onorato and Luscombe, 2019), and the double-layer (Tybrandt et al., 2017) coupling of conjugated polymers (Fan et al., 2019).

In addition, the Bernards' model demonstrates that both the ionic and the electronic circuit limit the response time. On the other hand, the efficiency of transduction, from small voltage signals on the gate to large current signals in the channel, is

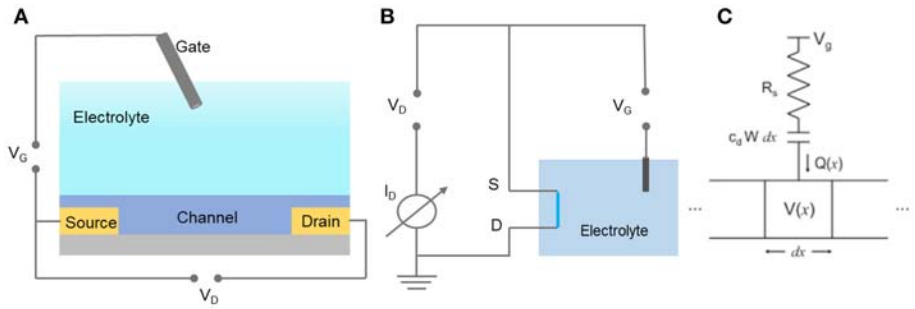

FIGURE 3 | The schematic configuration of OECT sensor **(A)** and it's equivalent circuit **(B)**. **(C)** The typical ionic and elctronic circuit (Bernards and Malliaras, 2007). Reproduced with permission (Bernards and Malliaras, 2007). Copyright© 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim.

characterized with the first derivation of the transfer curve, called transconductance ($g_m = \partial I_D/\partial V_G$). High transconductance values reflects the effective gating but leads to the slow operation of OECTs (Khodagholy et al., 2013b; Rivnay et al., 2013). In general, OECTs with the liquid electrolyte have the response time about tens of microseconds, which is suitable for most biosensor and for electrophysiological recordings (Rivnay et al., 2015c; Onorato and Luscombe, 2019). While the OECT with gel or solid electrolytes as ion transportation matrix is slower than that in liquid electrolytes (Bongo et al., 2013; Yi et al., 2015), which is more appropriate for the applications where a rapid response is not necessary.

With respect to the effective gating, the geometry of OECTs sensor plays an essential role (Cicoira et al., 2010; Lee and Someya, 2019). The geometry of the OECT includes the area ratio of channel and gate, the thickness of channel, and the distance between the gate and channel electrodes. OECTs with different area ratios of channel and gate will result in the following properties: (1) OECTs with small gates have smaller background noise; (2) devices show better sensitivity with small gates; (3) $\Delta I/I_0$ always becomes unchangeable at the same substrate concentration but not depend on channel/gate area; (4) the channel/gate area ratio is irrelevant to the detection linear (Hütter et al., 2013). The redox reactions produced by redox enzymatic active molecules, such as H_2O_2, control the potential drop at the interface of metal electrolyte/channel and gate/electrolyte (Bernards et al., 2008). Therefore, if the gate area for sensing application was small, the potential drop would be mainly on the interface of gate/electrolyte. And the reactions on the gate can be effectively amplified through the nature of transistor, and vice versa (Bernards et al., 2008).

Conducting Polymers for OECTs

The channel for OECTs is always constructed by organic semiconducting polymers which always bears excellent redox activity. So far, several kinds of conjugated conducting polymers of p-type (polythiophenes, polyfluorene, donor-receptor copolymer, etc.) and n-type (commonly based on copolymers of thiophene and fluorene) has been used for constructing OECTs. Among of them, the PEDOT: PSS (**Figure 4A**) is most common polymer as the semiconducting channel of OECTs. The PEDOT is p-type doped (oxidation state), therefore holes can hop among chains, so that applied positive bias on drain will produce the hole current. The sulfonate anions of PSS are added to stabilize the oxidized polymer PEDOT, to compensate for the shortage of negative charges. The p-type conducting polymers based OECTs always perform the depletion modes (ON state at the zero gate-source bias). While the n-type polymers working in accumulation modes are lagged behind the p-type, they are significant for preparing PN-junction and logic circuits, which is crucial for neuromorphic computing and bioelectronic applications. Most recently, n-type copolymer p(gNDI-T2) and p(gNDI-gT2) (**Figure 4B**) have been developed for OECT fabrication in aqueous electrolyte (Giovannitti et al., 2016), and P-90 (**Figure 4C**) is applied to detect lactate (Pappa et al., 2018). In addition, organic small molecule materials, such as pentacene, rubrene, fullerene, octa hydroxyquinoline, was also used as the semiconductor channel. However, the conjugated polymers always possess long strip and conjugated π or p-π structure, which will facilitate the preparation and readily built the thin film with low condition requirements. Therefore, the conjugated polymers are superior to organic small molecules not only for the excellent ability to conduct carriers (holes and electrons), but also their low-cost property and accessible fabrication (Flagg et al., 2019).

The particular identification of OECTs is the doping reactions appear among the whole volume of the organic film, which is different from FETs occur on a thin interfacial region. Therefore, low-gate voltages can achieve large modulations in the drain current, herein, OECTs are effective switches, and powerful amplifiers. In addition, compared with the solid dielectric layers, the electrolyte solutions are more applicable for larger flexible devices and various substrates' integration (Volkov et al., 2017; Fidanovski and Mawad, 2019). Moreover the intrinsic quality of the tunable organic molecules will further optimize the transport of ions and electrons and simplify the bio-interfaces (Giovannitti et al., 2016; Inal et al., 2016; Pappa et al., 2018; Sun et al., 2018). All these unique properties of OECTs essentially guaranty its wide applications in biological systems as demonstrated below.

BIOLOGICAL APPLICATIONS OF OECTS

Biological Sensing

In this section, we mainly introduced the operating mechanisms and reviewed recent applications of the OECT-based biological sensors. For electrochemical sensors, biomolecules in biological system could be classified into electroactive and electro-inactive species (Wu et al., 2017). The electroactive molecules (e.g., norepinephrine (NE), dopamine (DA), serotonin (5-HT), histamine, ascorbic acid (AA), uric acid (UA), CO, NO, H_2S, etc.) can be directly oxidized or reduced on the electrode. While the electro-inactive molecules (e.g., glucose, glutamate, lactate, ATP, small molecule proteins, nucleic acid) can be detected by electrochemical technique through bio-recognition methods. Guided by changes of the potential drop on the gate and channel, the biosensors can generally be subdivided into the enzymatic sensing, immune-sensing, and aptamer sensing (Gentili et al., 2018). Other kinds of OECT-based sensors utilizing the changes of doping state of the conducting polymer altered by the factors, such as ions concentration and pH, are essential to advocate the progress of OECTs biological sensing (Qing et al., 2019).

The electroactive chemicals (e.g., DA, E, NE, 5-HT) in biological system, can be directly oxidized or reduced on the electrodes. For example, DA can be oxidized to o-Dopamine quinone (**Figures 5A,B**) at a certain voltage. The OECTs as a kind of transistors possesses the characteristics of amplifying in-put signals, while coupling with the nanomaterials technology, the OECT-based sensors will result in significant sensitivity improvement (Liao et al., 2014; Mak et al., 2015). In this case, the construction of the high-performance gate electrode is crucial for high-sensitive sensing. Tang et al. (2011) built a dopamine OECT sensor by comparing five kinds of gate electrodes (including graphite, Au and Pt electrode, etc), and found that the Pt gate bears the highest sensitivity as to detect 5 nM DA at the potential of 0.6 V. The synergistic effect of gate and channel for redox signals transduction will further increase the sensitivity. Gualandi et al. built an all-PEDOT: PSS OECT to sensing AA (Gualandi et al., 2015), in which by modulating the V_G and film thickness, the detection limit can be reach to 10^{-8} M level.

Selectivity is another important parameter for OECT-based sensors, especially for complicated samples. Gualandi et al. (2016) constructed an all-PEDOT: PSS-based OECT, which got the separated transconductance (g_m) linear calibration of DA without the interference from AA and UA, through changing the scan rates and gate voltages, in which case, the scan rate is an essential property for sensitivity. Classic electrochemical methods cooperate with OECT will promote the development of biosensing: fast scan cyclic voltammetry (FSCV) is widely used to detect electroactive chemicals, especially DA in neuro system, (Tybrandt et al., 2014)

combined the FSCV technology and OECT (**Figures 5C,D**) successfully amplified the small detected signals under no shielding environment. This integration paves the way for multifunctional bioelectronics applying in various devices (Sivakumarasamy et al., 2018).

OECTs Based Enzymatic Biosensors

The most widely used OECTs biosensors are coupled with enzymes. The first application of the OECTs interfacing with enzymes was based on the device model developed by Nishizawa et al. (1992). They detected the conductivity of the polypyrrole channel on account of the film's responsiveness to pH induced by the penicillinase enzyme reaction. However, the polypyrrole film is pH-dependent and the linearity range is limited by the thickness of polymers, losing the regulating ability in neural pH environments. Zhu et al. (2004) illustrated a PEDOT: PSS-based transistor for glucose sensing in neutral pH electrolytes. Since PEDOT: PSS is stable in a wide pH range, it is applicable in the enzymatic sensing under neutral environment. Moreover, the bias potentials between gate and channel are small so there exists no hydrolysis of electrolyte, and the known initial properties of the transistor are enough

to meet the need for detecting several analytes, from then on, PEDOT: PSS plays an important role in the OECTs enzymic sensors.

The sensing mechanism of the typical enzymatic OECTs sensors is shown in (**Figures 6A,B**): Enzymes are immobilized on the gate electrode and catalyze the substrates into enzymatic product, through which they obtain or lose electrons on the electrode, the electrical signals are transferred to the gate electrode and further leading to channel current changes simultaneously. To maintain the charge neutrality in the whole circuit, including the ionic circuit and electronic circuit, a cation penetrates into the conducting polymer film and replaces the

role of the cationic polymer (e.g., $PEDOT^+$) compensating the anionic polymer (e.g., PSS^-), which leads to a change of the V_g ^{eff}, then a decrease of the channel current which is logarithmically proportional to concentration of enzymatic substrates.

The sensitivity of OECTs devices, lies on the nature of amplification provided by the optimized geometry and the sensitive enzymatic modification. After optimization using new materials and different modification technology, the detection levels of bioactive molecules can be promoted to a large extent. Apart from the mostly used p-type conjugated polymer, Pappa et al. (2016) demonstrated a new kind of OECTs enzymatic sensor by using an n-type conducting polymer in accumulation mode. The n-type conjugated polymer is based on the NDI-T2 polymer (also called P-90). The side glycol chains ensure the solubility of the polymer in an electrolyte and enable the enzymes anchored on the polymer and strengthen polymer's water absorbability. By modifying LOx on both channel and gate, the detection concentration of lactate can low to 10 μM, while still can't overmatch with nM level of PEDOT: PSS modified OECTs.

In addition to the high sensitivity, selectivity is another key role for the biological sensors. So far, there are several methods to improve the selectivity by rationally designing the surface chemistry of gate electrode (e.g., modifying special materials and/or modulating the interaction of ions (Yu et al., 2015). Liao et al.(**Figures 6E,F**) (Liao et al., 2015), reported a highly selective OECTs-based enzyme sensors. By modifying a bilayer film on the gate electrode, the interference of charged molecules coexisting in the solution with the analytes effectively decreased. The high selectivity of the device in this work is accomplished by firstly covering a thin layer of the compound graphene flakes and Nafion, then a thin layer of polyaniline (PANI) polymer on the gate electrode. The graphene flakes in the film are used to enhance the electrochemical catalytic performance and the conductance of gate electrode, the PANI film carrying positive charge can repel the positively charged bioactive molecules as NE, and Nafion film that is negatively charged can hinder the anionic electroactive molecules like AA and UA.

The outstanding performance of the biosensors compromise the reaction both on the gate and the channel, thus they have equivalent ability to tune the potential drop on the electrode-electrolyte interfaces, receiving the amplified signal. Wang's group (Wang et al., 2017), successfully built an OECTs glucose biosensor based on a novel woven fiber composed of polypyrrole (PPy) nanowires and reduced graphene oxide (rGO). They reported that the addition of rGO nanosheets will enhance the electronic performance of the fiber electrodes. The composites-based transistors exhibit high switch capability, fast switch speed, and long durability under electrical experiments. The transistor exhibits remarkably sensitivity for glucose sensing, the NCR/decade can be reach to 0.773. Besides, the sensors show the fast response time (i.e.g,0.5 s), good reversibility, wide linear range of glucose concentration and a lower detection limit compared with conventional methods.

Moreover, the OECTs can be used for multianalyte detections by combination with the array techniques. Pappa et al. (2016), developed a multianalyte biosensing platform using the OECTs array. The device is able to sense three typical clinically related molecules, such as glucose, lactate, and cholesterol by immobilizing relative glucose oxidase (GOx), lactate oxidase (LOx), and cholesterol oxidase (ChOx) on the PEDOT: PSS coated gate electrodes, without the electrical and chemical cross-talk over different transistors. This biosensor could be used for real sample analysis in saliva. Braendlein et al. (2017b), introduced a reference-based sensor circuit, through compromising two OECTs functionally differently, used the popular p-type semiconductor PEDOT: PSS, toward a Wheatstone bridge design. One of the two OECTs is used as the reference (immobilized with BSA) and the other is functionalized (immobilized with lactate oxidase) as the indicator. The sensor shows a low limit of detection generated by cells, estimated to be $\approx 10 \times 10^{-6}$ M, and the reference lactate concentration of fresh cells is assessed to be 50×10^{-6} M (**Figures 6C,D**). Such a circuit was firstly applied to clinically relevant testing and significantly help to accurately diagnose preliminary tumor treatment.

Disposability and stability are another key performance for the biosensors, which are benefit from the application of multifunctional materials and simple configuration techniques. Shim et al. (2009), demonstrated an all-PEDOT: PSS OECT-based glucose biosensor by introducing the mediator (e.g., ferrocene) to transfer generated electrons of redox reactions to the gate. This facile fabrication of OECT-based enzymatic biosensors realizes the character of low-cost. Khodagholy et al. (2012), incorporating ionic liquids and conjugated polymers, constructed an OECTs-based lactate biosensor by solid state gel, which contains: lactate oxidase and the mediator ferrocene for shuttling the electron transfer. This type of device is a promising wearable sensor for continuously monitoring lactate levels in athletes. Bihar et al. (2016), built an OECT-breathalyzer, with the conducting polymer PEDOT: PSS printed on paper, and the enzymatic reaction occurred in the electrolyte gel. This device is easy to use for the low-cost and disposable portable sensors to facilitate blood alcohol content sensing.

OECTs Immunosensors

Immunoassay is crucial in clinical analysis (cancer cells, biomarkers, pharmaceuticals), toxins, and microbials in the environments (Wen et al., 2017). Antibodies of the immune system are regarded as the biorecognition element, and lead to the high specificity and sensitivity of the immunosensors. As to the immune sensing, the competitive and sandwich types are widely accepted. For competition reactions, the immobilized biorecognition molecule can be either an antibody or an antigen. The sandwich-type immunosensor consists of a fundamental antibody fixed on the platform of a sensor, and the specific antigen marker in a sample solution, the secondary antibody reacts with the antigen bound, then the detectable and low noise signal are generated via enzymes (Zhang and Heller, 2005; Yu et al., 2006), redox substrates (Viswanathan et al., 2009), or nanomaterials (Liu and Lin, 2007; Kerman et al., 2008). Based on this principle, Kim et al. (2010) demonstrated an immunosensor based on OECT to sense prostate specific antigen (PSA), through conjugating AuNPs with PSA specific

antibody on the conducting channel. The limit of detection was low to 1 pg/mL compared with the maximum detection value of 4 ng/mL. Torsi's group has developed various OECT-based immunosensors transistors. In their recent study, they developed the anti-human Immunoglobulin G (anti-IgG) sensor at the detecting limit of femto-molar (Macchia et al., 2017). The anti-IgG OECT sensors have the ability to detect IgG with high biomolecular interaction in the femtomolar (fM) range by immobilizing the anti-IgG on the gold gate. They also showed a plastic OECT sensor (Macchia et al., 2018) by the gate modification, which possess the low-cost, ultra-sensitive properties, and further paves the way for application of immunoassay technology. Fu et al. (2017) have successfully applied OECTs to the sensing of protein by detecting protein cancer biomarkers in cells. The gate is modified with antibodies and catalytic nanoprobes so that the gate electrode can capture the target and output the current response for the product of catalytic reaction (i.e., electroactive H_2O_2). For the amplification nature of organic electrochemical transistors, the biosensor that detect the cancer marker HER2 has the detection limit low to 10^{-14}g mL^{-1}, which is several magnitudes lower than original electrochemical methods. Moreover, the OECTs based HER2 biosensors have a detecting concentration range from 10^{-14} to 10^{-7}g ml^{-1}, which covers the detect amount of HER2 in normal and breast cancer cells. Additionally, these protein sensors can distinguish the cancer cells from the breast cancer cells attribute to the specificity of the modified antibody.

OECTs Aptamer Sensors

Aptamer-based technology bearing the high specificity or even superior to antibodies, that has the potential for applications of diagnostics and therapy. DNA sensor based on OECT has been fabricated by Lin et al. (2011), they integrated the OECT with a flexible microfluidic device. The label-free DNA sensor was fabricated with single stranded DNA which was immobilized on the gate as the DNA probe to detect the complementary DNA targets, and the detection limit was 1 nM. More importantly, the detection limit could be extended to 10 pM if an electric pulse was applied to the gate to increase the hybridization of DNA. The modulation mechanism is the changes of surface charge on the gate electrode generated by hybridizing DNA. They hypothesized that the thickness of the electrolyte double layer is much thicker than the DNA layer, therefore, the potential of gate is not affected by the concentration of ions in the electrolyte. Peng et al. (2018) have built an OECT sensor for detecting microRNA21 by using the Au NPs and capturing probe protein to modify gate electrode. The amplification effect of OECTs and the immobilized Au NPs, leading to the high sensitivity, selectivity, and acceptable applicability of microRNA21 assay in total RNA sample, which provides potential application in the future microRNA analysis.

OECTs Coupled With Artificial Receptors

Artificial receptors possess comparatively higher chemical stability than natural receptors under physical environments, consequently they provide possible alternatives on widespread biological applications (Labib et al., 2016). Very recently, molecularly imprinted polymers (MIPs) shows great potential for the development of biotechnology, diagnostics, and stretchable devices. Parlak et al. developed an artificial receptor based wearable OECT device by preparing the molecularly selective membrane for cortisol detection (Parlak et al., 2018). The artificial receptors can overcome the instability of natural biomolecules, such as enzymes and antibodies. The biomimetic membrane based OECT was configured with wearable substrates and sample reservoirs, this device can readily get the stable signals reading-out by collecting enough sweat about 10 to 50 μL. The MIP were entrapped into a plasticized poly (vinyl chloride) (PVC), which acts as an ionic barrier to decrease the g_m but

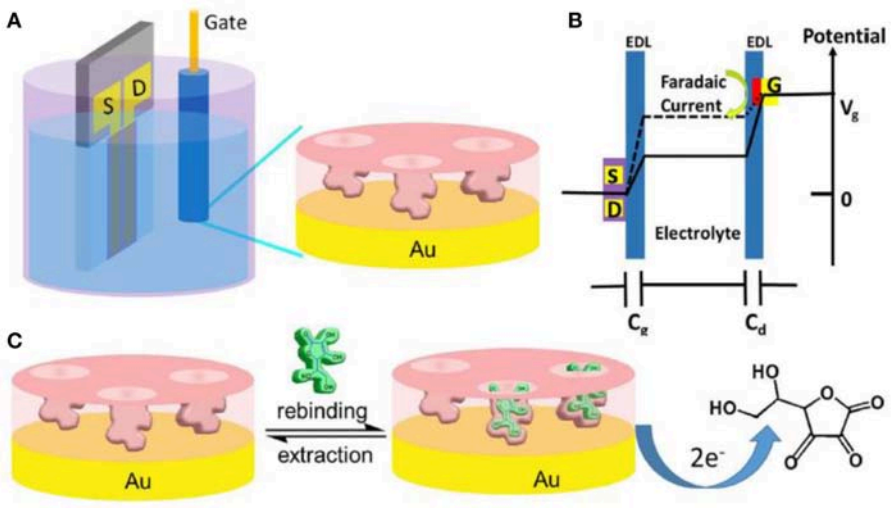

FIGURE 7 | (A) Schematic diagram of an AA sensor based on the MIP modified OECT. **(B)** Potential drop between the channel and gate of the OECT. **(C)** Schematic for the sensing of AA by MIP film modified gate (Zhang et al., 2018). Reproduced with permission (Zhang et al., 2018). Copyright© 2017 Elsevier B.V. All rights reserved.

still maintain the efficient OECT capability. And the device was applied *in vitro* and on body to conduct the cortisol changes by measuring electrochemical performance. It's meaningful that the device was used in exercising human to detect the cortisol concentration. Zhang et al. (2018) combined the molecularly imprinted polymers (MIP) with OECT-based sensor to detect ascorbic acid (AA) (**Figure 7**). The selectivity of the MIP films on the gate was conducted by the preparation of the polymer with AA removal and rebinding on the surface, then the polymer film acted as the recognition unit of the sensor. They found various species, such as H_2O_2, Gly, GSH, UA, Glu, Na^+, K^+, Fe^{2+}, Mg^{2+}, Ca^{2+}, and ASP, that has almost no interferences for AA detection. The sensors could be used for the AA analysis of vitamin C beverages.

OECTs Ion Sensing

The OECTs can be used for ion detection due to the ions transfer freely in the whole bulk of electrolyte, which includes not only aqueous solution but also other ionic and electronic media, such as gel and ionic liquid (Duc et al., 2017; Dai et al., 2018). Recently, Gentili et al. (2018) demonstrated a new principle of current-driven inverter-like, low-voltage, high-sensitivity ion detection OECT. Differently with the voltage-driven OECTs, the current-driven OECT configuration provides, low-voltage operation and high sensitivity, where the sensitivity depends on the large g_m and load resistor. However, the applied voltage should consistent with the physiological environment. So that the trade-off among sensitivity, operating range, and applied voltage are needed. The current-driven OECT configuration is based on the recording of the changing voltage generated by the ions concentration, differentiating it from the usual ion sensors where the changing of ion concentration transferred as the output voltage. Consequently, the current-driven OECT study take advantage of the large g_m of OECTs in an absolutely different way in relative to regular voltage amplifier structures, which introduce a new kind of trade-off between sensitivity and working voltage. While (Del Agua et al., 2018) introduced a PEG-based Na^+ conducting hydrogel as OECT electrolyte. The hydrogel is prepared by fast photopolymerization with commercial monomer. And the hydrogel has high ionic conductivity and can be contained during the fabrication of photolithography device. With the high performances at room temperature, this hydrogel has the possibility to replace liquid electrolytes in versatile OECTs and accomplish print integrated into flexible OECT devices.

OECTs Cell Monitoring

The coupling of OECTs with live mammalian cells for monitoring toxicology/diagnostics and other properties was developed in the past decade. Bolin et al. (2009) firstly coupled the OECTs with cells and detected the gradients of cells on the OECT channel. They seeded Madin Darby canine kidney (MDCK) epithelial cells on an OECT channel and the channel bias added and produced a potential gradient. The gate potential controls and modulates the potential gradient of channel. Therefore, the MDCK cell quantity gradient on the channel depended on the gate and source voltages. Lin et al. (2010) reported sensors based on OECTs combined with cancer cells and fibroblasts for sensing *in-vitro* cell activities. The sensing principle is the electrostatic actions on the interfaces of the cells and the OECT reactive layer. Since the device is sensitive to the surface charge changes induced by the adhesion of cells, it's applicable for solution processing to miniature and integrate cell-based sensors can further promote the cell relevant testing, such as screening drugs and testing toxic

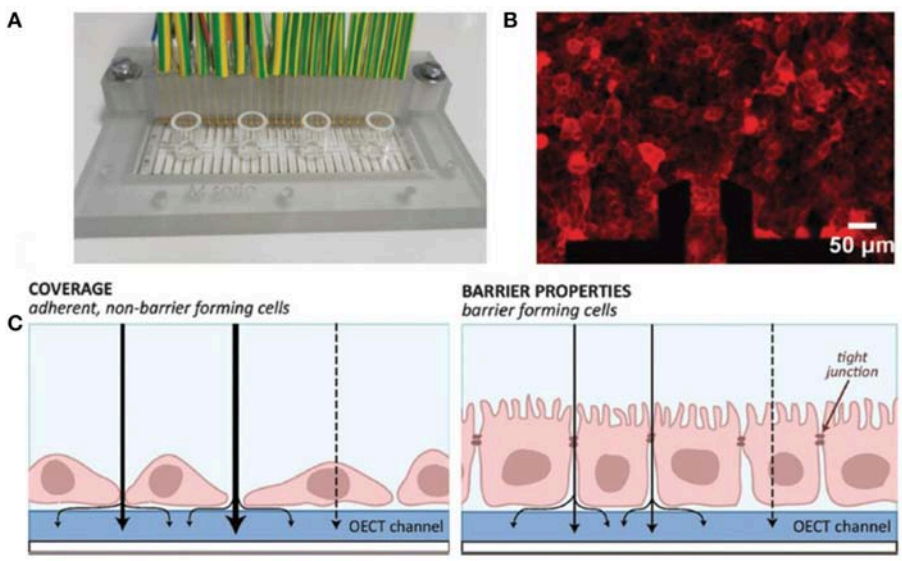

FIGURE 8 | The OECT device for monitoring adherent cells. **(A)** Measurement platform consisting of 24 OECTs divided between four glass wells. **(B)** MDCK II cells transfected with RFP actin construct seeded on device for fluorescence imaging. **(C)** Schematic diagram of the cell coverage with low ion flow through barrier (right) or high ion flow through non-barrier (left) (Ramuz et al., 2015). substances. The potential can predict the adhesion of cell and formation of epithelium (Gu et al., 2019). Ramuz et al. (2015) found that barrier tissue cells adhered on the polymer surface can be deprived of function in calcium switch assay, and re-addition of calcium lead to improvement of the cells function. The process is monitored both electronically and optically, enabling the capture of cells images while simultaneously recording electronic information (**Figure 8**).

Wei et al. (2017) presented the first report to apply OECTs for detecting the microalgae H. pluvialis cell. The constructed OECT array is a platform with advantages of convenience, and efficiency, and is able to monitor the real-time signals induced by settling H. pluvialis cells on the active conducting polymers. The results can help to estimate the time point approximately for producing the maximum astaxanthin in the commercial fermentation. Rivnay et al. (2015c), combined OECT with the impedance sensing technique by applying gate current to generate complicate low error impedance signals. They applied the method *in vitro* to sense a layer of epithelial tissue and concluded that the data is suitable to an equivalent circuit, allowing the resistance of trans-epithelial, and capacitance values of cell layer in accordance with literatures. Very recently, Chen et al. (2018) reported sensitive glycan sensors based on OECTs to detect the glycan on cells surface. PEDOT: PSS as the channel and the concanavalin A (Con A) loaded by poly dimethyl diallyl ammonium chloride (PDDA)–multiwall carbon nanotube (MWCNTs) modified the gate, which can correctly connect mannose by capturing the cancer cell. Specialized mannose nanoprobes are equipped by binding horseradish peroxidase (HRP) and aptamers on gold nanoparticles, then HRP-aptamer-Au NPs can be used to identify the human-breast cancer (MCF-7) cells, the prepared OECT-based glycan sensor leverage the electrochemical reaction on the gate electrode with the mannose on surface of captured cells. The HRP-catalyzed reduction to MCF-7 cells on the gate induced channel current responses, which generated H_2O_2 even when the cell concentration is low to 10 cells μL^{-1}. To prove the specific recognition reaction, they added N-glycan inhibitor stimulation and the signal is dramatically decreased for the decrease of mannose on cells. Furthermore, the as-formed device can be applied to analyze other glycans and cancer cells by simply altering the binding lectins and aptamer sequences. This strategy paves the way for various glycans analysis on a cell surface.

Neural Recording and Stimulation With OECTs

Recording electric signals of brain has been the most important but tough challenge in the past few decades since many kinds of diseases are strongly related to the change of signals between neurons. With the flourishing of semiconducting polymers and electrochemical transistors in the recent years, neural recording and stimulation get more opportunities to detect more precisely and applicable for more complicated *in vivo* sensing. This section focuses on the recent progress on the neural recording and stimulation based on OECTs, mainly including the development history, working mechanisms, and recent applications, and illustrate the enhanced performance for the multifunctional transistors.

Brief Introduction

In the brain, information transfer is achieved by the adjoining neurons generating bioelectrical signals, named action potential, propagating over the synapses. In the last decade, electric recording and stimulation based on metal electrodes have extremely conductive to our fundamental cognizing of real neural activities (Gilletti and Muthuswamy, 2006; Rivnay et al., 2017; Xiao et al., 2017). Conventional small metal or carbon-based microelectrodes are able to probe and stimulate neural activities with high resolution at the level of single-cell (Jasper et al., 1961). The metal microelectrode arrays can record the activities of a large population of neurons at the same time (Lee et al., 2017). Nowadays, implanting stimulating electrodes into the brain is progressively applied to deal with neurological disorders (Leleux et al., 2014; Lee et al., 2018). To compensate for available methods, the bioelectronics can be implanted into deep brain and conduct high temporal resolution, capable of directly communicating with the neuro net through electronics, and transduce neuron's electronic signals from bioelectronic signals (Jonsson et al., 2015). However, transformation presently challenged by the matching ability and electrons transfer on neural interfaces. For that metals transmit electrons signals while neural systems transmit ionic signals, the signal-to-noise signals (SNR) recorded and stimulated by bioelectronics are almost depended on the coupling transmission of electrons and ions on the metal/neural interfaces. Generally used metal electrode arrays are made of hard materials, such as gold, with their elastic module distinctly exceed the neural tissue in the range of kPa to MPa (Gilletti and Muthuswamy, 2006). The implanted electrodes in the neural tissues will cause inflammatory response results from the mechanical incompatibility, which will eventually result in electrode failure in long-term studies. In order to obtain favorable neuron/electrode interfaces, novel materials, organic conducting polymers-based bioelectronics, has exhibit strengthen neural recording and stimulation characteristics along with their merits of biocompatibility and low mechanical strength.

Mechanisms

The mechanisms of neural recording by metal electrodes or transistors is explained hereunder: the active potential of a neuron, contributes to ionic currents flux over the cell membrane, which changes the cell membrane potential, then the potential results in an electrochemical signal on the interface of metal/electrolyte or changes potential-drop of the conducting polymer. While in the brain, an enormous neural network system, the total neural electric currents generated from numerous neurons in a small bulk at a specified area will generate local field potential (LFP). This LFP called the electrocorticography (ECoG) when using the electrode on the cortical surface, and when recording with the electrode inserted deep into the brain called stereoelectroencephalography (SEEG). The longer

distance between the recording electrode and the location leads to useless signals for understanding the processes of neuropathology, hence the SEEG conduct the most informative signals. Conducting polymer-based electrode has extensively enhanced the electrical performances and biocompatibility of mental inserted intracortical electrodes. However, compared with the SEEG, the ECoG is non-invasive, the characteristics of ECoG have been significantly improved by using more stable polymers and rational building of devices (Khodagholy et al., 2016) (**Figure 9**).

As for the neural stimulation, charges flow from electrodes to neurons, and the charge injection ability on the electrode/neural interfaces is regarded as the parameters to be measured (Lee and Someya, 2019). The neural stimulation generated charges have the quantity that many orders of magnitude higher than the electrodes recorded signals, which mostly because of the meaningless coupling on the electrode/neuron interface. The ideal stimulation electrodes would be small enough to selectively put on the target. However, the small electrode requires high potential which leads to undesirable reactions and confuses the recording signals. Therefore, organic conducting polymers advanced the neural recording and stimulation, promoted OECTs application in the field of neural recording (Green et al., 2013).

Recent Advances

Implantable ECoG electrodes with flexibility and biocompatibility are of great importance in conforming stable neural interfaces (Campana et al., 2014). Green et al. (2013) examined the long-term stability and injecting limit of PEDOT-coated Pt electrode arrays stimulated under

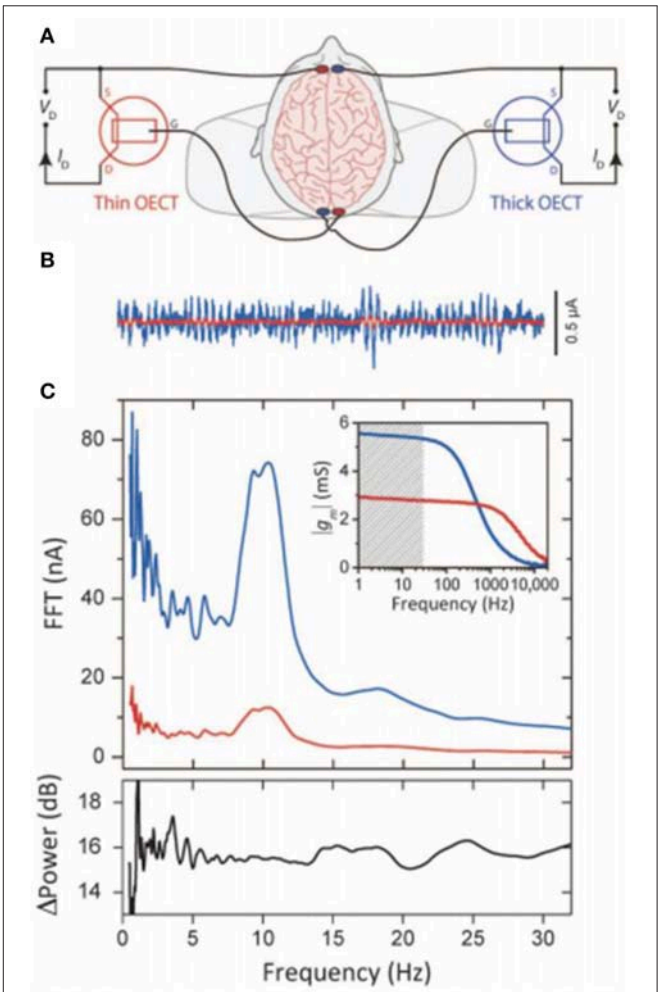

FIGURE 10 | High-transconductance OECTs enhanced EEG recordings. **(A)** Schematic wiring of simultaneously recording human EEG signals by two OECTs. **(B)** The rhythm from a thin (red) and thick (blue) 6-s recordings of OECT. **(C)** Top: fast Fourier transform (FFT) of simultaneous 60 s EEG recordings (inset: response of transconductance frequency, shaded band is the EEG-relevant frequencies). Bottom: the power enhancement recording from the thick compared to the thin device, showing the richer spectral content below the α band and using the thick device leading to the enhanced low-frequency signal (Rivnay et al., 2015a). biological electrolytes. The PEDOT-coated Pt electrodes have the charge injection limit of 30 times larger in physiological relevant media and 20 times larger in protein supplemented media compared with bare Pt electrodes. Additionally, the PEDOT-coated electrode that has lower potential excursion can read out signals in the visual cortex in *in-vivo* studies and electrically stimulated potentials. Concerning the continual stimulation, the PEDOT electrodes perform high duration and amplification. The high frequency pulsing of 2,000 Hz stimulation rate, didn't induce loss in stimulation performance, so that the electrodes could be applied to evoke the neural response of injected charge at the average of 76.0 nC (67.0 $\mu C\ cm^{-2}$), which has no obviously difference with the Pt electrodes, with the average threshold response of 84.5 nC (74.5 $\mu C\ cm^{-2}$). Tunable channel thickness can result in tunable transconductance (Rivnay et al., 2015a), which relatively demonstrate a novel high-performance method for human brain rhythms using the organic transistors (**Figure 10**).

Information transfer within the brain occurs in the network where neurons are associated with each other by enormous synapses and immersed in the same physiological environments (George et al., 2019). The electrolyte builds complex connections between different synapses, and the global regulations would induce the overall behavior of a large neuro population (Bettinger, 2018). Gkoupidenis et al. (2017) firstly demonstrated the concept of global regulation through the electrolyte gating with neuromorphic devices, they established an array device based on PEDOT: PSS to access the global control characteristics of neurons in a common electrolyte. The array of two-terminal devices immersed in 100 mM electrolyte and the PEDOT: PSS channels of each device serves as the hard connection between the input and output wire. The voltage bias applied on the electrolyte and concentration of ions globally modulate the hard connections. To make use of this effect, they proved synchronism of I/O transmission and the behavior of global clock, similar with the coupling of individual neuron activity and global oscillation in neural networks. These results show the electrolyte gating is advantageous to realize the neuromorphic devices with higher precision and complexity. Khodagholy et al. (2016) introduced a neural interface device (NeuroGrid) (**Figure 10**) that can simultaneously recording LFP and the action potential from brain surface. The recording signals with the PEDOT: PSS-based NeuroGrids between mid-γ waves (75 to 90 Hz) decreased correctly to the distance on separate electrodes, demonstrating NeuroGrids have high–spatial resolution when representing activities of small populations of neurons.

Coupling of OECTs with *in vivo* electrophysiological recordings is necessary and beneficial for brain-machine interfaces (Won et al., 2018; Gu et al., 2019). Because the organic transistors with conducting channels can connect both electronics and ions within the electrolyte. Ions can penetrate into the volume of the polymer channel and compensate the semiconductor, which will consequently change the conducting ability and thus modulate the current density of the channel. There are many factors can be tuned to obtain the ideal devices, such as channel thickness and the geometry of the channel. van de Burgt et al. (2018), demonstrated the ECoG recording of OECTs. The device, with an organic electrochemical transistor embedded on a thin organic film, recording *in vivo* epileptiform discharge, and performing great signal-to-noise ratio compared with state-of-the-art surface electrode. In addition, the OECTs can record the low-amplitude activities on the surface of the brain, which was superior to the traditional surface electrodes (Martin and Malliaras, 2016). Finally, the biocompatible, mechanical flexible devices for recording brain activities with superior signal-to-noise ratio hold promising future for medical applications.

CONCLUSIONS

Organic bioelectronics, as a promising popular interdisciplinary subject, targets to interface electronics and biology so that improve present biomedical technologies. The OECT lies in the center of this field mainly due to its initial nature of interfacing with biological components and has been proven to exceed general devices such as traditional electrochemical method. Moreover, various biological applications have been explored, including detecting metabolite and monitoring physiological signals since the OECTs bear the following advantages: (i) Stability is an extremely valued performance for biosensing. The OECT has been proven to work stably in various electrolytes, such as cerebrospinal fluid, cell media, sweat, and tears. The durability in these complex electrolytes can last; (ii) Sensitivity could be largely improved by OECT. Since small changes on the input will lead to enormous changes on the output. OECTs display high transconductance values, characteristically high gain, and the time response can be improved by tuning the geometry and size of the channel; (iii) OECTs could be easily integrated with biological system, such as individual cells, tissues, and even whole organs. Moreover, the gate electrode and conducting polymers could be easily modified by various recognition molecules; (iv) Compatibility with photo lithographical techniques also promote the microscale devices construction, especially interesting for monitoring activities of *in vitro* or *in vivo* cells.

In the past decade there has been noticeable progress on the advancing of OECTs for biological applications, however, numerous challenges still remain. These including: (i) The discovery and implementation of innovative active conducting polymers with enhanced properties with regard to conductivity, stability, patterning and restorability; (ii) The fabrication of devices for integrating multiplexed miniaturized arrays on versatile sensors, which may possibly power, record, or transmit the signals; (iii) The selectivity remains a big challenge for multi-chemicals and molecules sensing, especially for complicated samples (e.g., micro dialysate from brain); (iv) The response time was slow for the OECT devices due to the ions of electrolyte moving into or out of the volume of channel. The solution of these questions would largely accelerate the wide application of OECT in biological system, especially for the development of wearable device and brain-machine interface.

AUTHOR CONTRIBUTIONS

LB, CE, and WL collected the publications related to this review article, wrote the first draft of the manuscript and made subsequent corrections. PY, JF, and LM completed critical literature analysis and checked subsequent manuscript drafts.

FUNDING

A fluorescence strategy for alkaline phosphatase (ALP) assay in complicated samples with high sensitivity and strong stability is developed based on an allosteric probe (AP). This probe consists of two DNA strands, a streptavidin (SA) aptamer labeled by fluorophore and its totally complementary DNA (cDNA) with a phosphate group on the 5′ end. Upon ALP introduction, the phosphate group on the cDNA is hydrolyzed, leaving the unhydrolyzed cDNA sequence for lambda exonuclease (λ exo) digestion and releasing SA aptamer for binding to SA beads, which results in fluorescence enhancement of SA beads that can be detected by flow cytometry or microscopy. We have achieved a detection limit of 0.012 U/mL with a detection range of 0.02∼0.15 U/mL in buffer and human serum. These figures of merit are better than or comparable to those of other methods. Because the fluorescence signal is localized on the beads, they can be separated to remove fluorescence background from complicated biological systems. Notably, the new strategy not only applies to ALP detection with simple design, easy operation, high sensitivity, and good compatibility in complex solution, but also can be utilized in ALP-linked immunosorbent assays for the detection of a wide range of targets.

Keywords: aptamer, alkaline phosphatase, allosteric-probes, complex sample, immunoassay

INTRODUCTION

Alkaline phosphatase (ALP), a type of hydrolase enzyme, is widespread in nature for removing phosphate groups from various biomolecules like nucleic acids, proteins, and carbohydrates. ALP is present in all tissues in the human body. Due to ALP's important role in metabolism in the liver and development of the skeleton, an abnormal level of ALP is often related to bone disease (Garnero and Delmas, 1993), liver dysfunction (Ooi et al., 2007), diabetes (Berberoglu et al., 2007), and breast cancer (Brar et al., 1993). Hence, development of ALP detection methods is important for clinical diagnosis and cancer screening. In addition, like horseradish peroxidase (HRP), ALP can conjugate to streptavidin (Zhou et al., 2016) or a detection antibody for signal amplification and output in enzyme-linked immunosorbent assay (ELISA) (Porstmann et al., 1985). Therefore, development of new assays for ALP not only satisfies clinical diagnostic requirements but also improves the performance of ALP-labeled ELISAs.

Because ALP catalyzes the dephosphorylation processes of various substrates, many methods have been applied to quantify ALP's enzymatic activity, including fluorescence (Liang et al., 2013; Qian et al., 2015; Hu et al., 2016), colorimetry (Jiao et al., 2014; Yang et al., 2016), electrochemistry (Barroso et al., 2016), chemiluminescence (Jiang and Wang, 2012), and surface-enhanced Raman spectroscopy (Ruan et al., 2006). Most assays employ small molecules as substrates, including pyrophosphate (PPi), ascorbic acid 2–phosphate (AAP), p-nitrophenyl phosphate (PNPP), and p-aminophenyl phosphate (PAPP). Due to the easy labeling with a signal molecule and digestion by nuclease, nucleic acids are ideal phosphorylation substrates. Lambda exonuclease (λ exo) is a highly processive 5'-3' double-stranded DNA (dsDNA) exodeoxyribonuclease, which can selectively digest the 5'-phosphorylated strand of dsDNA, while work inefficiently on single-stranded DNA (ssDNA) and non-phosphorylated DNA. Miao et al. reported an electrochemical strategy to detect ALP by using dsDNA probes, and λ exo was employed for enzyme-mediated signal amplification (Miao et al., 2011). However, the complex preparation steps for electrochemical sensors make the workload heavier and test time longer. In addition, the poor limit of detection (LOD) (100 U/L) still needs improvement. Colorimetric strategies exploiting nucleic acids as the substrates coordinating with λ exo for ALP detection have also been developed. For example, a perylene probe can induce the aggregation of gold nanoparticles, which causes a color change from pink red to dark blue (Jiao et al., 2014). Disadvantages include preparation difficulty and poor LOD (32 U/L), limiting the practical applications in biological samples. More recently, Liu et al. developed a new fluorescent ALP assay using prior binding of graphene oxide (GO) to ssDNA over dsDNA (Liu et al., 2016), resulting in a lower LOD (0.19 U/L), but performance of this method may be compromised in human serum without a separation step. Overall, it is apparent that these sensors often suffer from complicated probe preparation and detrimental effects of the biological matrix, such as the influence of sample autofluorescence. So far, the detection of ALP in complicated samples in these methods is mostly performed in 1% human serum (Ma et al., 2016) or cell extracts (Jiao et al., 2014). Higher concentrations of complicated samples may affect the probes, leading to failure of the biological assay. To solve these problems, new signaling strategies with high sensitivity and strong stability in complicated samples are highly desired for ALP detection.

In our previous work, we proposed the design and application of allosteric molecular beacons (aMBs) (Song et al., 2011, 2012; Zhang et al., 2016; Gao et al., 2017) for highly sensitive and selective detection of nucleic acids, proteins and small molecules in complicated biological systems. Briefly, an aMB is an ssDNA labeled by fluorophore containing a molecular recognition sequence, streptavidin (SA) aptamer and its cDNA. The hybridization allows the probe to form a stable hairpin structure, preventing the probe from binding to SA beads. When the target is present, the recognition sequence binds to the target, which opens the hairpin structure to release SA aptamer, allowing the probe to bind to SA beads, consequently leading to fluorescent signal readout. The bead-based separation (Huang and Liu, 2010) and the single-fluorophore-labeled reporter contribute to the low background and little influence of matrix effects.

Herein, we report the design of an allosteric probe (AP) based on an aMB to improve the ALP detection performance in complex environments. The AP contains two complementary sequences, an SA aptamer labeled by fluorophore and its total cDNA modified with a 5'-phosphoryl terminus. In the absence of ALP, the cDNA is promptly cleaved by λ exo to release the SA aptamer, which binds to SA beads within 5 min incubation, resulting in fluorescence enhancement of SA beads that can be detected by microscopy or flow cytometry. In contrast, ALP catalyzes hydrolysis of the 5'-phosphoryl terminus from the cDNA, producing a 5'-hydroxyl end product that prevents λ exo cleavage. As a consequence, no SA aptamers bind to SA beads yielding weak fluorescence. Compared to the reported ALP detection methods, interfering autofluorescence from species in the complex biological system can be easily isolated by a bead-based separation, such as simple centrifugation or filtration, to reduce non-specific adsorption-induced background. Besides, a large surface-to-volume ratio enriches the fluorescent signals on the beads which improves the signal-background-ratio (SBR). Without the need for nucleic acid amplification, the developed AP avoids the use of multiple enzymes and consequent complicated operation and cross-contamination, thereby decreasing operational difficulty and time-consumption for signal readout. The results show a detection limit of 0.012 U/mL and a linear response over the range of 0.02–0.15 U/mL in buffer and human serum with high sensitivity and selectivity. Furthermore, the method can be applied to the inhibitor screening of ALP and ALP-labeled ELISA, expanding the scope of practical applications. This strategy introduces a new way to detect ALP and shows the potential for applications in drug discovery and cancer diagnosis.

MATERIALS AND METHODS

Materials

Alkaline phosphatase (ALP, 1000 U/mL) and p-nitrophenyl phosphate (PNPP) were purchased from Thermo Fisher Scientific Inc (Shanghai, China). Lambda exonuclease (λ exo, 5000 U/mL) and T4 ligase were obtained from New England Biolabs (Ipswich, MA, USA). Thrombin was supplied from Haematologic Technologies (Essex Junction, VT, USA). Lysozyme was purchased from R&D Systems (Minneapolis, MN, USA). Human serum albumin (HSA) was bought from Tagene Biotechnology Co., Ltd. (Xiamen, China). Proteinase K was purchased from BBI Science (Shanghai, China). Trypsin was purchased from Biofroxx (Einhausen, Germany). Na_3VO_4, human IgG and anti-human IgG-coated ELISA plates were purchased from Sigma-Aldrich (St. Louis, MO, USA). L-cysteine was bought from Sinopharm Chemical Reagent Co. Ltd (Shanghai, China). Human serum was obtained from Affiliated Chenggong Hospital (Xiamen University). Streptavidin (SA) Sepharose beads were purchased from GE Healthcare (Chicago, IL, USA). ALP-labeled goat anti-human IgG was purchased

from Abcam (Cambridge, MA, USA). RIPA and PMSF were bought from Solarbio life sciences (Beijing, China). All other chemicals were analytical reagent grade and used without further purification. All oligonucleotides used in this study were synthesized and HPLC purified by Sangon Biotechnology Co., Ltd. (Shanghai, China) and sequences are listed in **Table S1**.

Optimization of the AP

To obtain the best SBR, the SA aptamer sequences were optimized. To prepare the DNA for hybridization, 10 μM AP (including the SA aptamer and its total cDNA) was heated to 95°C for 5 min and then held at 37°C for 30 min. In a typical ALP assay, 200 nM AP in 100 μL buffer (70 mM Tris-HCl, 10 mM $MgCl_2$, pH = 8.0) with 10 U/mL ALP was incubated at 37°C for 10 min. Then 100 U/mL λ exo was added to the solution and incubated at 37°C for 30 min to digest the 5'-phosphorylated cDNA. After incubation, the enzyme was inactivated at 75°C for 10 min. The mixture was cooled to room temperature, and 3 μL SA beads was added and rotated slowly for 5 min to interact with the free SA aptamers. After washing 3 times with buffer, the fluorescence of SA beads was quantitatively characterized by flow cytometry or fluorescence microscopy.

Quantitative Assay of ALP Activity

To achieve quantitative detection of ALP activity, a series of different concentrations of ALP was added to the reaction system. For complex biological systems, 10% human serum was utilized as the reaction buffer with different concentrations of ALP. After the enzyme-deactivation step, the precipitate was removed by centrifugation. The subsequent steps were the same as those described in the previous section.

Selectivity Study

The selectivity of the ALP assay was investigated by using other enzymes or proteins, including thrombin, T4 ligase, lysozyme, HSA, proteinase K, trypsin and de-activated ALP. The concentration of ALP was 2 U/mL, and the concentrations of other enzymes and proteins were 20 U/mL or 10 nM. Other procedures were the same as those stated above.

ALP Inhibitor Screening

The ALP inhibitor screening was performed by utilizing Na_3VO_4 and L-cysteine. Different concentrations of inhibitors were mixed with 2 U/mL ALP, and the mixture was added to 200 nM AP in 100 μL buffer. The remaining steps were the same as those stated above.

ALP-Linked Immunosorbent Assay

To achieve quantitative detection for human IgG activity, each well of an anti-human IgG coated ELISA plate was filled with human IgG (100 μL, 30–960 ng/mL) at ambient temperature for 2.5 h with gentle shaking and then washed 4 times with washing buffer (300 μL). Detection antibody, ALP-labeled goat anti-human IgG (100 μL, 1:1000) was added to each well, and incubated for 1 h at room temperature with gentle shaking and then washed 4 times with washing buffer (300 μL). Then, 200 nM AP in 100 μL buffer was added to each well and incubated at 37°C for 10 min. After incubation, all the solutions were transferred to centrifuge tubes, and the remaining steps were the same as those stated above.

Preparation of Cell Lysates

Hela cells were cultured in DMEM medium with 10% fetal bovine serum (FBS). The cells were washed three times with PBS, and treated with 1 mL RIPA and 10 μL PMSF for 1 h on ice. A suspension of 10^5 cells/mL was centrifuged at 10,000 rpm for 30 min at 4°C, and the supernatant was used as complex matrix and spiked with ALP for detection.

ALP Detection Using PNPP Substrate

Four microgram per microliter PNPP substrate dispersed in diethanolamine was prepared and added to 96-well plate. A series concentration of ALP was added to each well and incubated for 30 min at 37°C. Then the stop solution of 2 M NaOH was added for stopping reaction. Finally, the absorbance of 405 nm was recorded by microplate reader.

RESULTS AND DISCUSSION

Working Principle

As illustrated in **Figure 1**, the AP holds its duplex conformation with ALP and changes to single-stranded form without ALP, which means allosteric effect, resulting in the fluorescence readout for the detection. An AP is composed of two complementary sequences, including an SA aptamer labeled by fluorophore and its total cDNA modified with a 5'-phosphoryl terminus. When ALP is present, the 5'-phosphoryl terminus of cDNA would be hydrolyzed, thus avoiding cleavage by λ exo and blocking the SA aptamer binding affinity, resulting in low fluorescence. Without ALP, the terminus of the cDNA would remain phosphorylated, leading to degradation by λ exo to release the fluorophore-labeled SA aptamer for binding to SA beads. The decreased fluorescence of SA beads in the presence of ALP is quantitatively detected by fluorescence microscopy or flow cytometry.

Optimization of the AP and Reaction Conditions

To achieve highly sensitive detection of ALP, we designed the AP by imitating the allosteric effect in nature and optimized the SA aptamer sequences, ALP incubation time, and the concentrations of lambda exo. The sensitivity of the method relies heavily on the allosteric effect of the AP, which depends on the relative binding affinities of SA aptamer to streptavidin vs. cDNA. As shown in **Figure S1** (A), we chose three SA aptamers from the literature (Bing et al., 2010), named SA1, SA2, and SA3, with different compositions of the stem and bulge. We equilibrated SA aptamers and their cDNAs in buffer with or without ALP, then added λ exo and SA beads in succession, and finally calculated the SBR (F_0/F, where F_0 and F are fluorescence intensities without and with ALP, respectively). As shown in **Figure S1** (B), SA3 provided best SBR among all three aptamers. Since the binding affinities of SA1 and SA2 to streptavidin are higher than that of SA3, when ALP is present, SA1 and SA2 are more inclined to

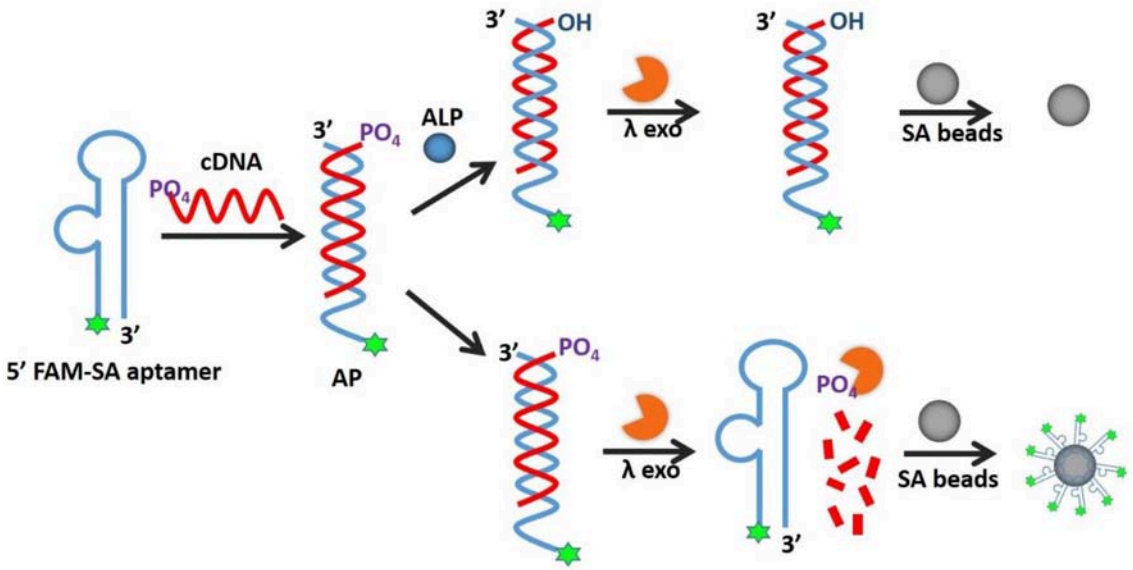

FIGURE 1 | Schematic illustration of AP for detection of alkaline phosphatase activity.

dissociate from duplex sequences and bind to SA beads, resulting in false positive signals which decreased their SBRs. Thus, SA3 was chosen for subsequent experiments.

Furthermore, as shown in **Figure S2**, we optimized the ALP incubation time from 10 to 60 min, and chose the shortest one of 10 min, since the reaction efficiency is similar for all time durations. Considering that λ exo plays an important role in sequence degradation, we optimized λ exo concentrations including 25, 50, 100, and 150 U/mL. With insufficient λ exo, the degradation efficiency on the 5'-phosphoryl terminus of cDNA3 decreases clearly. While excessive λ exo also causes non-specific degradation and waste of reagents. As shown in **Figure S3**, 100 U/mL λ exo was chosen for subsequent experiments. We also optimized λ exo incubation time ranging from 15 to 90 min (**Figure S4**). There was little difference for all tested incubation time. We chose 30 min for further experiments just to be sure the complete reaction. Fluorescence enhancement is also affected by the amount of beads present, thus we optimized the SA beads volume with 0.5–5 μL for binding to 200 nM SA3. As shown in **Figure S5**, 0.5 and 1 μL SA beads exhibited higher fluorescence intensity, but they are easy to lose during washing steps. For 3 and 5 μL SA beads, it seems that fluorescence intensity is a little lower but still noticeable. Finally, 3 μL beads were chosen as the optimal beads volume for further experiments.

Feasibility of the AP

We designed the AP consisting of SA3 and cDNA3 to test the feasibility for ALP activity detection. As shown in **Figure 2A**, the blue peak showed a low fluorescent signal, demonstrating the successful formation of the double-stranded structure to inhibit the aptamer's binding affinity. The pink peak had a higher fluorescence intensity compared to the blue peak, confirming the cleavage of cDNA3 by λ exo. Simultaneously, the fluorescence of the green peak was much lower than that of the pink one, indicating the hydroxylation of the AP by ALP. We also utilized 15% native PAGE to prove the feasibility (**Figure 2B**). Lane 1 was SA3 for comparison. For lane 2 and 3, in the absence of λ exo, SA3, and cDNA3 remained good hybridization with or without ALP. For lane 4, without ALP, cDNA3 was degraded so that the upper band was decreased as well as SA3 band recovered. For lane 5, ALP dephosphorylated the AP and protected it from λ exo cleavage, leaving the AP intact. Therefore, gel electrophoresis verifies the good hybridization between SA3 and cDNA3, dephosphorylation of 5'-phosphoryl terminus by ALP and specific digestion of phosphorylated ssDNA by λ exo. Furthermore, with the fluorescence microscope (**Figure 2C**), there was no fluorescence of the AP in the presence of 10 U/mL ALP, while the beads remained highly fluorescent in the absence of ALP. Therefore, the consistent results of flow cytometry, gel electrophoresis, and fluorescence microscopy indicate the feasibility of the AP design.

Quantitative Measurement of ALP in Buffer and Biological Samples

The quantitative detection of ALP was conducted with a series of concentrations of ALP by flow cytometry. As shown in **Figure 3A** and **Figure S6**, $(F_0\text{-}F)/F_0$ increased with the growing concentration of ALP in buffer, where F_0 and F are fluorescence intensities without and with ALP, respectively. From the fitting curve in **Figure 3A**, the LOD was 0.012 U/mL (3σ/S) and the linear range was 0.02–0.15 U/mL ($R^2 = 0.9902$), which are both superior or comparable to those of other reported methods (**Table S2**) (Dong et al., 2015; Xing et al., 2016). For clinical applications, the normal range of ALP in human serum is from 0.04 to 0.11 U/mL. In this case, the proposed method covers the normal detection range of ALP in clinical applications and

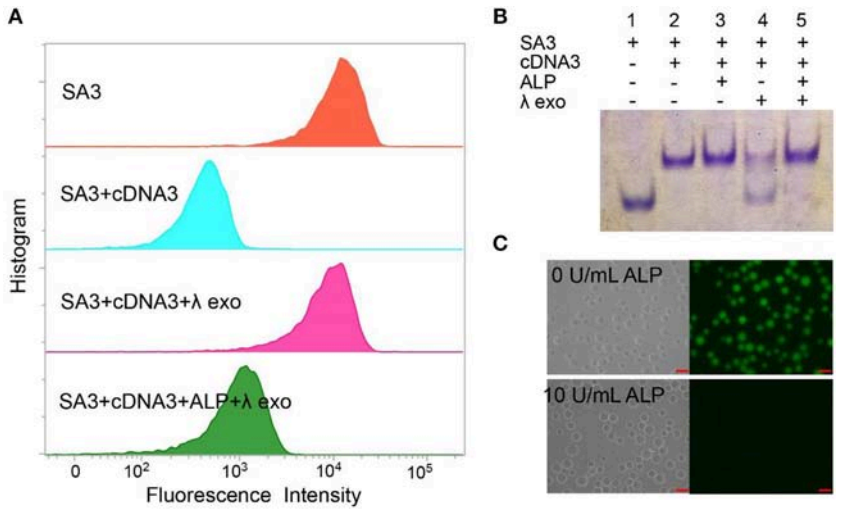

FIGURE 2 | Different methods for proving the feasibility of AP with 10 U/mL ALP: **(A)** flow cytometry, **(B)** 15% native PAGE. Lane 1, SA3; Lane 2, SA3, and cDNA3; Lane 3, SA3, cDNA3, and ALP; Lane 4, SA3, cDNA3, and λ exo; Lane 5, SA3, cDNA3, ALP, and λ exo. **(C)** fluorescence microscope.

meets the need for clinical diagnosis (Wolf, 1978). As further evidence of the effect of added ALP, fluorescence microscopy was also used for ALP screening. As shown in **Figure 3C**, distinct fluorescence decrease was observed with an incremental introduction of ALP from 0.02 to 0.15 U/mL, which is consistent with the result of flow cytometry. Therefore, based on the enrichment of fluorescence on beads with no or low levels of ALP, the signal output of the assay could be achieved by different detection methods, including flow cytometry and fluorescence microscope, providing multiple choices for ALP activity screening.

The localization of SA3 on the microbeads made it possible to separate signal generation from the interfering autofluorescence from species in the complicated biological matrix, making the AP applicable to biological samples. To verify this advantage, 10% human serum was chosen as a model complex system for our assay. Since human serum contains multiple components with autofluorescence, including amino acids, vitamins, lipids, and nucleic acid derivatives, as well as growth factor, which added to the background signal and increased homogeneous detection difficulty (Wolfbeis and Leiner, 1985). In our experiment, bead-based separation integrated the signal collection and interfering species separation, leading to highly sensitive and selective detection in complex samples. As shown in **Figure 3B**, $(F_0\text{-}F)/F_0$ increased with increasing concentrations of ALP in 10% human serum. Based on the fitting curve in **Figure 3B**, the LOD was found to be 0.019 U/mL (3σ/S) and the linear range was 0.02–0.15 U/mL ($R^2 = 0.9768$), both of which are comparable to those in buffer. In addition, 20% human serum sample was also tested (**Figure S7**), and similar results were obtained with LOD of 0.021 U/mL (3σ/S) and the linear range of 0.025–0.15 U/mL. Moreover, the AP was also spiked in Hela cell lysate of 10^5 cells/mL. As shown in **Figure S8**, the linear range was obtained as 0.05–0.20 U/mL and the LOD was 0.014 U/mL (3σ/S). Therefore, the result indicates that our proposed method is promising for detection in complex biological matrix and clinical sample.

To compare with traditional methods, we also conducted the ALP detection using PNPP substrate. As shown in **Figure S9**, the linear range was 0.15–0.35 U/mL and the LOD was 0.13 U/mL (3σ/S), which is nearly ten times higher than that of the AP. Therefore, the AP strategy outweighs the traditional method with higher sensitivity.

Selectivity Study

Selectivity of the AP assay was studied with six non-related enzymes or proteins, including thrombin, T4 ligase, lysozyme, HSA, proteinase K, trypsin, and de-activated ALP. As shown in **Figure 4**, $(F_0\text{-}F)/F_0$ was enhanced only in the presence of ALP, while negligible fluorescence change was observed for other enzymes or proteins with concentrations 10 times that of ALP. The results indicate that our proposed method exhibits good selectivity and enables distinguishing ALP from other interfering species, including other hydrolases such as proteinase K and trypsin.

Inhibitor Study

As a crucial index for clinical medicine, excess ALP in the human body can induce serious diseases (Hosking et al., 1998). Thus, it is important to study the inhibitor of ALP for medical treatment, drug development and cancer therapy. We chose sodium orthovanadate (Na_3VO_4) as a model for ALP inhibitor screening. Sodium orthovanadate is an inorganic compound that exhibits a variety of biological activities, commonly used in inhibition of phosphatases and ATPases for preventing proteins from phosphorylation or promoting phosphorylation of activation (Gordon, 1991). In principle, it is orthovanadate's resemblance to a transition-state analog of phosphate through hydration or chelation that is key to the mechanism of

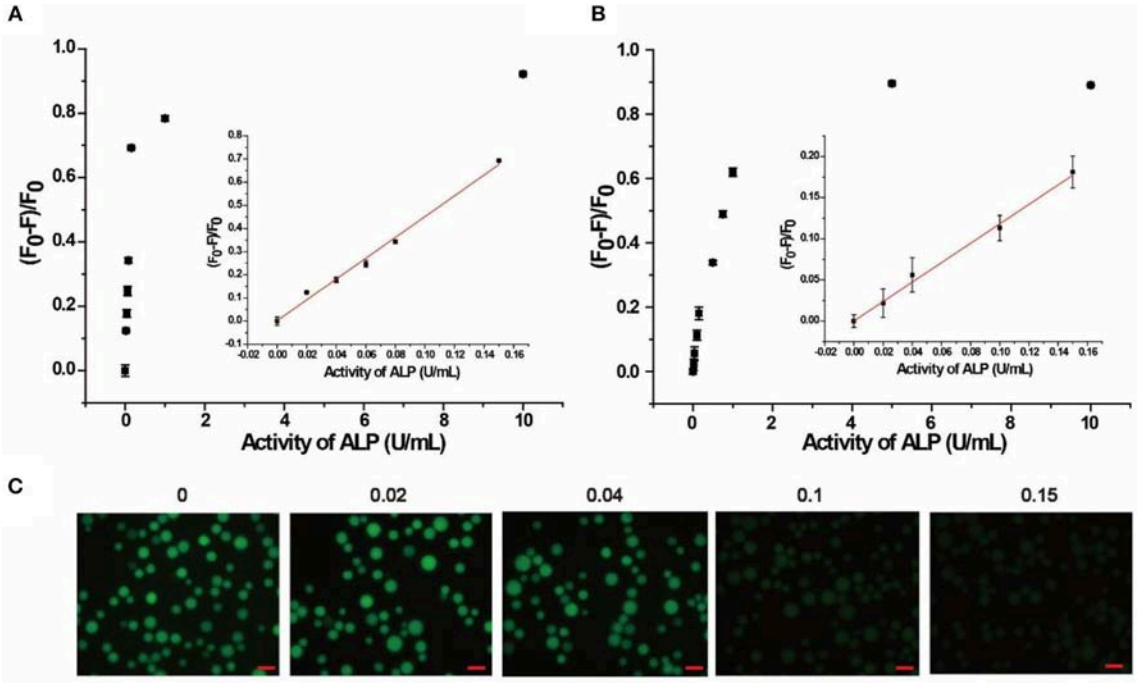

FIGURE 3 | Response of quantitative detection of ALP range from 0 to 10 U/mL in **(A)** buffer solution, **(B)** in 10% human serum monitored by flow cytometry. inhibition of ALP by orthovanadate (Seargeant and Stinson, 1979).

As shown in **Figures 5A,B**, fluorescence intensities of beads read by flow cytometry exhibited gradual enhancement with increasing concentrations of Na_3VO_4. The IC50 (half maximal inhibitory concentration) value was found to be 400 μM (±150 μM), which is in good accordance with other reported work (Chen et al., 2014; Wang et al., 2014). Besides, we have studied another inhibitor L-cysteine (**Figure S10**), the corresponding IC50 was estimated to be 125 μM (±50 μM), which is close to the values obtained by using other methods (Van, 1972), indicating that our method has general applicability in inhibitor screening. Hence, the AP strategy has the potential not only to detect ALP activity, but also to investigate ALP inhibitors and develop new anticancer drugs.

Quantification of IgG Based on ALP-Linked Immunosorbent Assay

Considering its low cost, good stability, high sensitivity, and wide substrate applicability, ALP is generally used to conjugate to streptavidin or a detection antibody for signal amplification in immunoassay (Gao et al., 2014). Since we have demonstrated the feasibility of ALP analysis of the AP, the probe was further applied into an ALP-linked ELISA, taking human IgG as a model. **Figure 6A** illustrates the integration of the quantification of human IgG through a sandwich immunoassay, ALP enzymatic hydrolysis of the AP and separation of the detection signal on SA beads. In the sandwich immunoassay, capture antibody of anti-human IgG was coated on a 96-well plate. After capture of target human IgG, the detection antibody of ALP-labeled goat anti-human IgG was added to form immune complexes. Then AP was added to react with ALP, resulting in hydrolysis of the 5'-phosphoryl terminus of cDNA3. The λ

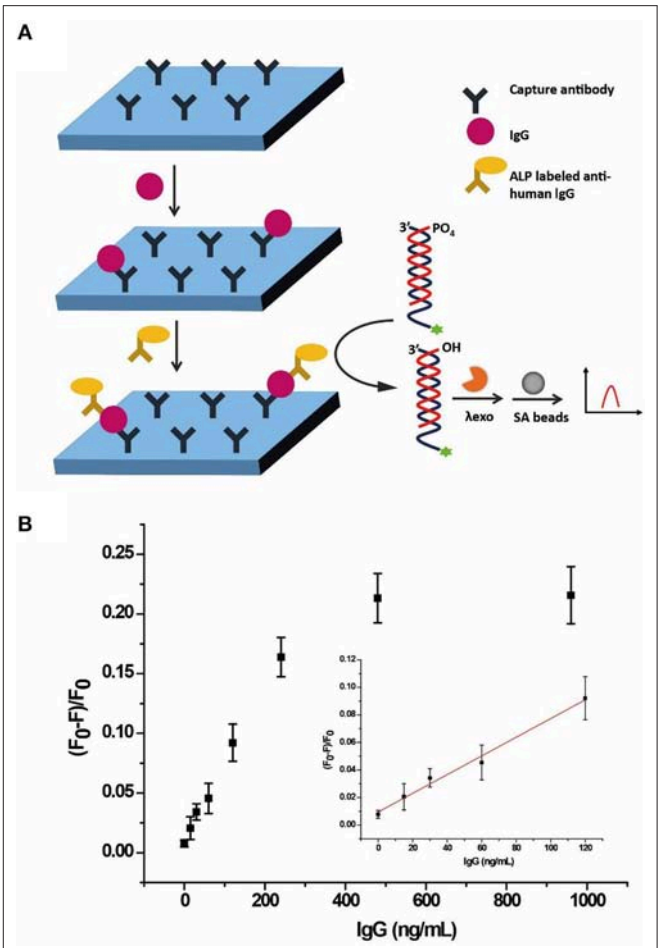

FIGURE 6 | (A) Schematic illustration of the allosteric probe for detection of IgG through ALP-labeled immunoassay. **(B)** Response of the AP to different concentrations of human IgG through ALP-linked ELISA in buffer solution monitored by flow cytometry. Error bars indicate the standard deviations of three samples.

exo digested the unhydrolyzed AP, releasing the single strand SA3 to be captured by SA beads. As a result, the fluorescence of SA3 was enriched on the beads and monitored by flow cytometry.

As shown in **Figure 6B**, $(F_0\text{-}F)/F_0$ gradually increased with the increasing concentration of human IgG from 0 to 960 ng/mL in buffer. The LOD was 12.9 ng/mL ($3\sigma/S$) and the linear range was 15–120 ng/mL ($R^2 = 0.9882$), where F_0 and F are fluorescence intensities without and with ALP, respectively. Since the normal range of IgG for healthy adults is 7–16 g/L (Dati et al., 1996), the result clearly showed that the AP with an adequate detection range and sensitivity could be applied to the quantification of human IgG.

CONCLUSIONS

In summary, we have developed a new class of probes based on the allosteric effect, called allosteric probes or AP, which can be applied for ALP activity detection. In AP assay, the single fluorophore-labeled design makes the probe simpler and cheaper than molecular beacons, which requires labeling by both fluorescence and quenching groups. Besides, only one exonuclease is used for cutting DNA sequences, avoiding the need for other assistant enzymes. In addition, the excellent binding affinity and specificity between SA aptamer and SA shortens the binding time to 5 min, and the bead-based enrichment enables a detection limit of 0.012 U/mL without the use of any nucleic acid amplification, especially avoiding complicated manipulations and cross contamination. Furthermore, due to the bead-based separation, the probe can be used in complex biological samples, averting interference from background fluorescence. Moreover, the extending applications of inhibitor study of ALP and analysis of human IgG were also explored. With the advantages of simple design, high sensitivity, easy operation, and good compatibility in complex solutions and in ALP-linked immunosorbent assays, our AP assay has great

potential for further applications in ALP inhibitor screening, drug discovery and early diagnosis of cancer. With further research to optimize the probe sequences, the AP could serve as an excellent probe for detection of other kinds of phosphatases and kinases.

AUTHOR CONTRIBUTIONS

ZZ, YS, and CY conceived and guided the study. JG performed the experiments and analyzed the data with help from MG, LL, and KZ. JG wrote the first draft of the manuscript. ZZ, YS, DL, and TT contributed to manuscript revision, read, and approved the submitted version.

Substrate-Assisted Visualization of Surfactant Micelles via Transmission Electron Microscopy

Zekun Zhang, Kaitao Li, Rui Tian and Chao Lu**

State Key Laboratory of Chemical Resource Engineering, Beijing University of Chemical Technology, Beijing, China

The visualization of the micellar morphological evolution for surfactant has drawn much attention due to its self-assemble ability to fold into various structures. However, the direct observation of the soft materials with low atomic number has been hampered because of the poor scattering contrast and complex staining process by the traditional transmission electron microscopy (TEM) techniques. Herein, we reported a novel strategy to the visualization of surfactant micelles with the assistance of layered double hydroxides (LDHs) via TEM. Owing to the uniformly distributed metal ions and positive charges in the LDHs, the surfactant at the micelle-water interface reacted with LDHs to form a stabilized architecture through electrostatic and hydrogen-bond interactions. The morphologies of the surfactant can be clearly observed through the surfactant-LDHs architectures, exhibiting high contrast by TEM techniques. Significantly, the micellar evolutions involving the spherical, rodlike, and wormlike shapes were successfully distinguished. Our results may provide great possibilities and inspirations for the visualization for morphology of soft matters.

INTRODUCTION

Surfactant is a widely applied soft material which exhibits self-assemble ability to fold into micelles with various structures (Jain and Bates, 2003; Stano and Luisi, 2010; Liu et al., 2018). The studies of the morphology and structure for micelles have drawn increasing attention due to their great significance in biological and material science (Landsmann et al., 2010; Wang et al., 2013; Hu and Chou, 2014). Transmission electron microscopy (TEM) is a valid technique widely applied to provide morphological aspects for visualization (Jung et al., 2003; O'Reilly et al., 2005; Honda et al., 2010). However, the observation for the surfactant micelles has been hampered due to the poor scattering contrast of the constituent elements with low atomic number (Egerton, 2013; Proetto et al., 2014). Although the supplemented attachments of TEM (such as liquid-cell and cryo-TEM) can provide supports for the morphological studies, this method suffered from sophisticated operation and sampling procedure (Geng and Discher, 2005; Parent et al., 2017; Zeng et al., 2017; Creatto et al., 2018; Stawski et al., 2018; Zhao et al., 2018; Suys et al., 2019). Therefore, it is a topic of significance to realize the visualization for the morphological evolution of the micelles during the formation process.

Staining is commonly done with heavy metal oxides (e.g., OsO_4 and RuO_4) for improving TEM contrast (Trent et al., 1983; Serizawa et al., 2000; Humphrey, 2009; Aramaki et al., 2017; Xu et al., 2017; Parker et al., 2018). Unsatisfactorily, the staining process usually comes along with inhomogeneity for staining segment, which might affect the true representation of the samples (Smith and Bryg, 2006). Moreover, the toxicity of the heavy metals has largely limited the application of staining. The fact has motivated us to explore an environmentally friendly alternative to enhance the scattering contrast and assist the visualization of micelles (Claypool et al., 1997; Aso et al., 2013).

Layered double hydroxides (LDHs) are a class of 2D inorganic metallic layered materials composed of edge-sharing metal-hydroxide octahedral structure (Abellan et al., 2012; Tian et al., 2018). The versatile di- and trivalent metal cations distributed uniformly in the host layer with the tunable electropositivity derived from the trivalent metal ions (Wang and O'Hare, 2012; Tian et al., 2015). The constituent metal elements, positively-charged layers and the abundant active sites of LDHs provided great possibilities for the construction of functional composites through electrostatic interaction and hydrogen bonds (Rogez et al., 2011; Fan et al., 2014). These superiorities inspired us to explore the potential of LDHs to assist the visualization of surfactant micelles by TEM technique.

In this study, we demonstrated the visualization of surfactant micelles with the assist of LDHs via traditional TEM. An amphoteric surfactant *N*-hexadecyl-*N,N*-dimethyl-3-ammonio-1-propanesulfonate (SHDAB) with sulfonate anion in the head was employed. The functional groups at the micelle-water interface could react with LDHs to form a stabilized SHDAB@LDHs architecture by electrostatic and hydrogen-bond interactions (**Figure 1**). Owing to the capillary-compensated flow during droplet evaporation process, the LDHs nanoplates deposited at the edge of the droplet as "coffee-ring" (Deegan et al., 1997; Parneix et al., 2010; Cui et al., 2012) (**Scheme S1**). Visualization images with excellent contrast were achieved for SHDAB@LDHs architecture through TEM techniques. More importantly, the whole micellar morphological transition involving the spherical, rodlike and wormlike shapes could be effectively recognized with the continuously increased concentration of SHDAB (**Scheme S2**). The sizes of the micelles in the evolution identified with the data obtained from atomic force microscope (AFM). Therefore, it is anticipated that LDHs-assisted visualization of surfactant micelles may open new possibilities of TEM applications, especially for the soft materials.

METHODS

Materials, Reagents, and Instruments

All reagents in experiments are of analytical grade and used without further purification. NaOH, $Al(NO_3)_3{\cdot}9H_2O$, $Mg(NO_3)_2{\cdot}6H_2O$ are purchased from Beijing Chemical Reagent Company (Beijing, China). SHDAB is purchased from Tokyo Chemical Industry Co. Ltd (Tokyo, Japan). Ultra-pure water was obtained from the Milli-Q purification system (Barnstead, CA, USA).

Surface tension measurements of the SHDAB surfactant were measured on a Force Tensiometer (K100) by the Wilhelmy plate technique (Kruss, Germany). Electrical conductivity measurements were accomplished using an EC 215 conductivity meter (Shanghai Jingmi Instrumental Co., China). The ultrasonic treatment was implemented in an ultrasonic cleaning machine (Kunshan Ultrasonic Instrument Co. Ltd., China) with the frequency of 100%. TEM images were measured by the Tecnai $G^2$20 (FEI Company, USA) with the accelerating voltage of 200 kV. The morphological studies of the LDHs were implemented on a scanning electron microscope (SEM Hitachi S-4700). The morphology data of SHDAB micelles were acquired on AFM by the NanoScope 9.1 (Bruker, Germany) instrument. X-ray diffraction (XRD) patterns of SHDAB, LDHs and SHDAB@LDHs architectures were measured on a D8 ADVANCE X-ray diffractometer (Bruker, Germany). FT-IR spectra were performed on a Nicolet 6700 (Thermo Electron). Zeta potentials of all the samples were recorded on a Malvern Zetasizer 3000HS nano-granularity analyzer. Isothermal titration calorimeter (ITC) was employed to study the interaction between SHDAB and LDHs on a Nano ITC (TA Instruments Waters, LLC, UT). 1.0 mL SHDAB aqueous (3.69×10^{-4} mol·L^{-1}) was titrated into 0.25 mL LDHs (2.00×10^{-3} mol·L^{-1}) in the measurement which was periodically calibrated with an internal electric heater. The heats of interaction during each injection were measured by integration of each titration peak using the ORIGIN software delivered with the ITC.

Synthesis of MgAl-CO_3-LDHs

According to the reported method (Gao et al., 2017; Tian et al., 2018), the LDHs were prepared with a few modifications. A mixed salt solution of $Mg(NO_3)_2{\cdot}6H_2O$ (19.200 g, 0.075 mol) and $Al(NO_3)_3{\cdot}9H_2O$ (9.375g, 0.025 mol) was dissolved in 150 mL water in a 250 mL flask. Subsequently, the prepared alkaline liquor of NaOH (8.000 g, 0.200 mol) was added to keep a constant pH value of 8.5. Then, the suspension was stirred for another 20 min, followed by transfer to a furnace tube at 110°C for 24 h. Finally, the precipitate was centrifuged, washed with water and stored at 4°C for further use.

Preparation of Surfactant Micelles

The stock solution was prepared by dissolving SHDAB (0.017 g, 0.044 mol) in 30 mL ultra-pure water. Then, the SHDAB solution with different concentration (0.0295 mM, 0.059 mM, 0.295 mM, 1.48 mM) was prepared. After the ultrasonic treatment at 50°C for 4 h, the micelles with different morphologies were acquired.

Synthesis of SHDAB@LDHs Architecture

Firstly, the LDHs suspensions were treated under ultrasonic to obtain a uniformly dispersed colloidal solution. Then, the as-prepared LDHs with different volumes (3.53, 7.06, 35.29, 176.45 μL) were added into the SHDAB surfactant micelles solution of different concentration (0.04 mM, 0.08 mM, 0.40 mM, 2.00 mM), respectively. Finally, the mixtures were treated under ultrasonic irradiation at 50°C for 4 h to prepare the SHDAB@LDHs architectures. In order to evaluate the morphological evolution of SHDAB micelles, *m*-SHDAB@LDHs architectures were prepared

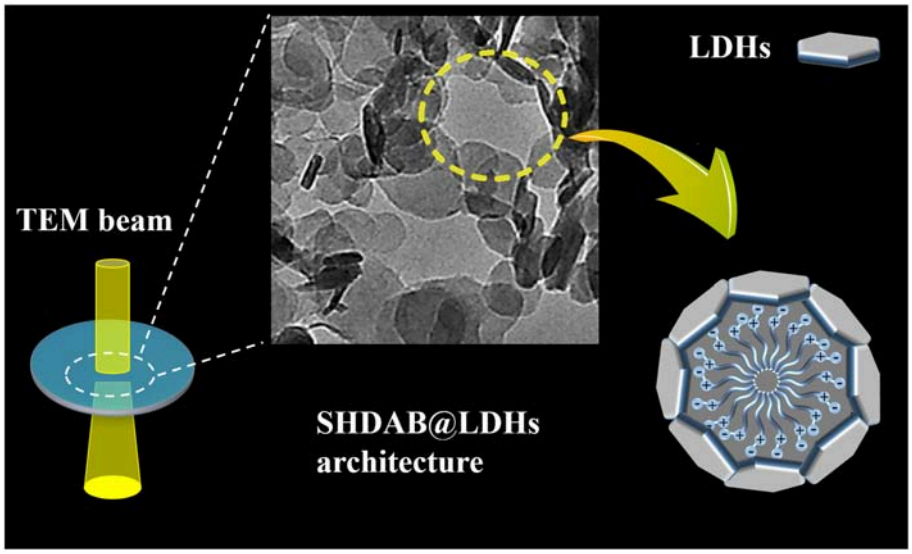

FIGURE 1 | Schematic representation of visualization for surfactant micelles with the assist of LDHs via TEM imaging.

TABLE 1 | The concentrations of SHDAB and LDHs in samples *m*-SHDAB@LDHs architectures.

Samples	SHDAB/mM	LDHs/mM
$m = 0.0295$	0.0295	0.04
$m = 0.0590$	0.0590	0.08
$m = 0.295$	0.295	0.40
$m = 1.48$	1.48	2.00

with the molecular ratio of SHDAB to LDHs determined as 0.295 to 0.400. The detailed compositions in *m*-SHDAB@LDHs architectures were listed in **Table 1**.

RESULTS AND DISCUSSION

Characterizations of the Surfactant

N-hexadecyl-*N,N*-dimethyl-3-ammonio-1-propanesulfonate (SHDAB) is a kind of betaine surfactant with negatively charged sulfonic acid in headgroup (**Figure S1**). To study the morphological transitions of SHDAB, the critical micelle concentration (CMC) has been investigated through the surface activities study (Claussen, 1967). The surface tension (γ) was plotted with the logarithm value of concentration for SHDAB. With the increased logarithm value of concentration for SHDAB, the surface tension of SHDAB decreased sharply at first and reached a relatively constant value after a marked change at 0.0295 mM for SHDAB (**Figure 2A**). The phenomenon was attributed to the presence of SHDAB monomers which preferred to adsorb at the water-air interface when the concentrations were below the CMC. When the adsorption at the water-air interface got saturated with the increased SHDAB monomers, the SHDAB tended to form micelles in the solution, exhibiting an almost constant surface tension. The inflection point from **Figure 2A** demonstrated that the CMC of SHDAB was 0.0295 mM. Moreover, the value of CMC was also investigated by conductivity measurements (Guégan et al., 2016). **Figure 2B** showed that the conductivity (κ) grew linearly with the logarithm value of concentration for SHDAB increased. Then, a slow growth was observed when the concentration of SHDAB was larger than 0.0295 mM. Such a turning point manifested the formation of micelles was determined as CMC for SHDAB, in agreement with that obtained by surface tension measurement. Notably, the CMC value of 0.0295 mM for SHDAB accorded with previous work (Liu et al., 2013).

Visualization of Surfactant Assisted by LDHs

To observe the morphological evolution of SHDAB micelles in different concentrations, MgAl-LDHs nanoplates were prepared via a hydrothermal method (**Figure S2**) (Gao et al., 2017; Tian et al., 2018). As shown in **Figure 3A**, the LDH particles were well-dispersed after ultrasonic irradiation. High contrast of inherent LDHs can be observed, as a result of the presence of metal elements (Mg and Al) in the host layers. On the contrary, TEM image of SHDAB micelles (0.295 mM) showed the blurred boundaries on account of weak scattering contrast by the constituent light elements (**Figure 3B**). In order to distinguish the SHDAB micelles, LDH particles were added into SHDAB to construct the SHDAB@LDHs architecture for visualization. Significantly, uniformly-distributed porous structure surrounded by continuous LDHs could be observed (**Figure S3**). The reason for the formation of the porous structure may be due to the fact that the positively charged LDHs were attached at the edges of the SHDAB micelles. During the evaporation process, the LDHs nanoparticles fell apart to the edge and accumulated at the border of the SHDAB@LDHs composites, and a "coffee-ring"

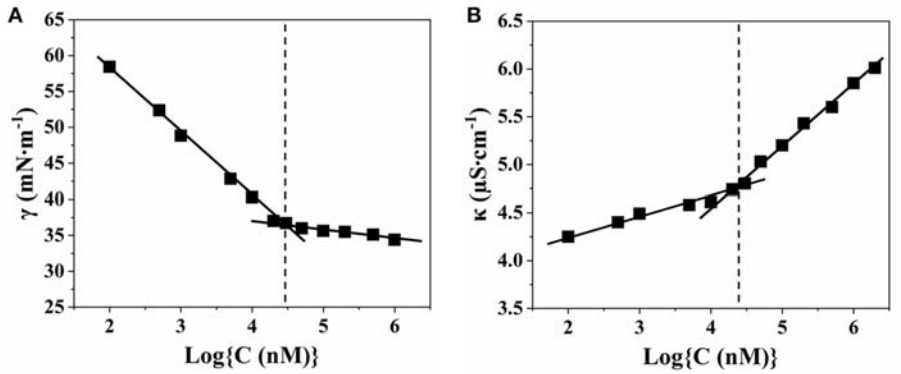

FIGURE 2 | Relationship between the concentration of SHDAB with **(A)** surface tension (γ) and **(B)** conductivity (κ), respectively.

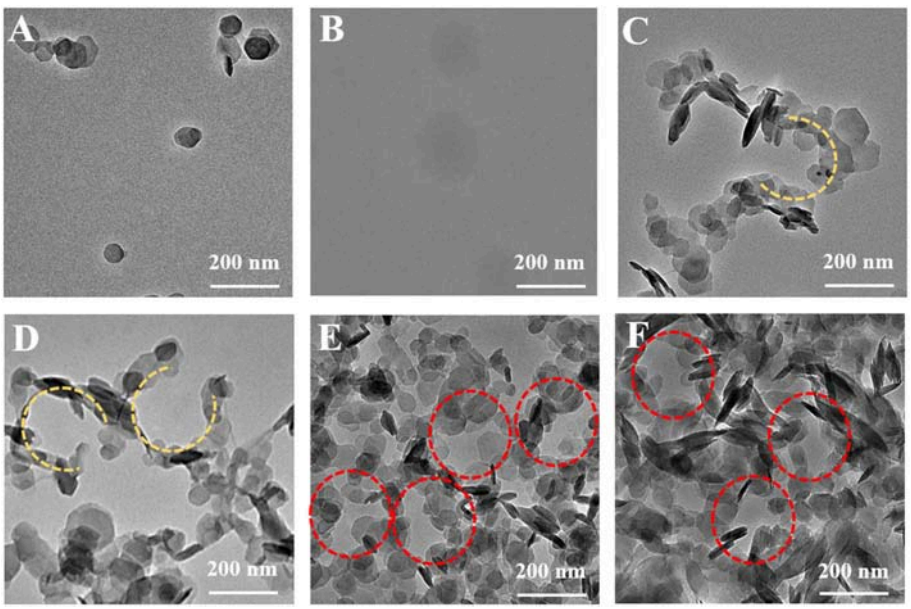

FIGURE 3 | TEM images of **(A)** the LDHs, **(B)** the SHDAB micelles and **(C–F)** the SHDAB@LDHs architectures with increased concentration of LDHs in SHDAB aqueous solution (0.295 mM); from C to F: 0.04 mM, 0.08 mM, 0.40 mM and 2.00 mM, respectively.

was observed (**Scheme S1**) (Deegan et al., 1997; Parneix et al., 2010; Cui et al., 2012). The results demonstrated the success of LDH-assisted visualization of SHDAB by TEM technique.

The optimum conditions for the visualization of SHDAB micelles were carried out. Firstly, the LDHs and SHDAB micelles were mixed and treated under continuous stirring. However, the LDH particles aggregated randomly (**Figure S3A**), which failed to give a description for SHDAB micelles. With the assistance of heat treatment at 50°C to accelerate the interaction, porous structures were gradually formed (**Figure S3B**). The irregular morphology indicated the insufficient combination between LDHs and SHDAB micelles. It has been reported that the ultrasonic irradiation is a powerful strategy for the improvement of the reaction efficiency due to the active energy of ultrasound waves (Hasaninejed et al., 2013). Herein, the porous structure appeared under the condition of ultrasonic irradiation (**Figure S3C**). Moreover, heating treatment (50°C) was taken to optimize the conditions. The 0.295-SHDAB@LDHs architecture was successfully formed and stabilized with well-organized morphologies under ultrasonic irradiation along with thermal treatment (**Figure S3D**).

The quantities of LDHs in the visualization process were evaluated. LDHs with different concentrations (0.04 mM, 0.08 mM, 0.40 mM, 2.00 mM) were added into the SHDAB micelles (0.295 mM) under ultrasonic irradiation and thermal treatment. It can be observed that the LDHs nanoparticles accumulated around the SHDAB micelles gradually to form the SHDAB@LDH architecture (**Figure 3**). The porous structure was subsequently formed with the increased content of LDHs (**Figures 3C,D**), and a complete porous structures can be

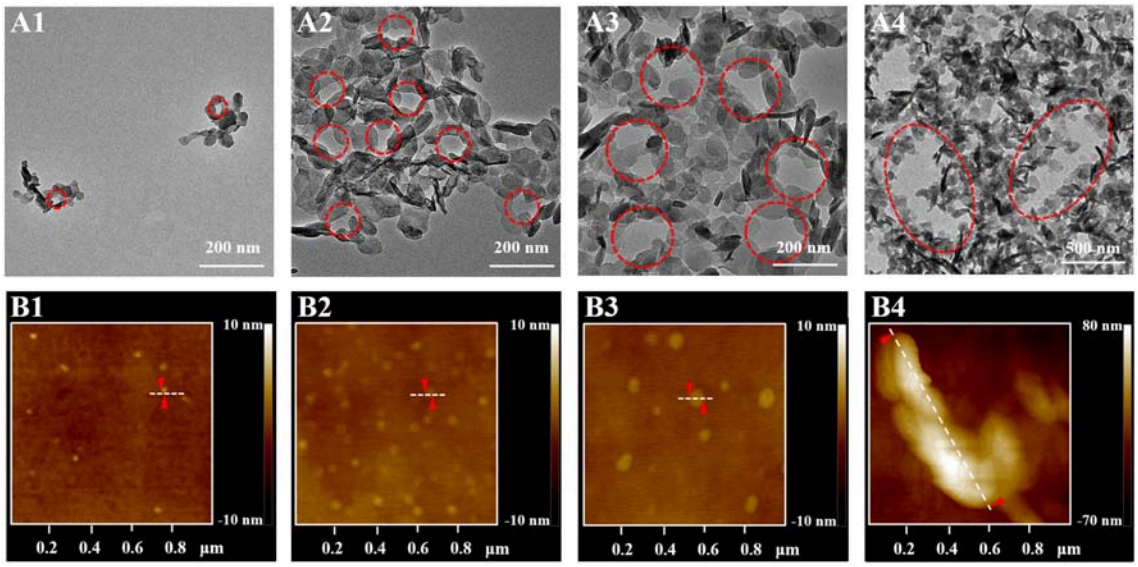

FIGURE 4 | (A) TEM images of the proposed LDHs-assisted visualization of SHDAB, and **(B)** AFM investigations of SHDAB micelles; the concentration of SHDAB varied from 0.0295 mM (CMC), 0.0590 mM, 0.295 mM to 1.48 mM, respectively.

formed with the LDHs content of 0.40 mM (**Figure 3E**). Moreover, the excess increase of LDHs (up to 2.00 mM) led to the aggregated LDHs overlapped with the SHDAB@LDH architecture (**Figure 3F**). Therefore, to achieve the visualization of micelles, the molecular ratio of SHDAB to LDHs was determined as 0.295 to 0.400. In addition, the time of ultrasonic irradiation also exerted an influence on the SHDAB@LDHs architectures. With the prolonged time, LDHs got adjacent to electrical double layers formed at the micelle-water interface. As depicted in **Figure S4**, the 0.295-SHDAB@LDHs architecture exhibited excellent morphology until 4 h' treatment and achieved an equilibrium state afterwards. Therefore, a finely tuned visualization strategy for micelles has been successfully established, which showed high contrast and distinguished imaging effect.

Visualization of the Morphological Evolution for the Surfactant

It has been reported that surfactants could be assembled into varied shapes when the concentrations of surfactant were larger than the CMC value (Shah et al., 2016). The SHDAB@LDHs architectures with increased concentration of SHDAB were prepared at the optimized ratio of SHDAB to LDHs (**Table 1**). With the concentration of SHDAB at the CMC value (0.0295 mM), a near-spherical porous structure was formed with an approximate radius of 26 nm, and the surfactant micelles were labeled with red dash line (**Figure 4A1**). The results indicated that the SHDAB micelles were surrounded by LDH nanoparticles. Interestingly, the porous architecture grew up to 58 nm with the concentration of SHDAB increased to 0.0590 mM (**Figure 4A2**). For the tenfold concentration of CMC value (0.295 mM), the SHDAB transformed from spherical to rodlike architecture with the size of 169 nm (**Figure 4A3**). Moreover, closely packed LDHs nanoplates around a lanky wormlike shape (length of 879 nm) can be observed with growing concentration of SHDAB to fiftyfold concentration of CMC (1.48 mM, **Figure 4A4**). It is noteworthy that the regulated activities of SHDAB from spherical, rodlike and wormlike structures can be visualized with the assist of LDHs by TEM imaging technique.

The dimensional and morphological properties of micelles in the transition process were testified by AFM. **Figure 4B** showed the AFM profile images of the pure SHDAB in the different concentrations from one to fifty times of CMC value. It was obvious that the micelles grew up from spherical to wormlike shape along with the increased concentrations. The section analysis was implemented to acquire the size of the micelles. The micelles changed from 30 nm, 62 nm and 178 nm of spherical shape to oval with the length of 903 nm when the concentration of LDHs changed from 0.0295 mM to 1.48 mM (**Figure S5**). The AFM data were in good conformity with the TEM images assisted by LDHs (**Table S1**). Moreover, the SHDAB@LDHs architectures can also be constructed by LDHs nanoparticles with smaller size (∼25 nm, **Figure S6**), and the transformation of the micelles morphology can be visualized (**Figure S7**). These results demonstrated that the size of LDHs did not influence the visualization of SHDAB, and the proposed method showed good accuracy by the assistance of LDHs.

Mechanism Studies

In order to study the mechanism for the formation of SHDAB@LDHs architectures, several experiments were carried out. As illustrated from the structure of SHDAB in **Figure S1**, the SHDAB surfactant can self-assemble into micelles by the synergetic functions of the hydrophobic interaction between

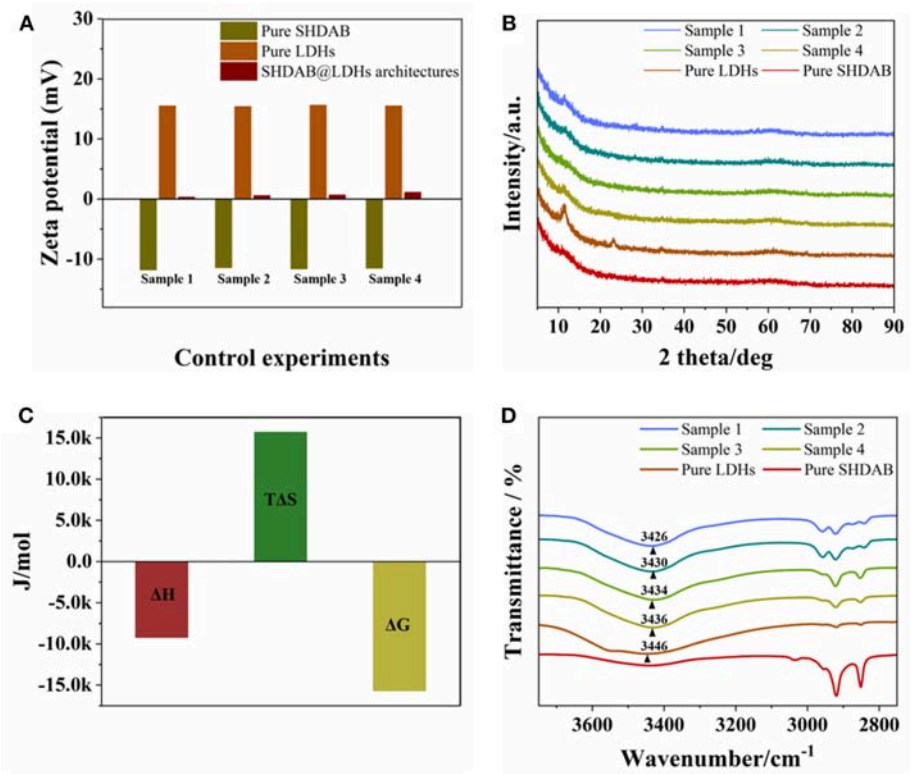

FIGURE 5 | (A) Zeta potentials, **(B)** XRD patterns, **(C)** ITC, and **(D)** FT-IR measurements of SHDAB, LDHs and SHDAB@LDHs architectures. Sample 1 to 4 represented the 0.0295-SHDAB@LDHs, 0.0590-SHDAB@LDHs, 0.295-SHDAB@LDHs and 1.48-SHDAB@LDHs architectures, respectively.

the alkane tail groups and electrostatic repulsion between the anionic head groups. As a result, the zeta potential value at the micelle-water interface of electrical double layer was −11.5 mV, indicating the stability of the SHDAB micelles with the negatively-charged groups exposed in solution (**Figure 5A**). Notably, the zeta potential of 15.5 mV for LDHs was beneficial for the electrostatic attraction toward the adjacent SHDAB micelles. The stabilized SHDAB@LDHs architecture with slight positive charge (0.3 mV) was obtained. The XRD measurements were implemented to study the structure of LDHs. The results demonstrated the unchanged interlayer space of LDHs, indicating that the SHDAB micelles were only attached at the surface of LDHs for the SHDAB@LDHs architectures (**Figure 5B**). To take a deep insight into the interaction between SHDAB micelles and LDHs, ITC measurement was carried out (**Figure S8**). The data indicated the simultaneous process for self-assembly of SHDAB micelles and the formation of the SHDAB@LDHs architectures (Kroflic et al., 2012). As shown in **Figure 5C**, the negative value of the free enthalpy showed the autonomous formation process of SHDAB@LDHs architectures (Zheng et al., 2016). Furthermore, the obvious vibration peaks in the range 3,650–3,200 cm^{-1} can be observed for the SHDAB@LDHs architectures. The peaks were blue-shifted in comparison with the FT-IR spectra for the pristine LDHs (**Figure 5D**). These results demonstrated the hydrogen bond interactions between quaternary ammonium cations of SHDAB and hydroxyl groups of LDHs. Therefore, both electrostatic and hydrogen bond interactions contributed to the formation of SHDAB@LDHs architectures for the visualization of SHDAB.

CONCLUSION

In summary, we have presented an attractive approach for the visualization of surfactant SHDAB with the assist of LDHs via TEM imaging. Based on the electrostatic and hydrogen bond interactions between LDHs and SHDAB, well-organized SHDAB@LDHs architectures were formed. The morphologies of SHDAB surfactant can be distinguished with high scattering contrast and clear boundary, as a result of the environmentally friendly staining by LDHs. Notably, the morphological evolution involving spherical, rodlike and wormlike shapes can be witnessed, in accordance with AFM measurements. Therefore, our facile strategy opens up viable possibilities for the direct visualization of soft materials.

Viscosity of body fluid is an established biomarker of pathological conditions. Abnormality of cellular viscosity occurs when cells are challenged with external stresses. Small molecule probes to assess the viscosity are sought after for both disease diagnostics and basic studies. Fluorescence based probes are particular attractive due to their potentials for convenient and high spatiotemporal resolution microscopic monitoring of biological samples. The dyes with a floppy push-pull backbone or dyes with a rotatable substituent exhibits a viscosity responsive fluorescence enhancement and therefore viable viscosity probes. The scaffold of the existing viscosity probes contains typically one such floppy site. Therefore, they typically linearly respond to log(viscosity). We argue that minor viscosity fluctuation could potentially be physiological as the biological system is dynamic. We wish to develop a type of conceptually-new, threshold-limited viscosity probes, to complement the existing probes. Such probes do not exhibit a fluorescence enhancement when challenged with minor and presumably physiological enhancement of viscosity. When the viscosity is higher than a certain threshold, their fluorescence turns on. We hypothesize that a dye with two far-apart floppy sites could potentially yield such a threshold-limited signal and designed **VPZ2** and **VPZ3**. Through spectral titration, **VPZ3** was found to yield the desired threshold-limited signal. **VPZ3** was suitable for *in vitro* bioimaging of viscosity under one-photon or two-photon excitation. **VPZ3** is potentially useful in many downstream applications. Future work includes fine-tune of the threshold to allow tailored limit for fluorescence turn-on to better meet the need of different applications. Besides the implications in the real-world applications, the design concept could also be translated to design of alternative substrates.

Keywords: threshold-limited, probe, viscosity, two-photon, fluorescence

INTRODUCTION

Viscosity is a biophysical parameter of homeostasis (Tsien, 1989; Balkwill et al., 2012; Wang et al., 2017). By altering the molecular diffusion kinetics, biomolecular trafficking, lipid fluidity, and protein conformational rate, all physiological processes including enzymatic activity, energy metabolism, and signal transduction are affected (Miyamoto et al., 1990; Uribe and Smpedro, 2003; Boric et al., 2012; Liu et al., 2014; Sekhar et al., 2014). Abnormal fluctuation of microenvironmental viscosity is found to be reliable biomarker of underlying diseases or stresses

(Aydemir et al., 2008; Harisa, 2014; Kasperczyk et al., 2014; Herranz et al., 2018). Oxidative burst can alter the membrane fluidity through lipid peroxidation and hence disrupts its function (Richter, 1987; Hormel et al., 2013). Lysosome storage disorders are associated with increased local viscosity (Platt et al., 2012; Devany et al., 2018). Viscosity is also vital to maintain the mitochondrial network organization and energy metabolism (Mecocci et al., 1997). Hyperviscosity, or macroscopic high blood viscosity, is found with patients of many blood diseases, such as myeloma, leukemia, anemia, and sepsis (Gustine et al., 2016). Therefore, fluorescent probes for viscosity are in need for both basic biomedical studies and disease diagnosis to monitor the viscosity of complex biological systems (Haidekker and Theodorakis, 2007; Kuimova et al., 2008; Sutharsan et al., 2010;

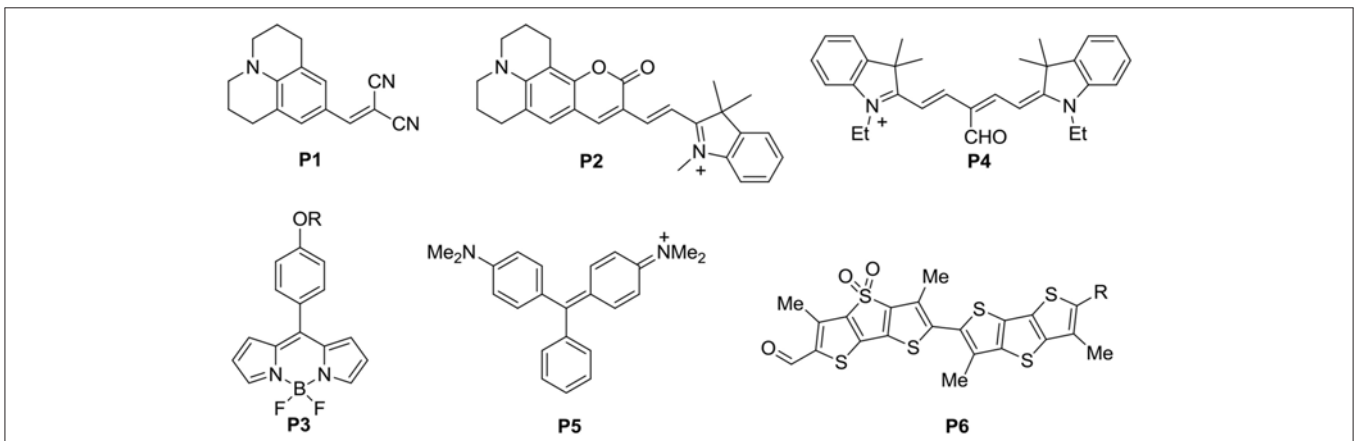

FIGURE 1 | Structures of a number of classic molecular rotors (**1**–**6**).

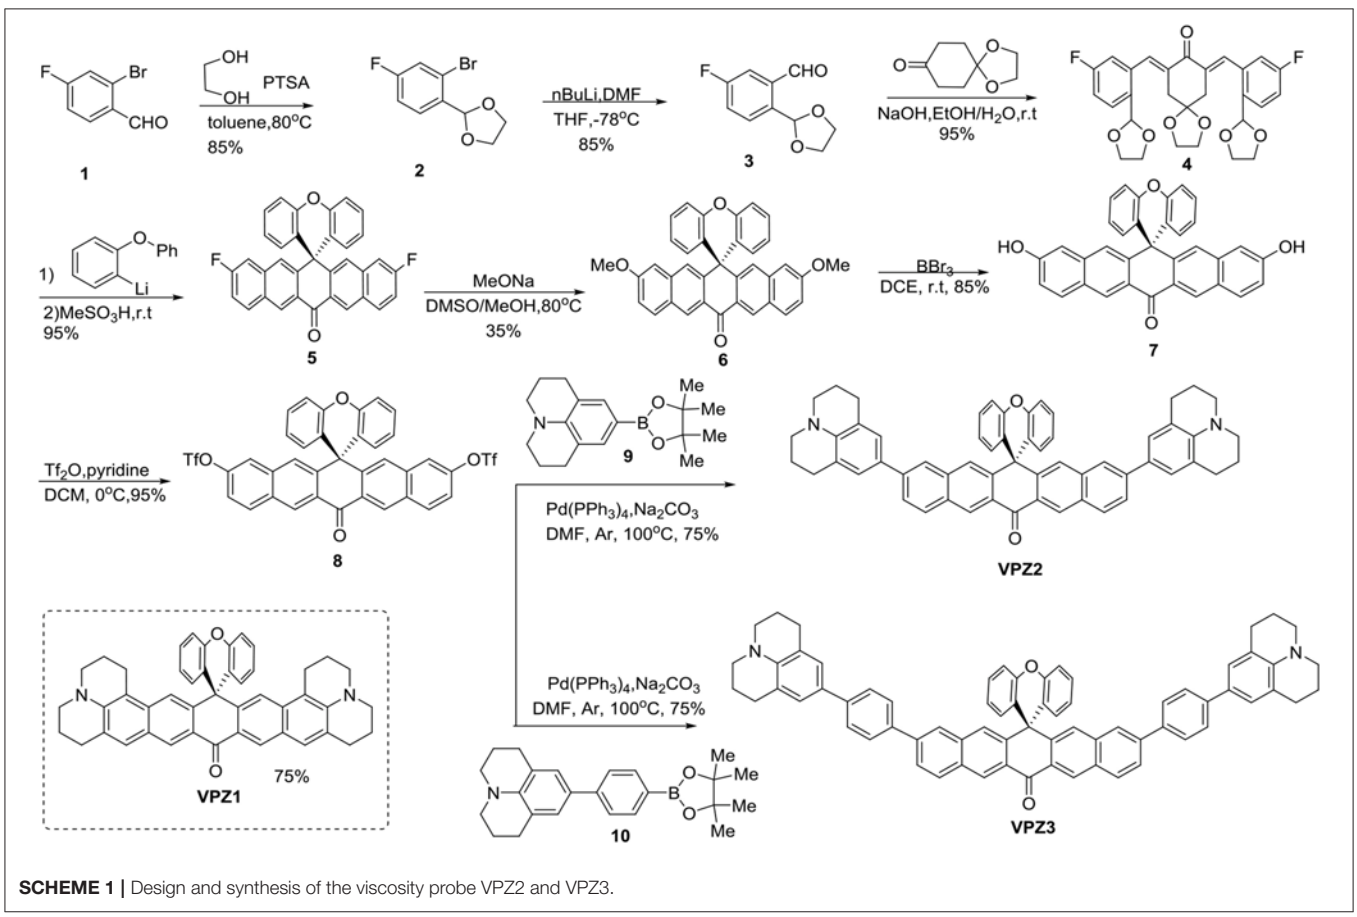

SCHEME 1 | Design and synthesis of the viscosity probe VPZ2 and VPZ3.

Kuimova, 2012; Wang et al., 2013; López-Duarte et al., 2014; Yang et al., 2014; Chen et al., 2015; Vyšniauskas et al., 2015, 2016; Lee et al., 2016; Ren et al., 2016; Su et al., 2016; Zhu et al., 2016; Klymchenko, 2017; Lyubov et al., 2017; Ning et al., 2017; Song et al., 2017).

The capability of a dye to sense environmental viscosity originates from its excited state dynamics, including non-radiative rotational deactivation and radiative deactivation (Klymchenko, 2017). For a fluorophore exhibiting a high degree of rotational freedom, it is typically non-fluorescent. When the rotational freedom is restricted, possibility of radiative deactivation enhances. The structural freedom of the fluorophore may come from rotatable bonds of the push-pull backbone, as seen in **P1** (Loutfy and Arnold, 1982), and **P2** (Cui et al., 2019) (**Figure 1**). Or, a group may be installed to a rigid push-pull backbone via a single bond to construct a molecular rotor, e.g., **P3** (Kuimova et al., 2008). Or, it could be a flexible push-pull backbone installed with a rotatable group, e.g., **P4** (Peng et al., 2011), **P5** (Babendure et al., 2003), and **P6** (Colom et al., 2018) (**Figure 1**). Typically, these molecular rotors respond linearly to log(viscosity). Minor enhancement of microscopic viscosity could be physiological considering the dynamic nature of a biological system. Therefore, we are interested in development of a new class of molecular rotors which does not respond to minor enhancement of viscosity, until the viscosity surpasses a certain threshold limit. Such threshold-limited molecular rotors could potentially be very useful in disease diagnostics. The existence of one site of high rotational freedom in the scaffold of a fluorophore is required to yield a viscosity-sensitive fluorescence enhancement. We propose that two such sites are warranted to exhibit threshold-limited response to viscosity. Intuitively, minor enhancement of viscosity may restrict the rotational freedom of one site, leaving the other site unaffected to quench the fluorescence of the fluorophore. When the viscosity is higher than a certain limit, the chances of simultaneous restriction of both sites becomes possible and fluorescence enhancement should be noticeable. Also, sterics should be present in the scaffold of such a probe to minimize unintended fluorescence turn-on by aggregation or unselective binding with native biomacromolecules (Lei et al., 2017).

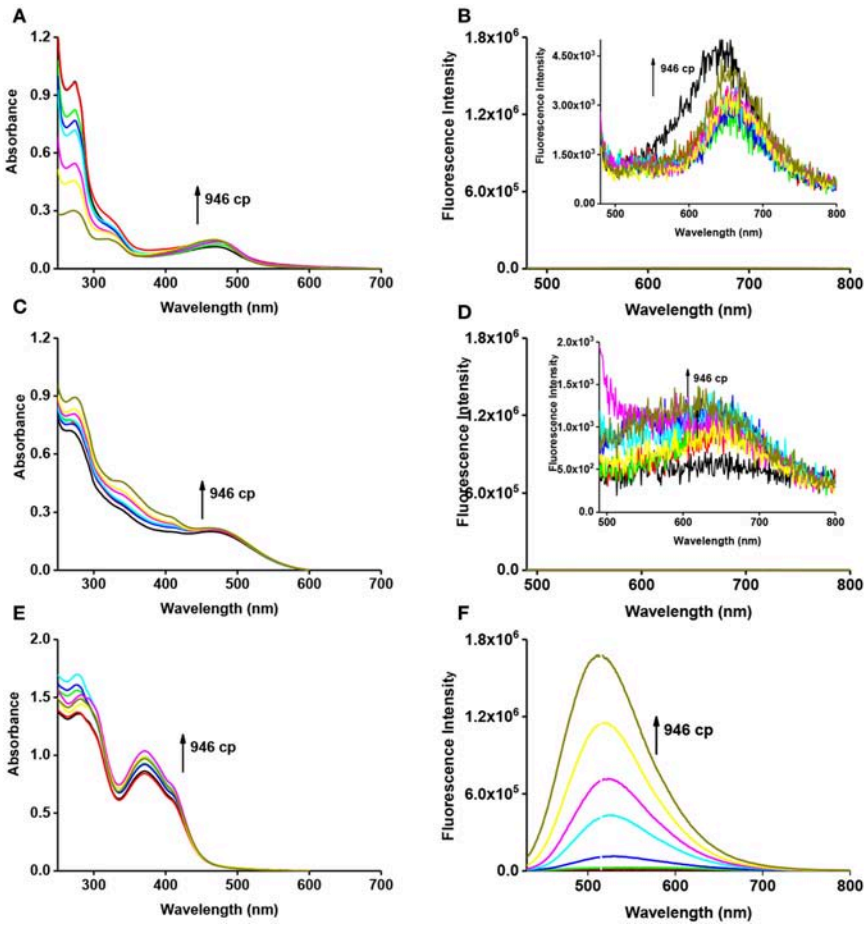

FIGURE 2 | Absorption (**A**, **VPZ1**; **C**, **VPZ2**; **E**, **VPZ3**) and emission (**B**, **VPZ1**; **D**, **VPZ2**; **F**, **VPZ3**) spectra of **VPZ** probes in different viscosity (glycerol and water), concentration: 10 μM.

Herein, we report the synthesis, spectral titrations and proof-of-concept bioimaging of threshold-limited fluorescent probe (**VPZ1-3**) for microscopic viscosity.

RESULTS AND DISCUSSIONS

Compound Synthesis

VPZ1 is a known compound and synthesized according to the reported method (Lei et al., 2017). The synthesis **VPZ2** and **VPZ3** are displayed in **Scheme 1** 2-Bromo-4-fluorobenzaldehyde (**1**) was condensed with ethylene glycol in the presence of p-toluene-sulfonic acid to the corresponding 1,3-dioxolane derivative (**2**) in an 85% yield. Then **2** was treated with nBuLi at −78°C to generate the nucleophilic intermediate phenyllithium reagent *in situ*, which was quenched with DMF to yield the benzaldehyde derivative (**3**) in good yield. Through aldol condensation of **3** and 1,4-cyclohexanedione monoacetal under basic conditions, **4** was obtained in an 95% yield. (2-Phenoxyphenyl) lithium was added into a solution of 4 in THF. The resulting carbinol product was isolated and treated with methylsulfonic acid without further purification to afford **5** through a cascade of reactions. The crystal structure of the compound 5 was obtained and the diphenylether moiety and the bottom dinaphthylmethanone unit are perpendicular. Replacement of fluorine atoms of **5** with methoxide gave **6** in an 35% yield. Then the two methoxys groups of **6** was demethylated by BBr_3 to get **7,** the hydroxyls of which were converted to triflate by treatment of triflic anhydride to obtain the key intermediate **8**. The viscosity probes (**VPZ2** and **VPZ3**) were furnished by the Suzuki–Miyaura cross coupling reactions with **9** and **10**, respectively. The NMR and the HRMS spectra of all new compounds are provided in the SI (**Figures S1**–**S25**). The crystal structure of compound 5 was obtained (**Figure S26**).

Spectral Titrations

With the probes in hand, we firstly tested the photophysical properties of these probes (**Figure 2**, glycerol and water). The maximum absorption wavelength of **VPZ1**, **VPZ2,** and **VPZ3** in pure water is about 470, 465, and 373 nm, respectively. Their fluorescence is very weak but still observable. The emission wavelength of **VPZ1**, **VPZ2,** and **VPZ3** is about 650, 650, and 515 nm, respectively. With their symmetric D-A-D structure, the **VPZ** probes typically exhibit a Stokes shift of ca. 140–190 nm, much larger than that of a list of common fluorophores, such as fluorescein (24 nm), tetramethylrhodamine (25 nm), BODIPY (20 nm), Cy5 (20 nm), Cy7 (23 nm), which is desirable for imaging-based applications. We tested the viscosity related spectral responses (**Figure 2**). **VPZ** probes were added into solvent mixtures of water and glycerol exhibiting different viscosity values, their absorption and emission spectra were recorded. As shown in **Figure 2**, the absorption of **VPZ** probes exhibited only very subtle changes with respect to the increase of the solvent viscosity. The fluorescence emission intensity of **VPZ1** and **VPZ2** remained essentially unchanged with respect to the increase of the solvent viscosity. Notably, **VPZ3** show a strong increase in fluorescence (ca.126-fold) with the increase of viscosity. Very interestingly, the fluorescence intensity of **VPZ3** did not immediately increase when the solvent viscosity increased (**Figure 3**). Instead, the fluorescence intensity remained unchanged until the Log(viscosity) of the solution was higher than 10. After that, the fluorescence of **VPZ3** enhanced linearly with respect to Log(viscosity). This is in good agreement with the design rational of the **VPZ** series of probes. The fluorescence life-time decay of VPZ3 in different solvent mixtures of H2O and glycerol was acquired (**Figure S27**). Since **VPZ3** has the best performance against different viscosity, we chosen **VPZ3** as the viscosity probe for the cell imaging study. The fact that **VPZ1** and **VPZ2** do not fluoresce in this solvent mixture is intriguing and subject to further in-depth photophysical studies.

Cell Images

The short absorption wavelength of **VPZ3** limits its usage in imaging-based application *in vivo* with one photon excitation.

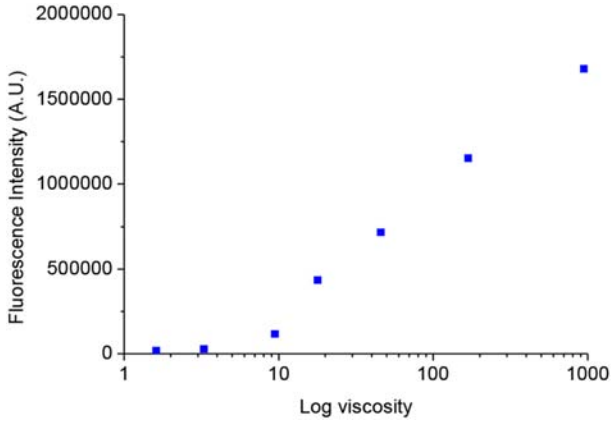

FIGURE 3 | The relationship of the fluorescence intensity of **VPZ3** at varying solvent viscosity.

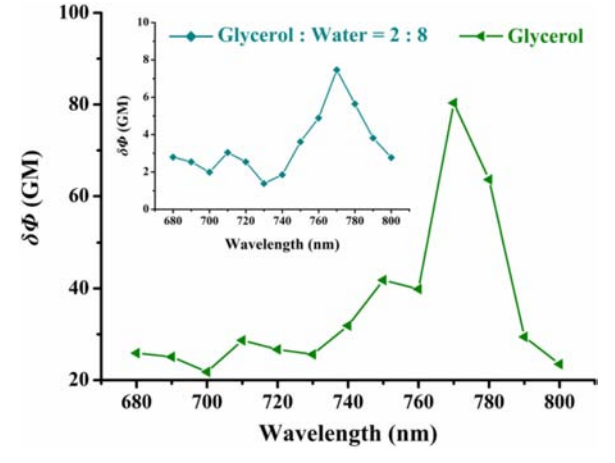

FIGURE 4 | Two-photon excitation action cross-section of **VPZ3** in the glycerol–water system with different viscosities (20% glycerol and 100% glycerol). Two-photon excitation wavelength range: 680–880 nm ($\Delta\lambda = 10$ nm).

To apply **VPZ3** in cell study, we firstly performed the two-photon cross-section (δ) test (**Figure 4**) since the short one photon excitation problem can be circumvented by two-photon excitation. The maximum δ is about 80 GM at 770 nm in glycerol. Therefore, 770 nm was used for the cell imaging study.

The cytotoxicity of **VPZ3** was determined by MTT. In short, HepG2 cells were incubated with **VPZ3** with different concentration for 24 h. The cell viability remained 85% at up to 25 μM (**Figure S28**). The low cytotoxicity of **VPZ3** promotes us to further explore the possibility of **VPZ3** as a fluorescence probe for the detection of cell viscosity. In order to demonstrate the imaging ability of **VPZ3** in living cells, the HepG2 cells were incubated with **VPZ3** (10 μM) at 37 and 25°C for 30 min separately. The ptimages of the cells were collected under two-photon excitation. As we known, lower temperature means higher viscosity for the cells. The fluorescence intensity of cells incubated at 25°C was higher than those at 37°C significantly (**Figure 5**). The imaging results supported that the **VPZ3** could be used for monitoring the viscosity in the cytoplasm of living cells.

To further demonstrate the potentials of **VPZ3** in monitoring the micro-viscosity change of cells, **VPZ3** was used to monitor the real-time viscosity change during cell apoptosis. Because etoposide (a chemotherapy drug used to treat many types of cancer) can cause cell death, the micro-viscosity of the cells will change greatly during the apoptosis process. HepG2 cells were incubated with etoposide. The two-photon fluorescence images were collected at different times during the apoptosis process. As shown in **Figure 6**, the fluorescence intensity of the cells increased greatly during the apoptosis upon addition of etoposide. In contrast, the fluorescence of the cells without the addition of etoposide kept unchanged (**Figure S29**). These results clearly show that **VPZ3** could be used to monitor the viscosity changes during the apoptosis process.

CONCLUSION

In summary, we have developed a series of new fluorescence probes (**VPZ**) for viscosity monitoring based on a symmetric D-A-D framework. Among the three **VPZ** probes, **VPZ3**

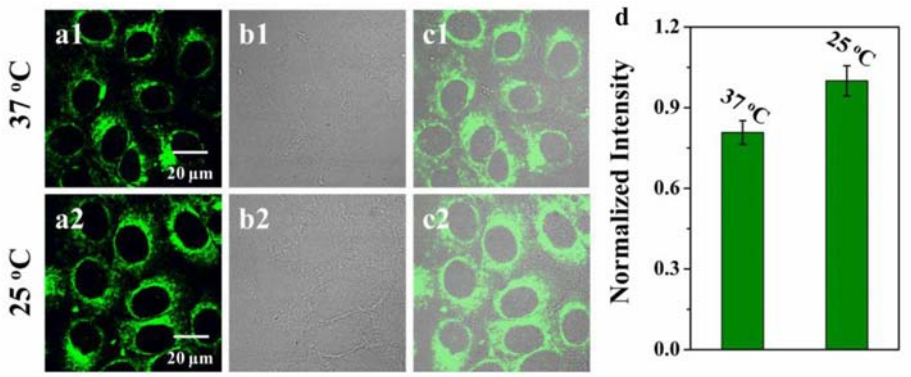

FIGURE 5 | Two-photon confocal images of HepG2 cells incubated with **VPZ3** (10 μM) after 30 min of incubation at **(a1)** 37°C and **(a2)** 25°C, respectively and then washed with 10 mM PBS buffer. λ_{ex} = 770 nm, emission wavelength from 500 to 540 nm; **(b1,b2)** bright-field images of HepG2 cells; **(c1)** the overlay of panels **(a1,b1)**; **(c2)** the overlay of **(a2,b2)**. **(d)** Normalized intensity analysis of the probe at 37 and 25°C, respectively. Scale bars: 20 μm.

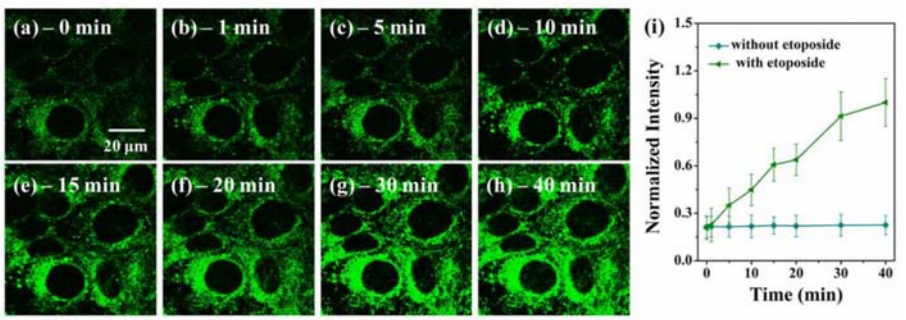

FIGURE 6 | (a–h) Two-photon confocal images of HepG2 cells incubated with **VP3** (10 μM) at different time points after the addition of 2.0 μM etoposide, λ_{ex} = 770 nm, emission wavelength from 500 to 540 nm. **(i)** Plot of normalized intensities of **the probe** against time with (triangle, green line) and without (circle, blue line) etoposide. Scale bars: 20 μm.

showed a great "off-on" fluorescence response (ca. 126-fold) with increasing viscosity in the glycerol-water system. **VPZ3** shows low cytotoxicity and could be used to monitor the real-time viscosity change during the cell apoptosis process. We expect **VPZ3** to find applications in basic biological studies related cell apoptosis and disease diagnostics.

DATA AVAILABILITY

All datasets generated for this study are included in the manuscript and/or the **Supplementary Files**.

AUTHOR CONTRIBUTIONS

ZL prepared the compound synthesis. KX and SQ involved in the synthesis and carried spectral titrations. LH carried out biological studies. YY and XM conceived the project. Everyone contributed to manuscript preparation.

Phosphate Assay Kit in One Cell for Electrochemical Detection of Intracellular Phosphate Ions at Single Cells

Haiyan Xu†, Dandan Yang†, Dechen Jiang and Hong-Yuan Chen*

State Key Laboratory of Analytical Chemistry for Life Science, School of Chemistry and Chemical Engineering, Nanjing University, Nanjing, China

In this paper, phosphate assay kit in one cell is realized for the electrochemical detection of intracellular phosphate ions at single cells. The components of the phosphate assay kit, including maltose phosphorylase, maltose, mutarotase, and glucose oxidase, are electrochemically injected into a living cell through a nanometer-sized capillary with the ring electrode at the tip. These components react with phosphate ions inside the cell to generate hydrogen peroxide that is electrochemically oxidized at the ring electrode for the qualification of intracellular phosphate ions. An average 1.7 nA charge was collected from eight individual cells, suggesting an intracellular phosphate concentration of 2.1 mM. The establishment in the electrochemical measurement of phosphate ions provides a special strategy to monitor the fluctuation of intracellular phosphate at single cells, which is significant for the future investigation of phosphate signal transduction pathway.

INTRODUCTION

Inorganic phosphate ions are the most abundant anions inside the cells that are essential for nucleic acid and phospholipid biosynthesis, as well as for energy metabolism (Bevington et al., 1992). The concentration of intracellular phosphate is tightly maintained by membrane transporters, and the disorder of intracellular phosphate level is known to be related with multiple pathological conditions (Bun-Ya et al., 1991). For example, elevated phosphate is reported to be associated with ischemia and hypoxia, while less phosphate is related with skeletal muscle fatigue and hypophosphatemia (Bergwitz and Jüppner, 2011). Therefore, monitoring the fluctuation of intracellular phosphate is important for the biological study of phosphate signal transduction pathways. Considering the significant cellular heterogeneity, the ability to measure the phosphate level at single cells will provide more elegant information to elucidate these pathways (Wang and Bodovitz, 2010).

Many techniques, such as the colorimetry (Dickman and Bray, 1940; Cogan et al., 1999), ion chromatography (Galceran et al., 1993), fluorescence (Huang et al., 2008; Saeed et al., 2010), electrochemistry (Forano et al., 2018), and flow injection analysis (Pérez-Ruiz et al., 2001), have been well developed for the measurement of phosphate ions in the solution. The detection limit using these classical instrumental methods in the laboratories is between 20 and 150 nM (Lawal and Adeloju, 2013). To measure phosphate ions in the biological samples, a series of chemosensors

were synthesized that are capable of detecting inorganic phosphates at a physiological pH (Hatai et al., 2012; Liu et al., 2016). However, very few fluorescent probes have been synthesized to recognize phosphate ions inside the cells, which are partially due to the poor selectivity for phosphate in presence of structurally similar anions in cells (Guo et al., 2015; Zhang et al., 2018).

The phosphate assay kit includes the biologically specific maltose phosphorylase that converts maltose (in the presence of phosphate) into glucose 1-phosphate and glucose. Then, glucose oxidase included in the kit reacts with glucose to generate gluconolactone and hydrogen peroxide for the colorimetric or fluorescent determination of phosphate (McDermott et al., 2006). Due to good selectivity of the enzymes in the assay, this kit has been widely applied for the specific analysis of phosphate ions in the solution (Mousty et al., 2001) and cellular lysate (Zhang et al., 2015). Accordingly, the loading of these kit components into one cell to initialize the reaction with intracellular phosphate and the immediate detection of the product (e.g., hydrogen peroxide) should provide an alternative strategy to detect phosphate ions at single cells.

Nanoelectrochemistry is a robust tool for the detection of intracellular species at single cells that positions a nanometer-sized electrode into a living cell and collects the current or charge after the electrochemical conversion of the target molecules at the electrode surface (Wightman, 2006; Wang et al., 2012; Li et al., 2014). Previously, our group designs a nanometer-sized capillary with a ring electrode at the tip that is filled with the kit components. Upon the position of the capillary inside one living cell, a voltage is applied at a metal wire in the capillary to induce electroosmotic flow (EOF) that results in the electrochemical pumping of these components into the cell (Pan et al., 2016). After the reaction between the kit components and the target molecule for a certain time, the hydrogen peroxide generated could be electrochemically detected at the ring electrode. As a result, intracellular glucose and the activity of sphingomyelinase have been successfully quantified without the significant interruption of cellular activity. Using this approach, the loading of the phosphate assay kit in one cell is feasible, and thus, the detection of phosphate ions at single cells could be realized. As compared with the previously reported approach using the synthesized probes, this kit-based method uses the commercially available kit components that avoid the complicated structural design of the probe and guarantee the specific recognition of phosphate ions.

In this paper, the components of the phosphate assay kit, including maltose phosphorylase, maltose, mutarotase, and glucose oxidase, are filled into the nanocapillary, which is electrochemically loaded into the cell, as demonstrated in **Figure 1A**. Intracellular phosphate reacts with maltose phosphorylase and maltose to form α-glucose, which is transformed into β-glucose for the following oxidation by glucose oxidase (**Figure 1B**). The hydrogen peroxide generated is then electrochemically oxidized at the ring electrode for the quantification of phosphate ions inside the cells. The detection ability of this approach for phosphate ions in aqueous solution and inside the cells is investigated.

EXPERIMENTAL SECTION

Chemical and Cells

The phosphate assay kit (P22061) is obtained from Molecular Probes, Inc. (OR, USA). All the other chemicals are purchased from Sigma Chemical Co. (MO, USA). HeLa cells were obtained from the Institute of Biochemistry and Cell Biology, Shanghai Institute for Biological Science of Chinese Academy of Science (Shanghai, China). HeLa cells were cultured in DMEM/high glucose medium supplemented with 10% fetal bovine serum and 1% penicillin/streptomycin at 37°C under a humidified atmosphere containing 5% CO_2.

Apparatus and Measurement

The nanocapillaries with a Pt layer at the tip opening (∼130 nm in diameter) are fabricated following our previously reported protocol (Pan et al., 2016). The kit components, including maltose phosphorylase (50 U/ml), maltose (40 mM), glucose oxidase (10 mg/ml), and mutarotase (50 U/ml), are filled into the capillary. A Pt wire is inserted into the capillary that is applied with a voltage of 1 V to electrochemically pump the kit components outside the capillary. Immediately after the egression and the following reaction with phosphate ions, a voltage of 0.6 V is applied at the Pt layer at the nanocapillary for

the electrochemical detection using a CHI 660E electrochemical station (CH Instruments) at room temperature.

Single-Cell Analysis

Single-cell analysis is performed under a microscope (Nikon ECLIPSE Ti-U, Nikon, Japan). Prior to each measurement, the cells are washed and re-cultured in extracellular buffer (ECB buffer: 135 mM NaCl, 5 mM KCl, 10 mM HEPES, 2 mM $MgCl_2$, and 2 mM $CaCl_2$) in the absence of extracellular phosphate ions. The nanocapillary is mounted on a 3D translation stage to achieve the penetration into the target cell.

RESULTS AND DISCUSSION

Analysis of Phosphate Ions in the Buffer

To validate our approach for the measurement of phosphate ions, the initial experiment is conducted in ECB buffer with different concentrations of phosphate ions. As compared with 1× phosphate buffer saline (PBS), ECB buffer has almost the same ion strength and viscosity, resulting in similar EOF rate in the capillary. Therefore, the electrochemical loading condition optimized in the previous work, including a voltage of 1 V and an application time of 30 s, is used to egress femtoliter (fl) volume of kit components outside the capillary (Pan et al., 2016). The non-faradic (or charging) charge from the Pt layer at the tip of the capillary is collected in the buffer without any phosphate ions after the electrochemical egression (**Figure 2A**, trace a). Once 0.1 mM phosphate ions are added into the buffer, an increase in the charge is observed (trace b) after the egression of fresh kit components. When one kit component (maltose phosphorylase, maltose, or glucose oxidase) is removed from the mixed solution inside the capillary, this charge increase disappears. Both of the results suggest the occurrence of chemical reactions of kit components and phosphate ions outside the tip that generates hydrogen peroxide and the following charge increase.

The addition of more phosphate ions in the buffer elevates the concentration from 0.1 to 3 mM. Consequently, the gradual increases in the charge are observed (**Figure 2A**, traces c–f), which are correlated with the concentration of phosphate ions. After subtracting the background charge, the charge increases at the time of 250 s from three independent experiments are measured and plotted with the concentrations of phosphate ions, as shown in **Figure 2B**. The coefficient of determination in the fitting curve is 0.98, exhibiting a near-linear relationship between the charge increase and the concentrations of phosphate ions. The relative standard deviation in this detection range is less than 16.8%. Accordingly, the charge collected in our approach could be applied to quantify the phosphate ions.

To characterize the conversion of phosphate ions by the kit components, these charge increases are compared with those collected from the measurement of glucose. Experimentally, the nanocapillaries loaded with glucose oxidase are applied to collect the charge increases in the presence of aqueous glucose, as shown in **Figure S1** (supporting information). These

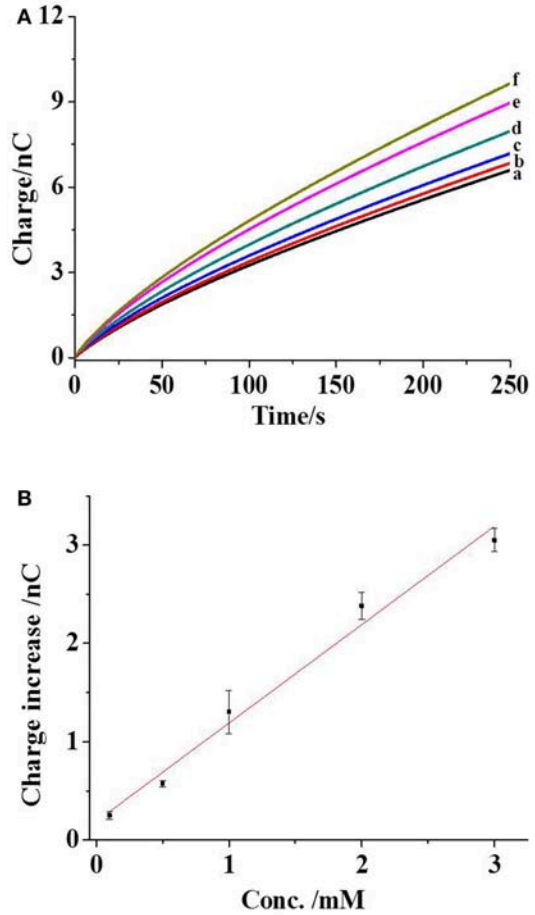

FIGURE 2 | (A) The charges of capillary exposed to the ECB buffer (curve a), with 0.1 (curve b), 0.5 (curve c), 1 (curve d), 2 (curve e), and 3 mM phosphate ions (curve f). The capillary is filled with maltose phosphorylase (50 U/ml), maltose (40 mM), glucose oxidase (10 mg/ml), and mutarotase (50 U/ml). The condition for the electrochemical loading is 1 V for 30 s. **(B)** The correlation between the charge increase and the concentration of phosphate ions. The error bars present the standard deviations from three independent measurements. The line is the linear fitting curve.

charge increases are rationed with those from the measurement of phosphate ions, which are in the range of 20 and 56%. These values exhibit the limited conversion of phosphate ions by multiple enzymes, and thus, the control of the egression and the following detection time are critical to obtain the reproducible result. For the specificity of our measurement, various phosphate-containing species, such as pyrophosphate, hexametaphosphate, tripolyphosphate, and ATP, are measured successively using the nanocapillaries (Wang et al., 2018). As shown in **Figure S2** (supporting information), no significant charge increase is observed at all these species, exhibiting good specificity of our assay.

Single-Cell Analysis

The same measurement process is conducted after the insertion of a nanocapillary into a living cell, as imaged in **Figure 3A**.

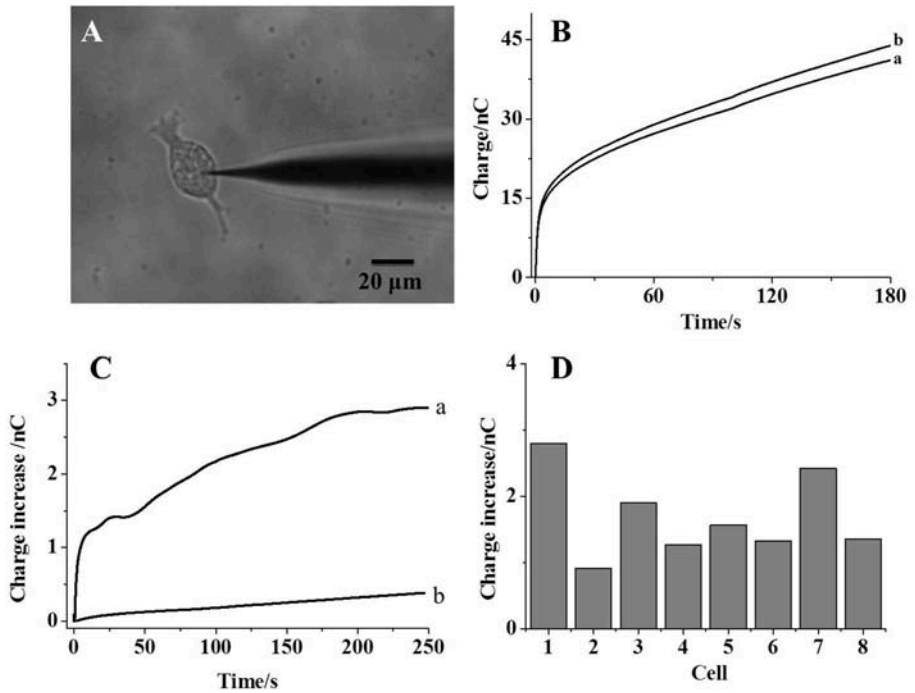

FIGURE 3 | (A) The bright-field image of a nanocapillary inserted into a living HeLa cell; **(B)** the charges collected before (curve a) and after (curve b) the electrochemical loading of kit components into the cells; **(C)** trace a: the charge difference between curve a and b in **(B)**; trace b: the charge difference before and after the electrochemical loading of maltose, mutarotase, and glucose oxidase only into the cells; **(D)** the charge increases collected from eight individual cells.

Because the reaction of kit components with phosphate ions generates glucose, intracellular glucose needs to be minimized to reduce the additional contribution on the charge. Therefore, the cells are starved overnight prior to each measurement, and the intracellular glucose was reported to be ∼0.12 mM (Zhang et al., 2014). After the collection of the background charge (**Figure 3B**, trace a), a voltage of 1 V is applied at the Pt wire inside the capillary for 30 s to egress the kit components into the cell. Intracellular calcium concentration is continuously monitored using the Fluo-3 probe under the fluorescence microscope (Gobet et al., 1995). As shown in **Figure S3** (supporting information), no significant increase in the calcium concentration suggests minor interruption of cellular activity during the penetration and the following electrochemical loading. After the egression of the kit components and the recording of the charge, an increase in the charge is observed (**Figure 3B**, trace b), which should be ascribed to hydrogen peroxide generated from the reaction with intracellular phosphate ions. To exclude the possible contribution from intracellular glucose or reactive oxygen species on the charge increase, the control experiment is performed by the introduction of the solution with glucose oxidase only. No charge increase obtained suggests that the charge increase in **Figure 3B** is mainly contributed by intracellular phosphate ions.

The charge difference before and after the introduction of kit components (trace a and b) is calculated and plotted in **Figure 3C** (trace a). An initially fast increase in the charge clearly exhibits a fast reaction between the kit components and phosphate ions. After the reaction for 200 s, the charge difference reaches the steady state, which should be attributed to the depletion of phosphate ions inside the cells. Thus, this steady-state charge increase could be used to estimate the amount of intracellular phosphate ions. Eight cells are analyzed individually and the steady-state charge increase is listed in **Figure 3D**. An averaged 1.7 nC is calculated from these cells with a relative standard deviation of 35.3%. According to Faraday's law, 8.5 fmol phosphate ions are detected in one cell. Because the size of a single cell is 20 μm and the cellular volume is estimated to be 4 pl, 2.1 mM phosphate ions are determined in one cell, which is consistent to the literature result (Bevington et al., 1986). Since some glucose is still present inside the starved cells, the control experiment is conducted using the nanocapillary loaded with maltose, mutarotase, and glucose oxidase only. The absence of maltose phosphorylase should not initialize the generation of glucose from phosphate ions. The charge difference before and after the introduction of these components into one cell is shown in **Figure 3C** (trace b). Only a slight increase in the charge supports the minor contribution of intracellular glucose on the measurement of phosphate ions inside the cells. The successful detection of intracellular phosphate ions at individual cells supports the accuracy of our approach to determine intracellular phosphate ions at single cells.

CONCLUSION

In summary, the electrochemical detection of intracellular phosphate ions at single cells is realized by the loading of phosphate assay kit into one cell. This approach utilizes the commercially available kit to react with phosphate ions and, thus, avoids the design and preparation of the recognition probe. This simplification facilitates the detection of phosphate ions at single living cells. The future development will focus on the application of this approach to analyze the activity of phosphatase that releases a phosphate group from its substrate. The qualification of the activity of phosphatase, especially phosphatase and tensin homolog (PTEN), at single cells could provide the important information for the drug development. To realize this aim, the detection limit of our assay should be improved, which is undergoing in the lab.

Catalysis and Photocatalysis

Maylis Orio

Maylis Orio is a theoretical chemist specializing in quantum chemistry applied to bioinorganic systems. After obtaining a PhD studying the structure and properties of polynuclear iron complexes, her three-year postdoctoral work was dedicated to the theoretical study of metalloprotein active sites. She has acquired expertise in EPR spectroscopy while appointed as a CNRS researcher. She eventually joined an experimental laboratory with the aim to reinforce her skills toward mechanistic investigation in biocatalysis. She has an important background in computational chemistry and can handle sophisticated theoretical methods to study structures, properties, and reactivity of bioinorganic systems at the molecular level.

Shinya Furukawa

Shinya Furukawa obtained his BEng, MEng, and PhD at Kyoto University in March 2012. He joined the Tokyo Institute of Technology as an Assistant Professor in April 2012. He then moved to Hokkaido University as an Associate Professor in June 2016. His research is focused on the catalytic chemistry of metallic materials, metal complexes, and semiconductor photocatalysts. His current interest is focused on catalysis over the surface of bimetallic materials such as alloys and intermetallics. He likes not only to develop highly efficient catalytic systems but also to deeply clarify the reaction mechanism in an atomic scale using experimental and theoretical approaches.

Gufeng Wang

Gufeng Wang holds BSc and MSc degrees from Nanjing University, and a PhD degree from the University of Iowa. He then worked as a postdoc associate in Iowa State University and US DOE for 5 years. Afterwards, he joined the faculty of the Chemistry Department at North Carolina State University in 2011. His research interests are focused on developing novel nanoparticles that have unique optical and chemical properties, super resolution optical imaging techniques, and light-actuated molecular machines, to solve problems relevant to human health and renewable energy.

Jonathan Zacharias Bloh

Dr Jonathan Zacharias Bloh studied Life Science and later obtained his PhD in Technical Chemistry in 2012 at Leibniz University, Hannover. Thereafter he spent one and a half years as a postdoc at the University of Aberdeen in Scotland. Since 2014, he is the head of the Chemical Technology group at the DECHEMA Research Institute in Frankfurt am Main, Germany. His current research covers photocatalysis, reaction engineering, and chemo-enzymatic processes.

Ljiljana Fruk

Ljiljana studied chemistry at the University of Zagreb, obtained a PhD in biospectroscopy from the University of Strathclyde, Glasgow, and worked on DNA structuring and enzyme reconstitution as a postdoctoral fellow at the University of Dortmund. She established her own research group at Karlsruhe Institute of Technology in 2009 to focus on the nanomaterial biofunctionalization and design of light-triggered nanodevices. Since 2015 she is a lecturer at the Department of Chemical Engineering and Biotechnology, University of Cambridge. Her research is focused on the design of biocompatible hybrid materials for nanomedicine and catalysis, and the development of mild strategies for nanomaterial biofunctionalization. She is also a well-known science popularizer and co-author of the field-establishing Molecular Aesthetics book.

In the following work, we carried out a systematic study investigating the behavior of a thiosemicarbazone-nickel (II) complex (**NiTSC-OMe**) as a molecular catalyst for photo-induced hydrogen production. A comprehensive comparison regarding the combination of three different chromophores with this catalyst has been performed, using **[Ir(ppy)$_2$(bpy)]PF$_6$**, **[Ru(bpy)$_3$]Cl$_2$** and **[ZnTMePy]PCl$_4$** as photosensitizers. Thorough evaluation of the parameters affecting the hydrogen evolution experiments (i.e., concentration, pH, solvent nature, and ratio), has been performed in order to probe the most efficient photocatalytic system, which was comprised by **NiTSC-OMe** and **[Ir(ppy)$_2$(bpy)]PF$_6$** as catalyst and chromophore, respectively. The electrochemical together with the photophysical investigation clarified the properties of this photocatalytic system and allowed us to propose a possible reaction mechanism for hydrogen production.

INTRODUCTION

One of the most important challenges of our society, that still lie ahead, is to discover renewable and abundant energy sources (Hosenuzzaman et al., 2015; Hosseini and Wahid, 2016). Solar energy is indeed an attractive and unlimited energy source which nonetheless requires the development of novel as well as efficient storage technologies (Styring, 2012; Tachibana et al., 2012; Faunce et al., 2013). Interestingly, hydrogen could unquestionably be applied for such a purpose: (i) it is the simplest and the most plentiful element on earth, (ii) the energy of the hydrogen-hydrogen bond is high, and (iii) it is considered as a non-polluting fuel (Peel, 2003). Hence, photocatalytic water splitting leading to hydrogen production is a method that without any doubt could be proved as an auspicious solution (Lewis and Nocera, 2006). Photocatalytic hydrogen production can be accomplished by systems containing a photosensitizer, a sacrificial electron donor and a catalyst (Ladomenou et al., 2015; Yuan et al., 2017). Nevertheless, there are plenty unsolved issues that still rest in the field of photocatalytic hydrogen production. Specifically, the development of systems utilizing earth-abundant materials with enhanced efficiency and durability (Wang and Sun, 2010; Du and Eisenberg, 2012). To that end, numerous hydrogen evolution catalysts along with a great number of different photosensitizers have been extensively examined over the last years (Tran et al., 2010, 2012; Du and Eisenberg, 2012; Wang et al., 2012; Sartorel et al., 2013).

Photocatalytic systems involving low-cost molecular catalysts and compounds prepared through easy synthetic approaches have been widely studied over the past decade (Artero et al., 2011; Eckenhoff et al., 2013; Ladomenou et al., 2015). Specifically, cobaloximes (Fihri et al., 2008; Lazarides et al., 2009, 2014; Du and Eisenberg, 2012; Landrou et al., 2016; Panagiotopoulos et al., 2016), and other polypyridine cobalt complexes have been applied as noble-metal-free catalysts (Eckenhoff et al., 2013; Yin et al., 2015; Zee et al., 2015). Although, several of these catalysts are efficient for photocatalytic hydrogen evolution reaction (HER), their stability was greatly limited upon visible light irradiation. Moreover, many researches draw inspiration from Nature trying to replicate the function of the hydrogenase enzymes (Lubitz et al., 2014; Brazzolotto et al., 2016), leading to the design of nickel complexes that were evaluated as molecular catalysts for HER. As a result, plenty nickel catalysts such as nickel bis(diphosphine) (DuBois and DuBois, 2009a,b; Helm et al., 2011; McLaughlin et al., 2011), and pyridinethiolate (Han et al., 2012, 2013; Rao et al., 2016) have been applied in such schemes, since they reproduce the structure of the active site of hydrogenase. Due to the effect of non-innocent ligands, (Han et al., 2012, 2013; Rao et al., 2015, 2016; Inoue et al., 2017) such nickel complexes have displayed excellent efficiency as catalyst reaching around 7,500 TON (Han et al., 2013; Rao et al., 2016). Thiosemicarbazone metal complexes are an emerging class of new HER electrocatalysts (Haddad et al., 2016, 2017; Straistari et al., 2017, 2018a,b) that have already been proved to be redox active (Blanchard et al., 2005; Haddad et al., 2017; Straistari et al., 2017) The presence of S-donors as well as N-atoms in thiosemicarbazone allows the protonation of the ligand and serve as proton relays (Campbell, 1975; DuBois, 2014; Coutard et al., 2016). One of the most essential aspect of light-driven proton reduction is the appropriate choice of the light-harvesting unit (i.e., photosensitizer, Ps). Despite the fact that $[Ru(bpy)_3]Cl_2$ remains the most widely employed chromophore in such systems (Khnayzer et al., 2014; Lo et al., 2016), iridium complexes are still the most efficient entities found in several photocatalytic systems (Goldsmith et al., 2005; Andreiadis et al., 2011). Additionally, porphyrins and other tetrapyrrolic derivatives can be effective candidates for HER due to their unique stability, electrochemical properties, and appropriate energy levels (Ladomenou et al., 2015). For this reason, various metalloporphyrins such as Zn(II) or Sn(IV), have been utilized as photosensitizers for photocatalytic HER over the years (Lazarides et al., 2014; Koposova et al., 2016; Landrou et al., 2016; Queyriaux et al., 2018).

Here we will discuss the implications of our findings regarding a novel photoinduced HER scheme using a noble-metal-free *bis*-thiosemicarbazone nickel (II) complex (Straistari et al., 2017), namely **NiTSC-OMe**. In this study, three different light harvesting complexes, **$[Ir(ppy)_2(bpy)]PF_6$ (Ps1)**, **$[Ru(bpy)_3]Cl_2$ (Ps2)**, and **$[ZnTMePy]PCl_4$ (Ps3)** (Andreiadis et al., 2011; Lazarides et al., 2014; Natali et al., 2014) were used as photosensitizers and trimethylamine (TEA) as the sacrificial electron donor (**Figure 1**). The efficiency of the resulting photocatalytic system was optimized by studying different concentrations of the catalyst, the effect of solvent mixture, the solvent ratio, and the influence of pH in the buffer solution. The electron transfer processes that occur were examined through fluorescence spectroscopic techniques. To solidify the photochemical stability of our system, regeneration experiments were conducted and the homogeneous nature of our catalytic system was proved using poisoning experiments. Based on the results gathered from these studies we were finally able to propose a possible reaction mechanism for light-driven hydrogen production with our photocatalytic system.

EXPERIMENTAL SECTION

Materials and Methods

Reagents and solvents were purchased as reagent grade from usual commercial sources and were used without further purification, unless otherwise stated. **$[Ir(ppy)_2(bpy)]PF_6$** and **$[Ru(bpy)_3]Cl_2$** were purchased from commercial sources and used without further purification. The nickel thiosemicarbazone complex (**NiTSC-OMe**) (Straistari et al., 2017) and the Zinc (II) *meso*-tetrakis (1-methylpyridinium-4-yl) porphyrin tetrachloride (**$[ZnTMePy]PCl_4$**) (Lazarides et al., 2014) were prepared as previously reported.

Photophysical Measurements

UV-Vis absorption spectra were measured on a Shimadzu UV-1700 spectrophotometer using 10 mm path-length cuvettes (**Figure S1**). The emission spectra were measured by exciting the samples at 337 nm using a JASCO FP-6500 fluorescence spectrophotometer equipped with a red sensitive WRE-343 photomultiplier tube (wavelength range 200–850 nm).

Photocatalytic HER Experiments

For the photoinduced HER studies, each sample was prepared in a 42 mL glass vial with silicone septum. The buffer solutions were prepared by dissolving the sacrificial electron donor [triethylamine (TEA) or ascorbic acid (AA)] in water. It was necessary to add a small amount of acetonitrile in order to obtain a homogeneous solution. The pH was adjusted to the required value using concentrated HCl or NaOH solutions. Then the organic solvent (CH_3CN or EtOH) was added in order to obtain the desired ratio. For the sample preparation, the chromophore was dissolved in the buffer solution and consequently a solution of the catalyst in CH_3CN or EtOH was added. The final volume of the sample was 5 mL and the mixture was degassed for 10 min using nitrogen. The vials were sealed and the samples irradiated with a white LED lamp (power of 40 W, color temperature of 6,400 K and lumen of 3,800 LM, **Figure S2**). The amounts of produced hydrogen were determined by gas chromatography (external standard technique) using a Shimadzu GC-2010 plus chromatograph with a TCD detector and a molecular sieve 5 Å column (30–0.53 mm). Gas samples of 100 μL were taken from the headspace and injected immediately into the GC. In all cases, the reported results are the average of three independent experiments. The TONs were calculated using the produced moles of hydrogen vs. the moles of the catalyst. Control experiments were performed under the same conditions after the removal of the catalyst from the hydrogen generating system.

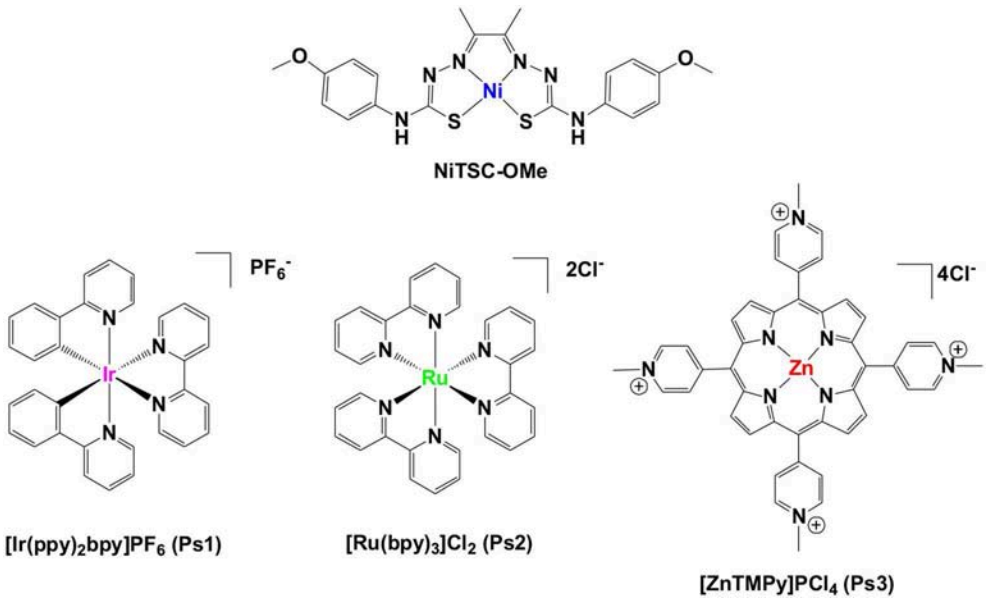

FIGURE 1 | Structures of the molecular catalyst and the photosensitizers used in this work.

Mercury poisoning experiments were performed, in order to examine the possible formation of metallic nanoparticles or colloids during the hydrogen evolution process. In these studies, an excess of mercury (ca. 40 equiv.) was added to the hydrogen evolution solutions (prepared with the above mentioned procedure).

RESULTS AND DISCUSSION

In our recent work, we reported the synthesis of a novel nickel catalyst (**NiTSC-OMe**, **Figure 1**) that exhibits high electrocatalytic activity for proton reduction to dihydrogen (Straistari et al., 2017). Based on these encouraging results we wanted to examine the capability of this catalyst toward photochemical hydrogen production. Thus, in the present study three different chromophores (**Figure 2**) were tested as photosensitizers and combined with the **NiTSC-OMe** catalyst to determine its ability as an effective photocatalytic system to reduce protons into hydrogen. We have analyzed various parameters, such as the concentration of the catalyst (10^{-5} – 5×10^{-8} M), the pH of the buffer solution, the effect of the solvent ratio in the photocatalytic mixture and the stability of our system. We carried out several experiments using TEA [5% (v/v)] or AA (0.2 M) as the sacrificial electron donors in various pH buffers (from pH = 2.5 to pH = 10). In addition, different concentrations of the catalyst and the chromophore were tested using varied solvent mixtures. Notably, in all cases no hydrogen production was observed using $[\mathbf{Ru(bpy)_3}]^{2+}$ (**Ps2**) or $[\mathbf{ZnTMePy}]^{+}$ (**Ps3**) as photosensitizers. However, when $[\mathbf{Ir(ppy)_2(bpy)}]^{+}$ (**Ps1**) was used as photosensitizer and TEA [5% (v/v)] as sacrificial electron donor, a photocatalytic hydrogen evolution of 140 μL from 1 ml of H_2O was recorded, highlighting once more that the photosensitizer is an essential component in such photocatalytic HER systems.

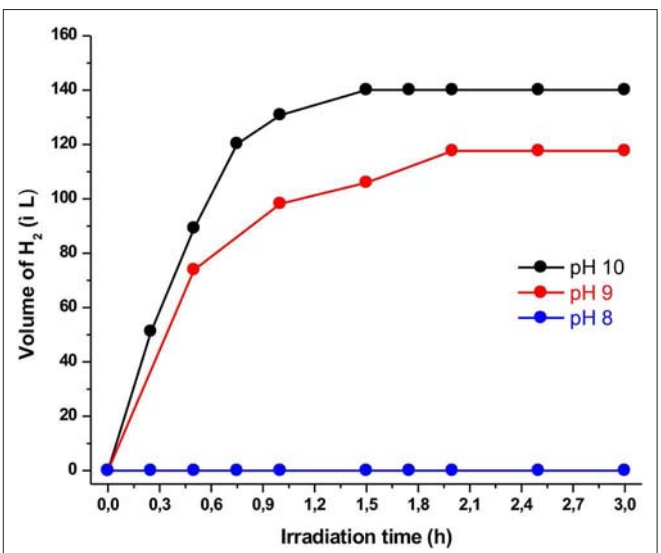

FIGURE 2 | Plot of hydrogen production upon irradiation of solutions (4:1 CH_3CN/H_2O) containing **Ps1** (5×10^{-4} M), **NiTSC-OMe** (10^{-5} M), and TEA [5% (v/v)] at different pH values.

In the above mentioned system, the first parameter that we examined was the effect of the protons concentration (pH). In detail, we used three different buffer solutions with pH values of 8, 9, and 10, concluding that the optimum one was at pH = 10. As presented in **Figure 2** using the solution with pH = 8, no hydrogen production was observed after 3 h of irradiation. On the contrary, using buffer solutions of pH = 9

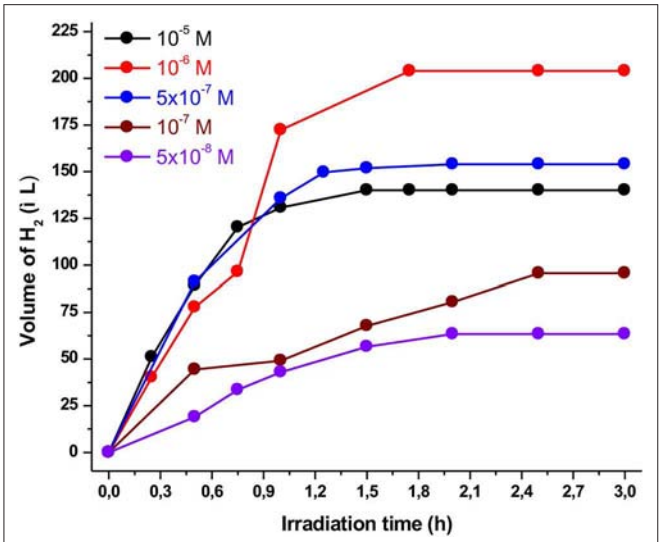

FIGURE 3 | Plot of hydrogen production upon irradiation of different **NiTSC-OMe** concentrations containing **Ps1** (5×10^{-4} M), TEA [5% (v/v)] in a 4:1 CH_3CN/H_2O solution at pH 10.

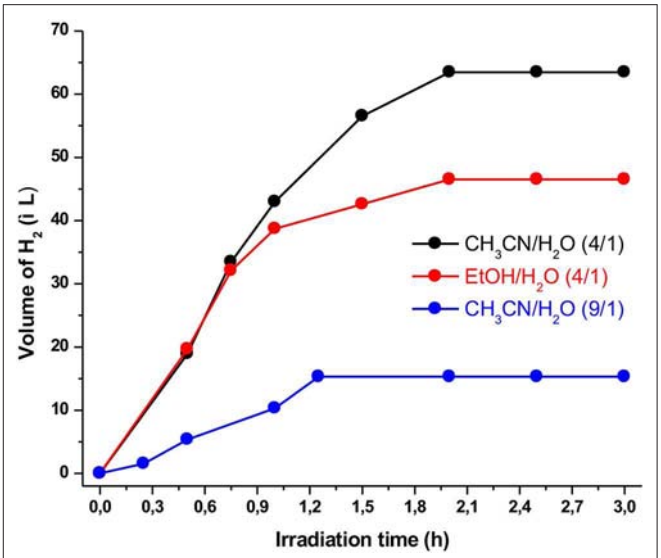

FIGURE 4 | Effect of various solvent mixtures on hydrogen production using the photocatalytic system containing **Ps1** (5×10^{-4} M), **NiTSC-OMe** (5×10^{-8} M), and TEA [5% (v/v)] at pH 10.

and pH = 10 we detected hydrogen production of 105 and 125 TONs, respectively. These findings are consistent with results derived from similar systems in which the optimum pH value is close to the pKa value of the sacrificial electron donor. Namely, in our case since the pKa of TEA is 10.7, the optimum pH of the buffer solution was expected at pH = 10 (Pellegrin and Odobel, 2017). Moreover, at pH values lower than its pKa value TEA is protonated and loses its electron donating ability (Rao et al., 2016).

Furthermore, the performances of the photocatalytic HER systems strongly depend on the catalyst concentration as well as the relative ratio between the photosensitizer and the catalyst. Accordingly, we kept the concentration of the **Ps1** photosensitizer constant (5×10^{-4} M), while the concentration of the catalyst varied from 10^{-5} to 5×10^{-8} M. As illustrated in **Figure 3**, the volume of the produced H_2 was increased when the concentration of the catalyst decreased from 10^{-5} to 10^{-6} M, reaching a maximum of 204 μL. In addition, further decrease in the concentration of the catalyst (5×10^{-7}–5×10^{-8}) resulted in lower catalytic efficiency. On the other hand, the catalytic activity of the system (TON) was increased when the concentration of the catalyst decreased from 10^{-5} to 5×10^{-8} M (**Figure S4**). Notably, when the concentration of the **NiTSC-OMe** was 5×10^{-8} M the system displayed the maximum TON and TOF values, namely 11,333 and 7,971, respectively (see **Table S1**). These results are in contrast with our previous work (Lazarides et al., 2014; Panagiotopoulos et al., 2016), where the maximum photocatalytic activity was observed when the concentration of the catalyst was in excess compared to that of the photosensitizer. This behavior can be attributed to two possible reasons: (i) the quenching of the excited state of the **Ps1** by the **NiTSC-OMe** complex and (ii) the great difference in the molecular absorptivity (ε) of complexes. Concerning the first hypothesis, since the reductive quenching process of photosensitizer by the catalyst is in competition with the expected reaction with TEA, decreasing the catalyst concentration will possibly favor the suggested reductive pathway. Moreover, regarding the second probable assumption, in our previous work the photosensitizer $[\mathbf{ZnTMePy}]^+$ exhibited an absorption coefficient of $\varepsilon = 1{,}80{,}000\ M^{-1}.cm^{-1}$. In the present study though, the **Ps1** exhibits an absorption coefficient of $\varepsilon = 6000\ M^{-1}.cm^{-1}$ (Andreiadis et al., 2011), and the catalyst (**NiTSC-OMe**) displays an absorption band at 470 nm with an epsilon value of $\varepsilon = 17{,}000\ M^{-1}cm^{-1}$ (Straistari et al., 2017). Consequently, the absorption properties of the catalyst can reduce the available photons for the photosensitizer, thus the catalyst concentration should be lower than that of the photosensitizer in order for the system to be more efficient.

The nature as well as the ratio of the solvents definitely plays a significant role in the HER. As a result, we examined two different solvent mixtures, i.e., CH_3CN/H_2O and Ethanol/H_2O, using also different ratio (from 4:1 to 9:1). As shown in **Figure 4**, the best solvent mixture was found to be CH_3CN/H_2O in a 4:1 ratio producing a maximum volume of hydrogen of 63 μL after almost 2 h of irradiation. We concluded that the solvent ratio induced critical changes on the hydrogen production, most likely because affecting the solubility properties. These solubility properties can be altered via the dielectric constant and the diffusion coefficient of each solvent (Rao et al., 2015; Pellegrin and Odobel, 2017). When CH_3CN/H_2O in a 9:1 ratio was utilized as the solvent mixture, the photocatalytic performance dramatically decreased. The smaller water concentration probably leads to lower solubility with direct impact on the photocatalytic activity of the system.

In all presented photocatalytic experiments, H_2 production stops after almost 2 h of irradiation. Therefore, regeneration

and photolysis experiments have been performed in order to examine the stability of our system (**Figure 5** and **Figure S3**). As illustrated in **Figure 5** (right part), we performed UV-Vis absorption photolysis experiment in a solution containing **Ps1** and **NiTSC-OMe**. The characteristic absorption bands of our system (416 for **Ps1** and 460 nm for **NiTSC-OMe**) were significantly decreased after 15 min of irradiation, suggesting bleaching of the photolysis solutions. After the addition of either the catalyst or the photosensitizer we didn't observed any hydrogen evolution. However, when both components were added to the reaction mixture, the catalytic system was effectively regenerated, leading to 3,067 TON (**Figure 5**, left), suggesting that both these components undergo concomitant decomposition after almost 2 h of irradiation.

The degraded compounds can form metallic nanoparticles, which can act as the catalytic species during HER (Lazarides et al., 2014). In order to exclude this possibility we performed mercury poisoning experiments. Photocatalytic experiments in the presence of mercury showed no significant change in the amount of the produced H_2 (11,787 TONs), thus confirming the homogeneous nature of our photocatalytic system.

To shed light into the mechanism of photocatalytic system, fluorescence spectroscopy was used. Specifically, emission spectroscopy experiments were carried out using **Ps1** (4×10^{-5} M) as photosensitizer upon its excitation at 337 nm in CH_3CN solution. While the photocatalytic measurements were performed in a CH_3CN/H_2O mixture, the photophysical studies were carried out using CH_3CN as a solvent. This is due to the fact that TEA was not soluble enough in the high concentrations needed for the Stern Volmer plots in the CH_3CN/H_2O mixture. Firstly, we examined the quenching process on **Ps1** by increasing the concentration of either TEA ($0 \rightarrow 0.36$ M)] (**Figure S5**, left) or **NiTSC-OMe** ($0 \rightarrow 4.1 \times 10^{-5}$ M) (**Figure S6**, left). In addition, we have calculated the Stern-Volmer constant (K_{SV}) based on Stern-Volmer plot (**Figures S4, S5**, right), using the equation $I_o/I = 1 + K_{SV}[Q]$, where I_o and I are the fluorescence intensities observed in the absence and in the presence of each quencher, respectively, and [Q] is defined as the quencher concentration (Keizer, 1983). In perfect agreement with previous publications, the K_{SV} constant was higher in the case of the catalyst ($K_{SV} = 13{,}419.5\ M^{-1}$) compared to the TEA ($K_{SV} = 11.7\ M^{-1}$). Moreover, we calculated the quenching constant for

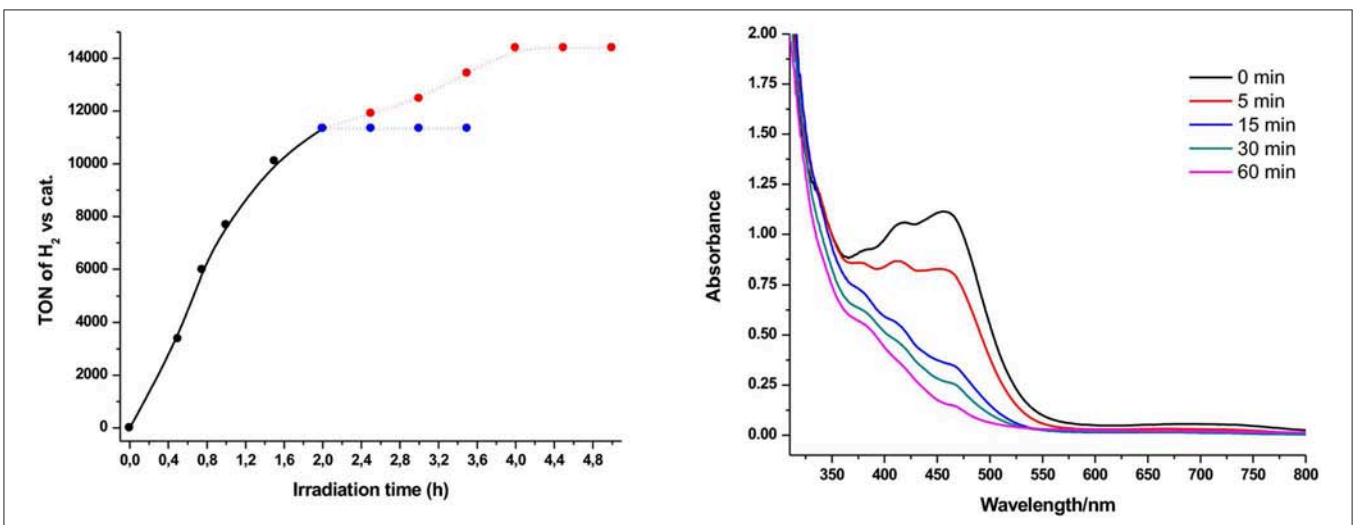

FIGURE 5 | Hydrogen production upon irradiation of solutions (4:1 CH_3CN/H_2O) containing **Ps1** (5×10^{-4} M), **NiTSC-OMe** (5×10^{-8} M), and TEA [5% (v/v)] at pH = 10. Regeneration of **Ps1** and **NiTSC-OMe** (red dot line). Regeneration of **Ps1** or **NiTSC-OMe** (blue dot line) **(left)**. UV-vis absorption spectra recorded during the course of the photolysis experiment in 10 mm cuvette, containing **Ps1** (7×10^{-5} M), **NiTSC-OMe** (5×10^{-5} M), and TEA [5% (v/v)] at pH = 10 **(right)**.

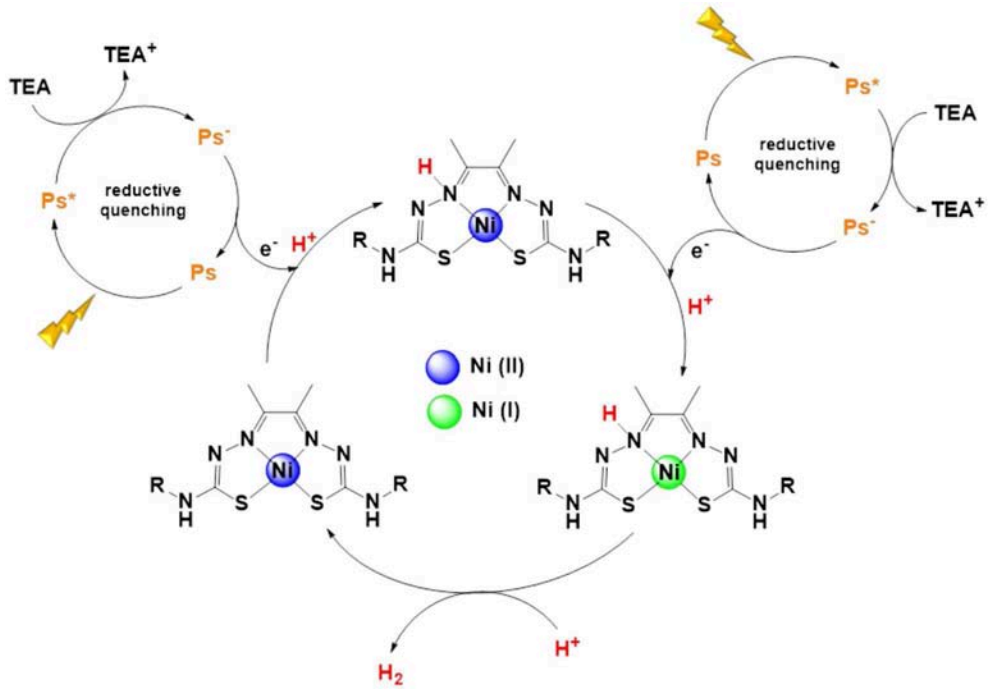

SCHEME 1 | Proposed mechanism of hydrogen photogeneration.

NiTSC-OMe ($K_Q = 4.99 \times 10^{10}\ M^{-1}s^{-1}$) and for TEA ($K_Q = 4.35 \times 10^{7}\ M^{-1}s^{-1}$) as well, which are derived from the equation: $K_{SV} = K_Q\ \tau$, where τ stands for the excited state lifetime in the absence of the quencher (Han et al., 2013; Yuan et al., 2016). However, under similar conditions to the H_2 production experiments in the emission spectra of **Ps1**, we observe that the characteristic fluorescence peak of the photosensitizer (at 590 nm) decreases only when the sacrificial electron donor (TEA) is added (**Figure S7**). What is more, there is a great difference in the quenching process, namely 50% in case of TEA and 1% in case of the catalyst. Therefore, even though, the rate constant by the **NiTSC-OMe** is greater than the rate constant by TEA, the major electron transfer pathway occurs from the excited photosensitizer to TEA, since the concentration of electron donor is bigger than that of the catalyst in the system (Han et al., 2013). In summary, hydrogen production in our system is initiated via reductive quenching of the photosensitizer.

The redox potentials of the reported compounds used in this study are listed in **Table 1**. Based on these values the thermodynamic driving forces for the different electron transfer processes, ΔG^i(PS/Cat), were calculated [(Queyriaux et al., 2017) and references herein, Goldsmith et al., 2005]. The resulting ΔG^1(PS/Cat) values turn out to be in agreement with the fluorescence quenching measurements which seems to indicate that the initial step is the reductive quenching of the photosensitizer. Indeed, the calculated ΔG^1(PS/Cat) values are positive for a reduction from Ps^+/Ps^* for **Ps1** and **Ps2** (+0.44 and +0.18, respectively) whereas they are negative for a reduction from Ps/Ps^- (−0.13 and −0.24, respectively). It is also possible to find that whatever the mechanism is, the **Ps3** potentials are not negative enough to reduce the nickel catalyst, which would explain the observed lack of photocatalytic activity. The double reduction of the catalyst is also unlikely since the values of ΔG^2(PS/Cat) are largely positive (> +0.40 eV) which would not be in favor an EECC mechanism (E corresponds to an electron transfer step and C to a chemical reaction, here protonation). Finally, the difference in activity between **Ps1** and **Ps2** does not seem to be rationalized by the little difference in driving force of injection (respectively, −0.13 and −0.24 eV), but rather by the difference of driving regeneration force ΔG(SED/PS) which is larger in the case of **Ps2** than for **Ps1** (respectively, +0.09 and 0 eV).

Taking into consideration all studies reported in this work, we propose a possible H_2 production mechanism as illustrated in **Scheme 1**. First, $[Ir(ppy)_2(bpy)]^+$ (Ps) is excited by visible light irradiation to form the excited state of the photosensitizer (Ps*). Subsequently, the sacrificial electron donor (TEA) transfers an electron to the excited photosensitizer via reductive quenching process forming its oxidized state (TEA^+) and the reduced state of the photosensitizer (Ps^-) (**Scheme 1**).

Then, a protonation of coordinated *N*-atom of the ligand on nickel complex takes place (Straistari et al., 2017) followed by an electron transfer process from the photosensitizer (Ps^-) to the nickel catalyst, creating the nickel (I) complex and forming an hydride intermediate as presented in the scheme bellow. Finally, H_2 production from the system through the nickel catalyst occurs together with its regeneration.

CONCLUSIONS

In summary, a systematic photocatalytic study toward light-driven hydrogen production is presented herein, using three different chromophores and one bis-thiosemicarbazone nickel complex. When **NiTSC-OMe** was combined with either **Ps2** or **Ps3**, no hydrogen production was observed under various experimental conditions. However, when Ps1 was utilized as a chromophore, H_2 production was detected. In order to estimate the optimal conditions we examined the influence of various parameters: the concentration of the catalyst, the pH value of the buffer solution and the ratio as well as the nature of the solvent mixture. Overall, the highest amount of H_2 (204 μL,) was attained using a 4:1 CH_3CN/H_2O solution containing **NiTSC-OMe** (10^{-6} M), **Ps1** (5×10^{-4} M), TEA [5% (v/v)] at pH 10. The maximum catalytic activity of the system though, with the highest TON and TOF values (11,333 and 7,971) were observed using **NiTSC-OMe** (5×10^{-8} M), **Ps1** (5×10^{-4} M), TEA [5% (v/v)] at pH 10 in 4:1 CH_3CN/H_2O solution. All the promising results displayed in this study offer new aspects regarding the combination of chromophores with nickel catalysts for hydrogen production. In addition, such efforts could in general provide new perspectives improving the efficiency and the function of catalytic systems developed for photoinduced hydrogen evolution using water.

AUTHOR CONTRIBUTIONS

MO and AC designed and directed the study. AP synthesized the catalyst. SP, GL, and VN performed the experiments. RH, JM, GC, AC, and MO analyzed the data. GC, AC, and MO wrote the paper with input from all authors. All authors contributed to the design and implementation of the research, to the analysis of the results and to the writing of the manuscript.

ACKNOWLEDGMENTS

General Secretariat for Research and Technology (GSRT) and Hellenic Foundation for Research and Innovation (HFRI) (project code: 508) are gratefully acknowledged for the financial support of this research. Also, the European Commission's Seventh Framework Program (FP7/2007-2013) under grant agreement no. 229927 (FP7-REGPOT-2008-1, Project BIO-SOLENUTI), and the Special Research Account of the University of Crete.

Highly Active Ni- and Co-Based Bimetallic Catalysts for Hydrogen Production From Ammonia-Borane

Shinya Furukawa[1,2]*, *Genki Nishimura*[3], *Tomoaki Takayama*[3] and *Takayuki Komatsu*[3]*

[1] Institute for Catalysis, Hokkaido University, Sapporo, Japan, [2] Elements Strategy Initiative for Catalysts and Batteries, Kyoto University, Kyoto, Japan, [3] Department of Chemistry, School of Science, Tokyo Institute of Technology, Tokyo, Japan

Ammonia-borane is one of the most promising candidates for hydrogen carriers. A series of Ni- and Co-based bimetallic catalysts supported on SiO_2 (Ni–M/SiO_2 and Co–M/SiO_2; M = Ga, Ge, Sn, Zn) was prepared and tested as catalysts for hydrogen production from ammonia-borane (AB) in water or methanol. Ni–Zn/SiO_2 and Co–Ge/SiO_2 exhibited catalytic activities much higher than those of monometallic Ni/SiO_2 and Co/SiO_2, respectively. Ni–Zn/SiO_2 showed a high catalytic activity when water was used as a solvent, where the reaction was completed within 6 min at room temperature with a specific reaction rate of 4.3 ml min^{-1} mmol-cat^{-1} mM-AB^{-1}. To the best of our knowledge, this is the highest value among those reported using 3d metal-based catalysts. Co–Ge/SiO_2 afforded a five-fold higher reaction rate than that of the corresponding monometallic Co/SiO_2. XRD, TEM, and HAADF-STEM-EDS analyses revealed that $Ni_{0.75}Zn_{0.25}$ and $Co_{0.8}Ge_{0.2}$ solid-solution alloys were formed with high phase purities. An XPS study showed that Co atoms in $Co_{0.8}Ge_{0.2}$ were electron-enriched due to electron transfer from Ge to Co, which may be the origin of the improved catalytic activity.

INTRODUCTION

Hydrogen has been considered as one of the best energy carrier alternatives to fossil fuels because of its high energy density, clean combustion product (only water), and environmental friendliness (Schlapbach and Züttel, 2011). Hydrogen is currently produced by steam reforming of methane contained in natural gas (Heinzel et al., 2002), which is not renewable and sustainable. Therefore, alternative methodologies such as photocatalytic (Moniz et al., 2015; Chen et al., 2017; Wang et al., 2017) and photoelectrochemical (Zhang et al., 2014; Zheng and Zhang, 2016; Han et al., 2017) water splitting have recently attracted increasing attention. On the other hand, storage, transport, and release of hydrogen are known as technological barriers to practical application in view of cost and safety (Züttel, 2003). Ammonia–borane ($H_3N{\cdot}BH_3$, hereafter AB) is one of the more promising candidates as a hydrogen carrier or source (Landge et al., 2018) owing to its high hydrogen content (19.6 wt%), high thermal stability, and low toxicity (Marder, 2007). AB can release three equimolar amounts of hydrogen at ambient temperatures using an appropriate catalyst through solvolysis

with protic solvents such as water and methanol. Using noble metals such as Pt, Rh, Ir enables the achievement of rapid hydrogen release typically within several minutes (Chandra and Xu, 2007; Xu and Chandra, 2007). Recently, development of non-noble 3d transition metal-based catalysts that are active for hydrogen production from AB has been increasingly focused (Xu and Chandra, 2006; Yan et al., 2008, 2009; Kalidindi et al., 2009; Metin et al., 2010; Patel et al., 2010; Ozay et al., 2011; Peng et al., 2015). To develop highly efficient catalytic systems using base metal elements, the catalytic activity of these metals should be greatly enhanced by appropriate catalyst design such as the modification of morphology, the addition of some cocatalysts, or the formation of alloy phases (Furukawa and Komatsu, 2017).

In this study, a series of Ni- and Co-based bimetallic catalysts was prepared (Ni–M/SiO_2 and Co–M/SiO_2; M = Ga, Ge, Sn, and Zn) and tested as catalysts for hydrogen production from AB in water or methanol as a solvent. The observed catalytic performances were discussed in view of the reaction mechanism. Herein, we report a novel and highly efficient catalytic system for hydrogen production from AB using non-noble metal catalysts.

MATERIALS AND METHODS

Catalyst Preparation

Monometallic Ni and Co catalysts were prepared by pore-filling impregnation using silica as a support. Aqueous solutions of $Ni(NO_3)_2{\cdot}6H_2O$ (Wako, 99%) or $Co(NO_3)_2{\cdot}3H_2O$ (Sigma Aldrich, 99%) were added to dried silica gel (CARiACT G-6, Fuji Silysia, S_{BET} = 470 m^2 g^{-1}) so that the solutions filled the silica pores. The mixtures were sealed overnight at room temperature and dried over a hot plate, followed by reduction under flowing H_2 at 600°C for 1 h. Silica-supported Ni- and Co-based catalysts (Ni–M/SiO_2 and Co–M/SiO_2; M = Ga, Ge, Sn, and Zn) were prepared by pore-filling co-impregnation. Mixed aqueous solutions of $Ni(NO_3)_2{\cdot}6H_2O$ or $Co(NO_3)_2{\cdot}3H_2O$ and a second metal salt, $Ga(NO_3)_3{\cdot}nH_2O$ (Wako, 99.9%), $(NH_4)_2GeF_6$ (Sigma Aldrich, 99.99%), $SnCl_2$ (Kanto, 97%), and $Zn(NO_3)_2{\cdot}6H_2O$ (Kanto, 99%) were used in a manner similar to that of the monometallic catalyst. The metal loading of Ni or Co, the atomic ratio of Ni/M or Co/M, and the reduction temperature during the catalyst preparation were set to 3 wt%, 3.0, and 600°C except for Ni–Ge and Co–Ge, which had a reduction temperature of 800°C, and Co–Sn with an atomic ratio of 1.0.

Characterizations

The crystal structures of the catalysts were determined by powder X-ray diffraction (XRD) with a Rigaku RINT2400 diffractometer using a Cu Kα X-ray source. Difference XRD patterns were obtained by subtracting the pattern for the SiO_2 support from those of the supported catalysts. Transmission electron microscopy (TEM) was conducted using a JEOL JEM-2010F microscope at an accelerating voltage of 200 kV. To prepare the TEM specimen, all samples were sonicated in tetrachloromethane and then dispersed on a Cu grid supported by an ultrathin carbon film. X-ray photoelectron spectra (XPS) of the bimetallic compounds were measured with an ULVAC PHI 5000 VersaProbe spectrometer. The catalyst was pressed into a pellet and placed into a quartz reactor, where it was reduced under flowing hydrogen (60 ml min^{-1}) at 450°C for 0.5 h prior to the measurement. The sample was put into a transfer vessel in a

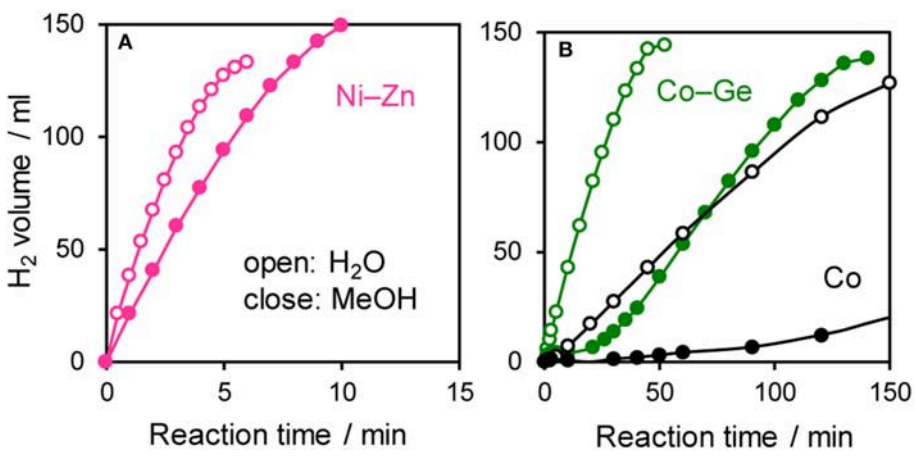

FIGURE 2 | Time course of H_2 evolution during catalytic hydrolysis (H_2O) and methanolysis (MeOH) of AB using **(A)** Ni–Zn, **(B)** Co–Ge, and Co catalyst.

grove box (O_2 concentration: <1 ppm) and then introduced into the spectrometer without exposure to air. Spectra were obtained with an Al Kα X-ray source, using C 1s as a reference for binding energy (284.8 eV). The reduction behavior of the catalyst was examined by temperature-programmed reduction (TPR). Under flowing H_2 (5%)/Ar, the temperature of the sample bed was raised from room temperature to 900°C at a heating rate of 10°C·min^{-1} and the consumption of hydrogen was continuously measured by a thermal conductivity detector (TCD).

Catalytic Reaction

A catalyst (100 mg) was placed into a 50 mL three-necked round-bottom flask equipped with a silicone rubber septum and a gas burette and pretreated under an H_2 stream (60 mL·min^{-1}) at 450°C for 0.5 h using a mantle heater. After the pretreatment, dry Ar (20 mL·min^{-1}) was passed into the flask to replace the residual H_2, and the flask was cooled to room temperature. A reaction mixture containing a solvent (deionized water or dehydrated methanol, Kanto 99.8%, 10 mL) and AB (Sigma-Aldrich, 97%, 2.0 mmol) was added into the flask through the septum at 25°C. The volume of the evolved H_2 was measured using the gas burette. The total volume of H_2 is expected to be 147 ml (6.0 mmol) at 25°C for the complete conversion of AB (2.0 mmol).

RESULTS AND DISCUSSION

The prepared Ni- and Co-based catalysts were tested for H_2 production from AB using methanol as a solvent (**Figure 1**). The monometallic Ni catalyst showed moderate catalytic activity with a short induction period. The Ni–Sn catalyst showed a very low catalytic activity with a long induction period. On the other hand, the Ni–Zn, Ni–Ga, and Ni–Ge catalysts exhibited high catalytic activities without an induction period. Particularly for the Ni–Zn catalyst, the reaction was completed within ca. 10 min. Co-based catalysts generally gave catalytic activities lower than those of Ni-based catalysts, which reflects the intrinsic difference of catalytic activity between Ni and Co for this reaction. Moreover, the catalytic activities were quite different depending on the second metal (Co–Ge > Co–Ga >> Co >> Co–Sn). Induction periods were observed for some catalysts (Ni, Ni–Sn, Co, Co–Ga, and Co–Zn), indicating that, for these catalysts, some real active species (probably, zero-valent Ni or Co species) were formed or increased during the catalytic reaction. A remarkable

[a] *Time needed for completion of H_2 evolution.*

enhancement in the reaction rate was achieved by addition of Ge to Co, suggesting the contribution of a specific effect of Ge on the catalysis. The discovered active catalysts, Ni–Zn and Co–Ge, were also tested in hydrogen production from AB in water as a solvent (**Figure 2**). For each catalyst, H_2 evolution in water was much faster than that in methanol as reported for Ni- and Co-based catalysts in the literature. Note that the reaction was completed within 6 min when the Ni–Zn catalyst was used. This is one of the best performances in AB hydrolysis reported to this day. The obtained catalytic performance was listed in **Table 1** with those of reported catalysts. Because the reaction conditions were different depending on each study, we quantitatively compared them based on the specific H_2 formation rates ($r_{cat[AB]}$) calculated by dividing H_2 formation rates (r_{H2}) by the amount of catalyst (mmol) and concentration of AB (mM). Since the number of active sites, such as metal atoms on the surface, was not clearly mentioned, the total number of metal atoms was used for this calculation. The difference in AB concentration was compensated for by assuming the first-order dependence of the formation rate on AB concentration. The Ni–Zn catalyst exhibited an $r_{cat[AB]}$ value higher than that of Ni_2P, which was reported to be the most active base-metal catalyst for AB hydrolysis (Peng et al., 2015). Therefore, the Ni–Zn catalyst is the most active 3d metal-based catalyst for H_2 production by hydrolysis of AB. We also examined the reusability of the catalysts. **Figure 3** shows the result of the reuse test for

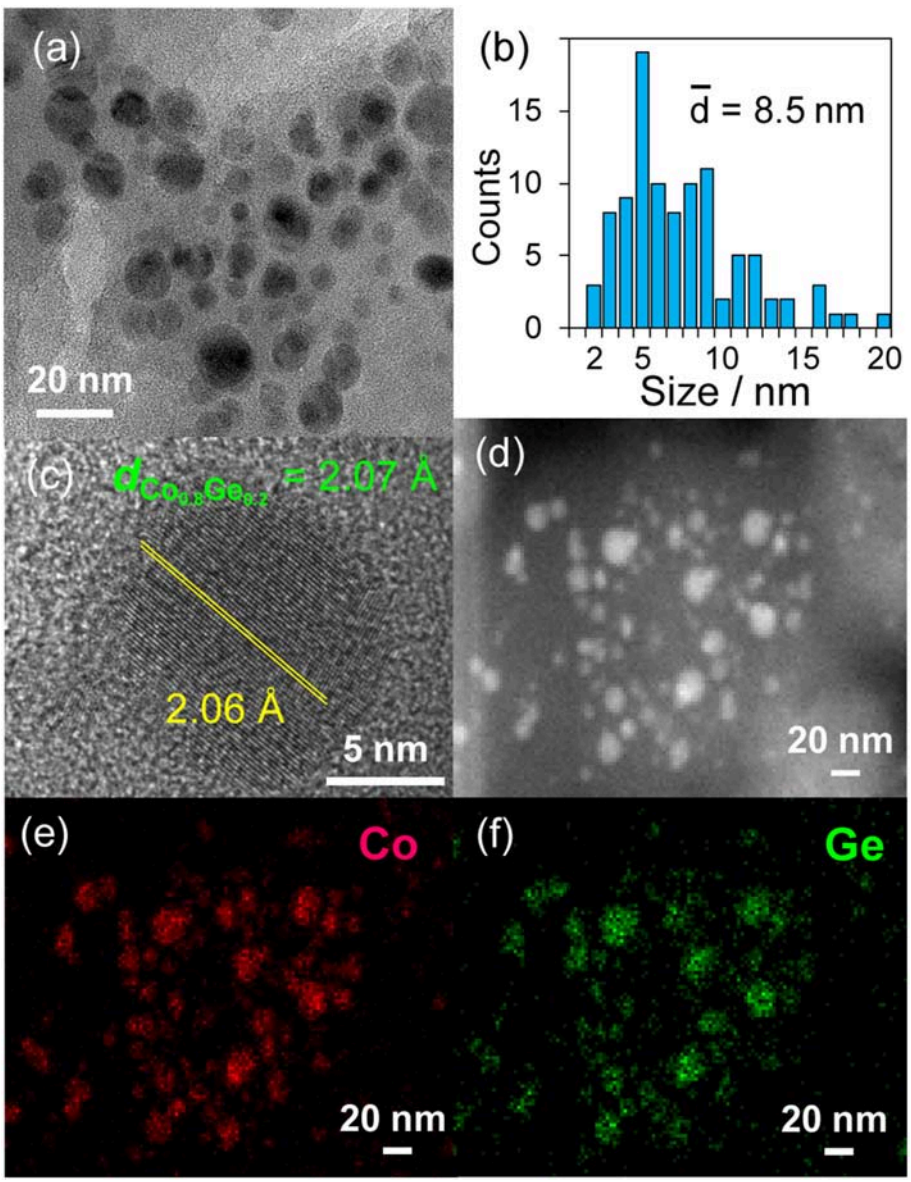

FIGURE 5 | (a) TEM image and the **(b)** size distribution of Co–Ge/SiO_2 catalyst. **(c)** High resolution TEM image of a single nanoparticle of Co–Ge. **(d)** HAAF-STEM image of Co–Ge/SiO_2 catalyst and elemental maps of **(e)** Co, and **(f)** Ge for the nanoparticles acquired using EDS.

the Co–Ge/SiO_2 catalyst in H_2 production in methanol. At the first reuse at 110 min, we added 1.33 mol of AB (2/3 equivalent to the standard condition). The total volume H_2 evolved decreased from 130.5 to 87 ml, showing complete conversion of AB at reuse. The reaction rate also became approximately two-thirds of the original (2.03–1.75), indicating that r_{H2} strongly depends on AB concentration. Although the reaction rate was slightly decreased at the second and third reuse, the Co–Ge/SiO_2 catalyst could be reused without any regeneration procedure. Thus, it was found that the Co–Ge/SiO_2 was a recyclable heterogeneous catalyst for H_2 production from AB.

Then, the discovered active catalysts were characterized to clarify their structures. **Figure 4** shows XRD patterns of the Ni–Zn/SiO_2 and Co–Ge/SiO_2 catalysts. For Ni–Zn/SiO_2, a solid-solution alloy between Ni and Zn with a 3: 1 ratio, namely $Ni_{0.75}Zn_{0.25}$ phase (Vassilev, 1992), was observed as single phase. A similar alloy phase ($Co_{0.8}Ge_{0.2}$) (Ishida and Nishizawa, 1991) was also observed as a main species for Co–Ge/SiO_2. One-to-one intermetallic phase of CoGe was also detected as a minor species. Thus, XRD analysis confirmed the formation of alloy phases with high purities. The crystallite sizes of Ni–Zn and Co–Ge were estimated using Scherrer equation as <3 and 9 nm, respectively. The larger crystallite size of Co–Ge may stem from the higher reduction temperature (800°C) during the catalyst preparation. **Figure 5** shows TEM and STEM images of Co–Ge/SiO_2, size distribution of nanoparticles, and the elemental map of Co and Ge acquired using EDS. Particle size ranged from 2 to 20 nm with a mean diameter of 8.5 nm (**Figures 5a,b**), which is consistent with the crystallite size estimated by the Scherrer equation (9 nm). **Figure 5c** displays the high-resolution TEM image of a single Co–Ge nanoparticle. Lattice fringes with 2.06 Å spacing were clearly observed, which agrees finely with the interplanar distance of the (111) plane of $Co_{0.8}Ge_{0.2}$ solid-solution alloy with an fcc structure (2.07 Å) (Ishida and Nishizawa, 1991). The elemental maps of Co and Ge that were acquired using the EDS analysis revealed that the Co and Ge atoms comprising the nanoparticles were homogeneously dispersed (**Figures 5d–f**). These results strongly suggest that the $Co_{0.8}Ge_{0.2}$ alloy nanoparticles were formed with high phase purities. Thus, the results obtained from the STEM-EDS analysis were consistent with that of XRD.

We then studied the reason why the catalytic activity was significantly enhanced by the formation of the alloy phase. Because the Co–Ge system exhibited a remarkable increase in the reaction rate (five times higher) compared to pure Co, we focused on the difference between the Co and Co–Ge systems.

Figure 6 shows the TPR profiles of the Co/SiO_2 and Co–Ge/SiO_2 catalysts. To evaluate the reduction temperatures of the component metals, as-impregnated catalysts were used for the TPR experiments. For both catalysts, intense peaks were observed at 150 and 200°C, which may be attributed to the reduction of O_2 or NO_2 derived from the decomposition of the $Co(NO_3)_2$ (van Steen et al., 1996). For Co/SiO_2, two reduction peaks were observed at 260 and 760°C, which are assigned to the reduction of Co^{2+} species that weakly and strongly interact with the silica surface, respectively (van Steen et al., 1996). On the contrary, for Co–Ge/SiO_2, three different reduction peaks were observed at 370, 550, and 740°C, which could be assigned to the reduction of Co^{2+}, Co^{3+}, and Ge^{4+} species. We previously reported a TPR profile of Ge/SiO_2, with reduction peaks appearing at temperatures higher than 650°C (Komatsu et al., 1997). Therefore, the reduction peak at 740°C can be attributed to the reduction of Ge^{4+}. The other reduction peaks assignable for Co species appeared at much higher temperatures than that for Co/SiO_2, suggesting that the strong interaction between Co and Ge inhibits the reduction of Co^{2+}. It can be said that Co species in Co/SiO_2 were not completely reduced because the reduction temperature for the preparation of Co/SiO_2 (600°C) is not sufficient to completely reduce all the Co species. This

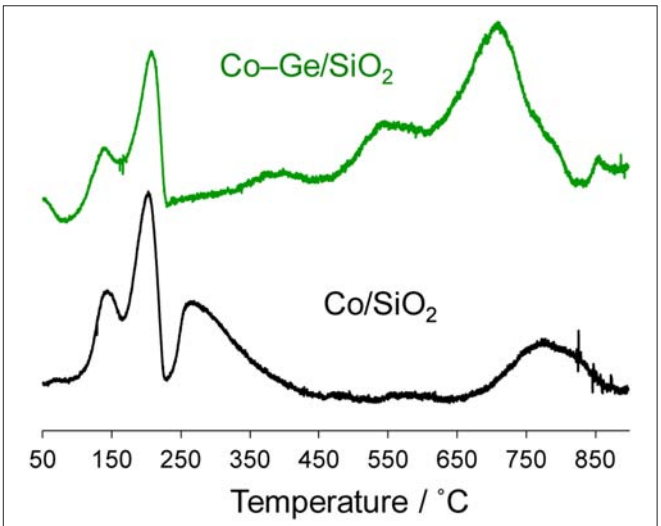

FIGURE 6 | TPR profiles for as-impregnated $Co(NO_3)_2/SiO_2$ and $Co(NO_3)_2$-$(NH_4)_2GeF_6/SiO_2$ catalysts.

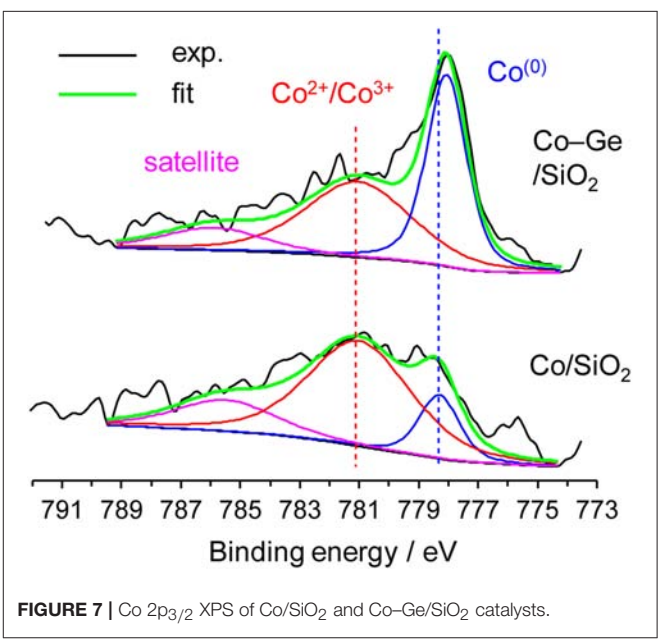

FIGURE 7 | Co $2p_{3/2}$ XPS of Co/SiO_2 and Co–Ge/SiO_2 catalysts.

may be one of the reasons why the Co/SiO_2 catalysts showed low catalytic activity. On the contrary, for $Co–Ge/SiO_2$, the reduction temperature for the preparation (800°C) is enough to reduce all the Co^{2+} and Ge^{4+} species.

We also investigated the electronic states of the Co/SiO_2 and $Co–Ge/SiO_2$ catalysts by XPS (**Figure 7**). For Co/SiO_2, the fraction of Co^{2+} or Co^{3+} species (Sexton et al., 1986) was much higher than that of $Co^{(0)}$, suggesting that a large part of the catalyst surface is oxidized. By contrast, for $Co–Ge/SiO_2$, $Co^{(0)}$ (Sexton et al., 1986) was detected as a main species. These results are consistent with the expectation derived from TPR mentioned above. It is also likely that Co atoms on the $Co–Ge/SiO_2$ catalyst are more resistant to aerobic oxidation than those on Co/SiO_2. Jagirdar et al. reported that Co^{2+} or Ni^{2+} ions could be reduced by the evolved H_2 during hydrolysis of AB to form Ni or Co nanoparticles (Kalidindi et al., 2008). Therefore, it is likely that similar *in situ* reduction of Co^{2+} could occur to completely reduce the catalyst surface in our system. This may be the reason why the induction period was observed in H_2 production from AB over Co/SiO_2. The binding energies of Co^{2+} or Co^{3+} for Co/SiO_2 and $Co–Ge/SiO_2$ were almost same, suggesting that Ge species do not affect the electronic state of Co cations. However, a different trend was observed for $Co^{(0)}$ species: $Co–Ge/SiO_2$ exhibited a lower binding energy than Co/SiO_2, indicating that Co atoms in Co–Ge are electron-enriched compared with pure Co. This is probably because electron transfer from Ge to Co occurs due to alloy formation. Similar electron transfer has also been reported for the relevant systems such as Pt–Ge alloys (Komatsu et al., 1997). Thus, XPS analysis revealed that the formation of Co–Ge alloy drastically changed the electronic state of Co. On the basis of these results, we considered that the difference in the electron density of $Co^{(0)}$ species, namely, electron-enrich Co by Ge via alloying, is the key factor for the remarkable enhancement in the catalytic activity.

The reaction mechanism of AB hydrolysis has been reported as follows: (1) the formation of an activated complex between AB and the metal surface, (2) B–N bond scission assisted by H_2O attack, and (3) hydrolysis of the resulting BH_3 moiety to form H_2 and BO_2^- (Xu and Chandra, 2006; Mahyari and Shaabani, 2014). It is also known that H atoms bound to the B and N atoms are slightly electropositive and electronegative, respectively, due to the different electronegativities of B and N. Therefore, it is likely that the alloy surface with polar active sites ($Co^{\delta-}$–$Ge^{\delta+}$) facilitates the formation of the active complex (1), thus enhancing the following steps and the overall reaction rate. A similar reaction mechanism has also been reported in the system of $Ru^{\delta-}$–$Ni^{\delta+}$ bimetallic catalysts for AB hydrolysis (Mori et al., 2016).

CONCLUSION

In this study, we prepared a series of Ni- and Co-based bimetallic catalysts ($Ni–M/SiO_2$ and $Co–M/SiO_2$; M = Ga, Ge, Sn, and Zn) and tested them in H_2 production from AB in water or methanol. Catalytic activity for hydrogen production is enhanced by the addition of second metals except Sn. Particularly, the addition of Ge to Co enables great enhancement in the catalytic activity, namely a five-fold higher r_{H2} than the monometallic Co/SiO_2 catalyst. The active species is electron-enriched Co atoms constituting the $Co_{0.8}Ge_{0.2}$ solid solution alloy phase. The $Ni–Zn/SiO_2$ catalyst exhibited an $r_{cat[AB]}$ value higher than those ever reported for hydrolysis of AB to the best of our knowledge. The $Ni_{0.75}Zn_{0.25}$ solid solution alloy phase acts as the active species.

AUTHOR CONTRIBUTIONS

SF designed the research and experiments. GN performed all the experiments. TT managed the HAADF-STEM-EDS analysis. SF and TK prepared the manuscript.

Harnessing Plasmon-Induced Hot Carriers at the Interfaces With Ferroelectrics

Vineet Kumar, Shaun C. O'Donnell, Daniel L. Sang, Paul A. Maggard and Gufeng Wang**

Department of Chemistry, North Carolina State University, Raleigh, NC, United States

This article reviews the scientific understanding and progress of interfacing plasmonic particles with ferroelectrics in order to facilitate the absorption of low-energy photons and their conversion to chemical fuels. The fundamental principles of hot carrier generation and charge injection are described for semiconductors interfaced with metallic nanoparticles and immersed in aqueous solutions, forming a synergistic juncture between the growing fields of plasmonically-driven photochemistry and semiconductor photocatalysis. The underlying mechanistic advantages of a metal-ferroelectric vs. metal-nonferroelectric interface are presented with respect to achieving a more optimal and efficient control over the Schottky barrier height and charge separation. Notable recent examples of using ferroelectric-interfaced plasmonic particles have demonstrated their roles in yielding significantly enhanced photocurrents as well as in the photon-driven production of molecular hydrogen. Notably, plasmonically-driven photocatalysis has been shown to occur for photon wavelengths in the infrared range, which is at lower energies than typically possible for conventional semiconductor photocatalysts. Recent results thus demonstrate that integrated ferroelectric-plasmonic systems represent a potentially transformative concept for use in the field of solar energy conversion.

BACKGROUND

Generation of Hot Carriers in Plasmonic Nanoparticles

The transformation of solar energy into chemical potential energy, e.g., such that which is stored in molecular hydrogen, represents a sustainable and favorable pathway to eventually displacing fossil fuels as the predominant energy resource. Noble metals have been drawing increasing attention as a component of efficient light-harvesting systems arising from the collective oscillation of their conduction electrons, i.e., surface plasmon resonances (SPR), that can be excited by photons over a very wide range of infrared to ultraviolet wavelengths (Brongersma et al., 2015; Linic et al., 2015; Moskovits, 2015). Within a metallic nanoparticle, localized surface plasmons are produced that are confined to an area that is similar to or smaller than the wavelength of light excitation. Subsequent to the absorption of light, a number of competing elementary processes and potential outcomes can occur (**Figure 1**), with timescales that are dependent upon the nanoparticle size, shape, and electronic structure. The basic features of these competing processes have been the focus of reviews.

Briefly, when a metal particle is irradiated by light, the electromagnetic field induces the polarization of the conduction electrons with respect to the positive ionic cores, creating an

electric dipole (**Figure 1A**). The Columbic interaction between the opposite charges acts as a restoring force, which leads to electronic oscillations, where the collective electronic oscillations are named plasmons. When the electronic oscillations occur locally at the nanoparticle as shown in **Figure 1A**, the corresponding surface oscillation is known as localized SPR (LSPR). Under resonance conditions, the particle absorption cross section is greatly enhanced, e.g., up to five orders of magnitude larger than those of typical dye molecules (Jain et al., 2006). The SPR wavelengths of the plasmonic nanoparticles are tunable, by varying size and shape, across the entire visible spectrum. The confined electronic oscillations in the particle enhance the local electric field distribution at the surface of the nanostructures. This leads to several interesting phenomena such as Surface-Enhanced Raman Scattering (SERS), etc., which is beyond the scope of this review article.

The plasmon resonances can decay radiatively by re-emission of photons or non-radiatively by Landau damping with the creation of electron-hole pairs, on the timescale of ∼1–100 fs. For small nanoparticles (∼10–25 nm) and sub-radiant plasmon modes, the branching ratio is predominated by the creation of electron-hole pairs. An example of the non-thermalized distribution of charged carriers is illustrated in **Figure 1B**, showing "hot" electrons and holes that are energetically above and below the Fermi level of the metal particle, respectively (Mukherjee et al., 2013; Linic et al., 2015). The resulting distribution is a sensitive function of the plasmon energy, particle size, and the electronic structure of the metallic nanoparticle, as described previously. These hot carriers will adiabatically re-equilibrate via electron scattering and Auger transitions on the order of 100 fs to 1 ps (**Figure 1C**) to produce a Fermi-Dirac like distribution with a high effective electron temperature of several thousand degrees. Thus, *high energy hot electrons* can be produced in the process even when the particle is excited by relatively low energy photons (Moskovits, 2015).

Shown in **Figure 2**, for example, a recent investigation into 15 nm Ag nanoparticles shows a wide calculated distribution of hot carriers for a continuously-irradiated particle and lifetimes that varied between 0.05 and 1.0 ps. Thus, the energetic distribution of the hot carriers, i.e., both their densities and energies, is a highly sensitive function of their re-equilibration lifetimes. For a photon energy of 3.65 eV, a wide range of excited states is ultimately achieved that ranges from 3 to 4 eV both above and below the Fermi level for the hot electron and hot hole states, respectively, as shown in **Figure 2**. These represent electrochemical potentials for both electrons and holes that exceed the band energy requirements for the water-splitting half reactions, as will be described below. For a larger particle size of 25 nm, a significantly smaller hot-carrier density (∼50%) results because of the higher number of allowable electronic states. Lastly, the thermal re-equilibration with the lattice requires on the order of several picoseconds (**Figure 1D**), followed by heat transfer to the surroundings in ∼10 ps to 10 ns.

Critical to solar energy conversion, high-energy hot electrons and holes are generated in plasmonic nanoparticles during the light absorption processes, with lifetimes on the order of 10 ps before thermal equilibration with the surroundings (Hoggard et al., 2013; Major et al., 2014; Linic et al., 2015). This realization has led to a surge of recent studies that have demonstrated that the excitation of the SPR of particle-based catalysts can be used to facilitate or greatly amplify their catalytic activities (Adleman et al., 2009; Bueno Alejo et al., 2011; Christopher et al., 2011; Liu et al., 2011; Warren and Thimsen, 2012; Hoggard et al., 2013; Mubeen et al., 2013; Mukherjee et al., 2013; Major et al., 2014; Marchuk and Willets, 2014; Linic et al., 2015). How specific catalytic reactions are impacted by excitation of the plasmonic nanoparticle is still under intense investigation and likely varies case-by-case. Generally, it is viewed that SPR can enhance photon-driven chemical reactions through two possible mechanisms. These include the local photothermal effect, i.e., the reaction is thermally activated or expedited by the hot lattice produced by thermal re-equilibration, and more interestingly, by hot charge transfer across interfaces to molecular absorbates to electrochemically induce reactivity. In the latter pathway, the excitation of the SPR causes the formation of hot electron-hole pairs that can then be transferred to the metal surface and the adsorbate molecules directly or indirectly, inducing the chemical reactions (Major et al., 2014; Brandt et al., 2016).

Prominent early examples of hot electron transfer include the dissociation of H_2 molecules on the surface of ∼10–20 nm Au particles, or the oxidation of ethylene by O_2 using 60 nm Ag nanocubes (Mukherjee et al., 2014). For the room-temperature dissociation of H_2 molecules, the study found that hot electrons transferred most effectively across a nanoshell of SiO_2 and less effectively across a nanoshell of TiO_2, owing to the lower-energy conduction band of TiO_2 that functions as a highly effective electron acceptor. Conversely, hot hole transfer has been demonstrated in the growth of Ag nanoprisms via oxidation of citrate anions in solution (Jin et al., 2003). The plasmon-induced growth of the Ag nanoprisms was found to be more sensitively dependent on the incident photon energy rather than the photon flux, owing to the increasing oxidizing power of the hot holes. Many other remarkable studies in this field have proven that the energies and lifetimes of the hot electron and holes can be sensitively manipulated and used to enable their facile transfer to adsorbates and/or through interfaces. These can be utilized to drive reactions that have significant activation energies, or alternatively, reactions that are thermodynamically uphill in energy.

Light-Driven Reactivity at Semiconductor Surfaces

The realization that light-absorption by semiconductors could be used to drive chemical reactions occurred in the early 1970s with the seminal research on *n*-type TiO_2 that demonstrated that water could be oxidized at its surfaces to molecular oxygen (Fujishima and Honda, 1972; Kawai and Sakata, 1980; Hoffmann et al., 1995; Kato et al., 2003; Maeda et al., 2005; Linic et al., 2011; Sivula et al., 2011; Ohno et al., 2012; Huang et al., 2017; Suzuki et al., 2018). Since that time, semiconductors from among many different chemical systems have been investigated for their ability to function at high solar-to-chemical efficiencies and stabilities, including in the oxides, chalcogenides, and nitrides. These have

included in applications such as in thin-film photovoltaics and photoelectrodes, as well as in the form of photocatalyst particles. However, the anatase polymorph of TiO_2 has been among the most highly investigated materials for the water splitting reactions to produce molecular hydrogen and oxygen (Kawai and Sakata, 1980; Hoffmann et al., 1995).

Shown in **Figure 3A**, a photocatalytic reaction consists of three basic steps, including the absorption of bandgap photons with the generation of electron (e^-) and hole (h^+) pairs, charge separation and transport to the surfaces via their diffusion and drift, and then electron transfer at the surfaces to drive redox reactions, e.g., such as for water splitting. A key element to the charge separation is the space charge layer that forms at the semiconductor surface as a result of its equilibration with the chemical potential of the solution. In an *n*-type semiconductor, this results in an upward band bending with a depth given by W_{sc} that is a function of the dopant density, dielectric constant, and space charge height. The electron-hole pairs will be separated if they are produced within this layer or if they can diffuse to it before recombining. In this case, the oxidation reaction occurs at the semiconductor surface and the reduction reaction occurs at a counter-electrode or at a surface cocatalyst island such as Pt.

The production of molecular hydrogen from the splitting of water is a thermodynamically uphill process with a Gibbs' free energy change of ∼238 KJ/mol, thus requiring the equivalent of >1.23 eV (<1,008 nm) per photon (Maeda et al., 2006; Ingram and Linic, 2011; Sivula et al., 2011; Wang and Astruc, 2014). A semiconductor with a bandgap size of >1.23 eV and suitable band energies that straddle the water redox couples can be used to drive the water splitting reaction at its surfaces from solar irradiation. A consideration of the required overpotentials at its surface catalyst sites increases the optimal photon energy to ∼1.6–2.0 eV, or to wavelengths less than about ∼600–775 nm for a single junction photoelectrode or photocatalyst particle. Considering that the solar irradiation, i.e., AM 1.5 G light, includes a large (>50%) contribution in the infrared energy range with wavelengths of >800 nm, there is a significant fraction of solar energy that cannot be utilized in single-junction semiconductor systems for photocatalysis (Navarro et al., 2009; Long et al., 2015). Other factors that negatively impact the light-driven reactions at the surfaces include the efficiency of charge separation, charge carrier lifetimes, and surface reaction rates and stability. Owing to these limitations, their practical efficiency in converting sunlight to chemical energy remains low (<1% for total solar energy) compared to the minimum solar-to-hydrogen efficiency of ∼10% that is required for commercial viability (Lewerenz and Peter, 2013).

Under ultraviolet irradiation, many large bandgap semiconductors show a high quantum efficiency and outstanding stability, e.g., La-doped $NaTaO_3$ and TiO_2 with bandgap sizes of ∼3–4.5 eV. This has led to numerous studies aimed at their sensitization to visible-light wavelengths, such as using molecular dyes via charge injection of their excited electrons. However, most molecular dyes degrade rapidly over time or cannot be used to drive the overall water splitting reaction. Plasmonic nanoparticles, either bare or combined with a semiconductor,

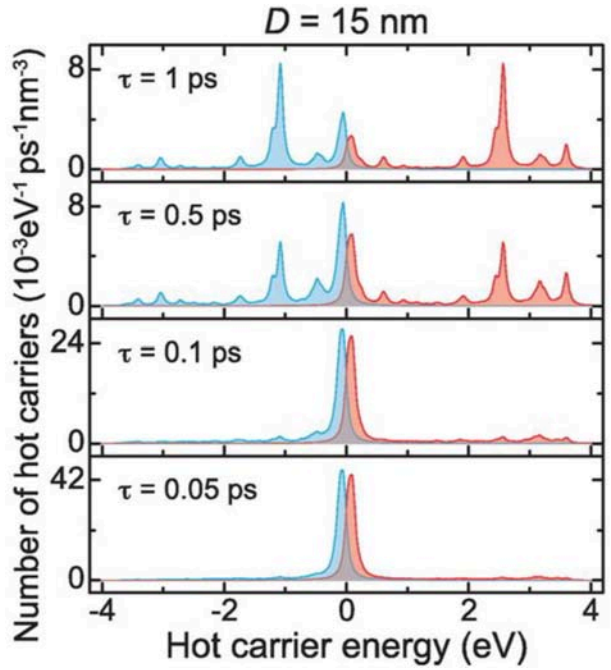

FIGURE 2 | Hot carrier distributions per unit time and volume as a function of energy, calculated for a 15 nm diameter Ag nanoparticle. Hot electrons and hot holes are plotted as the blue and red lines, respectively, with the Fermi level set at the zero energy. The stacked plots show the changes in the hot carrier distributions for relaxation lifetimes from 0.05 to 1.0 ps. An incident photon energy of 3.65 eV was used. have most recently been the subject of several key investigations for use in light-driven reactions (Zhu, 1994; Wang et al., 2008; Li et al., 2015; Ma, X. et al., 2016; Ortiz et al., 2017). The placement of a plasmonic particle and a semiconductor surface in close vicinity can have a remarkable impact on their catalytic activity. For example, Ma et al. found that the photocatalytic activity in a combined plasmonic-semiconductor particle can be increased through local electric field enhancement of photo-induced charge carrier generation at the semiconductor surface (Ma et al., 2014a). The photo-degradation of methyl orange under visible-light irradiation was investigated for Ag@AgCl, where AgCl is a wide band gap material (>3 eV). It was proposed that energy transfer from the Ag nanoparticle to the semiconductor AgCl required the presence of mid-gap defect states. In this case, the SPR of the Ag nanoparticles was found to enhance the excitations of AgCl involving these defect states.

More generally, photogenerated hot charge carrier injection from the plasmonic particles to the semiconductors has been found to play a dominant role in modulating semiconductor reactivity. Hot electron injection from plasmonic particles to semiconductors has been demonstrated, and hybrid plasmonic-semiconductor materials have been utilized in a growing number of investigations of photovoltaic devices (Atwater and Polman, 2010; Linic et al., 2011; Thomann et al., 2011; Mubeen et al., 2013; Clavero, 2014) and photocatalysts (Zhao et al., 1996; Christopher et al., 2011; Marimuthu et al., 2013; Mukherjee et al., 2013). Combining plasmonic nanoparticles with a semiconductor photocatalyst can significantly boost the efficiency of light absorption as well as induce high local electric fields for charge separation. More importantly, the semiconductor can serve as a sink for hot electrons generated in the SPR process, extending their lifetimes to be in the nanosecond time scale (Zhu, 1994). Many of these investigations have shown enhancements of the photocatalytic rates at their surfaces. As illustrated in **Figure 3B**, the concept is that the excitation of the localized SPR of nanoparticles will generate hot electrons and hot holes that can be injected into the conduction band or the valence band, respectively, of the metal oxide. Thus, the oxidation and reduction reactions can occur separately over the plasmonic nanoparticle and metal oxide. In addition, the operational wavelength range of such systems can be tuned by controlling the SPR resonance frequency from the infrared to ultraviolet photon energies.

However, the efficient utilization of the hot electrons has been a formidable challenge because of the extremely short relaxation lifetimes, on the order of a few picoseconds, owing to the multiple fast relaxation processes including electron-electron scattering, electron-interface scattering, electron–phonon interaction, photoluminescence, etc. (Linic et al., 2011; Manjavacas et al., 2014; Ma, X. C. et al., 2016). When combining the plasmonic particles with conventional semiconductors, the hot electron injection efficiency (HEIE) is usually low. The Schottky barrier (i.e., the energy barrier across the metal and the semiconductor interface, described later) is the main hurdle for the low efficiency. Practical factors, e.g., the occupation of surface oxygen vacancies of titania oxide by Au atoms during the synthetic process, may increase the barrier and expand the space charge region, which significantly decreases the HEIE (Ma et al., 2014b). Strategies to most efficiently use the hot charge carriers generated in an SPR process are currently under intensive investigation (Ma, X. C. et al., 2016). Current efforts to improve the hot electron injection efficiency include designing composite structures so that the hot electrons have sufficient momentum to cross the interface (Giugni et al., 2013), chemically modifying the surfaces so that efficient electronic coupling between the plasmonic particle and the semiconductor occurs (Tamura et al., 2009), and applying pressure, which shifts the positions of the valence/conduction bands and favors lowering the barrier height (Ma, X. et al., 2016; Lv et al., 2018). However, these efforts have so far not yielded an adequately efficient design to capture and harness the hot electrons.

Ferroelectric Surfaces for Extracting Hot Carriers of Plasmonic Nanoparticles

Ferroelectric materials have been extensively used in microelectronics, memory storage devices, temperature sensors and switches, thin film capacitors, and more (Daniel and Astruc, 2004). They are characterized as possessing a large, reversible electric polarization within their crystalline grains owing to a displacement of the centroid of positive and negative charges, as illustrated in **Figures 4A–C** for $BaTiO_3$ in the symmetric cubic

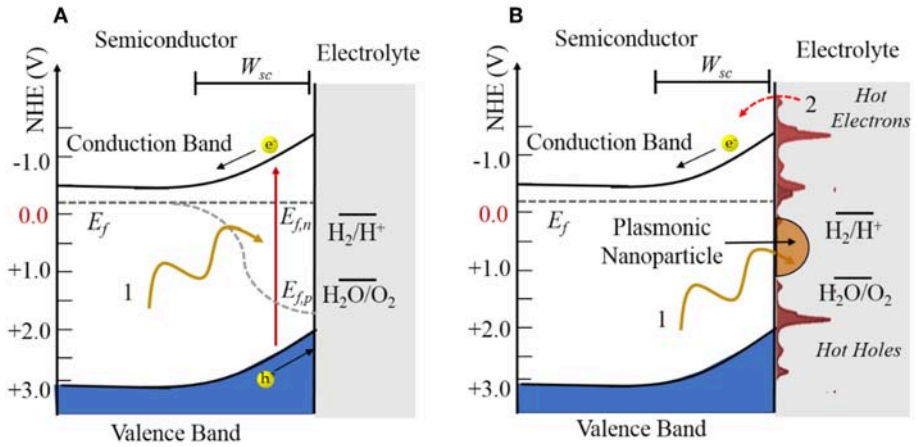

FIGURE 3 | Illustration of **(A)** an *n*-type semiconductor-electrolyte interface under irradiation and **(B)** an *n*-type semiconductor with a plasmonic nanoparticle attached at the surface. (*Pm-3m*) or distorted tetragonal (*P4mm*) polymorphs of the perovskite structure type. Many ferroelectrics with the common ABO_3 composition crystallize in perovskite-type structures that exhibit polar distortions. For example, ferroelectric $PbTiO_3$ exhibits a tetragonal structural distortion below a Curie temperature of ∼495°C and with a large, spontaneous

ferroelectric polarization of ∼80 μC cm^{-2} that persists even in the absence of an applied electric field (Qin et al., 2007; Arney et al., 2011; Cao et al., 2012b; Kakekhani and Ismail-Beigi, 2016; Kakekhani et al., 2016; Wang et al., 2016). A freshly prepared sample will have a large number of individual grains, or domains, with random orientations that are separated by domain walls, shown in **Figures 4D,E** for $BaTiO_3$. Unit cells within the domain have a shared polarization direction, labeled with arrows, owing to the collective displacements of the cations in the same directions. However, changes to the displacement of the cations around the oxygen anions can be induced by application of an external electric field, causing the polarization of individual grains to eventually be aligned with the external field in a process known as poling. This process is reversible, and thus ferroelectrics have a switchable polarization (Kalinin and Bonnell, 2001; Bonnell and Kalinin, 2002; Streiffer et al., 2002; Daniel and Astruc, 2004; Cai et al., 2007).

Many recent studies have suggested that the surfaces of a ferroelectric (FE) can yield potentially optimal configurations for achieving significant efficiency enhancements of charge separation and charge injection across interfaces. The spontaneous polarization can facilitate electron-hole separation within the ferroelectrics through coulombic interactions (Yun and Altman, 2007), and also where the domain walls can act as charge trapping centers or as reactive surface sites (Qin et al., 2007; Sakar et al., 2016; Zhu et al., 2018). Many prior studies have demonstrated that the internal polarization of a ferroelectric can result in the spatial segregation of oxidation and reduction reactions over its oppositely polarized surfaces. For example, photochemical deposition studies on $BaTiO_3$, $BiFeO_3$, and other ferroelectrics have shown spatial separation of the light-driven oxidation of Pb^{2+}(aq) to PbO_2(s) and the light-driven reduction of Ag^{+}(aq) to Ag(s) (Li et al., 2014). An illustrative case is depicted in **Figure 4** for $BaTiO_3$, wherein atomic force microscopy shows that its positively polarized surfaces are preferentially the sites for reductive reactivity and its negatively polarized surfaces are the preferential sites for oxidative reactivity. Recent calculations have shown that positively and negatively polarized domains, which are separated by 180°, lead to the highly efficient separation of the charged carriers to the oppositely polarized surfaces with internal quantum efficiencies that can exceed 90% (Glickstein et al., 2016). The advantage is that both types of carriers, i.e., majority and minority carriers, can be separated and reacted over adjacent surfaces without the need for extended diffusion pathways through a film, external circuit, or via redox shuttles in solution. Efficient charge separation within ferroelectrics is thus an attractive feature for photocatalytic reactions such as water splitting. For example, using the ferroelectric $PbTiO_3$, Maggard et al. investigated its photocatalytic activity for the reduction and oxidation of water and showed that high activities for both reactions occur for nanoparticles as well as micron-sized particles (Arney et al., 2011). A limiting feature of ferroelectrics is that, with a few rare exceptions, they usually have large bandgap sizes that fall within the ultraviolet energy range. For example, $PbTiO_3$ has a bandgap that falls at the edge of the visible range at ∼2.7 eV and does not absorb light with a wavelength longer than ∼460 nm. Thus, the many recent investigations into ferroelectrics have focused on their capabilities to increase charge separation or charge extraction when combined with semiconductors with smaller bandgap sizes (Bowen et al., 2014).

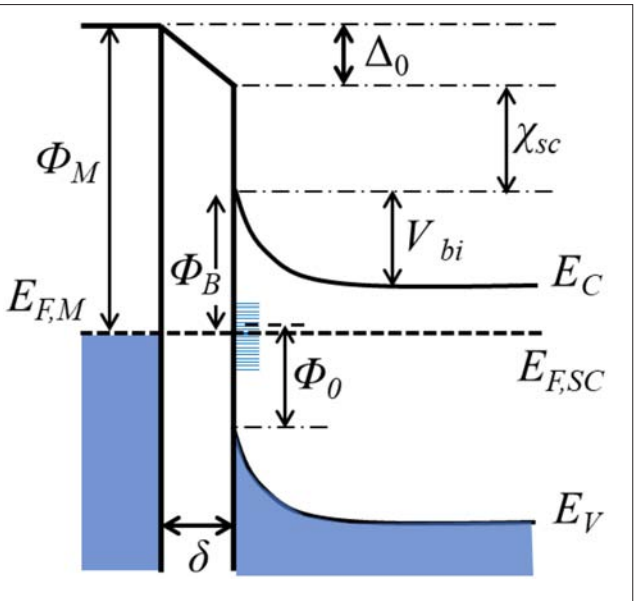

FIGURE 5 | Energy diagram of a metal-semiconductor(*n*-type) contact with an interfacial layer. Φ_0: energy change between the valence band edge and charge neutrality level.

Recent results, described below, have suggested that the tethering of plasmonic nanoparticles to the surfaces of a ferroelectric can lead to an optimal configuration for achieving an enhanced extraction of hot carriers from them. The basic idea is that a ferroelectric with a large surface polarization can facilitate the fast charge extraction of hot carriers from plasmonic nanoparticles. The unique advantages of this combined system include the capability to independently manipulate the electric polarization of the ferroelectrics as well as the local SPR wavelengths of the nanoparticles in order to achieve synergistic energetic conditions at their interface to optimize the injection of the hot charge carriers. In addition, better charge separation can be achieved in this combined system in which the domain walls of the ferroelectrics can serve as the charge trapping centers or as reactive surface sites (Qin et al., 2007; Sakar et al., 2016; Zhu et al., 2018). Furthermore, all potential advantages of an interfaced metal-semiconductor system are inherited, e.g., enhanced optical excitation of the semiconductor due to the local field effect (Ma et al., 2014b). The underlying mechanism for the enhanced charge injection involves a tuning of the band bending and the Schottky barrier height at the semiconductor-metal interface, which has also represented a long-standing

problem in the physics and chemistry of electronic materials. The impacts of the ferroelectric polarization and the composition of the metallic particles are described below, together with recent experimental results that have demonstrated that the hot charge carriers can be injected into ferroelectrics (Atwater and Polman, 2010; Grinberg et al., 2013).

MODELS OF METAL-FERROELECTRIC INTERFACES AND THE SCHOTTKY BARRIER

Currently very little is known, either theoretically or experimentally, about the hot charge injection from plasmonic particles to ferroelectric materials from a perspective of light-driven catalysis, e.g., such as for water splitting reactions. Investigations of the interfaces between metals and ferroelectrics have focused on their potential applications in solid-state photovoltaic devices, wherein the ferroelectric both functions as the light-absorbing component as well as the underlying driving force for charge separation. A model of the electronic structure and band bending at semiconductor surfaces interfaced with a metal is described first, followed by the impact of the ferroelectric polarization at this interface. This is critical to understanding the experimental photocurrents and photocatalytic properties in recent investigations.

Schottky Barrier Height at Semiconductor-Metal Interfaces

At the surface of a crystalline semiconductor, the periodic pattern of chemical bonds is interrupted and leads to the formation of dangling bonds from the incomplete atomic coordination environments. These dangling bonds can be responsible for the formation of localized surface states with energies that fall within the band gap of the semiconductor. An inversion layer, or depletion region, is formed near the surfaces, which results from a flow of its majority carriers, i.e., either *n*-type or *p*-type, either toward or away from the surfaces to fill the surface states and reach electrochemical equilibrium (Sze and Ng, 2006). The interface states are filled up to the charge neutrality level (CNL), above which these states are empty (Tersoff, 1986; Robertson and Chen, 1999). The charge transfer between the surface states and the bulk of the semiconductor causes the bands to bend at the interface (McCaldin et al., 1976; Spicer et al., 1980).

When a semiconductor is in contact with a metal, the difference in their work functions causes electrons to transfer between them. For example, if the metal work function is larger than that of the semiconductor, the electrons will flow from

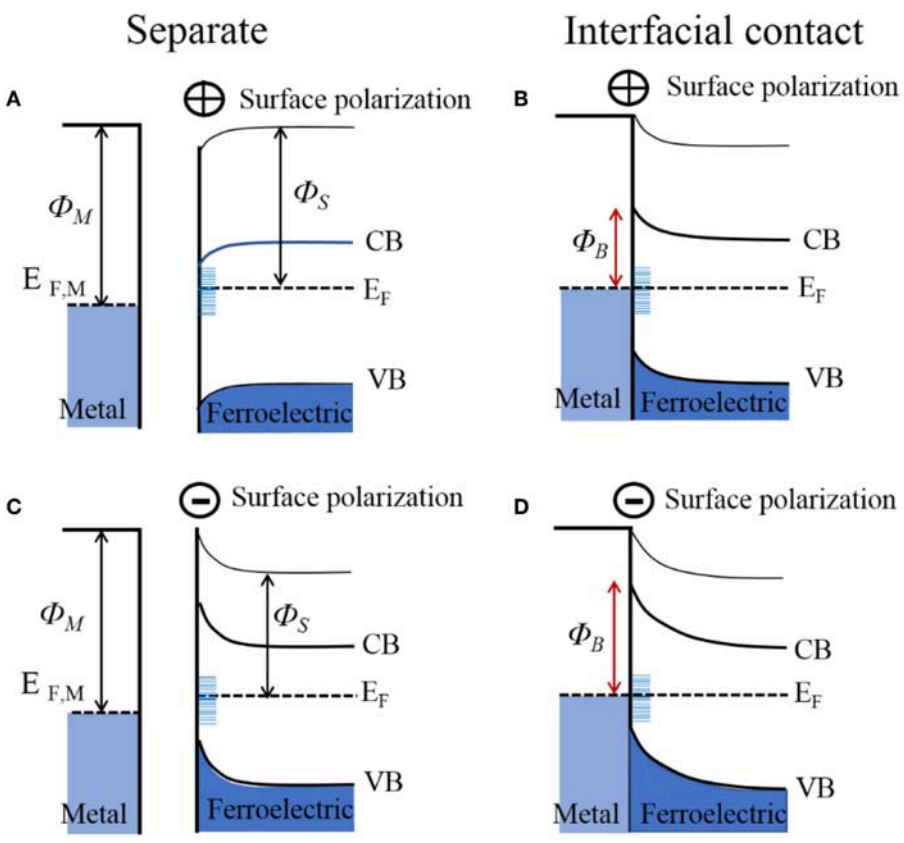

FIGURE 6 | Electronic energy levels of an *n*-type ferroelectric for its surfaces that are positively charged (upper; **A,B**) and negatively charged (lower; **C,D**), shown before and after interfacial contact with a metal. Φ_M, metal work function; Φ_S, semiconductor work function; Φ_B, Schottky barrier height; E_F, Fermi level; CB, conduction band; VB, valence band.

the semiconductor to the metal until the Fermi levels have equilibrated. Electron transfer from semiconductor to the metal (for $\Phi_M > \Phi_{SC}$) or from metal to semiconductor (for $\Phi_M < \Phi_{SC}$) will cause band bending upward or downward, respectively, at their interfacial region (Zhang and Yates, 2012). For example, **Figure 5** shows an example whereby Φ_M is larger than Φ_{SC} and upward band-bending has resulted. This junction, known as a Schottky junction, represents a potential energy barrier that manifests as a rectifying electrical contact between the metal and the semiconductor, i.e., the flow of electrons in this case occurs most easily from the semiconductor to the metal. The energy barrier for electrons to flow in the reverse direction from the metal and into the conduction band (CB) of the semiconductor is known as the Schottky barrier (Φ_B). The flow or injection of electrons across this barrier depends in an exponential manner on the height of the Schottky barrier and is thus one of the most critical properties of a metal-semiconductor interface. In the simplest case, the energetic height of the Schottky barrier follows the Schottky-Mott relationship, which for an *n*-type semiconductor is given by Equation (1):

$$\Phi_B = \Phi_M - \chi_{SC} \tag{1}$$

where χ_{SC} is semiconductor electron affinity. It can be taken that the voltage drop arising from the formation of an interface dipole, i.e., Δ_0, is considered to be zero for this simplified case. The band bending at the surface of the semiconductor functions as the driving force for charge separation, and is given by the built-in potential (V_{bi}) in Equation (2):

$$V_{bi} = \Phi_B - (E_C - E_{F,SC}) \tag{2}$$

where $E_{F,SC}$ is the Fermi level of the semiconductor, and E_C is the conduction band edge of the semiconductor. Hot electron injection will be favored when $\Phi_{SC} < \Phi_M$ and the semiconductor bands bend up, while hot hole injection will be favored when $\Phi_{SC} > \Phi_M$ and the bands bend down. Thus, in both cases, the unidirectional injection of hot carriers across the interface leads to their efficient separation via a drift current in the semiconductor that flows away from the metallic nanoparticle. Note that in this review article, the focus is exclusively on the injection of hot electrons, which are relatively better characterized and typically have high mobility. For a *p*-type semiconductor, the bands typically bend downward due to its low-lying Fermi level. In this case, the potential barrier (V_{bi}) will be nil and instead an accumulation layer will form. Thus, the interfaces between plasmonic metals and *p*-type semiconductors will not be favorable for hot electron injection. Hence, only *n*-type semiconductors are covered in this review.

With rare exceptions, however, the Schottky barrier height has been found to show a relatively weak correlation with the metal work function as predicted by Equation 1 (Tung, 2000; Dimoulas et al., 2006). The cause of this is known as Fermi level pinning and is driven by a large concentration of mid-gap states that form at the metal-semiconductor interface arising from metal-induced gap states, disorder-induced gap states, defect states, and other surface defects. These states become filled by charge flow from the semiconductor and result in an interface dipole and a voltage drop across the interface. Different models have been proposed to account for this phenomenon, including the most popular Cowley-Sze model, which takes semiconductor surface states and Fermi level pinning into consideration. The revised form of the Schottky barrier height is defined by the following Equation (3) (Bardeen, 1947; Cowley and Sze, 1965):

$$\Phi_B = S(\Phi_M - \chi_{SC}) + (1 - S)(E_g - \Phi_0) \tag{3}$$

Here, E_g represents the band gap of the semiconductor; Φ_0 is the energy difference between the CNL and the valence band edge of the semiconductor at the surface, and *S* is the pinning parameter depending on the surface state density of the semiconductor. Practically, *S* has been found to fall between 0 and 1, where "0" stands for maximum and "1" stands for minimum pinning, respectively (Cohen, 1979). Monch empirically found that the pinning parameter, *S*, follows a linear approximation (Mönch, 1987):

$$S = 1/(1 + 0.1(\varepsilon - 1)^2) \tag{4}$$

where the dielectric constant ε is taken as the square of the refractive index of the semiconductor. For ionic semiconductors such as ZnO or ZnSe, *S* approaches 1 (Schottky limit) and the Cowley–Sze model reduces to Schottky–Mott model (Equation 1). For covalent semiconductors, *S* approaches 0 (Bardeen limit). When the interface state density approaches infinity, then the Cowley-Sze model takes the form of Equation (5):

$$\Phi_B = E_g - \Phi_0 \tag{5}$$

In this case, the Fermi level of the metal is pinned to CNL, and hence the Schottky barrier height is independent of the metal work function (Bardeen, 1947; Kurtin et al., 1969). This relationship was found by Dimoulas et al. to be consistently followed at metal/Ge interfaces (Dimoulas et al., 2006). However, the Schottky barrier height is known to be intricately dependent upon the specific interfacial bonding, i.e., sensitive to surface orientation, surface relaxation, and other factors (Tung, 2014). It has been reported in many cases to typically vary by amounts of ± 0.2 to 0.8 eV for even the same metal and semiconductor combinations. Thus, the formation and height of the Schottky barrier must be investigated for each specific metal-semiconductor combination and under identical conditions of their preparation.

Ferroelectric Control Over the Schottky Barrier Height

At metal-ferroelectric interfaces, the spontaneous surface polarization must also be accounted for when considering the band bending and Schottky barrier height. This is a consequence of the fact that the ferroelectric polarization at the surface will establish an additional interface potential and, depending on its orientation, will modify the surface binding energies and Schottky barier height with the metal. The effect of the surface polarization has been observed in the photocatalytic reactivity of multi-domain ferroelectrics, notably including

$PbTiO_3$, $Pb(Ti_{1-x}Zr_x)O_3$ (PZT), $BaTiO_3$, and $BaBiFeO_3$ (Inoue et al., 1989; Apostol et al., 2013). In these cases, the different orientations of the surface polarization, e.g., represented as P(+), P(−), or P(0), can cause light-driven reduction reactions at P(+) surfaces and oxidation reactions at P(−) surfaces, as shown in **Figures 4F,G** for $BaTiO_3$ (Schultz et al., 2011). When P(−) and P(+) surface polarizations occur at the surface of the ferroelectric, the interface dipole leads to a negative and positive impact on the band bending, respectively, illustrated in **Figures 6A,C**. Thus, with bandgap excitation of electron-hole pairs in the depletion region, the electrons are separated and driven to P(+) surfaces and the holes to the P(−) surfaces. For a ferroelectric in contact with a metal, the difference in the work function of the metal and semiconductor will equilibrate with the flow of charged carriers between them, and either strengthen or weaken the surface ferroelectric polarization, thus modifying the Schottky barrier height. Shown in **Figures 6B,D** is the example of a metal in interfacial contact with the P(+) and P(−) of a ferroelectric, e.g., Au in contact with PZT. Pintilie and Alexe quantitatively expressed the band-bending of ferroelectric semiconductors by introducing the surface polarization as a sheet of surface charge located at a finite distance from the electrode interface, with a modified built-in potential V_{bi}' at the ferroelectric surface given by Equation (6) (Jones et al., 2008):

$$V_{\mathrm{bi}}' = V_{bi} \pm P\delta/\varepsilon_0\varepsilon_{\mathrm{st}} \tag{6}$$

where P is the component of the polarization that is perpendicular to the sample surface, ε_0 is the permittivity of free space, ε_{st} is the low-frequency (or static) dielectric constant, and δ is the interface thickness layer which is typically assumed to be on the order of a single unit cell. This gives a quantitative estimate of the degree of band-bending at polarized ferroelectric surfaces, as has been confirmed by recent investigations on PZT, $BaTiO_3$, and $BiFeO_3$ (Pintilie and Alexe, 2005; Pintilie et al., 2005, 2014). For *n*-type ferroelectric semiconductors interfaced to metals, the P(−) polarized surface will cause the Schottky barrier to be higher as compared to the unpolarized P(0), shown in **Figure 6D**. Correspondingly, the P(+) polarized surfaces will serve to either lower or completely reverse the Schottky barrier, shown in **Figure 6B**. Whether the bands on the P(+) surface bend downward or upward depends on the magnitude of the

band-bending introduced by the spontaneous polarization, as determined by Equation (6). However, the surface polarization of many strong ferroelectrics can have a predominating impact, e.g., changes to the Schottky barrier heights of up to ∼1.1 eV for $BaTiO_3$ and up to ∼0.9 eV for PZT (Pintilie et al., 2014).

EXPERIMENTAL INVESTIGATIONS OF SCHOTTKY BARRIER HEIGHTS AND BAND BENDING AT FERROELECTRIC-METAL INTERFACE

Manipulation of Interfacial Electrical Transport and Charge Separation

The strong polarization-dependent manipulation of the Schottky barrier at ferroelectric-metal interfaces has been investigated in several recent studies, such as has been typically characterized by current-voltage (I–V) curves or X-ray photoelectron spectroscopy (Yang et al., 2010; Alexe and Hesse, 2011; Cao et al., 2012a). For example, recent studies have focused on their rectifying electrical behavior, such as to yield switchable diodes, or in facilitating charge separation and transport in solar cells with the ferroelectric as the light absorber. It has been shown that by reversing the polarization of the ferroelectric the Schottky barrier can be reversed and induce a switchable diode behavior at the interface (Wang et al., 2011). For example, Wang et al. characterized the interfacial Schottky barrier between platinum/$BiFeO_3$ (BFO) using current-voltage hysteresis, shown in **Figure 7A**. A thin film of ferroelectric BFO was grown over a $SrTiO_3$ (001) (SRO) single crystal and ∼100 μm platinum dots were deposited over the BFO film. The Pt and SRO acted as the two electrodes to measure the electrical current and exhibited distinct hysteresis behavior that indicated large resistive switching between −6 and +6 V. Both the positive and negative polarization were characterized independently. First, the SRO/BFO/Pt heterojunction was polarized to induce upward and downward polarization, shown in **Figure 7B** with the two polarization directions. The I-V curves show that for the virgin state without poling, the current is very small and increases linearly with voltage at both positive and negative bias. For the polarized-up state, the current increases exponentially with the positive applied voltage, i.e., SRO as the anode and Pt as the cathode, but increases much more slowly with negative applied voltage. This shows a forward diode-like behavior. For the polarized down state, the current shows a reverse diode behavior. This switchable diode behavior demonstrated that the Schottky barriers between the *n*-type semiconductor ferroelectric BFO and metallic electrodes have been changed by the polarization switching. Changes in the interfacial band structure with the two different polarizations for the SRO/BFO/Pt sandwich are illustrated in **Figure 7B**. In the virgin state, the Schottky barrier heights at both interfaces are sufficiently large owing to the larger

work functions of the SRO and Pt contacts compared to that for BFO. This is consistent with the very small currents. For positive polarization, the Schottky barrier becomes reversed on the Pt side, forming an Ohmic contact, with the cell behaving like a forward diode as shown in **Figure 7B** (middle). For the opposite ferroelectric polarization, the Schottky barrier becomes reversed to form an Ohmic contact on the SRO side, and the cell behaves like a reverse diode [**Figure 7B** (right)]. These observations are consistent with Equation 6 and demonstrate the modulation of the Schottky barrier using the ferroelectric polarization at the interfaces.

Ferroelectric-based solar cells have been the subject of many recent investigations owing to their switchable photocurrents and higher-than-bandgap open circuit photovoltages, including for $BiFeO_3$, PZT, $BaTiO_3$, and Bi_2FeCrO_6 (Moubah et al., 2012; Zenkevich et al., 2014; Zheng et al., 2014; Nechache et al., 2015). For example, modification of the Schottky barrier height and depletion region at a ferroelectric-metal interface were investigated by Chen et al. and found to achieve solar cells with power conversion efficiencies of up to 6.7% and photocurrents of $\sim$19 mA cm^{-2} on electrically-poled samples (Chen et al., 2015). The ferroelectric methylammonium lead trihalide ($MAPbX_3$) (FE-MAP) was used with a configuration of TiO_2/FE-MAP/Au, shown in **Figure 8A**. Electric poling of $\pm$5 V DC voltage was used to switch the domain alignments (**Figure 8B**). The proposed band structure of all three subunits of the solar cell is illustrated in **Figures 8C–E**. In the pristine state, i.e., no poling, a Schottky barrier forms at the ferroelectric/Au interface owing to the greater work function of Au. At the other side, a compact TiO_2 thin layer serves as the *n*-type electron transport layer (ETL). The bands in $MAPbX_3$ are bent downward and upward at the TiO_2/ferroelectric and the ferroelectric/Au interfaces, respectively, shown in **Figure 8C**. Upon irradiation of the cell the two depletion regions drive the separation of the electron-hole pairs, with larger depletion regions favoring a more efficient charge separation. With no electrical poling, the solar cell gives a power conversion efficiency of only $\sim$0.09%, a photocurrent of 1.47 mA cm^{-2} and an open circuit photovoltage of 0.37 V. However, a positive electric poling of the ferroelectric at +0.2 V leads to significantly enhanced band bending, i.e., a higher Schottky barrier height at the ferroelectric-Au interface that widens the depletion region for more efficient charge separation, illustrated in **Figure 8D**. This gives a dramatically higher power conversion efficiency of 6.7%, a photocurrent of 18.5 mA cm^{-2} and an open circuit voltage of 0.72 V. Thus, the direction and magnitude of the surface polarization can be effectively used to manipulate the interfacial barrier heights, which for solar cell designs can yield a more efficient charge separation and higher open circuit voltage.

Facilitating Hot Carrier Extraction Using Ferroelectrics

While there are many recent investigations into the utility of ferroelectric-metal interfaces for charge separation in solar cells, currently very few studies have focused on the effects of the photo-excitation of the localized SPR of the metallic nanoparticles. The excitation of the localized SPR can lead to the efficient absorption of photons and the generation of hot carriers with sufficiently high energies compared to the Schottky barrier in order to facilitate injection. For example, Schottky barrier heights for several metal-ferroelectric combinations have been measured to fall within the range of $\sim$0.1 to 0.9 eV, such as those found for PZT-Au interfaces of $\sim$0.3 eV and $BaTiO_3$-Cu interfaces at 0.2 eV (Pintilie et al., 2014). Thus, the excitation of the localized SPR and the generation of hot carriers at energies only a few hundred millielectron volts above the Fermi level are sufficient for injection over the Schottky barrier and into the ferroelectric in many cases. The critical role of the barrier height in the injection of electrons from metals into semiconductors was first modeled by Fowler in the early 1900s, as given in Equation (7) (Fowler, 1931):

$$Y_{Fow}(h\nu) \approx \frac{1}{8E_F}\frac{(h\nu - \phi_b)^2}{h\nu} \tag{7}$$

where Y_{Fow} is the Fowler yield, h is Planck's constant; ν is the incident light frequency; ϕ_B is the barrier height at the interface, and E_F is the Fermi energy of the metal. This is a semiclassical model with the basic assumption that the kinetic energy of the hot electrons normal to the barrier must be greater than the barrier height. This equation shows that injection of hot carriers is proportional to the square of the barrier height and can be manipulated by interfacial ferroelectric polarization. Theoretical calculations have been used to determine the optimal energetic structure at the interface and have suggested efficiency limits of about 1–10% under the most optimistic conditions (Leenheer et al., 2014). Further studies, however, which take into account anisotropic particle shapes that impact the electron-phonon scattering events and diffuse reflections, have shown that these factors can significantly increase the hot electron injection efficiency up to a higher efficiency limit of about 20% (Blandre et al., 2018), which is a factor of four greater than Fowler's limiting efficiency. Only a few recent investigations have reported the use of metal-ferroelectric interfaces to further enhance the hot carrier injection efficiency, as described below.

Hot Charge Injection at Buried Nano-Au/PZT Interfaces

The earliest research efforts focused on extracting hot charge carriers using non-ferroelectric semiconducting oxides, especially TiO_2, as described above. Despite the intense surge of interest in this area, the resulting efficiencies are usually very low, and a detailed understanding of the hot carrier process has remained unclear. Ferroelectric-interfaced plasmonic nanoparticles represent a relatively unexplored and fertile research ground, wherein by contrast, the ferroelectric polarization can be used to systematically manipulate the Schottky barrier height and the extent of the depletion region as a function of the ferroelectric surface polarization and applied poling field. In the first reported study by Wang et al., solar cells were constructed using a ferroelectric $Pb(Ti_{1-x}Zr_x)O_3$ (PZT) film that was patterned with an array of Au nanoparticles with lateral dimensions of 270 $\times$ 270 nm^2 and a thickness of $\sim$60 nm.

For this relatively large size of Au nanoparticles, the radiative re-emission of photons significantly predominates compared to hot carrier generation, as described in the Background section. Further, the distribution of hot carriers is calculated to be only on the order of a few tenths of an eV different than the Fermi energy. However, prior studies have found the Schottky barrier of PZT-Au interfaces to be as low as ∼0.1 eV (Pintilie et al., 2014). The photocurrent was still boosted by nearly an order of magnitude when aligning the polarization direction in PZT and reversing the Schottky barrier with the electrolyte. This increased the external quantum efficiency from ∼0.1 to 0.3% at 600 nm, which is at significantly lower energies than the PZT band gap of ∼3.6 eV.

Broadband transient absorbance (TA) measurements were used to characterize the hot charge transfer between the Au nanoparticles and PZT. Femtosecond optical pulses centered at a wavelength of 400 nm were used for excitation, i.e., at photon energies below the PZT band gap. The nano-Au array on ITO/glass showed two distinct, spectrally well-separated components in the transient spectra, shown in **Figures 9A,D**: one increased transmission peak (ΔT/T, or decreased absorption peak) at 1.65 eV and the other reduced transmission peak at 2.5 eV. The former was linked to the photoinduced changes in the localized SPR absorption at 1.5 eV, and the latter was attributed to the bulk-like response of Au, governed by the photoinduced changes in the density of states for the d-band to Fermi level transition. A reduced transmission indicates the increased density of states after photo-excitation.

For devices of ITO/nano-Au/PZT and ITO/PZT/nano-Au/PZT, shown in **Figures 9B,C**, the time evolution of the low energy (1.3–2 eV) and the high energy (2.0–2.8 eV) responses were analyzed (**Figures 9E,F**). The relaxation dynamics of the low-energy part are similar for all three devices and can all be fitted with a single exponential decay. However, the high energy component shows a non-exponential relaxation, with the following trend in rates $k_{ITO/nano-Au/PZT} > k_{ITO/PZT/nano-Au/PZT} > k_{ITO/nano-Au}$. These results suggested that: (1) there are additional decay channels for the relaxation of the photo-excited density of states for nano-Au/PZT, and (2) nano-Au to PZT charge transfer yielded the accelerated relaxation of the bulk-like Au density of states. However, the photoinduced transmission on the poled ITO/PZT/nano-Au/PZT samples, i.e., at fields of +10 and −10 V, resulted in only minor changes in the relaxation dynamics. The conclusion suggested that the polarization at the PZT surface had little impact on the band bending and charge injection efficiency, in

surprising contradiction to prior studies on ferroelectric-based solar cells. Independent characterization of the Schottky barrier heights could help elucidate their role in impacting the injection of hot carriers.

Hot Charge Injection From Au Nanoparticles to $PbTiO_3$: Photochemical Reactions

Direct evidence of hot carrier injection from metal to ferroelectric $PbTiO_3$ (PT) particles was first reported by Ortiz et al. via the photochemical reduction of Pt on composite AuNRs/PT particles (Ortiz et al., 2018). The AuNR particles were synthesized as long nanorods with high aspect ratios of ∼5:1 and impregnated onto micron-sized ferroelectric PT particles. The AuNRs/PT particles were suspended in an aqueous solution of H_2PtCl_6 with methanol as a sacrificial agent. The light-driven reaction proceeds by the photochemical reduction of the Pt(IV) cations in solution to form Pt(s) islands on the PT surfaces, together with the concomitant oxidation of methanol to carbon dioxide. The AuNRs/PT particles were irradiated by photons from 976 nm near IR light (NIR, 2.0 W/cm^2), thus exciting the localized SPR and excluding the direct bandgap excitation of the ferroelectric PT. After irradiation under 976 nm light for 30 min, the AuNR/PT particles were then characterized by SEM to exhibit photochemically deposited Pt islands over the surfaces. The Pt islands were localized within a region about <100 nm from the AuNRs on the PT surfaces, as shown in **Figure 10A** (regions 1 and 2, see **Figure 10C**) and confirmed using EDX scans. As a control, no Pt islands were found to grow on the ferroelectric PT particles in the absence of AuNRs (**Figure 10B**). These results demonstrated that hot carrier injection occurs from the AuNR to ferroelectric particles, which drove the photochemical reduction of the Pt at the surfaces.

As $PbTiO_3$ is a known photocatalyst for water reduction when excited by bandgap light, it is anticipated that the hot carrier injection at the Au-PT interface should also lead to the light-driven production of molecular hydrogen at its surfaces, but with the use of photons lower than bandgap energies. In a study by Wang et al., the first example of water reduction to molecular hydrogen driven by hot carrier injection was demonstrated for the combination of Pt-end-capped AuNRs, i.e., Pt-AuNRs, and ferroelectric PT. Similar conditions were employed for the photochemical deposition of Pt, which involved

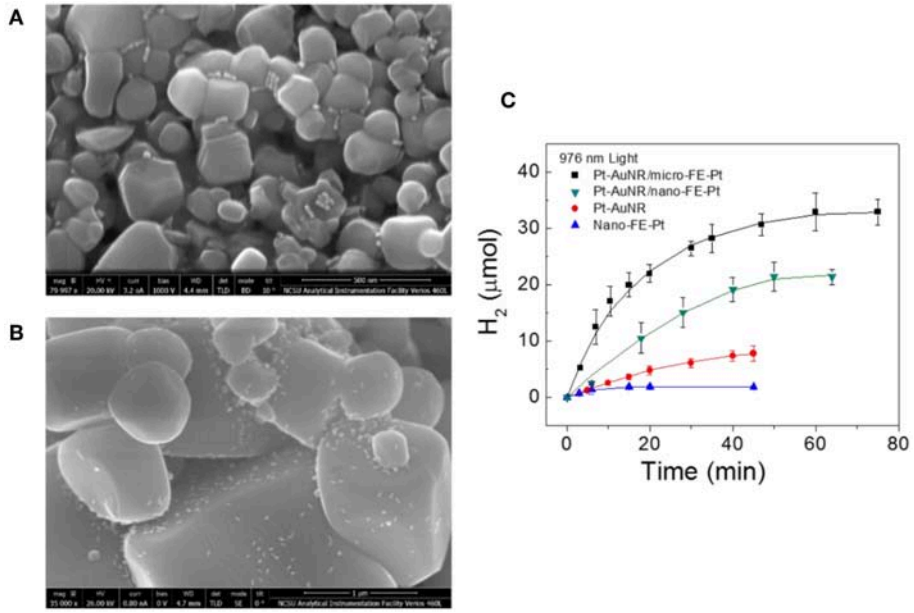

FIGURE 11 | SEM images of ferroelectric PT particles impregnated with Pt-end-capped AuNRs, for the **(A)** nano-PT particles with dimensions of ∼125 nm and for the **(B)** micro-PT particles with dimensions of ∼1 μm. The AuNRs appear as white dots, with scale bars of 500 nm. **(C)** Hydrogen production vs. time for the Pt-AuNR/micro-FE-Pt and Pt-AuNR/nano-FE-Pt particles under near-IR irradiation. irradiating the samples with near IR light at a wavelength of 976 nm and methanol as a sacrificial reagent. For the ferroelectric PT, both micron-sized (micro-PT; average diameter of ∼1 μm) and nanosized (nano-PT; average diameter of ∼125 nm) particles were used to determine the relative impacts of the surface area and loading with AuNRs. Shown in **Figures 11A,B**, the SEM images show that the AuNRs are distributed evenly over the nano-PT and micro-PT surfaces. The average loading of the AuNRs on the particles were ∼0.60 (AuNRs:PT) for nano-PT and ∼280 for 1 μm micro-PT. As the AuNRs are relatively sparsely deposited on the PT surfaces, the net "effective PT surface area," i.e., the area beneath the AuNR and in its vicinity that the hot electrons can diffuse (∼100 nm), is nearly a constant, enabling a direct comparison of the hydrogen production rates. Using sub-bandgap photons with a wavelength of 976 nm and a power density of 2.0 W cm^{-1}, molecular hydrogen was produced with the AuNRs/PT particles at initial rates of 1.41 ± 0.40 μmol H_2 min^{-1} for nano-PT particles and 0.88 ± 0.27 μmol H_2 min^{-1} for micro-PT particles, as shown in **Figure 11C**. As controls, the ferroelectric PT particles alone showed little detectable activity, while the Pt-end-capped AuNRs alone exhibited a low initial photocatalytic rate of ∼0.25 μmol H_2 min^{-1}. For equal amounts of plasmonic Au nanorods, the initial photocatalytic rates for hydrogen production were thus increased by a factor of ∼5.6 when interfaced with the ferroelectric PT particles. A photon efficiency of up to ∼0.28% for near-infrared light was measured, significantly higher than for previously reported metal-semiconductor combinations (0.01–0.1%) (Pu et al., 2013; Robatjazi et al., 2015).

The photocatalysis experiments have demonstrated that AuNRs can inject hot electrons into the ferroelectric particles upon irradiation of their localized SPR, and that the injected electrons are driving reduction reactions at the ferroelectric surfaces. It is notable that the interfaces between the plasmonic and the ferroelectric particles were not controlled in terms of positive or negative surface polarization. The natural randomization of the surface sites over which the AuNRs are deposited will lead to these making interfacial contact over a fraction of surfaces with suitable polarization directions, which favors hot electron injection over a Schottky barrier, i.e., the P(+) surfaces. Yet, a significant enhancement of the photocatalytic rates is found.

To further probe how the SPR-generated hot electrons are involved in the photocatalytic reaction, the initial hydrogen production rates were measured as a function of the near-IR irradiation power, plotted in **Figure 12**. Interestingly, a non-linearly increasing rate ∼ power relationship is observed, in contrast to the linear relationship for the same reaction usually observed on metal-only particle surfaces. The non-linear relationship is possibly introduced during the charge injection process: only when the hot electrons have an energy higher than the interfacial energy barrier can they be transferred to ferroelectric particles and participate in the chemical reaction. The photo-excited electron energy, i.e., shown in **Figure 1C**, follows Fermi-Dirac distribution:

$$f(E) = \frac{1}{\exp[(E - E_F)/k_B T] + 1} \tag{8}$$

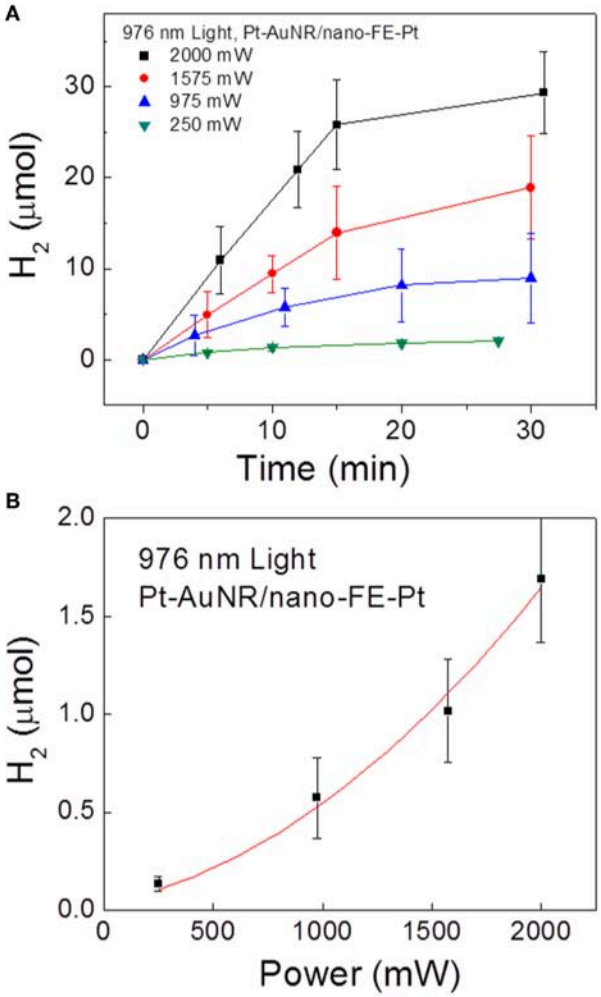

FIGURE 12 | Photocatalytic H_2 gas production on Pt-AuNR/nano-PT particles under 976 nm light at power densities of 250, 975, 1,575, and 2,000 mW. **(A)** Measured H_2 production vs. time at the different irradiation powers, and **(B)** initial reaction rate vs. irradiation power. where f is the probability an energy level is filled, E_F is the Fermi level, k_B is the Boltzmann constant, and T is the effective temperature. Given that recent models show that the effective electron temperature increases linearly with respect to the fluency of the photon flux, the total number of "high energy" hot electrons exceeding a large threshold value increases non-linearly, as described previously (Manjavacas et al., 2014). This is consistent with the observed non-linear reaction rate ~ irradiation power relationship.

In these studies using Au nanoparticle interfaced with ferroelectrics, the Au nanoparticles were utilized to generate hot electrons because of their efficiency in harvesting solar energies down into the infrared wavelengths (Hartland, 2011; Ye et al., 2012; Jing et al., 2014; Kakekhani and Ismail-Beigi, 2016). The ferroelectrics, PT and PZT, were selected owing to their large and stable ferroelectric polarization, and they have been investigated in several prior studies that demonstrated a strong polarization-dependent modulation of the Schottky barrier height with the surface Au nanoparticles. For example, the ferroelectric PT has been characterized as an *n*-type semiconductor with a bandgap of ~2.7 eV (Reddy and Parida, 2013) and an electron affinity χ of ~3.5 eV (Pintilie et al., 2008; Li et al., 2012; Suriyaprakash et al., 2017). When Au (work function $\Phi_M = 5.1$ eV) is in contact with a normal semiconductor with a similar electron affinity as that of PT, the semiconductor bands bend upward at their surface, leading to a low-energy Schottky barrier on the order of ~0.1–0.3 eV (Zhang and Yates, 2012; Pintilie et al., 2014). On the P(+) oriented surfaces of PT, the band bending is decreased or even reversed, while on the P(–) surfaces of PT the band bending will be further increased. It is conjectured that the lower energy barrier would favor the charge injection from Au to ferroelectric particles, leading to a higher efficiency in hot charge injection. In addition, it is also proposed that the surface polarization in the ferroelectric particles could trap the injected electrons at the domain boundaries (Wu et al., 2012; Sluka et al., 2013), which prevents them from flowing back to the metal (being quenched) and extending their lifetimes.

CONCLUSIONS

In summary, the synergistic combination of plasmonic and ferroelectric particles represents a novel pathway for harnessing the efficient production and injection of hot carriers generated by the excitation of localized SPR. The energetic distribution of hot carrier generation in plasmonic nanoparticles is a sensitive function of the particle sizes and chemical compositions, and under optimal conditions, can result in the generation of hot carriers with energies that are from ~0.1 to 1.5 eV above and below the Fermi level. Concomitantly, a detailed understanding of the energetic structure at metal-ferroelectric interfaces is emerging and demonstrating that the modulation of the Schottky barrier height and band bending can be manipulated by the ferroelectric surface polarization. The Schottky barrier height, for example, typically varies from ~0.1 to 0.4 eV for common metal-ferroelectric interfaces and is thereby compatible with the energetic distribution of hot carrier generation in plasmonic nanoparticles. These synergistic features of their electronic properties have resulted in several novel studies involving the use of metal-ferroelectric interfaces for investigating switchable diode behavior as well as solar cells with high power conversion efficiencies. Most promisingly, these results show that by combining plasmonic and ferroelectric particles, novel photoelectrochemical and photocatalyst designs are possible for solar energy conversion.

FUTURE PROSPECTS

Currently, the field of ferroelectric-interfaced plasmonic nanoparticles is still in its infancy, with only a very limited number of studies in this novel direction. Future

investigations will aid in more deeply understanding the underlying mechanisms of hot electron generation and injection at metal-ferroelectric interfaces, designing more optimal integrated systems, and using these catalysts to efficiently drive photocatalytic reactions at the surfaces using solar energy. Among the prominent current challenges, the quantitative relationship between the charge injection/reaction rate and the ferroelectric polarization needs to be elucidated, such as via characterization of the band banding using I–V curves and X-ray photoelectron spectroscopy (XPS) (Chen and Klein, 2012). Second, the reactive sites, including both reductive and oxidative sites, need to be mapped out over these integrated systems. Third, the ferroelectric-plasmonic systems can be further tuned through changes in composition, e.g., in order to tune the bandgap of the ferroelectric or its surface polarization to facilitate changes in interfacial band-bending and charge injection. Fourth, the exposed facets of the ferroelectrics may play an important role in the Schottky barrier height. For example, facet-dependent photocatalytic activity is a common feature of photocatalyst particles, such as what has been reported for Cu_2O (Yuan et al., 2016). Controlling the anisotropic growth of ferroelectric particles can also serve as a means in tuning the photocatalytic activity. Finally, alternative plasmonic materials can also be investigated which are less expensive, such as silver or copper. It can be anticipated that the optimization of interfacial metal-ferroelectric systems will offer remarkable new capabilities to achieve high solar conversion efficiencies at low-energy wavelengths, i.e., extending into the infrared wavelengths, and which is not possible in conventional semiconductor-based systems.

A Holistic Approach to Model the Kinetics of Photocatalytic Reactions

*Jonathan Z. Bloh**

DECHEMA-Forschungsinstitut, Frankfurt am Main, Germany

Understanding and modeling kinetics is an essential part of the optimization and implementation of chemical reactions. In the case of photocatalytic reactions this is mostly done one-dimensionally, i.e., only considering the effect of one parameter at the same time. However, as discussed in this study, many of the relevant reaction parameters have mutual interdependencies that call for a holistic multi-dimensional approach to accurately model and understand their influence. Such an approach is described herein, and all the relevant equations given so that researchers can readily implement it to analyze and model their reactions.

Keywords: photocatalysis, kinetic analysis, high light intensity, temperature effects, heterogeneous photocatalysis, molecular photocatalysis, photoredox catalysis

1. INTRODUCTION

The importance of photocatalysis in fundamental and applied science has expanded tremendously over the last decades (Schneider et al., 2014; Augugliaro et al., 2015; Balzani et al., 2015; Romero and Nicewicz, 2016). Next to applications of heterogeneous photocatalysis in the removal of air pollutants (Ballari and Brouwers, 2013; Patzsch et al., 2018) and waste-water treatment (Alfano et al., 2000; Malato et al., 2009), a variety of applications in the field of organic synthesis (Friedmann et al., 2016; Bloh and Marschall, 2017) have emerged, particularly using molecular photoredox catalysts (Zeitler, 2009; Romero and Nicewicz, 2016).

In the latter field, this interest is in part due to the need of more efficient, sustainable and eco-friendly reactions as photons are essentially traceless reagents, but also partly due to the emergence of LEDs as very affordable and efficient high-power light sources which have made it very easy to perform photocatalytic reactions with appreciable rates. However, if these reactions are to be implemented in industrially relevant processes, they need to be both efficient and productive, i.e., and have both high quantum yield and reaction rates at the same time. This requires a precise knowledge about kinetics and the influence of all relevant reaction parameters. Yet, relatively little is known about the behavior of these reactions at the very high photon fluxes required to reach molar conversions within hours. Generally, at least for heterogeneous reactions, the observation is that at some point the response of the reaction rate to the light intensity becomes non-linear and yields increasingly diminishing returns (Dillert et al., 2013; Dilla et al., 2017; Deng, 2018).

Kinetic modeling and analysis of heterogeneous photocatalysis is mostly based on relatively simple Langmuir-Hinshelwood type kinetics, with linear or mixed linear and square root dependence on the light intensity (Mills et al., 2015; Camera-Roda et al., 2016). The major problem with this approach is that using this rate law, with an average light intensity, is only a valid approach if the reaction rate scales linearly with the light intensity at every point in the reaction vessel. Considering the distribution of the light intensity and absorption inside the reactor and calculating local reaction rates to integrate into a global average, is only done in a select few and very specific cases (Camera-Roda et al., 2016; Grčić and Li Puma, 2017).

Bloh JZ (2019) A Holistic Approach to Model the Kinetics of Photocatalytic Reactions. Front. Chem. 7:128. doi: 10.3389/fchem.2019.00128

In photoredox catalysis, kinetic analysis is almost exclusively based on fluorescence methods such as Stern-Volmer analysis (Arias-Rotondo and McCusker, 2016; Pitre et al., 2016).

As shown recently, most reaction parameters show a mutual interdependence on each other and therefore cannot be properly studied in one-dimensional approaches, where just one parameter is varied (Burek et al., 2019). Instead, a holistic approach is needed to take the light intensity and distribution, catalyst and substrate concentration and the temperature into account at the same time. This contribution describes this approach in detail.

2. HETEROGENEOUS PHOTOCATALYTIC REACTIONS

The model used herein to describe heterogeneous photocatalytic reactions is based on three elementary steps (*R*1-3), which are illustrated in **Figure 1**. While in the overall reactions, reduction and oxidation always have to take place, we only consider one of those half-reactions, whichever one is slower and rate-determining. The other half-reaction is consequently assumed to be much faster and has no effect on the overall observed reaction rate. It should also be considered that contrary to molecular systems, reduction and oxidation neither have to take place in a set sequence, nor necessarily at the same time, as the photocatalyst particle has a certain capacity to store excess charges over short time-frames (Mohamed et al., 2011).

The first reaction step (*R*1, Equation 1) is the generation of reactive surface sites (c_R^*) which are essentially charge carriers (electrons or holes, depending on whichever reaction is rate-limiting) trapped at surface sites. The rate of this reaction is dependent on the local volumetric rate of photon absorption (LVRPA, L_p^a), the quantum yield (ϕ) and is normalized to the fraction of available surface trap sites that are not already filled. This is based on the assumption that a trap already filled cannot take up additional charges.

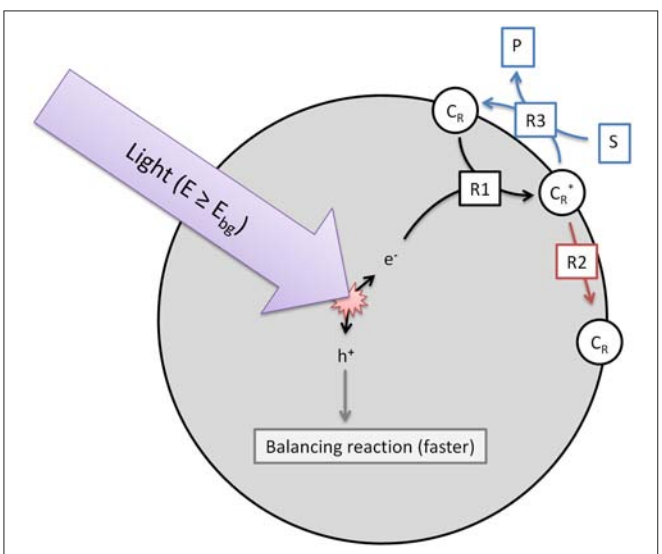

FIGURE 1 | Illustration of the three elementary reactions which are the basis of the kinetic model. Shown are the generation of reactive surface sites (*R*1), the recombination (*R*2) and the charge transfer to the target substrate (*R*3).

Many kinetic models assume that the reaction rate is dependent on the concentration of conduction band electrons (or valence band holes). However, this approach is flawed since the electrons and the substrate molecules are present in separate phases and can therefore not freely interact with each other. Since the reaction happens *via* the surface, only electrons present (or trapped) at the surface matter for the reaction rate. We simply consider the whole process of photon absorption, electron/hole pair generation and migration and trapping at surface sites as one process. Consequently, the respective quantum yield (ϕ) already comprises all loss processes along this pathway, e.g., bulk recombination. The efficiency of this process should theoretically be a property of the photocatalyst and be independent of the reaction studied. Additionally, the normalization to the total number of available surface trap sites is necessary, otherwise, given a high enough light intensity the model could theoretically create an infinite number of reactive active sites, which will never be the case for a limited number of catalyst particles.

$$R1(c_R \rightarrow c_R^*): \phi \cdot L_p^a \cdot \frac{c_R}{c_{R,0}} \tag{1}$$

These reactive surface sites can relax back to the ground state by recombining with their respective charge-carrier counterpart (*R*2, Equation 2). Note that this represents only the (relatively slow) decay of surface traps, as bulk recombination is already accounted for in *R*1. We model this as a simple first-order reaction, dependent on the recombination rate (k_r) and the density of trapped charges, given here by the fraction of filled surface traps to total surface traps.

Often, the recombination rate is modeled as a second-order reaction with respect to the concentration of electrons or holes (Zhang et al., 2012). This is a problematic approach, as the concentration (in electrons per reaction volume unit) of charges is not an appropriate measure since the electrons cannot freely move inside the reaction medium, only inside their photocatalyst (nano)particle. If for instance, in a given volume element there are 10 photocatalyst particles each containing a single charge, the recombination rate should be different than if it is just one particle containing 10 charges. It is for this reason that we chose to model the recombination rate as a function of density of trapped charges (in the photocatalyst particles) rather than a concentration of charge carriers. It should be noted however, that for an invariant catalyst concentration this is still proportional to the concentration of charges.

There is considerable disagreement in the literature about whether the decay of charge carriers follows first- or second-order kinetics (Zhang et al., 2012). In this case, while *R*2 models this as a first-order decay, the total rate of recombination (factoring in the contribution of bulk recombination from *R*1) is actually predominantly second-order with respect to the light intensity,

cf. Burek et al. (2019), SI.

$$R2(c_R^* \rightarrow c_R) : k_r \cdot \frac{c_R^*}{c_{R,0}} \tag{2}$$

Finally, the charge transfer to the target substrate can be considered (*R*3, Equation 3). This is dependent on the concentration of reactive surface sites, the surface coverage (θ) of the photocatalyst with the target substrate and a monomolecular kinetic constant (k). The surface coverage can simply be modeled as a function of substrate concentration ([*S*]) and adsorption constant (K_{ads}) using a Langmuir isotherm, Equation (4).

$$R3(c_R^* + S \rightarrow c_R + P) : k \cdot \theta \cdot c_R^* \tag{3}$$

$$\theta = \frac{K_{ads} \cdot [S]}{1 + K_{ads} \cdot [S]} \tag{4}$$

Under the assumption that these processes (*R*1-3) happen on a timescale much faster than macroscopic mixing and changes in the substrate concentration, a pseudo-steady-state approach ($c_R, c_R^* = const.$, $R1 = R2 + R3$) yields an explicit equation for the concentration of reactive surface sites, Equation (5), and the target (observed) reaction rate ($r = R3$), Equation (6).

$$c_R^* = \frac{\phi \cdot L_p^a \cdot c_{R,0}}{\phi \cdot L_p^a + k_r + k \cdot \theta \cdot c_{R,0}} \tag{5}$$

$$r = R3 = \frac{\phi \cdot L_p^a \cdot c_{R,0} \cdot k \cdot \theta}{\phi \cdot L_p^a + k_r + k \cdot \theta \cdot c_{R,0}} \tag{6}$$

Since the concentration of reactive sites is difficult to determine and typically unknown, it is more practical to normalize the rate constant to the catalyst mass (c_0), Equation (7), which leads to Equation (8), which represents the general case for calculating the *local* reaction rate. It is important to understand that this equation cannot be directly used to calculate observed *average* reaction rates unless certain criteria are met (*vide infra*), since the local reaction rate dramatically varies throughout the reaction medium.

$$k^* = \frac{k \cdot c_{R,0}}{c_0} \tag{7}$$

$$r = \frac{\phi \cdot L_p^a \cdot k^* \cdot \theta \cdot c_0}{\phi \cdot L_p^a + k_r + k^* \cdot \theta \cdot c_0} \tag{8}$$

2.1. Effect of Catalyst Concentration and Light Intensity

This general rate law (Equation 8) can be simplified if one of the limiting cases implies that the light intensity is either very high or very low in relation to the reaction's kinetic limit, Equations (9) and (10), these limiting cases can also be seen in **Figure 2**. At low light intensity, the reaction is purely governed by the flux of absorbed photons, in this regime, the observed overall photonic efficiency is constant. Parameters affecting the rate of electron transfer from the photocatalyst to the substrate have only negligible effect here. If on the contrary, the local light intensity is very high, the reaction is completely limited by the intrinsic kinetics of the reaction. In this case, the photocatalyst effectively behaves like an ordinary heterogeneous catalyst, since all of the reactive sites are permanently active due to the high photon flux.

$$(\phi \cdot L_p^a) \gg (k_r + k^* \cdot \theta \cdot c_0) : r = k^* \cdot \theta \cdot c_0 \tag{9}$$

$$(\phi \cdot L_p^a) \ll (k_r + k^* \cdot \theta \cdot c_0) : r = \phi \cdot L_p^a \cdot \frac{k^* \cdot \theta \cdot c_0}{k_r + k^* \cdot \theta \cdot c_0} \tag{10}$$

It is very important to understand that only if the former case of low light intensity and constant photonic efficiency is fulfilled in the whole reaction medium (i.e., even at the point of highest absorbed photon flux), the local reaction rate equals the average (observed) reaction rate $\langle r \rangle$ when using the average volumetric rate of photon absorption (AVRPA, $\left\langle L_p^a \right\rangle$) instead of the LVRPA, Equation (11). However, particularly for reactions with bad kinetics this will often not be the case even for moderate light intensities (*vide infra*).

$$(\phi \cdot L_{p,max}^a) \ll (k_r + k^* \cdot \theta \cdot c_0) : \langle r \rangle = \phi \cdot \left\langle L_p^a \right\rangle \cdot \frac{k^* \cdot \theta \cdot c_0}{k_r + k^* \cdot \theta \cdot c_0} \tag{11}$$

Furthermore, the rate equation (Equation 8) shows a saturation-curve behavior with respect to both the light intensity and the catalyst concentration. Interestingly, the value of one of those parameters needed to achieve saturation increases with higher values of the other. This is illustrated in **Figure 3**, where it is obvious that the catalyst concentration needed for saturation increases linearly with the light intensity. Likewise, if the reaction rate is considered as a function of light intensity, one can see that the higher the catalyst concentrations is, the longer the linear regime and the more light is needed to be fully saturated with photons, *cf.* **Figure 2**. This inter-dependency of catalyst concentration and light intensity was recently observed by us for the first time in the case of photocatalytic hydrogen peroxide formation by reduction of molecular oxygen (Burek et al., 2019). Since typically, the two parameters are not studied in depth at the same time, this effect has been largely invisible up to now. The conclusion here is that the higher the employed light intensity is, the higher should also be the catalyst concentration in order to keep the same efficiency. Since there are obvious limits to this in terms of solubility/dispersibility of the photocatalyst in the reaction medium, other measures should also be taken at very high light intensities (*vide infra*).

2.2. Effect of Substrate Concentration

The local reaction rate equation (Equation 8) can be rewritten into a pseudo-Langmuir-Hinshelwood form, Equation (12). Consequently, if the substrate concentration is the only parameter varied, the behavior might look like classical Langmuir-Hinshelwood and can be modeled and analyzed this way. This approach, however, might lead to false conclusions,

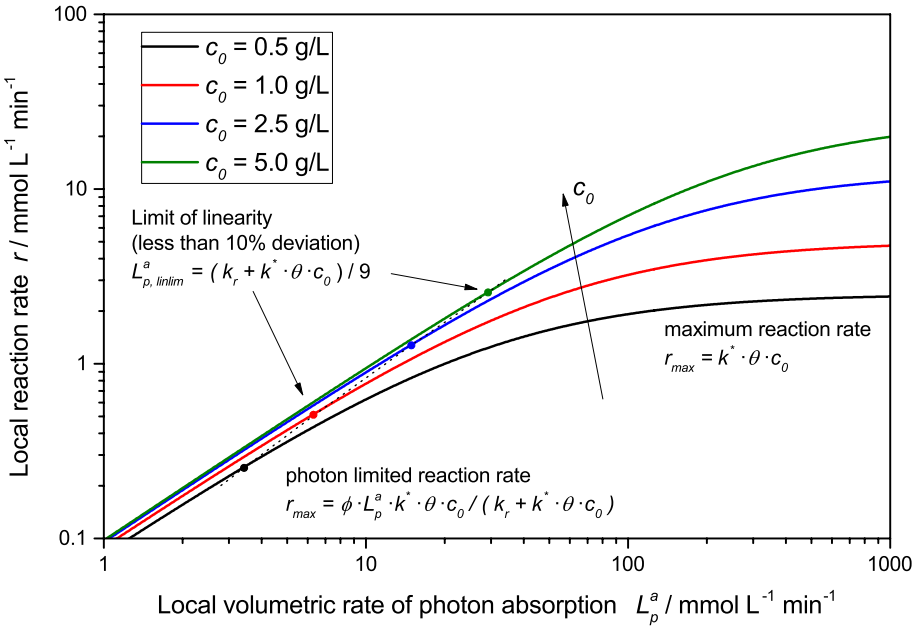

FIGURE 2 | Exemplary dependency of the local reaction rate (Equation 8) on the light intensity for different catalyst concentrations in a double logarithmic plot. Parameters used: $\phi = 0.1, k_r = 500\,\mu\text{mol}\,\text{L}^{-1}\,\text{min}^{-1}, k^* = 5.000\,\mu\text{mol}\,\text{g}^{-1}\,\text{min}^{-1}, \theta = 1$.

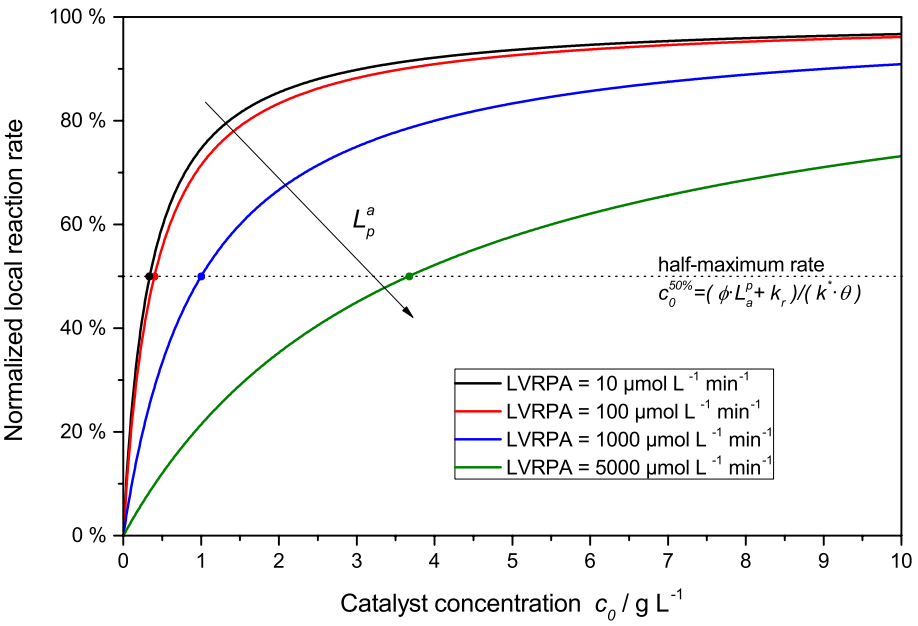

FIGURE 3 | Exemplary dependency of the (normalized) local reaction rate (Equation 8 divided by L_p^a) in dependence of the catalyst concentration for various LVRPA. Parameters used: $\phi = 1, k_r = 500\,\mu\text{mol}\,\text{L}^{-1}\,\text{min}^{-1}, k^* = 1.500\,\mu\text{mol}\,\text{g}^{-1}\,\text{min}^{-1}, \theta = 1$.

as the respective parameters k' and K'_{ads} do not resemble their classical physical meaning and are, in fact, influenced by a number of other parameters, *cf.* Equation (13).

$$r = \frac{k' \cdot K'_{ads} \cdot [S]}{1 + K'_{ads} \cdot [S]} \tag{12}$$

$$k' = \frac{\phi \cdot L_p^a \cdot k^* \cdot c_0}{\phi \cdot L_p^a + k_r + k^* \cdot c_0}; K'_{ads} = K_{ads} \cdot \left(1 + \frac{k^* \cdot c_0}{\phi \cdot L_p^a + k_r}\right) \tag{13}$$

The fact these pseudo-Langmuir-Hinshelwood parameters are dependent on the light intensity for instance, has already

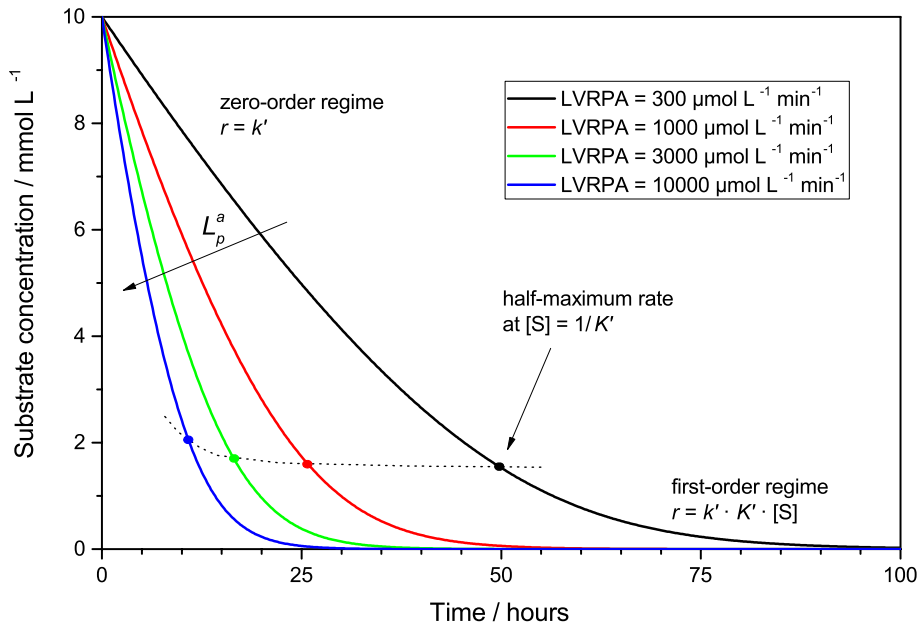

FIGURE 4 | Exemplary course of the substrate concentration (starting from $10\,\mathrm{mmol\,L^{-1}}$) over time in a given volume element for different LVRPA according to Equation (12). Parameters used: $\phi = 0.026$, $c_0 = 2.5\,\mathrm{g\,L^{-1}}$, $k_r = 653\,\mu\mathrm{mol\,L^{-1}\,min^{-1}}$, $k^* = 1358\,\mu\mathrm{mol\,g^{-1}\,min^{-1}}$, $K_{ads} = 0.1\,\mathrm{L\,mmol^{-1}}$.

been suggested and experimentally observed by other authors (Ollis, 2005; Dillert et al., 2012; Mills et al., 2015; Camera-Roda et al., 2016).

Consequently, the observed reaction is rate mixed zero- and first-order at high and low substrate concentration, respectively, *cf.* **Figure 4**. Interestingly, due to the light intensity dependence of the pseudo-adsorption constant, the inflection points between the zero- and first-order regimes given by the half-maximum rate gradually shifts to higher substrate concentration with higher light intensity. If concentration-time profiles for a given reaction are recorded, they can be modeled and analyzed using Equations (8) or (12), to extract useful information about the respective parameters. Since integration of this rate law does not yield an explicit equation, modeling has to be done numerically using for instance the Euler-Cauchy method. While the possibility to analyze these kinetics using a linearized approach exits, the author advises against that and to use the numerical approach instead, since linearization suffers from error inversion and weighting problems.

2.3. Average Reaction Rates

In many cases, rate laws similar to the ones presented above are applied to analyze the concentration-time profiles of photocatalytic reactions. However, this completely ignores the fact that these are *local* reaction rates, depending on the *local* absorbed photon flux, which varies dramatically throughout the reaction medium. As mentioned above, using the average photon flux to calculate the average reaction rate is only valid if the reaction rate is linearly dependent on the light intensity even at the "brightest spot" of the reaction, i.e., where the absorbed photon flux is at its maximum, Equation (11). In a linear light path, by ignoring scattering and calculating the light absorption behavior using the Lambert-Beer law, Equation (14), the LVRPA can be approximated using the negative derivative of the intensity attenuation, Equation (15), with the irradiance (I_0, given in photons, not energy) and the extinction coefficient (ϵ). From this, the maximum locally absorbed light intensity at the very beginning of the light path ($z = 0$) can be calculated using Equation (16).

$$I(z) = I_0 \cdot 10^{-\epsilon \cdot c_0 \cdot z} \tag{14}$$

$$L_p^a(z) = \frac{-dI(z)}{dz} = \epsilon \cdot c_0 \cdot ln(10) \cdot I_0 \cdot 10^{-\epsilon \cdot c_0 \cdot z} \tag{15}$$

$$L_{p,max}^a = L_p^a(0) = \epsilon \cdot c_0 \cdot ln(10) \cdot I_0 \tag{16}$$

With this equation it becomes apparent that the maximum locally absorbed photon flux can easily be 2 to 3 orders of magnitude higher than the average. Consequently, only if the condition given by Equation (17) is met, the above mentioned simplification of using Equation (11) is valid. Experimentally this can be checked by studying the reaction rate's response to a varied light intensity. If the response is completely linear across the studied range, the simplified approach is allowed.

$$(\phi \cdot \epsilon \cdot c_0 \cdot ln(10) \cdot I_0) \ll (k_r + k^* \cdot \theta \cdot c_0) \tag{17}$$

However, if this not the case, then the local reaction rate needs to be integrated over the whole reaction medium, taking the LVRPA distribution into account to obtain the average observed reaction rate. Particularly for complex light source and reactor geometries, this can be a quite challenging and time-consuming task which involves calculating the LVRPA across

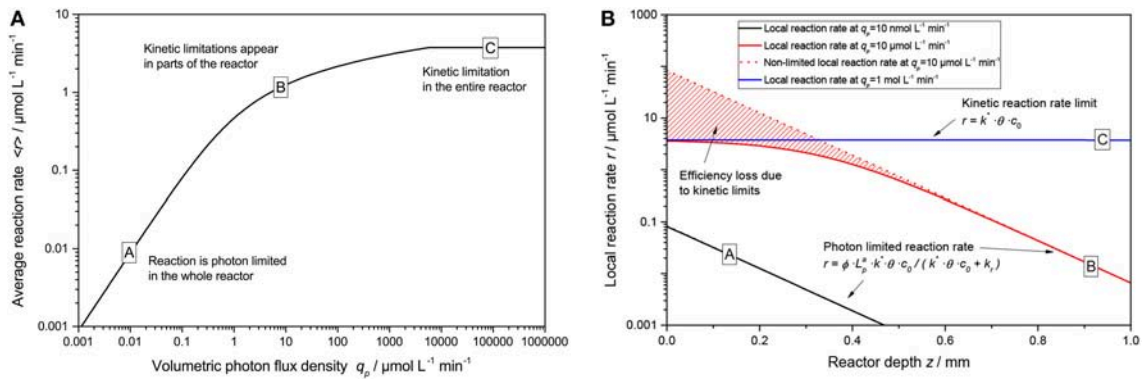

FIGURE 5 | (A) Exemplary course of the average reaction rate $\langle r \rangle$ in dependence of the volumetric photon flux density q_p according to Equation (19). **(B)** Locally resolved reaction rate as a function of reactor depth z according to Equation (8) with Equation (15) for the three cases marked A–C in **(A)**. Parameters used: $\phi = 1, c_0 = 2.5\,\mathrm{g\,L^{-1}}, k_r = 500\,\mathrm{\mu mol\,L^{-1}\,min^{-1}}, k^* = 1.500\,\mathrm{\mu mol\,g^{-1}\,min^{-1}}, \theta = 1, \epsilon = 16.4\,\mathrm{L\,g^{-1}\,cm^{-1}}, d = 0.1\,\mathrm{cm}$.

the three-dimensional reaction volume with numerical methods. However, under certain conditions this can be vastly simplified: If the light path from the lamp is collimated and is only attenuated along one dimension of the reactor. This is for instance the case when using a tubular reactor that is irradiated from its circular base or top, for instance when using a standard cylindrical beaker and irradiating it from above. In this case, the LVRPA can be approximated to only vary alongside the direction of the beam (z) with the other two directions following rotational symmetry. This allows to estimate the LVRPA using Equation (15) and to calculate the average reaction rate by integrating the local reaction rate over the whole reactor volume, Equation (18), yielding Equation (19).

$$\langle r \rangle = \frac{1}{d} \cdot \int_0^d \frac{\phi \cdot L_p^a(z) \cdot k^* \cdot \theta \cdot c_0}{\phi \cdot L_p^a(z) + k_r + k^* \cdot \theta \cdot c_0} dz \tag{18}$$

$$\langle r \rangle = k^* \cdot \theta \cdot c_0 + \frac{k^* \cdot \theta}{d \cdot \epsilon \cdot ln(10)} \cdot ln \left(\frac{\phi \cdot I_0 \cdot \epsilon \cdot c_0 \cdot ln(10) + k^* \cdot \theta \cdot c_0 + k_r}{\phi \cdot I_0 \cdot \epsilon \cdot c_0 \cdot ln(10) + (k^* \cdot \theta \cdot c_0 + k_r) \cdot 10^{\epsilon \cdot c_0 \cdot d}} \right) \tag{19}$$

Unless very optically dilute solutions are used, the condition expressed by Equation (20) is true and a simplified version of the rate equation can be used, Equation (21).

$$10^{\epsilon \cdot c_0 \cdot d} \gg \frac{\phi \cdot I_0 \cdot \epsilon \cdot c_0 \cdot ln(10)}{k^* \cdot \theta \cdot c_0 + k_r} \tag{20}$$

$$\langle r \rangle = \frac{k^* \cdot \theta}{d \cdot \epsilon \cdot ln(10)} \cdot ln \left(\frac{\phi \cdot I_0 \cdot \epsilon \cdot c_0 \cdot ln(10)}{k^* \cdot \theta \cdot c_0 + k_r} + 1 \right) \tag{21}$$

Furthermore, by defining the optical density (α) and using the volumetric photon flux density (q_p) instead of the irradiance, Equation (22), the sometimes more practical variant Equation (23) is obtained.

$$I_0 = q_p \cdot d; \alpha = \epsilon \cdot d \cdot ln(10) \tag{22}$$

$$\langle r \rangle = \frac{k^* \cdot \theta}{\alpha} \cdot ln \left(\frac{\phi \cdot q_p \cdot \alpha \cdot c_0}{k^* \cdot \theta \cdot c_0 + k_r} + 1 \right) \tag{23}$$

An exemplary plot of Equation (19) is shown in **Figure 5A**. Here, three regimes are apparent: At low light intensity, the reaction scales linearly with the light intensity across the whole reaction medium (A), in this case the simplified rate law given by Equation (11) is applicable. At some point, non-linearities start to appear in some parts of the reactor (the "bright" zone) and the average reaction rate starts to show diminishing returns (B). This corresponds to the non-linear response (approximately following a square root dependence) that was often reported for photocatalytic reactions at higher light intensities. If extremely high light intensities are used, the reaction will be limited at every point in the reactor and the average reaction rate is given by Equation (9) (C). However, the latter case is practically impossible to achieve with conventional light sources unless very small reactors with dilute photocatalyst are used.

Recently, we could show on the basis of the photocatalytic reduction of molecular oxygen to hydrogen peroxide, that this approach yields very good results in describing the complex behavior of the reaction rate in dependence of both catalyst concentration and light intensity, *cf.* **Figure 6** (Burek et al., 2019).

Figure 5B nicely illustrates the fundamental problem of intensifying photocatalytic reactions. In order to avoid kinetic limitations, the light intensity needs to be so low that even at the beginning of the reactor, no limitations manifest. This in turn means that in the rest of the reactor, the reaction only proceeds with orders of magnitude lower rates. One way to circumvent that is by using very dilute solutions or small dimensions that the light falloff through the reactor is only small (e.g., $< 50\,\%$). In that case, the reaction rate would not vary so much in the reactor and the average reaction rate is almost equal to the maximum local reaction rate, vastly increasing catalyst efficiency. However, this would also mean that a significant portion of the light is transmitted though the reactor and not used, dramatically reducing the overall photonic efficiency. Another possible solution is to use delocalized internal illumination so that the light distribution in the medium is more homogeneous (Burek et al., 2017).

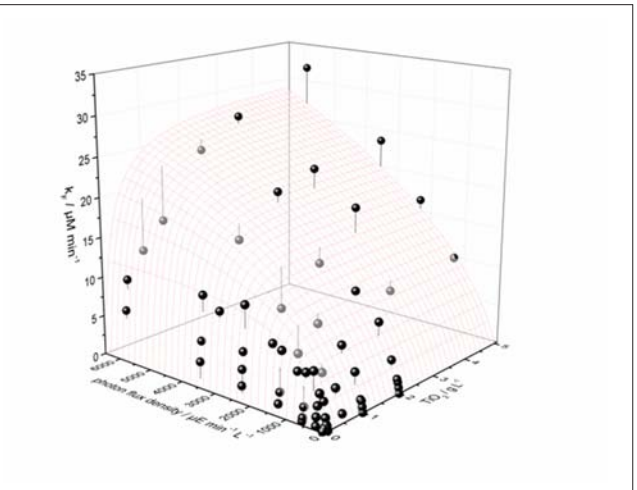

FIGURE 6 | Interdependence of the measured H_2O_2 formation rate constant k_F on the amount of catalyst and the photon flux density shown as black and dark gray dots. Also shown is the calculated best fit to the proposed model (Equation 23) as a surface plot; the vertical lines attached to the data points show their respective difference to the calculation. Data points that are black mean they are on or above the surface plot, and dark gray data points signify they are below the surface. Parameters used: $\phi = 0.02623, k_r = 653\,\mu mol\,L^{-1}\,min^{-1}, k^* \cdot \theta = 1358\,\mu mol\,g^{-1}\,min^{-1}, \epsilon = 16.4\,L\,g^{-1}\,cm^{-1}, d = 4\,cm$. 2.4. Effects of Temperature

Another important parameter of the reaction is the temperature. While this is one of the most important parameters in thermally activated catalysis and typically described via the Arrhenius law, Equation (24), this parameter is only studied in few photocatalytic systems. The rationale behind this seems to be that the reaction is initiated by the massive energy provided by the photons, so room temperature is sufficient to drive the reactions (Herrmann, 1999; Carp et al., 2004; Gaya and Abdullah, 2008; Malato et al., 2009). Yet, there are many publications which clearly show a temperature dependence of the photocatalytic reactions and use the Arrhenius law to calculate apparent activation energies (E_A^*) of 5 to 28 kJ mol^{-1} (Al-Sayyed et al., 1991; Hirakawa et al., 2004; Soares et al., 2007; Costacurta et al., 2010; Hu et al., 2010). While these are modest values in comparison with typical catalytic processes, they should not be neglected either. For instance, with these values, increasing the reaction temperature from 25 to 80 °C corresponds to an increase of 37 to 481 % in the kinetic constant.

$$k^* = A \cdot e^{\frac{-E_A}{R \cdot T}} \tag{24}$$

The Arrhenius law can easily be integrated into the present kinetic model by modulating the kinetic constant k^* by the temperature according to Equation (24). As shown in exemplary **Figure 7**, the temperature effects are strongly masked at lower light intensities, as improving the kinetics in that regime has negligible impact on the overall reaction, which is limited by the available photons here. However, at high light intensities, the temperature effect becomes much more prominent as it presents a way to overcome kinetic limitation there and to extend the linear regime. Consequently, using higher temperatures is a promising approach to combine high productivity and high quantum yield.

Interestingly, attempts to calculate the apparent activation energies (E_A^*) from the reaction rates obtained at a given light intensity, through Arrhenius plots (they mostly show acceptable fits), yields dramatically differing results with changing light intensity and range from 4.0 to 24.4 kJ mol^{-1}. The true activation energy (30 kJ mol^{-1}) is only revealed at very high light intensity, when the reaction is entirely kinetically limited. This would explain why authors in the past have reported vastly different apparent activation energies for the same reactions. Consequently, temperature effects of photocatalytic reaction cannot be properly studied at low reaction rates and will only yield misleading results.

Coincidentally, as at very high light intensities the energy input into the solution by the photons will be quite significant, achieving those higher temperatures will often be possible without additional heating. Researchers also need make sure to accurately control and measure the temperature in their reaction media, as to not mistake high light intensity effects for temperature effects that occur through unintentional radiative heating.

As pointed out by some authors, the solubility and adsorption of reactants is also strongly dependent on the temperature and this can significantly contribute to the observed overall temperature effects (Herrmann, 2005; Malato et al., 2009).

2.5. Limitations

It should be noted that while the above-mentioned approach has the advantage that it is very easy to implement given the low number of parameters and explicit equations, it also suffers from several drawbacks. The first is that here, a steady-state is assumed and therefore, dynamic processes are not taken into account. For instance, mass transport, adsorption and desorption rates are supposed to be much faster than the reaction are therefore have no effect, only their equilibrium state is modeled. This will obviously not be true in all cases, particularly for very intensified reactions and reagents with sluggish mobility. In those cases, dynamic models have to be used which will unfortunately make complex numerical simulation mandatory.

Furthermore, in the model we consider all photocatalytic reactions as one-electron transfers. If true concerted multi-electron transfers, not consecutive one-electron transfer events, drive the reaction (which typically requires a co-catalyst) this approach likely has to be modified accordingly.

Another potential problem is that scattering is completely neglected in the model (at least in the integrated form). Heterogeneous catalysts suspended in the reaction medium will scatter some of the incident light back out of the reactor, diminishing the actual available photon flux. This will lead to an underestimation of the LVRPA and consequently the quantum yield in the model. However, if the scattered-out light is determined either experimentally or computationally, the

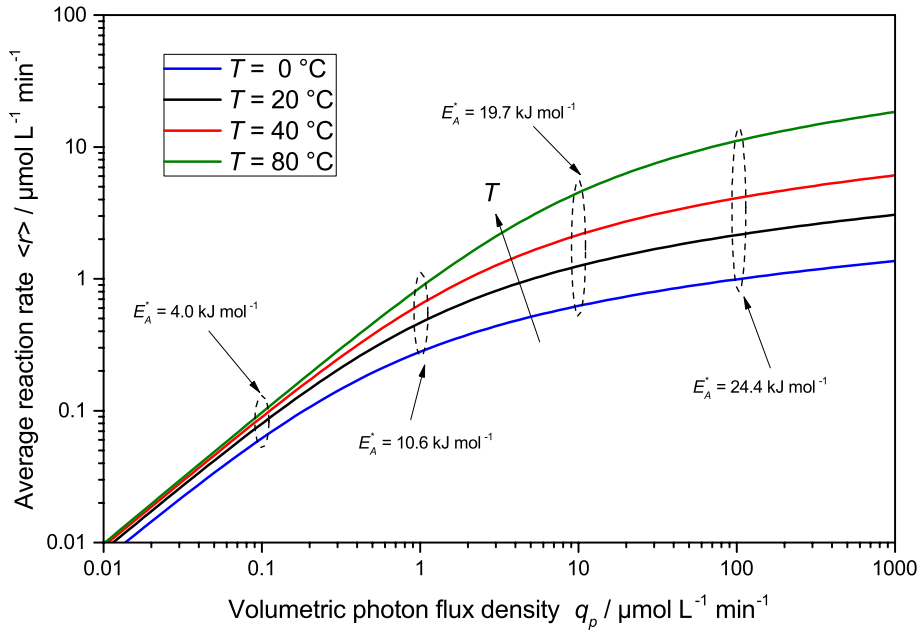

FIGURE 7 | The change in average reaction rate is a function of light intensity for different temperatures calculated according to Equation (23) with Equation (24). Also shown are the apparent activation energies E_A^* obtained from Arrhenius plots at a given light intensity. Parameters used: $\phi = 1, c_0 = 2.5\,\mathrm{g\,L^{-1}}$, $k_r = 500\,\mu\mathrm{mol\,L^{-1}\,min^{-1}}, A = 3.325 \times 10^8\,\mu\mathrm{mol\,g^{-1}\,min^{-1}}, E_A = 30\,\mathrm{kJ\,mol^{-1}}, \theta = 1, \epsilon = 16.4\,\mathrm{L\,g^{-1}\,cm^{-1}}, d = 0.1\,\mathrm{cm}$.

incident photon flux can be corrected for it and the model should be accurate with respect to this aspect.

The model also cannot account for changes in the solution properties such as solvent or pH. Since these parameters have very reaction-specific effects, they need to be studied on a case-by-case basis. However, it should be noted that theoretically, changes in the solvent or pH should only affect the rate constant, not the quantum yield or recombination rate.

If different photocatalysts are studied (different materials, surface area, synthesis routes, doping, etc.), this will most likely affect all three primary parameters (rate constant, quantum yield and recombination rate). Since this model requires a substantial amount of data points to deliver fairly accurate parameters, it will be quite time-consuming to compare different catalysts based on the kinetic model. However, doing so would likely provide interesting insight into their properties as changes in the kinetics (rate constant) and photophysical properties (quantum yield, recombination rate) can be separately attributed.

2.6. Application of the Model

Despite the limitations stated above, the model presented herein should be readily applicable to most standard photocatalytic reactions. Since most experimental setups feature illumination only from one direction, they are already compatible with the model. Ideally the light source should be collimated, and the beam should hit the reactor at a flat surface, although deviations from that likely only lead to small errors due to higher reflection losses. In almost all cases, Equation (23) can be directly used to model the observed reaction rates. For extremely high light intensities or very low photocatalyst concentrations, it should be checked if Equation (19) yields different values, in that case it has to be used instead.

$$\langle r \rangle = \frac{k^* \cdot \theta}{\alpha} \cdot ln\left(\frac{\phi \cdot q_p \cdot \alpha \cdot c_0}{k^* \cdot \theta \cdot c_0 + k_r} + 1\right) \tag{23}$$

This equation features the typically known parameters catalyst concentration (c_0) and incident light intensity (I_0, measurable for instance with physical probes at the reactor position) or volumetric photon flux density (q_p, measurable with chemical actinometry, see Equation (22) about how to interconvert these quantities). The optical density α can also be calculated using Equation (22) and determining the extinction coefficient (ϵ) by a simple transmission measurement. The surface coverage θ can be obtained using Equation (4) which adds the (known) substrate concentration and adsorption constant to the variables. If the substrate concentration is not varied, a constant, e.g., $\theta = 1$, may be used instead but this will scale the rate constant accordingly.

$$\theta = \frac{K_{ads} \cdot [S]}{1 + K_{ads} \cdot [S]} \tag{4}$$

This only leaves the rate constant (k^*), quantum yield (ϕ) and recombination rate (k_r) as unknown variables. These can be obtained by fitting the model to experimental data using non-linear optimization. Since there are three unknown parameters (four if the adsorption constant is unknown as well) the number of data points with varied light intensity and catalyst concentration should be significantly higher than that number to achieve good accuracy for the parameters. The rate equation can also be used to simulate concentration-time-profiles

of individual experiments by numerical methods such as the Euler-Cauchy algorithm.

If the effect of changing temperature should be accounted for as well, Equation (24) can be used to replace k^* in Equation (23). This adds the known parameter temperature and allows to determine the unknown pre-exponential factor A and activation energy E_A.

$$k^* = A \cdot e^{\frac{-E_A}{R \cdot T}} \tag{24}$$

Thorough analysis of the model parameters will reveal ways to optimize the reaction with respect to both high reaction rates and photonic efficiency. Typically, this will involve increasing substrate and photocatalyst concentrations to their saturation point as well as the temperature. However, these measures all have physical constraints due to solubility/dispersibility limits and in case of temperature, boiling point of the solvent. So, at a certain point, the reaction cannot be further improved by just tuning the reaction conditions and other measures have to be taken. This can either be improvements of the catalyst itself (which can directly increase the reaction rate kinetics, i.e., k^*) for instance by using co-catalysts which improve the charge transfer to the substrate. Another way is to improve the reactor used in order to reduce inhomogeneities in the light distribution. For instance, a shorter average light path will lead to a lower optical thickness and thereby allow higher average reaction rates at the same apparent quantum yield, *cf.* Equation (17).

3. MOLECULAR PHOTOCATALYTIC REACTIONS

The methodology used in the model, described above, can also be adapted to molecular (homogeneous) photocatalytic reactions. As shown in **Figure 8**, the first step of the catalytic cycle ($R1$) is again the excitation of the photocatalyst (PC) to its reactive state (PC^*), in dependence of the local volumetric rate of photon absorption (L_p^a). Since the reactive state is typically the triplet state, this reaction summarizes photon absorption and inter-system crossing. The quantum yield of this reaction (ϕ) consequently represents the yield of reactive (triplet) states that are generated upon photon absorption. The reaction rate is normalized to the fraction of unexcited photocatalyst to total photocatalyst. This is done under the assumption that multi-photon absorption does not lead to additional or faster reaction events, i.e., an already excited, oxidized or reduced photocatalyst may absorb additional photons, but this does not lead to an altered reactivity. This normalization is also needed, since if otherwise, given a sufficiently high light intensity, the model could mathematically create more excited photocatalysts than total photocatalysts.

The next step of the catalytic cycle is either relaxation of the excited state ($R2$) back to the ground state or reductive/oxidative quenching ($R3$). The former is usually accompanied by fluorescence and a first-order reaction with respect to concentration of the excited state. The rate of this reaction is usually expressed as the half-life-time (τ). The

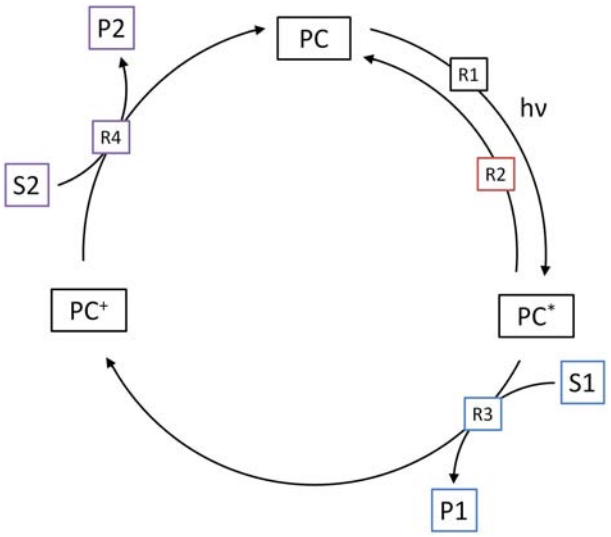

FIGURE 8 | Illustration of the four elementary reactions which are the basis of the kinetic model for molecular photocatalytic reactions. Shown are the generation of the excited state ($R1$), the relaxation ($R2$), oxidative quenching ($R3$) and regeneration of the photocatalyst ($R4$).

competing reaction is the electron transfer to or from one of the substrates. Since from a modeling perspective, oxidative and reductive quenching are identical, here only oxidative quenching ($R3$) is considered. This is typically a second-order reaction and therefore dependent on both the concentration of the excited state photocatalyst and the target substrate (S_1). The rate of this reaction is further described by the corresponding bimolecular rate constant (k_1).

In the last step, the cycle needs to be closed by regenerating (reducing) the oxidized photocatalyst (PC^+) back to the ground state ($R4$). This is done by reaction with the second substrate (S_2), again in a second-order reaction with the corresponding bimolecular rate constant (k_2). Note that either the first, second or both substrates might represent the target reaction.

$$R1(PC \rightarrow PC^*) : \phi \cdot L_p^a \cdot \frac{[PC]}{[PC_0]} \tag{25}$$

$$R2(PC^* \rightarrow PC) : \frac{[PC^*]}{\tau} \tag{26}$$

$$R3(PC^* + S_1 \rightarrow PC^+ + P_1) : k_1 \cdot [S_1] \cdot [PC^*] \tag{27}$$

$$R4(PC^+ + S_2 \rightarrow PC + P_2) : k_2 \cdot [S_2] \cdot [PC^+] \tag{28}$$

Since these reactions are usually significantly faster (ns to ms time-scale) than macroscopic mixing and changes in the substrate concentrations, it is assumed that a steady state is also present with respect to the local light intensity and substrate concentration. A steady-state approximation ($[PC], [PC^*], [PC^+] = const.$, $R1 = R2 + R3$, $R3 = R4$) yields Equation (29) for $[PC^*]$ and Equation (30) for $R3/4$.

$$[PC^*] = \frac{\phi \cdot L_p^a}{\frac{\phi \cdot L_p^a}{[PC_0]}\left(1 + \frac{k_1 \cdot [S_1]}{k_2 \cdot [S_2]}\right) + \frac{1}{\tau} + k_1 \cdot [S_1]} \tag{29}$$

$$r = R3 = R4 = \frac{k_1 \cdot [S_1] \cdot \phi \cdot L_p^a}{\frac{\phi \cdot L_p^a}{[PC_0]}(1 + \frac{k_1 \cdot [S_1]}{k_2 \cdot [S_2]}) + \frac{1}{\tau} + k_1 \cdot [S_1]} \quad (30)$$

This rate equation has the following limiting case which represents low light intensity. Note that contrary to heterogeneous systems, in molecular photocatalysis practically all cases fall into this category (*vide infra*).

$$L_p^a \ll \frac{[PC_0] \cdot (\frac{1}{\tau} + k_1 \cdot [S_1])}{1 + \frac{k_1 \cdot [S_1]}{k_2 \cdot [S_2]}} : \langle r \rangle = \phi \cdot \left\langle L_p^a \right\rangle \cdot \frac{k_1 \cdot [S_1] \cdot \tau}{1 + k_1 \cdot [S_1] \cdot \tau} \quad (31)$$

As stated above for heterogeneous systems, in cases when the response of the reaction rate to light intensity is linear in the entire reaction medium (low light intensity), the local volumetric rate of photon absorption may be replaced by the average volumetric rate of photon absorption ($\left\langle L_p^a \right\rangle$, AVRPA), to calculate the observed average reaction rate $\langle r \rangle$. The AVRPA can easily be measured using actinometry or calculated from the incident photon flux and the extinction of the photocatalyst. In this linear case, the well-known Stern-Volmer equation, Equation (33), can also be derived from the relaxation rate (*R*2), Equation (32), which it is proportional to the fluorescence intensity (*F*).

$$R2 = \frac{\phi \cdot \left\langle L_p^a \right\rangle}{1 + k_1 \cdot [S_1] \cdot \tau} \propto F \quad (32)$$

$$\frac{F_0}{F} = 1 + k_1 \cdot [S_1] \cdot \tau \quad (33)$$

As long as the light intensity is sufficiently small and the reaction rate increases linearly with the light intensity, the reaction kinetics can easily be described by Equation (31). This represents a mixed zero- and first-order reaction similar to Langmuir-Hinshelwood or Michaelis-Menten kinetics. At a high substrate concentration, the reaction is zero-order and the reaction rate is only dependent on the light intensity and quantum yield, Equation (34).

$$[S_1] \cdot \tau \cdot k_1 \gg 1 : r = \phi \cdot \left\langle L_p^a \right\rangle = r_{max} \quad (34)$$

At lower substrate concentration the reaction rate gradually shifts to first-order kinetics, where it is linearly dependent on the substrate concentration, quantum yield, light intensity, bimolecular rate constant and excited state life-time of the photocatalyst, Equation (35). A pseudo-inflection point between both regimes is given by the half-maximum reaction rate which is reached when $[S_1] \cdot k_1 \cdot \tau = 1$. This is exactly the behavior that is often observed if kinetics of photoredox catalysis are studied (Gazi et al., 2017; Le et al., 2017).

$$[S_1] \cdot \tau \cdot k_1 \ll 1 : r = \phi \cdot \left\langle L_p^a \right\rangle \cdot k_1 \cdot [S_1] \cdot \tau \quad (35)$$

Unfortunately, integration of this rate law (Equation 31) does not yield an explicit equation for the substrate concentration change over time, but it can readily be modeled and fitted using a numerical simulation (e.g., Euler-Cauchy method). Fitting this equation to a sufficiently detailed concentration-time-profile will also directly allow to extract both the quantum yield and bimolecular rate constant if τ and $\left\langle L_p^a \right\rangle$ are known, rendering Stern-Volmer analysis superfluous.

All of these simplifications are only applicable when the light intensity is so small, that the majority of the photocatalyst is always in its ground state. At higher light intensity, the reaction rate would yield increasingly diminishing returns with respect to the light intensity. Given the limits of linearity, it seems rather unlikely to actually reach the non-linear part in practical applications. Using the same method described above for heterogeneous systems, the maximum local absorbed light intensity present at the very beginning of the light path ($z = 0$) can again be calculated using Equation (16).

$$\epsilon \cdot ln(10) \cdot I_0 \ll \frac{(\frac{1}{\tau} + k_1 \cdot [S_1]) \cdot (k_2 \cdot [S_2])}{k_1 \cdot [S_1] + k_2 \cdot [S_2]} \quad (36)$$

This reduces the limiting case to Equation (36). Neglecting concentrated light sources such as lasers, irradiances of up to about $10\,W\,cm^{-2}$ are possible with current technology. This equals a photon flux of about $35\,\mu mol\,cm^{-2}\,s^{-1}$ in the UVA to blue light region. With $\epsilon = 15.000\,L\,mol^{-1}\,cm^{-1}$ and assuming the substrates are present in $10\,mmol\,L^{-1}$ concentration, this means that both bimolecular rate constants need to be much larger than $1.2 \times 10^5\,L\,mol^{-1}\,s^{-1}$, or in case of k_1, the half-life time of the photocatalyst's excited state may instead be much shorter than 0.8 ms. Given that both, rate constants are typically reported in the range of 10^6 to $10^8\,L\,mol^{-1}\,s^{-1}$ and the half-life time of the photocatalysts are often in the low µs regime, the limiting case seems to be fulfilled in practically all cases relevant today. However, if strongly absorbing photocatalysts are used in combination with high light intensity, slow kinetics and low substrate concentration, this limiting case needs to be revisited in order to make sure no non-linearities occur. The authors note that if a kinetic limitation takes place it is most likely caused by a slow regeneration reaction (*R*4). In those cases, similar measures defined for the heterogeneous reactions can be taken to accurately model the system and to overcome the limitations.

Similar considerations that were made for heterogeneous systems, concerning the temperature, can also be made for photoredox catalysis, however, one has to keep in mind that not just the target kinetic constant, but all the reaction constants will vary with temperature.

4. CONCLUSION

The vast majority of reports of photocatalytic reactions are one-dimensional studies that only look at the effect of one parameter. This very easily leads to misinterpretations as correlations of different parameters are invisible in this case. Moreover, the effect of some reaction parameters such as temperature are strongly masked under a variety of conditions and can therefore only be properly studied using a holistic multi-dimensional approach.

Using the average volumetric rate of photon absorption or any figure proportional to it, such as lamp power or irradiance, to

analyze the kinetics of photocatalytic reactions is only a valid approach if the light intensity is so low that the reaction rate is linearly proportional to the light intensity at every point in the reaction vessel. In that case it is also possible to use pseudo Langmuir-Hinshelwood kinetics to simulate and analyze the reaction rate, as long as the substrate concentration is the only parameter varied in a set of experiments. However, in this case care need to be taken not to misinterpret the corresponding parameters (k' and K'_{ads}) for their actual physical meaning, as they are in fact modulated by a number of other parameters such as the light intensity.

In case of moderate to high light intensities, the abovementioned simplification does not hold true and the reaction rate instead has to be integrated over the whole reaction volume, taking the light distribution into account. However, herein we could show that for some experimental setups there exist relatively simple explicit equations to solve this rather complex problem. These can easily be fit to the experimental data to obtain the underlying physically meaningful parameters. First examples already show that this approach yields very good results and can account for the effect of light intensity, catalyst and substrate concentration as well as temperature as well as their respective inter-dependencies (Burek et al., 2019).

Temperature is mostly neglected as a parameter in photocatalytic reactions as typically no significant influence is observed. However, this is only true as long as the intrinsic reaction kinetics are not rate-limiting and the reaction is purely governed by the number of available photons. At higher light intensities, the reaction kinetics play an ever-increasing role and here, temperature effects become apparent. In fact, we could show that a classical Arrhenius approach to modulate the rate constant yields very good results here. Similarly, the effect of other parameters affecting the reaction kinetics such as substrate concentration and catalyst concentration is much more prominent at high light intensities.

From a reaction engineering point of view, it would be desirable to work at the highest technically achievable light intensity, while still maintaining high photonic efficiency. Unfortunately, the reaction rate's response to light intensity becomes increasingly non-linear with increased intensity, which led several researchers to believe that high productivity and high efficiency are contradictory. However, the non-linearity can be compensated by increasing the reaction kinetics accordingly, e.g., by using a higher temperature, substrate or catalyst concentration. Yet, there are still limits to what extent this can be done to, so the ultimate goal should be to improve the employed catalyst or to reduce the inhomogeneity of the light distribution in the reaction vessel, e.g., by using delocalized internal illumination (Burek et al., 2017).

If the aim is only to achieve a maximum apparent quantum yield, the reaction should be run at low light intensity. Under these conditions, the reaction kinetics are also much more forgiving and using lower substrate/photocatalyst concentration and temperature should not have a significant negative impact on the observed reaction rate.

Similar considerations can be applied for molecular photocatalytic reactions and the respective equations, to simulate and analyze the mixed zero- and first-order kinetics of these reactions are given herein. However, integration over the reaction volume is likely not necessary in these cases, because, due to generally better kinetics, it is unlikely that non-linearities will appear when considering the technical limits of the current non-focused light sources.

Flavin Conjugated Polydopamine Nanoparticles Displaying Light-Driven Monooxygenase Activity

*Leander Crocker and Ljiljana Fruk**

Department of Chemical Engineering and Biotechnology, University of Cambridge, Cambridge, United Kingdom

A hybrid of flavin and polydopamine (PDA) has been explored as a photocatalyst, drawing inspiration from natural flavoenzymes. Light-driven monoxygenase activity has been demonstrated through the oxidation of indole under blue light irradiation in ambient conditions, to afford indigo and indirubin dyes. Compared to riboflavin, a flavin-polydopamine hybrid is shown to be more resistant to photobleaching and more selective toward dye production. In addition, it has been demonstrated that it can be recycled from the solution and used for up to four cycles without a marked loss of activity, which is a significant improvement compared to other heterogenous flavin catalysts. The mechanism of action has been explored, indicating that the PDA shell plays an important role in the stabilization of the intermediate flavin-peroxy species, an active component of the catalytic system rather than acting only as a passive nanocarrier of active centers.

Keywords: flavin, polydopamine, light-driven reaction, monooxygenase, indole

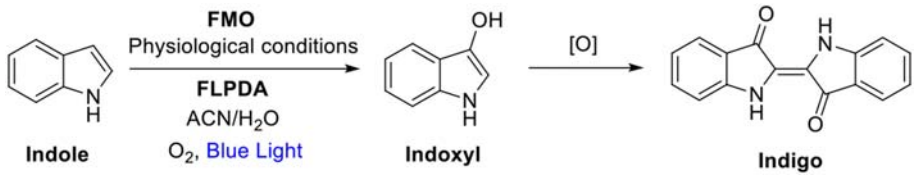
INTRODUCTION

Flavin-containing monooxygenases (FMOs) are an important class of xenobiotic-degrading enzymes present in both eukaryotic and prokaryotic organisms. For example, they are able to add molecular oxygen to the lipophilic xenobiotic compounds, thereby increasing their solubility enough to allow excretion. As a result, organisms are protected from potentially toxic exogenous compounds derived from natural sources and, particularly important for humans, the metabolism of drugs and pollutants (Krueger and Williams, 2005; Zhou and Shephard, 2006; Hodgson, 2010). One of the substrates for FMOs, which is also widespread in nature is the *N*-heterocycle indole. It is considered to be an aromatic pollutant due to its toxicity and potential mutagenicity (Sullivan and Gad, 2014), but it is also a versatile intermediate species and signaling molecule across families of organisms (Lee and Lee, 2010; Erb et al., 2015; Lee et al., 2015a,b). Indigo dyes are currently commercially produced by chemical synthesis using aniline, formaldehyde, and hydrogen cyanide to form phenylglycinonitrile, subsequently hydrolyzed to yield phenylglycine, which is finally converted to indigotin. This process involves use of toxic chemicals and extensive purification steps, limiting the environmental viability and prompting the design of more green-chemistry oriented strategies (Blackburn et al., 2009).

FMOs, as well as the other xenobiotic-degrading enzymes such as cytochrome P450s, have been shown to convert indole to the blue indigo dye through initial oxidation to indoxyl and subsequent dimerization to form the dye as shown in **Scheme 1**. This transformation has been utilized as an enzymatic assay to screen for oxygenases (O'Connor et al., 1997; Singh et al., 2010; Lin et al., 2012; Nagayama et al., 2015), but also as a greener alternative to the industrial manufacturing of indigo and related indigoid dyes. To achieve that, a whole cell biocatalysis relying on the cellular FMO's



SCHEME 1 | Indole oxidation to indoxyl and further oxidation and dimerization to indigo where FMO, Flavin-containing monooxygenases; **FLPDA**, flavin-polydopamine; CAN, acetonitrile; [O], further oxidation processes by O_2 (Mermod et al., 1986; Meyer et al., 2002).

is utilized to achieve that since the current industrial manufacturing of these dyes is highly energy demanding, results in large amounts of toxic waste products, and requires number of purification steps (Han et al., 2012; Hsu et al., 2018; Ma et al., 2018). However, a whole-cell biocatalysis is also faced with complex product separation and catalyst inhibition, which incurs large costs and reactor downtime periods (Lin and Tao, 2017). Alternatives such as the use of the isolated enzymes suffer from limited enzyme quantities, low stability under non-physiological conditions, sensitivity to organic solvents, as well as challenging post-reaction isolation, hence limiting large scale industrial applications (Reetz, 2002; Li et al., 2012).

Taken out of a protein environment, flavin analogs derived from cofactors flavin mononucleotide (FMN), flavin adenine dinucleotide (FAD) and riboflavin have shown huge potential for catalytic applications, especially in photocatalytic processes (de Gonzalo and Fraaije, 2013; König et al., 2013; Cibulka, 2015). Despite the relative ease of visible-light driven flavin photocatalysis, high yielding reactions, and low toxicity, there are still challenges related to their long-term stability and photobleaching, as well as the separation of the catalyst from the products and subsequent catalyst reuse. To address these issues, attempts have been made to immobilize flavins onto various solid carriers such as silica beads or resins to achieve a heterogeneous catalytic systems, although limited success has been reported in relation to recyclability and activity (Schmaderer et al., 2009; Špačková et al., 2017; Arakawa et al., 2018). Taking this into account, we have rationalized that the use of solid, polymeric carrier, which not only permits immobilization of flavin but also displays some intrinsic properties similar to protein shells such as H-bonding and electron transfer, could significantly improve both the activity and post-reaction recovery of the hybrid catalytic system.

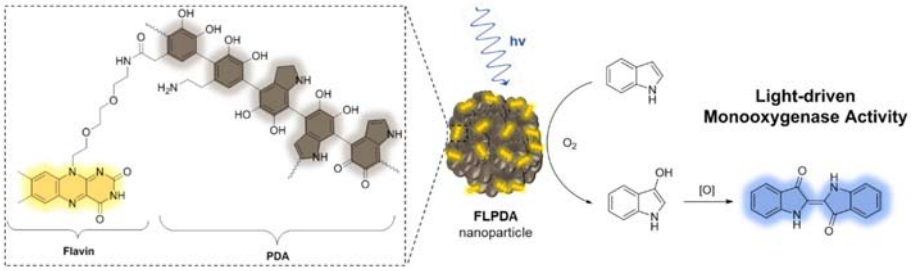
Herein, we present a new strategy to design a versatile enzyme-inspired photocatalytic system by embedding flavin within an active polymer matrix. We have chosen polydopamine (PDA) as the carrier polymer due to its reported biocompatibility (Hong et al., 2011; D'Ischia et al., 2014) and structural and electronic properties (Liu et al., 2014). Composed of a sequence of extended π-systems, PDA is considered to be an amorphous organic semiconductor, and has been used to improve various nanoparticle catalysts (Ma et al., 2015; Kunfi et al., 2017; Zhou et al., 2017), enhance the efficiency and stability of whole cell biocatalytic systems (Wang et al., 2017), and act as an electron gate for artificial photosynthesis due to its excellent electron accepting ability (Kim et al., 2014). Although PDA's main application has been to act as a molecular adhesive, due to its capability to form coatings on virtually any surface (Lee et al., 2007), an ability equally as interesting is its intrinsic catalytic activity (Mrõwczynski et al., 2014; Yang et al., 2014; Du et al., 2015), which has not yet been explored to afford hybrid organic systems with photocatalytic activity.

We hypothesized that monooxygenase activity of the flavin-polydopamine (**FLPDA**) system could be initiated through blue light irradiation to excite the flavin moieties, bypassing the use of external reducing agents or cofactors such as NADH. At the same time, PDA can be utilized as an active solid support enabling both the electron transfer and the stabilization of reactive intermediates. The latter was inspired by BLUF (blue light sensors using FAD) photoreceptors, in which an electron transfer between flavin cofactor and tyrosine in the protein shell is the key process enabling the stabilization of intermediates and switching from dark-adapted to light-adapted state, which guides biological signaling pathways (Mathes et al., 2012). In addition, the photoinduced electron transfer from tryptophan to flavin has been shown to be a crucial step in the control of CRY protein's activity, which is responsible for control of the light dependent circadian clocks in plants and animals (Lin et al., 2018). As shown in **Scheme 2**, the structure of PDA mimics both the tyrosine and tryptophan residues, indicating that the polymer could actively engage in electron transfer processes and impact the catalytic activity of embedded flavin. With this in mind, we focused our efforts to synthesize **FLPDA** nanoparticles through the co-polymerization of a flavin-dopamine monomer, **FLDA**, and dopamine. We then investigated the light-driven monooxygenase activity of the particles through blue light irradiation in the presence of indole under ambient conditions.

EXPERIMENTAL

General

All materials were purchased from either Acros Organics, Alfa Aeser, Sigma-Aldrich, or TCI Chemicals in the highest purity available and used without further purification. ^{1}H and ^{13}C NMR measurements were carried out using a 500 MHz DCH Cryoprobe Spectrometer. HRMS was recorded on a ThermoFinnigan Orbitrap Classic (Fisher Scientific). UV-Vis absorption spectra were obtained with an Agilent Cary 300 Spectrophotometer. Fluorescence emission spectra were obtained using a Varian Cary Eclipse Fluorescence



SCHEME 2 | Structure of flavin-polydopamine (FLPDA) units (left) and the reaction scheme illustrating explored light-driven oxidation of indole to indigo in presence of **FLPDA** nanoparticles (right).

Spectrophotometer using excitation and emission slits of 10 nm. DLS and Zeta Potential measurements were recorded using a Zetasizer Nano Range instrument (Malvern Panalytical). FTIR spectroscopy was carried out using a Bruker Tensor 27 spectrometer with samples pressed into KBr pellets. STEM images were obtained using a Hitachi S-5500 In-Lens FE STEM (2009) at an acceleration voltage of 1.0 kV. Samples were suspended in water and drop cast on lacey carbon copper grids (Agar Scientific). HPLC was carried out on an Agilent 1260 Infinity Quaternary LC equipped with a Zorbax Eclipse Plus C18 column (5 μm, 4.6 × 1.5 mm, Agilent) and diode array detector (monitoring at 270 nm). The mobile phase consisted of Solvent A (water + 0.1% formic acid) and solvent B (ACN/MeOH, 50:50, v/v) running along the following gradient: 0–8 min 85% A and 15% B at a flow rate of 1 mL/min, 8–15 min 65% A and 35% B at a flow rate of 2 mL/min. Indole (99%), isatin (97%), and oxindole (98%) were purchased from Sigma-Aldrich and calibration curves were obtained from 0 to 1.0 mM stock solutions in order to estimate product concentrations and % conversions. LC-MS was performed on an Agilent G6550 QTof mass spectrometer coupled to an Agilent 1200 Series Infinity LC system using a Zorbax Eclipse Plus C18 column (5 μm, 4.6 × 1.5 mm, Agilent). The mobile phase consisted of Solvent A (water + 0.1% formic acid) and solvent B (ACN + 0.1% formic acid) running along the following gradient: 0–14 min 85% A and 15% B to 5% A and 95% B at a flow rate of 0.8 mL/min. The electrospray source was operated with a capillary voltage of 3.0 kV and a nozzle voltage of 1.0 kV. Nitrogen was used as the desolvation gas at a total flow of 14 L/min. All *m/z* values stated are that of the $[M+H]^+$ molecular ion.

Synthesis of FLDA Monomer

See section Synthesis of Flavin-Dopamine Monomer in **Supplementary Information** for full synthetic details.

Synthesis of FLPDA

A mixture of ammonia solution (0.1 mL, 28%), ethanol (1.5 mL), and Milli Q water (4.5 mL) was stirred at room temperature for 30 min in reaction vessels protected from direct sunlight. Dopamine hydrochloride (15.80 mg, 0.083 mmol) dissolved in Milli-Q water (0.5 mL) and FLDA (8.73 mg, 0.017 mmol) dissolved in ethanol (0.5 mL) were mixed before being added dropwise to the reaction mixture. The resulting dark brown/black mixture was left to stir in the presence of air for 24 h. The mixture was then centrifuged at 25,000 × g for 30 min and the supernatant was removed. The precipitate was washed with Milli-Q water (3 × 40 mL) and then suspended in Milli-Q water (20 mL), frozen in liquid N_2 and lyophilized to yield a dark brown/black powder (5.5 mg, ρ = 22% where ρ is the percent weight conversion of monomers) (Jiang et al., 2014).

Photooxidation of Indole

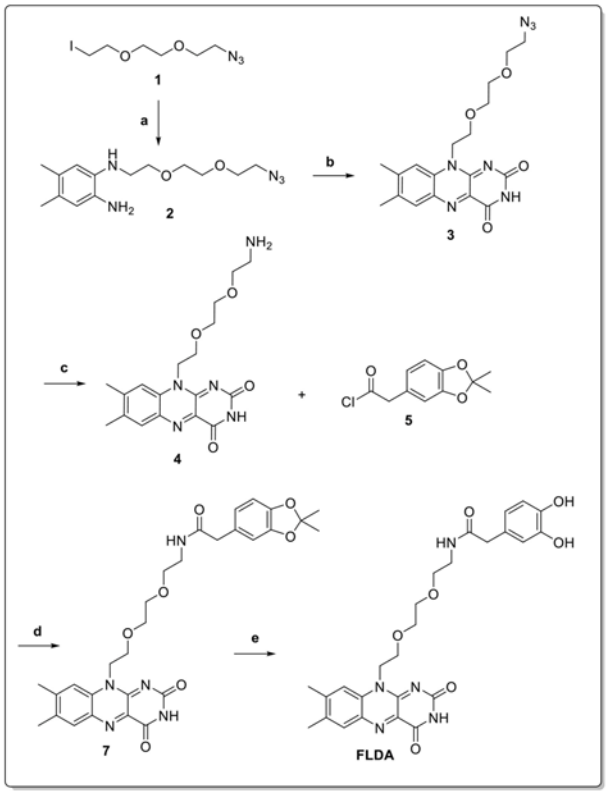
FLPDA (0.01–0.1 mg/mL) and indole (0.2 μmol—0.05 mmol) were added to a 50:50 acetonitrile/water (2 mL) solvent system and the mixture was saturated with O_2 gas for 10 min before irradiating with a custom-made blue LED strips setup (12 V) with a cooling fan to maintain a temperature of ∼25°C (see **Figure S1** for setup). For small scale reactions, 100 μL aliquots were taken from the reaction mixture and diluted to 1 mL (50:50 acetonitrile/water) for analysis by UV-Vis absorption spectroscopy. Post-irradiation (2–6 h), the reaction mixture was either diluted in 50:50 acetonitrile/water (10 mL) and the catalyst removed by centrifugation and washed with water (3 × 12 mL) for further use, or the catalyst was removed by centrifugation and the supernatant analyzed by HPLC-UV and LC-MS. For larger scale reactions the resulting supernatant was concentrated under reduced pressure and residue analyzed by ESI-MS and UV-Vis absorption spectroscopy.

RESULTS AND DISCUSSION

Synthesis of Flavin-Polydopamine

FLPDA nanoparticles were formed by the copolymerization of dopamine (**DA**) with the flavin derivative, **FLDA** that was synthesized according to the route shown in **Scheme 3**. First, the functionalized triethylene glycol species, **1** (Deng et al., 2011) was used in a mono-substitution reaction with 4,5-dimethylbenzene-1,2-diamine to form N^1-(2-(2-(2-azidoethoxy)ethoxy)ethyl)-4,5-dimethylbenzene-1,2-diamine, **2**.

Isoalloxazine formation was achieved through the double condensation reaction with alloxan monohydrate to obtain flavin derivative **3**. The azide functionality was then reduced *via* catalytic hydrogenation to yield the amine-bearing flavin derivative **4**. Conjugation of this compound to the activated



SCHEME 3 | Reaction conditions: (a) 4,5-dimethylbenzene-1,2-diamine, K_2CO_3, DMF, 50 °C, 12 h (70%); (b) alloxan monohydrate, B_2O_3, AcOH, RT, dark, 48 h (69%); (c) Pd/C, H_2, AcOH, RT, dark, 18 h (84%); (d) TEA, DMF, RT, dark, 18 h (62%); (e) TFA/DCM, RT, dark, 2 h (99%).

catechol-protected dopamine analog **6** resulted in protected **FLDA** derivative **7**, which was subsequently deprotected to afford the target **FLDA** monomer. Co-polymerization of dopamine and **FLDA** was carried out following a room temperature procedure adapted from Ai et al. (2013), and using ammonia addition to a water/ethanol solvent system in the presence of air. It should be noted that the reaction vessels were protected from direct light exposure to avoid any possible side reactions through the excitation of flavin moieties.

To validate the presence of flavin moieties, **FLPDA** was first analyzed by UV-Vis absorption and fluorescence spectroscopy. UV-Vis spectra of **FLDA** monomer shows absorption bands at λ_{max} = 445 nm and 373 nm (**Figure 1A**) corresponding to the transitions from the ground state (S_0) to the S_1 (λ_{max} ∼ 442–450 nm) and S_2 (λ_{max} ∼ 360–375 nm) excited states (Heelis, 1982). These bands are red-shifted to ∼ 456 nm for the $S_0 \rightarrow S_1$ transition and ∼ 376 nm for the $S_0 \rightarrow S_2$ transition in **FLPDA** (**Figure 1B**), which can be explained by an increase in proton donation from PDA (Kotaki et al., 1970) and by electron-withdrawing inductive effects on the flavin moieties due to incorporation into the highly conjugated PDA system (Mataranga-Popa et al., 2015). The fluorescence emission spectra of **FLDA** and **FLPDA** are characterized by emission maxima at 527 nm (λ_{ex} = 450 nm), which correlates well to other known flavin compounds (Kotaki and Yagi, 1970), and confirms the presence of flavin moieties in **FLPDA** NPs (see **Figures 1C,D**). An earlier study in which flavin compounds were complexed with eumelanin showed that the fluorescent properties of flavins did not change upon binding and there is no significant fluorescence quenching by the polymer (Kozik et al., 1990). We have used this fact to approximate flavin concentration within **FLPDA** by means of a calibration curve comparison (see **Figure S2** and **Table S2**). This gave an approximate concentration of flavin within **FLPDA** at 279.7 nmol/mg. It is worth noting that the amounts of flavin do not exactly match the monomer ratio used to synthesize the particles. The reason for this could be either the engulfing of the flavin moieties within particles or the base catalyzed cleavage/hydrolysis of flavin moieties during the polymerization, which results in the loss of characteristic flavin fluorescence (Smith and Bruice, 1975; Harayama et al., 1984).

FTIR spectroscopy was additionally employed to confirm **FLPDA** composition. The spectrum of PDA (**Figure 2A**) shows characteristic bands at 3,356 cm^{-1} relating to O-H and N-H stretching vibrations. In **FLDA** spectrum the bands corresponding to these vibrations broadens into one band at 3,414 cm^{-1}, which is also the case for **FLPDA**. Unlike for PDA, in the spectra of **FLPDA** bands at 2,924 and 2,855 cm^{-1} corresponding to C-H stretching vibration can be clearly identified and correlated well to the spectrum of **FLDA**. As seen in the zoomed spectra in **Figure 2B**, bonds characteristic for flavins such as the sharp bands at 1,545 cm^{-1} and 1,580 cm^{-1} relating to ν(C = N) modes in the isoalloxazine ring (Rieff et al., 2011) can clearly be observed in FLPDA, This is also true for the contributions from flavin carbonyl ν(C = O) (1,711 and 1,680 cm^{-1}) and ν(C = C). In addition, there are C = O and C-O vibrational modes of PDA, seen at 1,610 and 1,512 cm^{-1}, respectively, which are not observed in FLDA. Further C = N and C = C combined contributions can also be seen at shifted wavenumbers in the spectrum of **FLPDA** (1,292 cm^{-1}).

Finally, the size and morphology of **FLPDA** were investigated using STEM. As shown in **Figure 3** FLPDA solution is made up of spherical particles of similar size (∼200 nm) with relatively large size distribution (± ∼50 nm) (see **Table S1**). In contrast, PDA synthesized under the same conditions displays a narrower size distribution with an average size of 110 ± 18 nm (see **Table S1**), clearly indicating that the presence of flavin moieties affects the polymerization mechanism and oligomer aggregation to form particles with less defined shape and size. This is most likely due to H-bonding and electrostatic interactions between the flavin group and oligomeric units, and our ongoing work is focused on optimizing the polymerization procedure.

Indole Photooxidation

Having successfully prepared and characterized the **FLPDA** nanoparticles, we set out to investigate their catalytic activity in the presence of indole under blue light irradiation and explored their resemblance to the FMO enzyme activity. At first, small scale reactions were carried out using 1.0 mM indole with 50 μg/mL **FLPDA** and monitored by UV-Vis absorption spectroscopy. As shown in **Figure 4A** the absorption spectrum of indole (0 h) has a characteristic absorbance band at λ_{max} = 287 nm. After 0.5 h irradiation, this peak decreases in intensity and a new band appears at λ_{max} ∼ 380 nm which is consistent

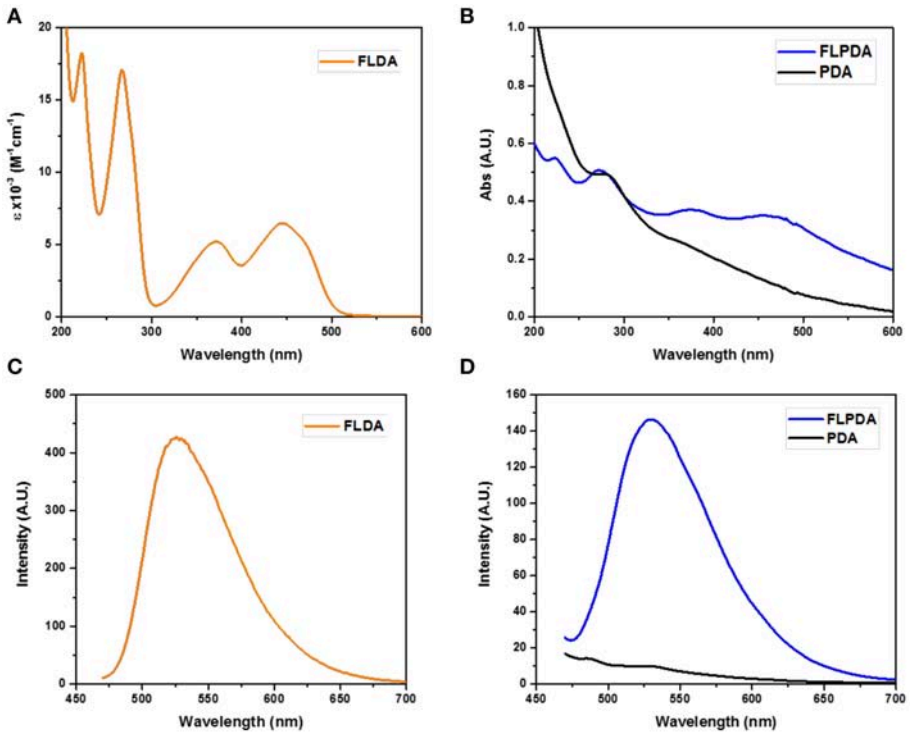


FIGURE 1 | UV-Vis spectra of **FLDA** (80 μM, 0.04 mg/mL in water **(A)**, and **FLPDA** and PDA (0.1 mg/mL in water **(B)**, and corresponding fluorescence spectra **(C,D)**.

with the consumption of indole and the production of 2 and 3-position hydroxylated indole species (Kumar and Kumar, 1998; Kuo and Mauk, 2012; Linhares et al., 2014). These bands increase in intensity with time and a shoulder replacing the characteristic band belonging to indole at 2 h indicates its consumption (Kuo and Mauk, 2012). We also monitored the fluorescence emission (λ_{ex} = 365 nm) of the reaction as shown in **Figure 4B** and observed the formation of fluorescent indoxyl species (λ_{em} = 465 nm) at 0.5 h and 1 h (Gehauf and Goldenson, 1957; Woo et al., 2000). After 1 h the signal disappears most likely due to indoxyl dimerization into the fluorescent, water-soluble leuco-indigo (λ_{em} = 523 nm) (Gehauf and Goldenson, 1957; Seixas De Melo et al., 2004). Control experiments were carried out in the dark showing no reaction after 18 h, and by irradiating indole alone, indole in the presence of pure PDA particles, and indole in the presence of **FLPDA** under inert Ar atmosphere; all of which

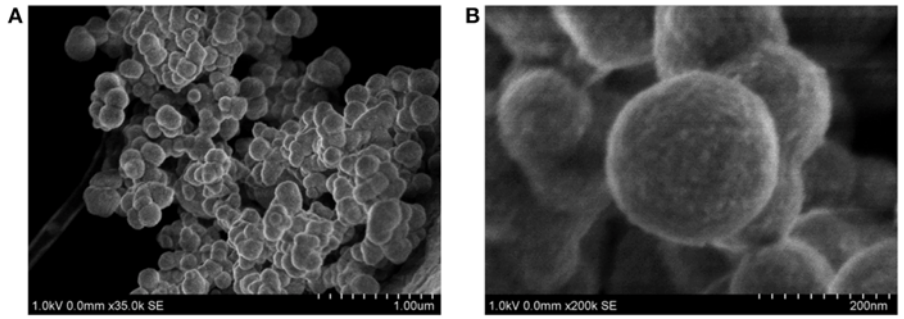

FIGURE 3 | STEM images of **FLPDA** at different scales **(A)** scale bar = 1.00 μm and **(B)** scale bar = 200 nm.

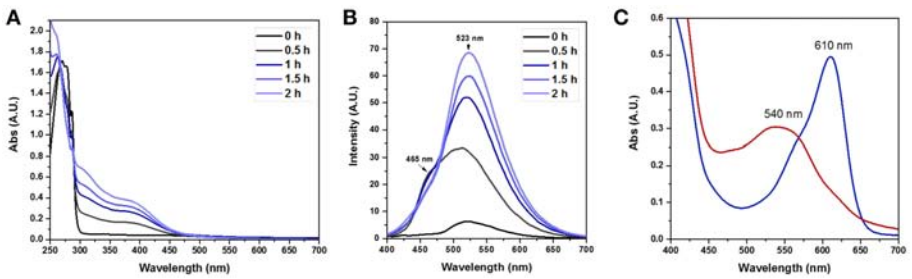

FIGURE 4 | (A) UV-Vis absorption spectra of the photooxidation of indole (1.0 mM) in the presence of **FLPDA** (50 μg/mL) in O_2 saturated ACN/H_2O (1:1, v/v). **(B)** Fluorescence emission spectra (λ_{ex} = 380 nm) of indole (1.0 mM) photooxidation in the presence of **FLPDA** (50 μg/mL) in O_2 saturated ACN/H_2O (1:1, v/v). All spectra are 10× dilutions of reaction mixture. **(C)** UV-Vis absorption spectra of produced indirubin (λ_{max} = 540 nm) and indigo (λ_{max} = 610 nm) in DMF.

showed negligible changes in indole's characteristic absorption band (see **Figure S3**).

Several oxidation products were obtained from the **FLPDA** catalyzed photooxidation of indole and three major products were identified by LC-MS (**Figure 5**) and compared to the commercial reagents. These were isatin **11** (7.07 min, *m/z*: 148), 2-oxindole **9** (7.69 min, *m/z*: 134), and indoxyl **10** observed as its more stable keto-form **10a** (4.23 min, *m/z*: 132). Other products with higher *m/z* values were also identified *via* LC-MS of the reaction mixture, including indigo/indirubin (two signals with *m/z*: 263) and two others with m/z values of 249 and 281. Their structures are proposed in **Scheme 4** and **Figure S5** as products **12** and **13**, and their production is particularly interesting as they were observed in reactions catalyzed by enzymes such as laccases and P450s that contain inorganic cofactors (Gillam et al., 2000; Ganachaud et al., 2008; Linhares et al., 2014).

The formation of indigo and indirubin were initially observed by TLC analysis of the reaction mixture and were then isolated after reaction workup and characterized by UV-Vis (indirubin λ_{max} = 540 nm and indigo λ_{max} = 610 nm as seen in **Figure 4C**). It should be noted that theses dyes were not observed to form during the reaction itself, but only upon removal of the solvent to initiate precipitation or with the addition of weak acid to the reaction mixture or supernatant which catalyzed their formation (Zelentskii et al., 1970). Yields of the dyes were measured by UV-Vis spectroscopy using published extinction coefficients (Seixas De Melo et al., 2004) and were generally low (<4%) when precipitated out of solution after solvent removal however this is comparable to other biomimetic systems using Fe(II) and Mn(III) porphyrin complexes in the presence of H_2O_2 (Linhares et al., 2014; Rebelo et al., 2014) indicating that low yields are the consequence of the non-specific binding sites, as the active site of FMO alters the product selectivity (Han et al., 2012). We noticed that adding weak acid to the reaction mixture after irradiation provided better yields of dye, however, primarily favored the formation of indirubin (see **Table 1**).The light-driven oxidation of indole by **FLPDA** is clearly non-specific due to the range of identified oxidation products, however, these main products resemble those formed by FMOs and other xenobiotic degrading enzymes. To our knowledge, this is the only reported example of an organic nanoparticle-based photocatalyst that shows this activity. In addition, the only other example of photocatalytic oxidation of indole to form indigo and related compounds are CdS quantum dots, the use of which has serious implications in terms of toxicity (Tsoi et al., 2013; Yong et al., 2013).

We also compared the activity of our hybrid catalyst to homogenous flavin, riboflavin (**RF**), under the same reaction conditions. To make an experimentally valid comparison, we used the same effective flavin concentration for both **FLPDA** and **RF** based on the fluorescence calibration curve utilized to characterize **FLPDA**, namely 20 μM for **RF** (2 mol%) and 36 μg/mL **FLPDA**. UV-Vis analysis of the reaction mixture containing **RF** showed an increased rate of indole consumption (shoulder formation at ∼280 nm as shown in **Figure 7A**) after

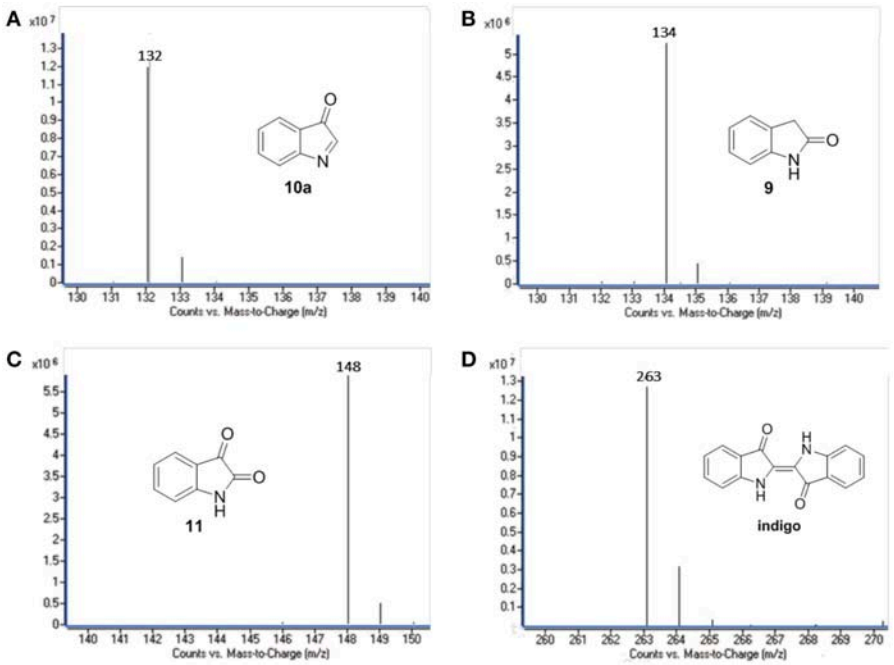

FIGURE 5 | LC-MS chromatograms of the major oxidation products: **(A) 9**, **(B) 10a**, **(C) 11**, and **(D)** indigo.

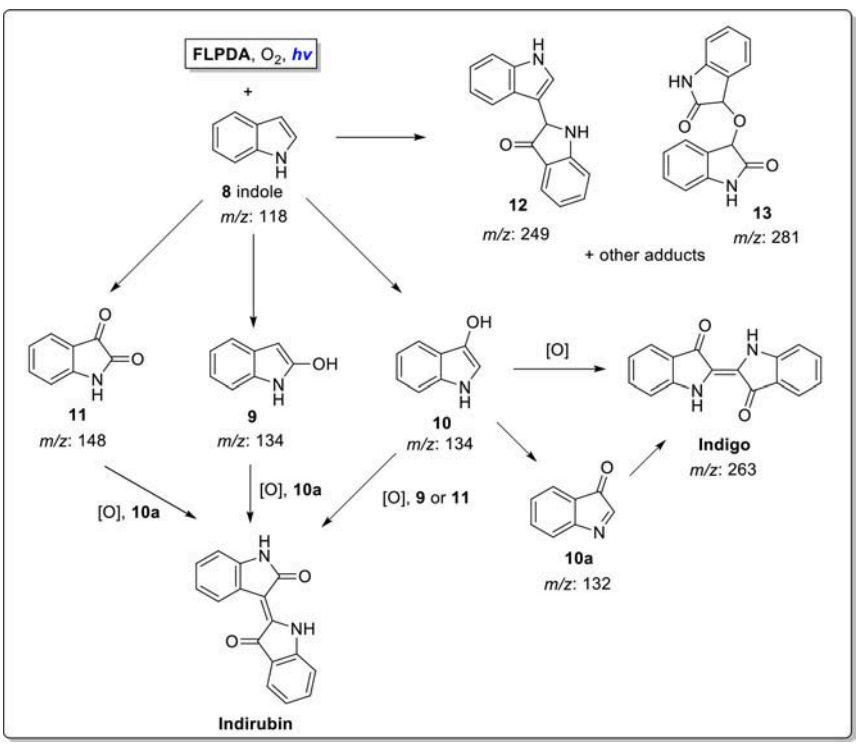

SCHEME 4 | Proposed reaction scheme for indole photooxidation in presence of enzyme mimicking **FLPDA**.

0.5 h. HPLC analysis indicated that there is a greater conversion of indole in presence of RF compared to **FLPDA,** and similar products although in different yields, were observed as shown in **Figure 6** and **Table 1**. We next compared the yield of dyes after the reactions through the addition of 2 drops of 1M HCl to each reaction mixture to initiate dimerization of hydroxylated

TABLE 1 | Amounts and conversions of major compounds identified by HPLC after acidification of reaction mixture using commercial standards as a calibration reference.

Catalyst	Indole (μM)	Oxindole (9) (μM)	Isatin (11) (μM)	Indole conversion	Indigoid yield*

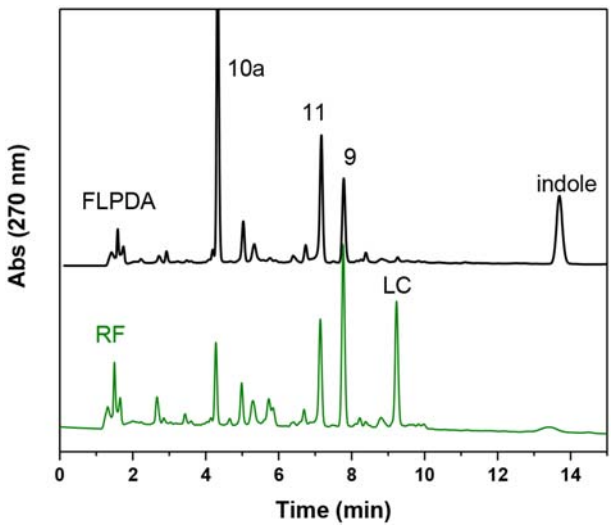

FIGURE 6 | HPLC chromatograms of the reaction mixture after 2 h blue light irradiation of indole (1.0 mM) in the presence of **FLPDA** (36 μg/mL) in ACN/H_2O (1:1, v/v) and riboflavin **RF** (20 μM).

indole species to form the indigoid dyes. As shown in **Figure 7B**, there was more indirubin obtained from the reaction conducted in the presence of **FLPDA** than **RF**, which was expected as 2.5 times more precursor **10a** can be detected in HPLC profile shown in **Figure 6**. Clearly, despite the decreased indole conversion, **FLPDA** appears to be more selective than its homogeneous counterpart toward dye conversion.

It is also worth noting that after the irradiation, **RF** could no longer be identified by TLC analysis within the reaction mixture and had degraded to lumichrome (LC), which was confirmed both by HPLC and LC-MS (9.22 min, *m/z*: 243) (**Figure 6**). Although there was some photodecomposition observed in **FLPDA**, the concentration of lumichrome was five times lower compared to **RF** (based on HPLC integration), indicating that the hybrid catalyst offers more protection toward photodecomposition of active flavin centers, and mitigates the loss of catalysis observed in homogenous systems.

Further Control Experiments and Possible Mechanism of Action

As this is a novel hybrid system, we were also interested in unveiling the photocatalytic mechanism of **FLPDA.** To achieve this we employed a superoxide radical scavenger TEMPO and the singlet oxygen scavenger DABCO to quench these prominent reactive oxygen species (ROS) that may be liberated from reduced and/or photoexcited flavin species (Massey et al., 1969; Müller and Ahmad, 2011). As can be seen from the HPLC chromatograms of the reactions shown in **Figure 8**, the addition of these quenchers did not appear to inhibit the reaction completely. In fact, we observed that in the case of DABCO, the basic character of the species may have played a role in lowering the activity of **FLPDA** as flavins and PDA are less stable within a basic environment (Song et al., 1965; Yang et al., 2018). In terms of product selectivity, **10a** was not detected most likely due to direct oxidization to isatin **11** in basic condition (**Table 2**). Based on these observations it could be assumed that singlet oxygen plays a minimal role in **FLPDA** activity as both compounds **9** and **11** are obtained in the presence of singlet oxygen quencher.

The addition to the superoxide scavenger, TEMPO had no deleterious effect on **FLPDA** activity either and in fact, it enhanced the production of **9, 10a**, and **11**. In fact, TEMPO most probably acts as a redox mediator and co-catalyst in the reaction, as previously shown for the synthesis of isatin derivatives in the presence of hypervalent iodine (Sai Prathima et al., 2015). TEMPO's participation in the reactions was additionally proved by appearance of the by-product 2,2,6,6-tetramethylpiperidine (TMP) at a retention time of 2.49 min, *m/z*: 142 (LC-MS analysis). It should be noted that pigment melanin, composed of PDA units, is capable of superoxide quenching (Tada et al., 2010), and it is safe to assume that any superoxide radical generated by flavin would be quickly quenched by PDA in its immediate proximity.

We further investigated the mechanism of **FLPDA**'s photocatalytic activity by using a fluorescence-based assay to monitor the release of H_2O_2 liberated from the unstable 4a-hydroperoxy-flavin species formed when reduced flavin moieties interact with oxygen (Usselman et al., 2014). We reasoned that the lower amount of H_2O_2 obtained in photo-reaction in presence of **FLPDA** compared to free flavin (riboflavin **RF**), would indicate potential stabilization of 4a-hydroperoxy-flavin species, and its interaction with indole (**Scheme 5**) instead of direct transformation into reactive oxygen species. To minimize the loss of photons due to the scattering effect of a colloidal heterogeneous catalyst, low concentration of **FLPDA** (10 μg/mL) was used, and the concentration of indole and effective concentration of free flavin were adjusted accordingly. The amount of H_2O_2 released after 1 h of irradiation was 3.62 ± 0.18 nmol for **FLPDA** and 5.13 ± 0.04 nmol for **RF** (see **Figure S4**). The lower value obtained for **FLPDA** suggest that the stabilization of 4a-hydroperoxy flavin species in **FLPDA** may occur, although this hypothesis can only be fully confirmed after the completion of already initiated EPR study.

Based on current data, we propose the mechanism shown in **Scheme 5**, which includes the formation of the 4a-hydroperoxy species as a result of indole and/or PDA photoreduction, and subsequent interaction with oxygen. This species could be stabilized by H-bonding with neighboring PDA moieties and be stable long enough to interact with the indole substrate. In addition, the appearance of compounds **12** and **13** indicates Type 1 photosensitization of indole through electron transfer to excited flavin moieties similar to that previously observed for riboflavin

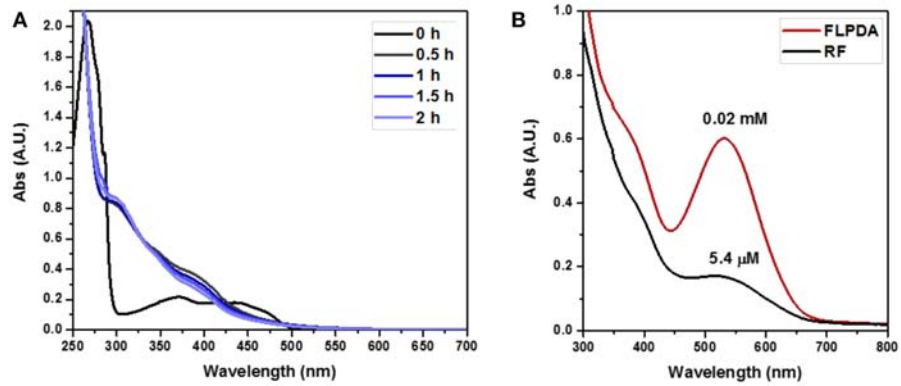

FIGURE 7 | (A) UV-Vis absorption spectra of the photooxidation of indole (1.0 mM) in the presence of **RF** (20 μM) in O_2 saturated ACN/H_2O (1:1, v/v). **(B)** Plot comparing the reactions post acid workup (3× dilutions of reaction mixtures).

Quencher	Indole (μM)	Oxindole (9) (μM)	Isatin (11) (μM)	Indole conversion
TEMPO	177	278	121	82%
DABCO	326	143	252	67%

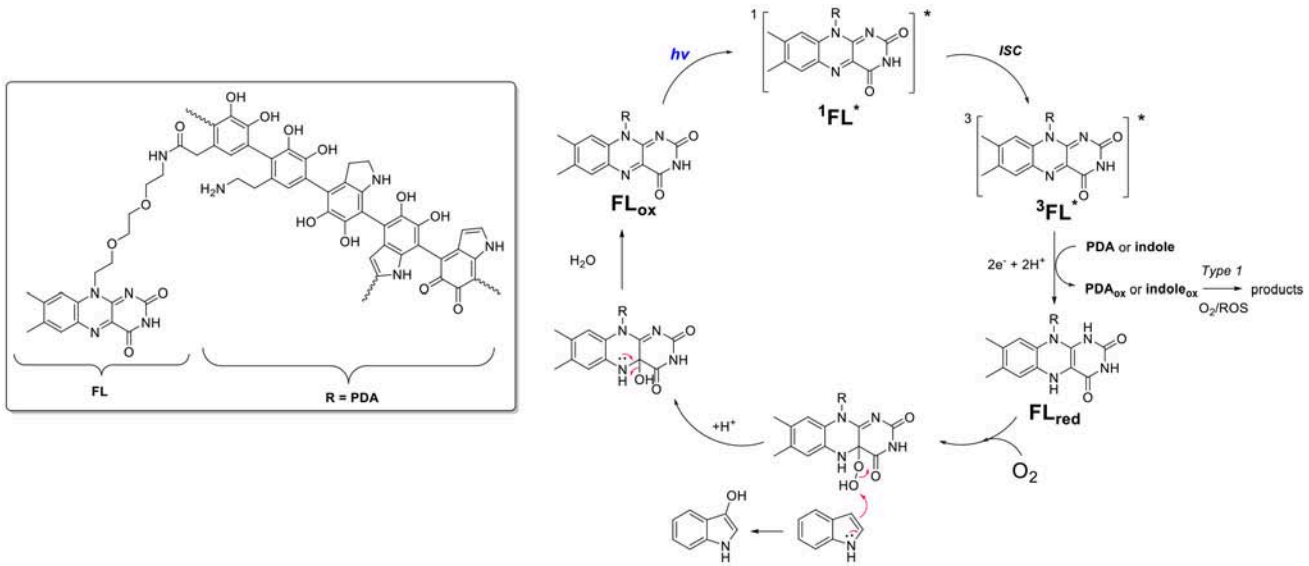
and tryptophan (Silva et al., 2019). However, as stated above further studies using EPR spectroscopy are being undertaken to confirm our theory.

Although some "dark" reactions in the presence of flavin species have resulted in excellent yields of desired products (Arakawa et al., 2017; Chevalier et al., 2018), use of light to trigger the reaction cascade that leads to complex dye formation would have multiple advantages in an industrial setting, including temporal and spatial control, ultimately leading to the design of more efficient reactors.

Recyclability

Finally, we were interested to estimate the reusability of **FLPDA** in this light-driven reaction as this is a desirable property for scaling up and industrial applications enhancing the green potential of the system. Previous work on a heterogeneous flavin-based photocatalytic system using mesoporous silica to immobilize flavin moieties suffered from a severe loss of activity after the first reuse, and a complete inactivation upon second and third attempt (Špačková et al., 2017). For our nanoparticle-based system, the catalyst was easily removed from the reaction mixture *via* centrifugation and maintained activity for 4 cycles. As a proof of concept study, activity was monitored by irradiation of **FLPDA** particles (50 μg/ml) with indole (1.0 mM) for 1.5 h and measuring the changes in absorption of the reaction mixture between 300 and 600 nm as shown in **Figure 9A**. The area within this region was integrated and used as a measure for oxidized indole species production. The first run showed a decrease in relative activity compared to the initial run only by a factor of 1.36 (**Figure 9B**) and the subsequent three runs stayed within a similar range before minimum activity, although not a complete loss, was observed by run 6.

The enhanced stability of our system could be explained by the electron transfer from PDA to flavin moieties upon irradiation as proposed in our mechanism (**Scheme 5**). It has already been shown that an addition of an electron donor, such as 2-(*N*-morpholino)ethanesulfonic acid (MES) buffer, limits photo-induced decomposition reactions that curtail flavin activity upon irradiation (Alonso-De Castro et al., 2017). However, during the recycling steps, the number of retrieved particles decreased with each run. Loss of particles and the catalytic activity could point toward the photo-degradation of PDA moieties similar to what was previously observed in melanin samples (Ito et al., 2018). However, we did not notice any difference in the particle size and morphology after 2 h of irradiation (**Figures 9C,D**), which



SCHEME 5 | Proposed mechanism of action involving electron transfer process between flavin (FL) and PDA moieties within **FLPDA** hybrid catalyst.

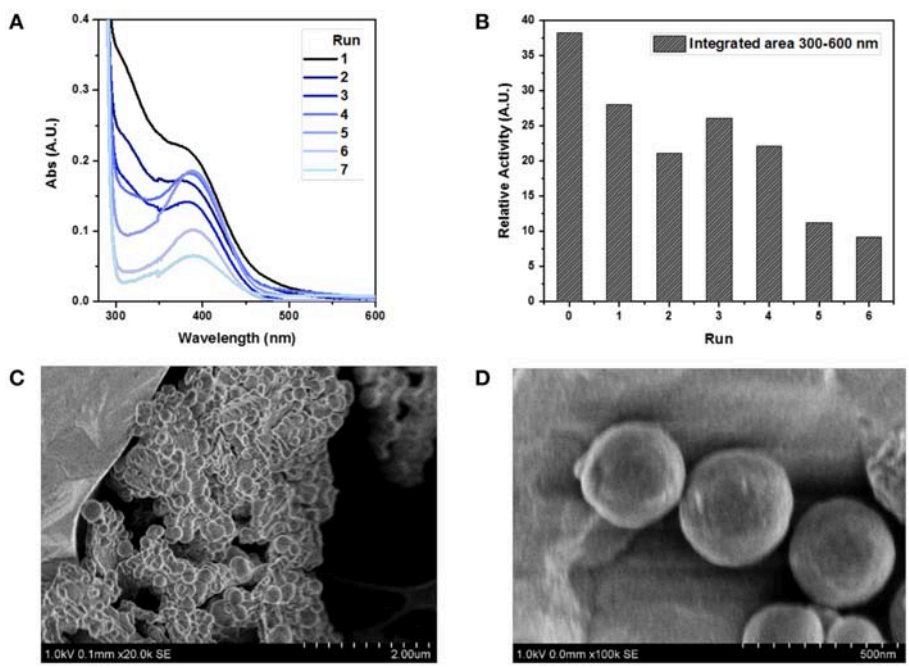


FIGURE 9 | Study of FLPDA catalyst recyclability. UV-Vis absorption spectra of different runs using a recycled catalyst **(A)** and the relative activity plot using the integrated area between 300 and 600 nm of each run **(B)**. Reaction conditions: indole (1.0 mM), **FLPDA** (50 μg/mL) in O_2 saturated ACN/H_2O (1:1, v/v) and irradiation for 1.5 h.

disputes this argument, and indicates a mere physical loss of particles during recovery procedures.

Our ongoing work is focused on exploring the long-term stability and photo-degradation of **FLPDA**, as well as establishing a detailed mechanism using EPR studies. We believe this information will allow us to rationally design better catalytic systems with enantio-selective potential. We are also currently working on improving the reusability of **FLPDA** by addition of magnetic Fe_3O_4 nanoparticles during co-polymerization to enable magnetically aided retrieval, which has already proven effective in various application using PDA (Liu et al., 2013, 2017; Xie et al., 2014; Yu et al., 2016).

CONCLUSION

We have developed a novel photocatalytic organic nanoparticle system made from flavin conjugated polydopamine. This was achieved through a convenient co-polymerization method involving dopamine and a flavin-dopamine analog, **FLDA**, to form **FLPDA**. The system effectively displays activity analogous to xenobiotic-degrading enzymes such as FMO, shown, using the oxidation reaction of indole, to form the indigo dye. In addition, it employs irradiation with visible light rather than an external cofactor for catalyst activation. The products observed in the reaction; indigo, indirubin, and related compounds, clearly indicated FMO-like activity of **FLPDA**. Additional ROS scavenging studies as well as the nature of some products, further confirmed that **FLPDA** displays mechanistic similarities to natural FMO, which is characterized by the formation of 4a-hydroperoxy flavin as a reactive intermediate. In contrast to our heterogeneous hybrid flavin, free flavin in a solution was characterized with higher photo-degradation and lower dye yields. In addition, **FLPDA** can easily be recovered from the reaction mixture and displays recyclable activity up to four cycles. We hope that this initial work sets the foundation to enable the design of more elaborate photocatalytic biopolymer hybrids comprising of flavin, PDA and additional functional moieties, to be applied in heterogeneous catalysis and artificial photosynthesis.

AUTHOR CONTRIBUTIONS

LC carried out all the synthesis, characterization and analyses, and wrote the draft manuscript. LF was involved in the experimental planning and manuscript proofreading and corrections. LF was the academic lead of the project in charge of experimental planning and funding.

FUNDING

The project was funded by the Department of Chemical Engineering and Biotechnology Start-up grant awarded to LF. LC would like to acknowledge support for DTP-EPSRC doctoral programme (EP/N509620/1).

ACKNOWLEDGMENTS

We would like to thank Dijana Matak, as well as Rhian Preece, Nitin Rustogi, and Sabine Bahn for their help with LC-MS analysis.

Chemical and Process Engineering (formerly Chemical Engineering)

Camille Petit

Dr Camille Petit is a Reader in the Chemical Engineering Department at Imperial College London. She leads the Multifunctional Materials Laboratory. She was a postdoctoral researcher at Columbia University and obtained her PhD in Chemistry from the City University of New York. Her research interests encompass the development of porous materials for energy and environmental applications. She focuses on metal-organic frameworks and nitride-based materials for molecular separations and solar energy conversion. She received the 2017 AIChE's 35 under 35 award, the 2017 ExxonMobil European Science & Engineering Program Award, the 2017 IOM3 Silver Medal, and the 2015 IChemE Sir Frederick Warner medal.

Kelly M. Schultz

Dr Kelly M. Schultz is an Associate Professor in the Department of Chemical and Biomolecular Engineering at Lehigh University. She obtained her PhD in Chemical Engineering advised by Eric Furst from the University of Delaware. She was a Howard Hughes Medical Institute postdoctoral research associate at the University of Colorado at Boulder working for Kristi Anseth. She began her position at Lehigh in 2013. She was named a TA Instruments Distinguished Young Rheologists in 2014, received an NSF CAREER Award in 2018, and a Libsch Early Career Research Award in 2019. Her group studies emerging hydrogel materials developed for consumer products and biological applications.

Florent Allais

Florent Allais is a Professor in Chemistry at AgroParisTech, Paris, France and the Director of the URD ABI in Pomacle, France. He obtained his PhD from the University of Florida in 2004 and his postdocs at ESPCI, Paris, France and ICSN, Gif-sur-Yvette, France. He has published approximately 80 papers and filed 16 patents. His multidisciplinary research team combine biotechnologies, green chemistry, and downstream processing approaches to develop durable processes to turn agro-resources into platform molecules as well as valuable chemicals that can be used in chemistry, in food/feed or cosmetics to name a few.

Tsuguyuki Saito

Dr Tsuguyuki Saito is an Associate Professor of the University of Tokyo, Japan. He obtained his PhD degree in 2008 from the University of Tokyo for his study on TEMPO-mediated oxidation of cellulosic fibers. He has further developed this oxidation as a tool to produce the finest type of cellulose nanofibers (CNF) with a width of approximately 3 nm from wood pulp in an energy-efficient way. For his ground-breaking discovery on CNF production, he was awarded the Marcus Wallenberg Prize by the Marcus Wallenberg Foundation in 2015, and the JSPS prize by the Japan Society for the Promotion of Science in 2019.

Porous Boron Nitride Materials: Influence of Structure, Chemistry and Stability on the Adsorption of Organics

*Sofia Marchesini, Xiyu Wang and Camille Petit**

Department of Chemical Engineering, Barrer Centre, Imperial College London, London, United Kingdom

Porous boron nitride (BN) is structurally analogous to activated carbon. This material is gaining increasing attention for its potential in a range of adsorption and chemical separation applications, with a number of recent proof-of-concept studies on the removal of organics from water. Today though, the properties of porous BN—i.e., surface area, pore network, chemistry—that dictate adsorption of specific organics remain vastly unknown. Yet, they will need to be optimized to realize the full potential of the material in the envisioned applications. Here, a selection of porous BN materials with varied pore structures and chemistries were studied for the adsorption of different organic molecules, either directly, through vapor sorption analyses or as part of a water/organic mixture in the liquid phase. These separations are relevant to the industrial and environmental sectors and are envisioned to take advantage of the hydrophobic character of the BN sheets. The materials were tested and regenerated and their physical and chemical features were characterized before and after testing. This study allowed identifying the adsorption mechanisms, assessing the performance of porous BN compared to benchmarks in the field and outlining ways to improve the adsorption performance further.

Keywords: boron nitride, vapor sorption, adsorption, separations, water stability

INTRODUCTION

Chemical separations account for more than half of the total energy consumed in industry owing to the many separation processes performed *via* distillation (Sholl and Lively, 2016). Adsorbent materials or membranes, which are able to separate molecules based on size exclusion principles and/or chemistries, offer a possibly less energy intensive and hence more sustainable route to separations (Sholl and Lively, 2016). Realizing the potential of adsorption and membrane separation requires the production of porous materials with tailorable properties and porosities. Today, research in this area primarily focuses on materials such as metal-organic frameworks (James, 2003), zeolites (Misaelides, 2011), carbon-based materials (Dias et al., 2007), covalent organic frameworks (Côté et al., 2005), and polymer of intrinsic microporosity (McKeown and Budd, 2006). A recent addition to this list is porous boron nitride (BN). Owing to its high thermal stability, "rich" chemistry, and high surface area [up to ~2,000 m^2 g^{-1} reported so far (Li et al., 2013b; Marchesini et al., 2017b)], porous BN has been tested for a range of different applications such as catalysis (Venegas et al., 2017), CO_2 capture, oil spill clean-up (Lei et al., 2013), hydrogen storage

(Portehault et al., 2010; Lei et al., 2014; Weng et al., 2014), and water cleaning (Zhang et al., 2012; Li et al., 2013a,b; Lei et al., 2015). Porous BN is somewhat analogous to activated carbon in terms of its turbostratic to amorphous structure with 6-member rings of alternating B and N atoms. Yet, its chemistry is obviously different from that of carbonaceous materials as the material is made of polar B-N bonds. BN materials are typically hydrophobic. Such a feature can be particularly advantageous for the adsorption of organics, either in the vapor phase or as part of a water/organic mixture in the liquid phase. In fact, a number of studies report the use of porous BN for the removal of organic molecules (e.g., dyes, pharmaceutical molecules, oils) from water Zhang et al., 2012; Li et al., 2013a,b; Lei et al., 2015. The sorption mechanisms are typically associated to: (i) π-π stacking interactions between the BN sheets and aromatic dye molecules (Zhang et al., 2012; Liu et al., 2014, 2015); (ii) electrostatic dipole-dipole interactions between the polar B-N bond and the polar dyes (Liu et al., 2014; Lin et al., 2016); (iii) physisorption in the micropores of BN (Liu et al., 2014; Lin et al., 2016), and (iv) hydrophobic interactions (Yu et al., 2018). The adsorption capacity can be highly dependent upon the pH of the solution in the case of dye sorption, due to electrostatic interactions with the polar dyes, which are weakened by competitive adsorption of protons or hydroxides (Singla et al., 2015; Li et al., 2016). For a similar reason, OH-functionalised BN adsorbs more cationic dyes (e.g., methylene blue) than its pristine counterpart (Li et al., 2015). Porous BN materials exhibit competitive sorption capacities of selected organics compared to other common adsorbents such as activated carbons (Yu et al., 2018). Interestingly, many studies on the removal of organics from water using porous BN, report multiple adsorption and desorption cycles with minimal (5–15%) decrease in performance (Li et al., 2013b, 2015; Lei et al., 2015; Zhao et al., 2015; Liu et al., 2016). This behavior is surprising given the demonstrated instability of some porous BN structures in the presence of water, which causes a decrease in porosity (Shankar et al., 2018). This raises a question around the effect of BN porosity in these applications. Overall, the studies above serve as proof-of-concept for the use of porous BN as adsorbent for a given organic. Today though, the materials parameters—i.e., surface area, pore network, chemistry—that dictate adsorption of specific organics remain vastly unknown.

Herein, we synthesized BN samples exhibiting a range of pore structures and crystallinity as well as distinct chemistries (Marchesini et al., 2017a; Shankar et al., 2018) The pore structure of the materials was controlled *via* manipulation of the precursor type and ratio used to synthesized BN (see our previous study Marchesini et al., 2017a). We tuned the crystallinity and chemistry—particularly the amount of O groups—using the synthesis temperature (Shankar et al., 2018). We tested all the porous BN samples for the adsorption of different organic molecules, either directly, through vapor sorption analyses or as part of a water/organic mixture in the liquid phase. The organics selected for this study cover different classes of chemicals in terms of polarity and molecular size: alkanes (linear and branched), cycloalkanes, aromatics alcohols, and dyes. We characterized the samples before and after adsorption and linked their materials features to the adsorption behaviors.

Materials Synthesis

We synthesized porous BN materials following a procedure previously developed by our group Marchesini et al., 2017b. Boron- and nitrogen- containing precursors were mixed and ground in different molar ratios. The precursors were placed in an alumina boat crucible and heated up to the 1050 or 1500°C for 3.5 h (10°C/min ramp rate) under nitrogen gas flow (50 cc/min during analysis, 3 h at 250 cc/min to purge). The furnace was cooled while flowing nitrogen until ambient temperature. We refer to porous BN samples synthesized at 1050°C as "low temperature BN" samples, and to porous BN samples synthesized at 1500°C as "high temperature BN" samples. We used three different sample formulations as follows:

- BN-U5: molecular ratio of urea:boric acid = 5:1;
- BN-MU0.25:5: molecular ratio of melamine:urea:boric acid = 0.25:5:1;
- BN-MU1:5: molecular ratio of melamine:urea:boric acid = 1:5:1.

Materials Characterization

Materials characterization techniques were used to: (i) verify that the synthesized samples cover a range of porosity, crystallinity and chemistry as envisioned initially and (ii) assess the impact of adsorption on the materials features and (iii) extract information of the adsorption mechanisms.

Structural Properties and Morphology

Nitrogen physisorption isotherms were measured using a porosity analyser (Micromeritics 3Flex) at −196 °C. Prior to nitrogen sorption analysis, the samples were degassed overnight at 120 °C at roughly 0.2 mbar pressure and degassed again *in-situ* on the porosity analyser for 4 h down to around 0.003 mbar at 120 °C. From the nitrogen isotherms, we derived the surface areas, total pore volumes, micro- and mesopore volumes of BN samples and pore size distributions (Rouquerol et al., 2013). The surface areas of the samples were calculated using the Brunauer-Emmett-Teller (BET) method (Brunauer et al., 1938). The total volume of pores was calculated from the volume of N_2 adsorbed at $P/P_0 = 0.97$. The micropore volume was determined using the Dubinin Radushkevich method (Chen and Yang, 1994). The pore size distributions were calculated using a DFT model for carbons with slit-shape pores using the Micromerics software.[1] We assessed the crystallinity (or lack of) of our samples *via* powder X-ray diffraction (XRD) using an X-ray diffractometer (PANalytical X'Pert PRO) in reflection mode. The operating conditions included an anode voltage of 40 kV and an emission current of 40 mA using monochromatic Cu Kα radiation (λ = 1.54178 Å).

Chemical Properties

The porous BN samples were characterized by Fourier Transform Infrared (FT-IR) spectroscopy. The samples were first ground in

[1] http://www.nldft.com

an agate mortar and spectra were collected in the range of 600–4000 cm^{-1} using a Perkin-Elmer Spectrum 100 Spectrometer equipped with an attenuated total reflectance (ATR) accessory. X-ray Photoelectron Spectroscopy (XPS) was performed using a Thermo Scientific K-Alpha$^+$ X-ray Photoelectron Spectrometer equipped with a MXR3 Al Kα monochromated X-ray source ($h\nu = 1486.6$ eV). X-ray gun power was set to 72 W (6 mA and 12 kV). All high resolution spectra (B 1*s*, N 1*s*, C 1*s*, and O 1*s*) were acquired using 20 eV pass energy and 0.1 eV step size. The samples were ground and mounted on the XPS sample holder using conductive carbon tape. Thermo Avantage software (ThermoFisher Scientific) was used to analyse the data. The XPS spectra were shifted to align the peak for adventitious carbon (C-C) at 285.0 eV.

Materials Testing

Organic Vapor Sorption

We conducted these analyses to assess the "idealized" (i.e., single adsorbate, no competitive adsorption) adsorption of several molecules with different polarities and molecular sizes. We performed vapor sorption experiments on an IGA gravimetrical analyser (Hiden Isochema). The IGA analyser is equipped with a microbalance with ± 1 μg resolution. The samples (∼30 mg) were degassed *in-situ* at 120 °C for 4 h using a furnace attachment, prior to analysis. An ultra-high vacuum of up to 10^{-6} mbar could be created inside the chamber. Solvents were purified by cycles of evacuation followed by vapor equilibrium, repeated for at least 10 times. The solvents were vaporized and dosed up to 90 % of their saturation pressures at 25 °C: n-heptane (P_0: 61.12 mbar), 2,3-dymethylpentane (P_0: 91.82 mbar), toluene (P_0: 37.93 mbar), methylcyclohexane (P_0: 61.79 mbar), 1-butanol (P_0: 9.22 mbar), methanol (P_0: 169.24 mbar). The temperature was controlled using an external water bath equipped with a thermocouple which maintained a temperature stability of ± 0.3 °C. Equilibrium for each pressure point was predicted by the IGA software after a minimum wait of 20 min, by checking for weight changes using the least squares regression to extrapolate the asymptote (tolerance of 99 %). Pressure increase/decrease was performed with a rate of ∼0.25–1 of the step pressure change. All solvents were of analytical grade. We performed *in situ*-degas in between each experiment at 250 °C to regenerate porous BN. Solvent selectivity was calculated as the ratio of quantity adsorbed of two pure solvents measured under the same conditions, assuming equal partial pressures.

Water Vapor Sorption

Prior to testing the removal of organics from water, we assessed water sorption to evaluate the affinity of the samples with water and quantify their water adsorption capacity. Porous BN samples were degassed at 120 °C at roughly 0.2 mbar pressure and again *in-situ* on the porosity analyser (Micromeritics 3Flex) for 4 h down to around 0.003 mbar. We collected water vapor isotherms at 30 °C for porous BN samples at up to 90% relative humidity in a gas/vapor volumetric analyser.

Organics Removal From Water

We used a dye [Rhodamine B, RhB (HPLC, Sigma Aldrich)] as a representative organic molecule owing to the ease of monitoring dye sorption using UV-vis spectroscopy. In a typical test, 250 mL of stock solution (of 40 mg/L in deionized water) were vigorously stirred and 100 mg of porous BN powder were added to the solution while stirring. At 0, 5, 10, 30, 60, 120, 240 min, about 2 mL of solution were collected with a syringe and filtered with a syringe filter (0.45 μm) to remove BN powder. We then analyzed these solutions using UV-vis spectrophotometry to determine the dye concentration. UV-vis spectra were collected between 400 and 650 nm ($\lambda_{maxRhodamine} = 554$ nm) at a scan speed of 480 nm/min using a Perkin Elmer Lambda 35 spectrophotometer with quartz cuvettes. Calibration was performed by preparing solutions with decreasing dye concentrations (see calibration curve in **Supplementary Figure 1**, $R^2 > 0.99$). After 240 min, BN samples were filtered using a Buchner filtration system, dried in the oven at 120 °C and then heated at 600 °C (10 °C/min) for 3 h in a tubular furnace under air gas flow (50 mL/min) before being reused for a second adsorption cycle. We selected this regeneration temperature based on the decomposition temperature of the dye, as determined by TGA analysis (Netzsch TG209 F1 Libra, 10 °C/min ramp rate, under air gas flow at 0.1 L/min; **Supplementary Figure 2A**).

RESULTS AND DISCUSSION

First, we confirmed the "profiles" of the materials synthesized using a number of characterization techniques to assess the range of porosity, crystallinity, and functionalization. As expected, the porous BN materials were all micro/mesoporous but displayed different pore volumes and BET surface areas (**Table 1**; **Figure 1A**). The samples covered a range going from 734 to 1650 m^2g^{-1} in terms of surface area and 31 to 62% in terms of microporosity volume compared to total porosity. For all samples, the surface area and porosity decreased upon thermal treatment, as expected (Shankar et al., 2018). All samples contained oxygen atoms as part of their structure, as determined from XPS analyses (**Table 1**) and high temperature porous BN samples generally exhibited a lower oxygen content compared to low temperature porous BN samples. All porous BN samples displayed very similar XRD patterns with the same peak position for the (002) peak between the different samples, indicating similar d (002)-spacing (∼0.35 nm) (**Supplementary Figures 3A,B**). The absence of other reflections other than the (002) and (100) and the large width and low intensity of the peaks confirmed that all samples were turbostratic. Despite a similar lack of crystallinity in the bulk phase between the low and high temperature BN samples, our prior work identified localized regions of increased crystallinity and thereby hydrophobicity in the high temperature BN sample (Shankar et al., 2018). We assessed the effect of these crystalline and hydrophobic regions on the adsorption behavior below.

We then tested the low temperature porous BN materials (different pore structures and similar chemistries) for adsorption of C-7 hydrocarbons exhibiting different sizes/shapes (e.g., linear n-heptane or branched 2,3-dimethylpentane) and/or chemistries (e.g., aromatic toluene or non-aromatic methylcyclohexane) and two different alcohols (methanol and 1-butanol). Through this study, we intended to identify links between the materials physical properties, including porosity, and the adsorption

performance. The results are presented in **Figure 1B** for methylcyclohexane and in **Supplementary Figure 4** for all other chemicals. The three samples exhibited different sorption isotherms. Given that their chemical composition was similar, the differences are attributed to differences in physisorption dictated by the pore structure of the materials. In fact, the organic vapor sorption isotherms followed the same patterns as the nitrogen sorption at −196 °C (compare **Figures 1A**,**B**). The total vapor sorption capacity increased with increasing surface areas and most of the vapors were adsorbed at low relative pressures,

in the microporous regions. The presence of mesopores caused capillary condensation (e.g., see BN-MU0.25:5) as indicated by the presence of hystereses in the desorption curves. Most of the vapors desorbed (**Figure 1B**) as the pressure was lowered, confirming that little/no chemisorption occurred.

We also evaluated water sorption for different low temperature porous BN samples at 30 °C (**Figure 1C**). Water uptake increased with the surface areas. Importantly, the water did not completely desorb upon reducing the pressure as observed from the "open" hystereses. As highlighted in a previous study (Shankar et al., 2018), this behavior originates from the hydrolysis of the BN materials through the following reaction: $2BN + 3H_2O \rightarrow B_2O_3 + 2NH_3$. The hydrolysis of porous BN takes place due to the presence of defects in the structure (Motojima et al., 1982; Alkoy et al., 1997; Streletskii et al., 2009; Cao et al., 2012; Shankar et al., 2018). Upon thermal treatment, as mentioned above, we form localized regions of increased crystallinity and hydrophobicity. Hence, the high temperature porous BN showed a reduced water uptake capacity, especially at low relative pressures (**Figure 1C**). At higher pressures, the remaining defects sites react with water leading to decomposition of the material (Shankar et al., 2018).

From the organic vapor sorption isotherms, we calculated the sorption capacity at 0.6 P/P_0 (**Figure 1D**). At this relative pressure, organic vapor uptake had ceased and BN materials were saturated. Sorption capacities of low temperature porous BN samples increased with increasing micropore volumes for all organics considered (**Figure 1D**). We found a linear trend between BN micropore volume and sorption capacity for porous BN materials with similar chemistries. This aligns with the behavior observed in activated carbons (Lillo-Ródenas et al., 2005). All porous BN materials adsorbed more toluene than any of the other tested adsorbates. We hypothesized that this is due to the presence of π-π interactions between the *h*-BN rings in porous BN and the aromatic rings in toluene, which contribute to improved physisorption. To put the results in perspective, porous BN exhibited toluene and methanol sorption capacities of the same order of magnitude to activated carbons with similar surface areas (toluene: 700 vs. 950 mg g^{-1}; methanol: 600 vs. 800 mg g^{-1}) (Xu et al., 2015). While the materials absorbed large amounts of organics, they were not selective (**Supplementary Figure 5**; linear n-heptane vs. branched 2,3-dimethylpentane; aromatic toluene vs. non-aromatic methylcyclohexane). This is related to the multimodal pore size distribution of the material—i.e., no narrow pore size distribution—that prevent size exclusion (**Supplementary Figure 6**). Similarly, we tested a high temperature porous BN sample for organic vapor sorption to evaluate the effect of the localized hydrophobic regions of the material (**Figure 1D**). Despite its lower porosity compared to the low temperature BN samples, the high temperature BN sample exhibited increased uptake of all organics. Further support for this observation is provided below when investigating dye sorption.

The adsorption potential of all porous BN materials was finally evaluated for a practical application. We employed

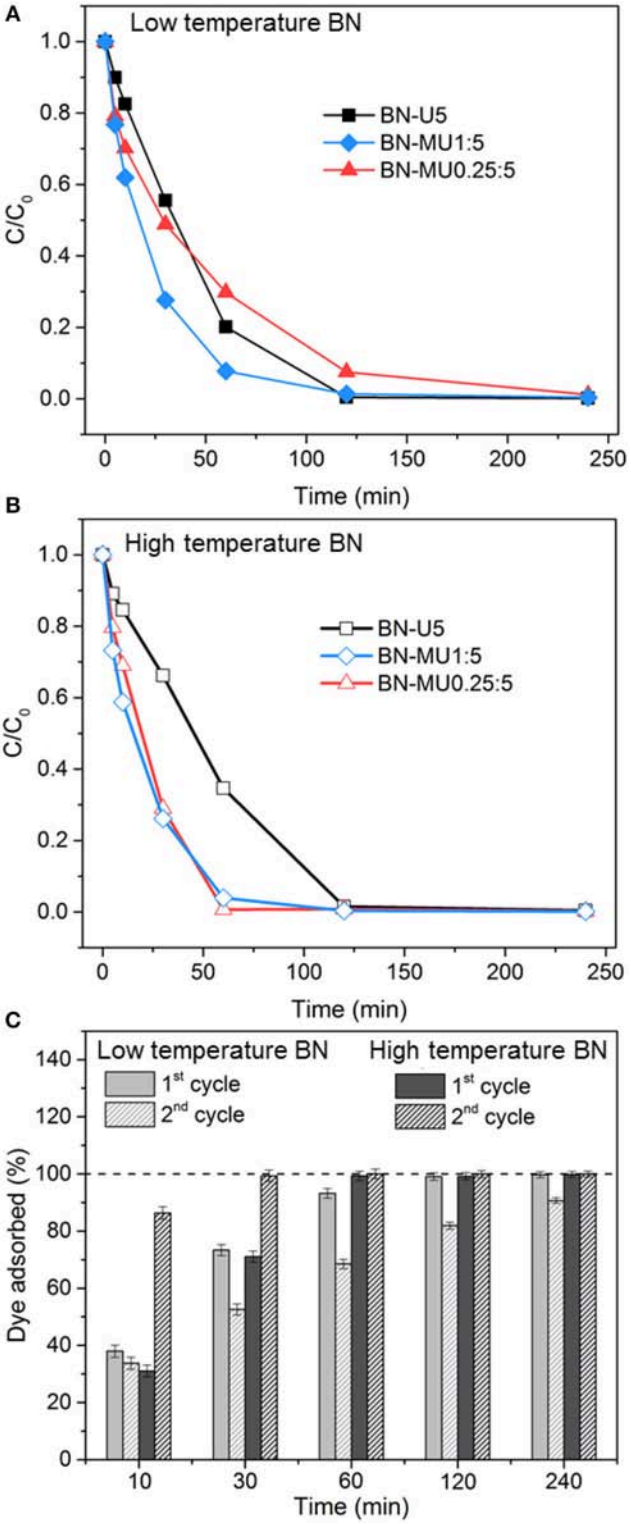

FIGURE 2 | Removal of an organic (Rhodamine B) from water using porous BN samples: **(A)** RhB sorption over time for the low temperature porous BN samples, **(B)** RhB sorption over time for the high temperature porous BN samples, **(C)** evaluation of the recyclability of the best performing porous BN samples at low (BN-MU1:5) and high (BN-MU0.25:5) temperature after regeneration in air at 600 °C.

the porous BN samples (low and high temperatures) for the removal of organics (here Rhodamine B, RhB) from water. The results are presented in **Figure 2**. All samples achieved complete removal of the dye within 4 h or less (**Figures 2A,B**). The time needed to reach complete removal reduced or remained unchanged (for BN-U5) when using the high temperature samples despite their initially lower surface area. Again, high temperature porous BN materials displayed a higher adsorption capacity for organics. We attribute this observation to the increased hydrophobicity and water stability of the high temperature BN samples, as well as to the presence of a larger quantity of π electrons, which allowed greater affinity for the adsorbate while preventing *in-situ* collapse of the material.

We regenerated the better performing low and high temperature samples (BN-MU1:5 and BN-MU0.25:5, respectively) at 600 °C in air and tested them for a second adsorption cycle. The results are reported in **Figure 2C**. While the low temperature BN sample exhibited a decreased capacity after regeneration (10 % decrease at 4 h), the high temperature BN sample maintained its original capacity. This is related to the greater stability of the high temperature sample in the aqueous environment compared to the low temperature sample. Analyses are presented below to confirm this aspect. Interestingly, the high temperature porous BN sample adsorbed more dye in the 2nd cycle than in the 1st cycle for the same exposure time. We explain this by the greater dispersibility of regenerated sample. Indeed, after regeneration and prior to the second sorption run, the sample exhibited finer particles.

We characterized the BN samples after the 1st cycle of dye removal from water and subsequent regeneration in air at 600 °C. This was done to confirm whether a collapse (partial or complete) of the porosity occurred and influenced the adsorption in the 2nd cycle as observed above. To quantify the impact of this potential collapse on the adsorption behavior, both the low and high temperature BN samples were analyzed—the high temperature BN samples being *a priori* less prone to collapse. We note that TGA and XPS analyses confirmed that the dye was completely removed upon regeneration in air at 600 °C (**Supplementary Figure 2**): no carbon residues were observed after regeneration.

First, we analyzed the changes in porosities of the BN samples before testing and after regeneration (**Figure 3**). All low temperature porous BN samples showed a significant decrease in surface area and micropore volume after regeneration pointing to a collapse of the structure *via* hydrolysis (Shankar et al., 2018). Interestingly, the percentage of micropores decreased significantly in all porous BN samples, indicating that the

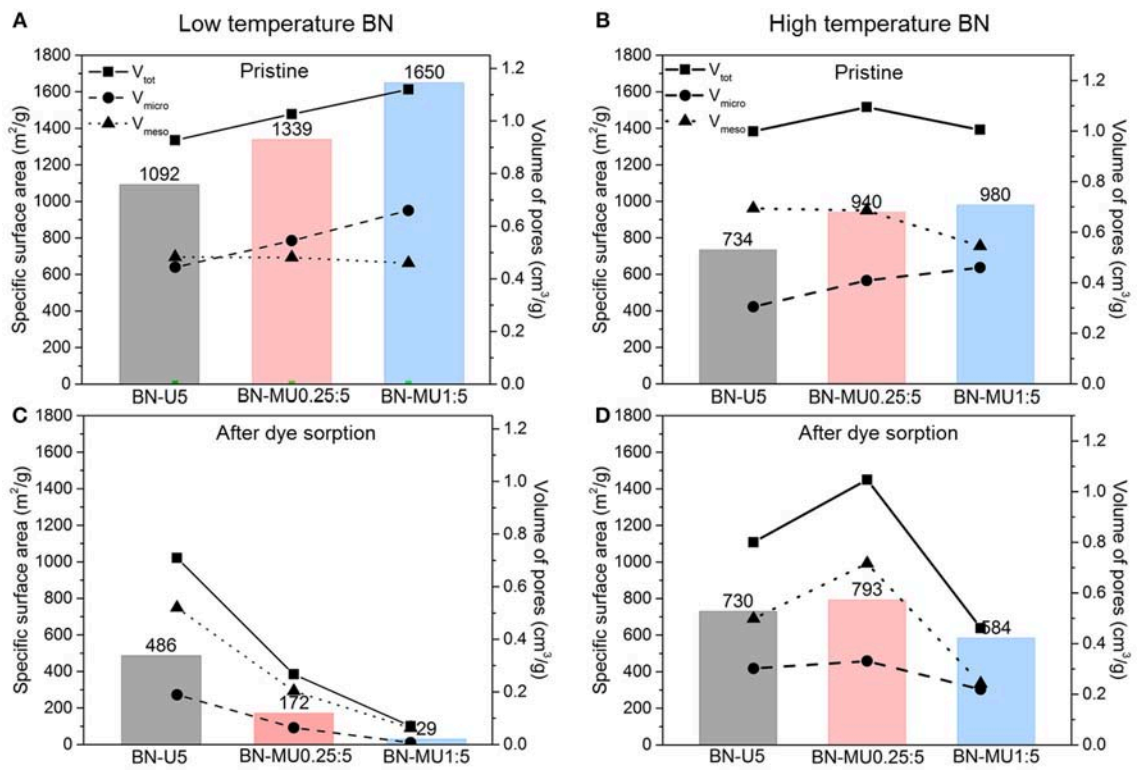

FIGURE 3 | Changes in the porosity of the BN samples upon adsorption and regeneration at 600 °C in air. Textural parameters derived from N_2 sorption isotherms at −196 °C for porous BN samples: **(A)** synthesized at low temperature, **(B)** synthesized at high temperature, **(C)** synthesized at low temperature after dye sorption and regeneration, **(D)** synthesized at high temperature after dye sorption and regeneration.

micropores were initially most susceptible to hydrolysis. This hypothesis is supported by the fact that porous BN samples with higher micropore volumes (BN-MU1:5 > BN-MU0.25:5 > BN-U5), were more unstable, as indicated by a larger decrease in surface area and pore volume. For instance, highly microporous BN-MU1:5 exhibited a significant decrease in surface area from 1650 to 29 m^2g^{-1}, while the surface area of less microporous BN-U5 decreased from 1092 to 486 m^2g^{-1}. This is not surprising as the more porous samples are probably more defective and therefore more prone to hydrolysis. Despite the large decrease in surface area after regeneration, the RhB adsorption capacity only decreased by about 10 %. We hypothesized that the RhB concentration used was not high enough to saturate the adsorbent. Therefore, despite a reduced surface area after regeneration, the adsorption capacity was not significantly affected. The high temperature BN samples exhibited higher stability than the low temperature BN samples after testing and regeneration. Indeed, the samples maintained a high porosity after testing and regeneration. This aligns with the better performance of the high temperature BN samples observed before (**Figure 2**).

Continuing on the characterization of the materials post testing and regeneration, all samples showed a higher relative intensity of the (002)/(100) peaks, possibly indicating a preferred orientation of the crystals along the (002) plane (**Supplementary Figure 3**). In addition, the peak position for the (002) peak (∼25°) shifted to higher angles, indicative of a decrease of the d(002)-spacing and the full width at half maximum (FWHM) decreased, demonstrating an increase in crystallite size (larger number of 2D layers). These three factors together showed that the samples exhibited higher crystallinity after exposure to water, probably as amorphous BN was more readily decomposed in water, resulting in an apparent increase in crystallinity.

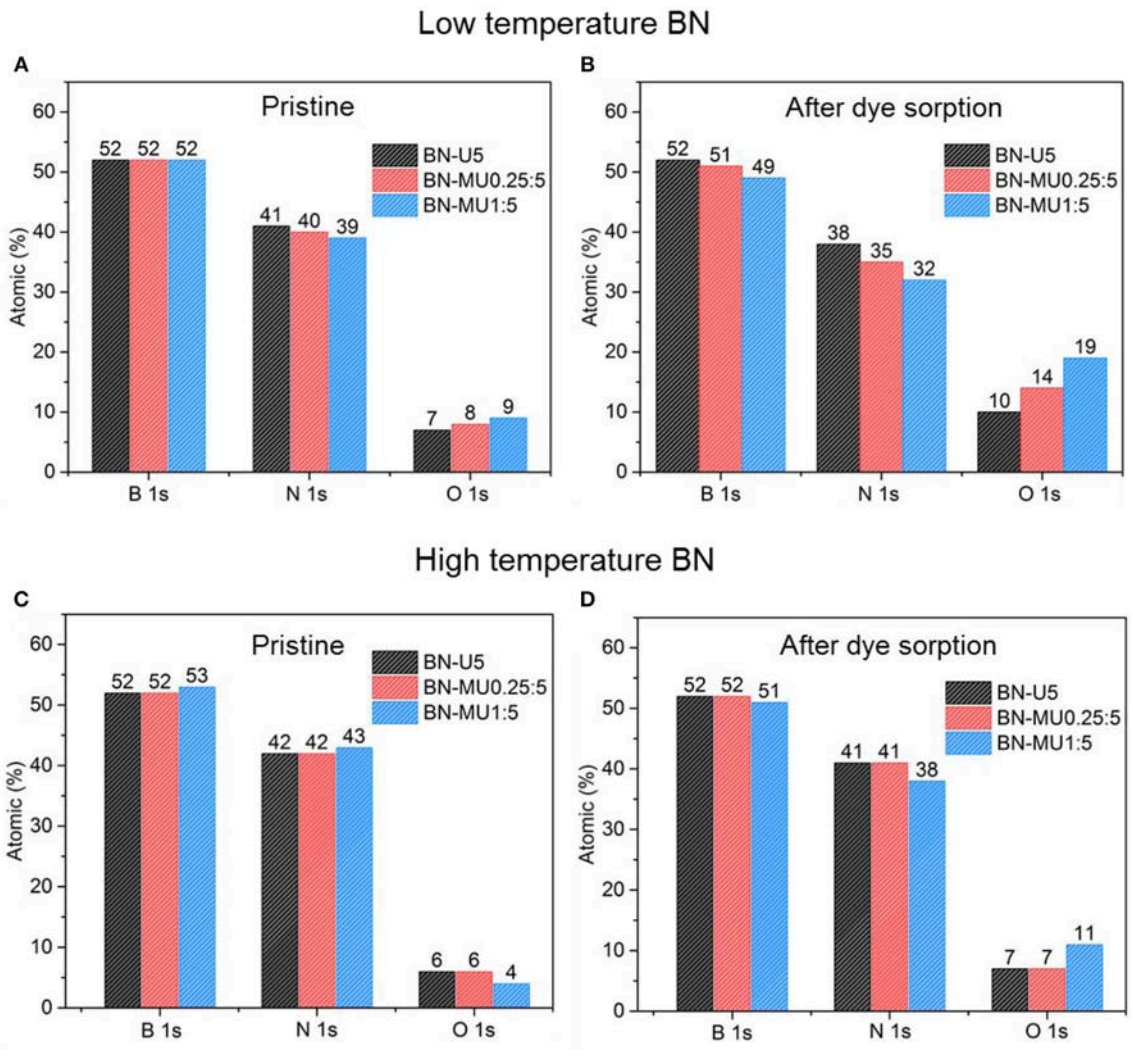

FIGURE 4 | Changes in the chemistry of the BN samples upon adsorption and regeneration at 600 °C in air: **(A,B)** low temperature porous BN samples and **(C,D)** high temperature porous BN samples.

After demonstrating that the porosity of the high temperature BN samples was maintained upon adsorption testing and regeneration, we investigated any potential changes in the chemistry of the materials using XPS analyses. The relative atomic percentages derived from XPS confirmed that the oxygen content increased in all low temperature porous BN samples after adsorption testing and regeneration (**Figures 4A,B**). This further supports the hydrolysis of the low temperature BN samples, causing the oxidation of BN and formation of a larger quantity of boronoxynitride and B-OH groups (Lin et al., 2011). Samples with higher micropore volumes and surface areas (BN-MU1:5 > BN-MU0.25:5 > BN-U5) showed higher increases in oxygen content, indicative of more extensive hydrolysis, in line with the previously described structural changes. The relative nitrogen content decreased in all samples after exposure to water, confirming that a decomposition reaction is occurring, in which water reacts with BN to release ammonia: $3H_2O + 2BN \rightarrow B_2O_3 + 2NH_3$ (Lin et al., 2011). On the other hand, the high temperature porous BN samples did not show any major variations in oxygen content from XPS analysis for two of the samples (**Figures 4C,D**) (BN-U5-1500C and BN-MU0.25:5-1500C).

CONCLUSIONS

We presented here a study on the adsorption behavior of porous boron nitride. For this, we synthesized porous BN samples with varied porosity, crystallinity and chemistry in order to identify the effect of these materials features on the adsorption of different organics. The main conclusions of this work are summarized below:

- Porous BN materials exhibit high sorption capacities for organics, as shown *via* gravimetrical vapor sorption analysis. The organic sorption capacity for toluene on porous BN (∼650 mg/g at 25 °C and 0.6 P/P_0) is comparable to the capacity of activated carbons previously reported in the literature;
- Porous BN materials exhibit low selectivity between the different organics tested here, as highlighted from similar adsorption capacities of organic vapors. This is attributed to their multimodal pore size distribution and amorphous nature, which prevent size exclusion separation.
- Porous BN materials demonstrate higher adsorption capacity of aromatic toluene compared to non-aromatic counterpart, methylcyclohexane. The enhanced toluene adsorption capacity is hypothesized to be due to π-π stacking interactions between the aromatic solvent and the B-N hexagonal rings.
- The adsorption of organics increases with the porosity when the chemistries of the materials are similar. Yet, porosity is not the dominating adsorption parameter. Increasing the crystallinity and hydrophobicity of porous BN materials *via* a heat treatment further allows enhanced organic removal from water, water stability and recyclability (2 cycles tested). The enhanced removal capacity was demonstrated from higher and more efficient removal of Rhodamine B dye from water. High temperature BN was also able to retain better the porosity and chemistry after regeneration. This is attributed to the reduced amount of defect sites that causes hydrolysis of the material and impairs its adsorption performance.
- Porous BN material can be used for organic adsorption from water, such as aromatic dyes (Rhodamine B) and shows complete removal and potentially good recyclability.

DATA AVAILABILITY

All datasets generated for this study are included in the manuscript and the **Supplementary Files**.

AUTHOR CONTRIBUTIONS

SM and CP designed the experiments. SM and XW carried out the experiments. SM, XW, and CP analyzed the data. SM and CP wrote the manuscript. All authors have read and agreed the submission of the manuscript.

ACKNOWLEDGMENTS

The authors would like to thank Dr. Les Bolton and Prof. Glenn Sunley from BP for their technical input. The authors would also like to acknowledge the funding and technical support from BP through the BP International Center for Advanced Materials (BP-ICAM), which made this research possible, as well as EPSRC for the funding through the CDT in Advanced Characterization of Materials (CDT-ACM) (EP/L015277/1). We also acknowledge support from the Department of Chemical Engineering at Imperial College London.

Structural Changes in Polymeric Gel Scaffolds Around the Overlap Concentration

*Han Zhang, Matthew D. Wehrman and Kelly M. Schultz**

Department of Chemical and Biomolecular Engineering, Lehigh University, Bethlehem, PA, United States

Cross-linked polymeric gels are an important class of materials with applications that broadly range from synthetic wound healing scaffolds to materials used in enhanced oil recovery. To effectively design these materials for each unique applications a deeper understanding of the structure and rheological properties as a function of polymeric interactions is required. Increasing the concentration of polymer in each scaffold increases physical interactions between the molecules that can be reflected in the material structure. To characterize the structure and material properties, we use multiple particle tracking microrheology (MPT) to measure scaffolds during gelation. In MPT, fluorescently labeled probe particles are embedded in the material and the Brownian motion of these particles is captured using video microscopy. Particle motion is related to rheological properties using the Generalized Stokes-Einstein Relation. In this work, we characterize gelation of a photopolymerized scaffold composed of a poly(ethylene glycol) (PEG)-acrylate backbone and a PEG-dithiol cross-linker. Scaffolds with backbone concentrations below and above the overlap concentration, concentration where polymer pervaded volume begins to overlap, are characterized. Using time-cure superposition (TCS) we determine the critical relaxation exponent, n, of each scaffold. The critical relaxation exponent is a quantitative measure of the scaffold structure and is similar to a complex modulus, G^*, which is a measure of energy storage and dissipation. Our results show that below the overlap concentration the scaffold is a tightly cross-linked network, $n_{avg} = 0.40 \pm 0.03$, which stores energy but can also dissipate energy. As polymeric interactions increase, we measure a step change in the critical relaxation exponent above the overlap concentration to $n_{avg} = 0.20 \pm 0.03$. After the overlap concentration the scaffold has transitioned to a more tightly cross-linked network that primarily stores energy. Additionally, continuing to increase concentration results in no change in the scaffold structure. Therefore, we determined that the properties of this scaffold can be tuned above and below the overlap concentration by changing the polymer concentration but the structure will remain the same in each concentration regime. This is advantageous for a wide range of applications that require scaffolds with varying stiffness and the same scaffold architecture.

INTRODUCTION

Synthetic gels are designed with unprecedented complexity from the bulk material properties down to the scaffold microstructure (Stauffer et al., 1982; Moradi-Araghi et al., 1988; Scanlan and Winter, 1991; Lutolf et al., 2003; Engler et al., 2006; Serra et al., 2006; Zolfaghari et al., 2006; Yamaguchi et al., 2007; He et al., 2009; Schultz et al., 2009a; Schwartz et al., 2010; Tse and Engler, 2010; Zustiak and Leach, 2010; Wylie et al., 2011; Tirrell, 2012; Jung et al., 2013; Tongwa et al., 2013; Purcell et al., 2014; Wang and Heilshorn, 2015; Escobar et al., 2017). This complexity grows out of the vast array of applications and high demand on gel versatility. Gels are part of everyday life from commonly used personal, fabric and home care products to exotic biomaterials designed to mimic the extracellular matrix (ECM) (Winter and Chambon, 1986; Scanlan and Winter, 1991; West and Hubbell, 1999; Raeber et al., 2005, 2007; Yamaguchi et al., 2007; Benton et al., 2009; Fairbanks et al., 2009b; Zustiak and Leach, 2010; Wylie et al., 2011; Wehrman et al., 2018). Cross-linked gels have also played a significant role in enhanced oil recovery (Moradi-Araghi et al., 1988; Zolfaghari et al., 2006; He et al., 2009; Jung et al., 2013; Tongwa et al., 2013). These materials are used to decrease permeability in high permeability zones near naturally fractured carbonates that require water shutoff but cannot be permanently plugged. Rheological measurement is a critical means for characterizing and validating gelation strategies and gaining insight into their structure and properties. Quantitatively identifying dynamic scaffold structure and properties and the relation to material function is crucial in advancing the design of these materials. These history-dependent systems are characterized during gelation to establish a quantitative framework to understand how polymeric interactions, i.e. overlap and entanglement, within macromer solutions change the gelation reaction and influence final material properties in a chain-growth system. We characterize the scaffold structure and rheological properties of a well-defined photopolymerized hydrogel scaffold with increasing polymeric interactions due to an increase in the concentration of the polymer backbone. This work can be leveraged to design gels with highly-engineered microstructures and properties that can be tailored throughout the phase transition.

In this work, polymeric interactions are varied to determine the change in the gelation reaction and final material properties. We are using a neutral polymer, poly(ethylene glycol) (PEG). Due to this, polymeric interactions are defined as only physical interactions between the macromolecules in solution. Polymeric solutions have three regimes in the concentration-viscosity curve: dilute, semi-dilute and entangled (Graessley, 1980; Doi and Edwards, 1988; Pavlov et al., 2003; Rubinstein and Colby, 2003; Wehrman et al., 2018). In the dilute regime, polymers do not interact. In the semi-dilute regime, the pervaded volume of the polymers begin to overlap. In the entangled regime, polymer molecules physically interact and entangle (Graessley, 1980; Doi and Edwards, 1988; Pavlov et al., 2003; Rubinstein and Colby, 2003; Wehrman et al., 2018). The overlap concentration, c^*, is defined in a good solvent as

$$c^* = \frac{M}{\frac{4}{3}\pi R_g^3 N_A} \tag{1}$$

where M is the molecular weight, N_A is Avogadro's number and R_g is the radius of gyration defined for a star polymer as $R_g^{star} = R_g^{arm}\left[\frac{3f-2}{f}\right]^{\frac{1}{2}}$ where R_g^{arm} is the radius of gyration of a single arm and f is the number of functional groups on the polymer. The entanglement concentration, c^{**}, is defined as

$$c^{**} = \frac{\nu\,(M_s/N_A)}{b^6} \tag{2}$$

where ν is the excluded volume parameter, M_s is the monomer molecular weight and b is the Kuhn length (Graessley, 1980; Doi and Edwards, 1988; Larson, 1999; Pavlov et al., 2003; Rubinstein and Colby, 2003). The gel characterized in this work is a four-arm star PEG-acrylate cross-linked with a linear PEG-dithiol. This is a photopolymerization reaction that uses lithium phenyl-2,4,6-trimethylbenzoylphosphinate (LAP) as a photoinitiator. PEG is chosen due to the versatility of this molecule. PEG is a hydrophilic molecule that can be functionalized with many different chemistries (Bhat and Timasheff, 1992; Iza et al., 1998; Kienberger et al., 2000; Bryant and Anseth, 2002; Hansen et al., 2003; Rubinstein and Colby, 2003; Lee et al., 2007; Aimetti et al., 2009; Fairbanks et al., 2009a). Due to this versatility, PEG has been widely used as the basis for polymeric gel scaffolds that are used in applications from consumer care products to implantable biomaterials. With the development of each new chemistry, the change in the rheology and structure must be understood to design these materials for each application.

Bulk rheological measurements have been the classic way to characterize gelling materials and polymeric solutions (Muthukumar and Winter, 1986; Winter and Chambon, 1986; Chambon and Winter, 1987; Winter, 1987; Adolf and Martin, 1990; Scanlan and Winter, 1991; Izuka et al., 1992; Winter and Mours, 1997; Larson, 1999; Rubinstein and Colby, 2003; Larsen, 2008; Larsen and Furst, 2008; Larsen et al., 2008). In these measurements the viscous, G'', and elastic component, G', of the complex modulus, G^*, is measured. When a material gels the viscous component decreases as the elastic component simultaneously increases. At the gel point, G' and G'' are parallel over all frequencies (Muthukumar and Winter, 1986; Winter and Chambon, 1986; Chambon and Winter, 1987; Winter, 1987; Adolf and Martin, 1990; Scanlan and Winter, 1991; Winter and Mours, 1997; Larson, 1999). To determine the point at which a material gels, which is defined as the first sample-spanning network cluster, time-cure superposition (TCS) is used. Time-cure superposition is the superposition of viscoelastic functions at different extents of reaction (Muthukumar and Winter, 1986; Winter and Chambon, 1986; Chambon and Winter, 1987; Winter, 1987; Adolf and Martin, 1990; Scanlan and Winter, 1991; Winter and Mours, 1997; Larson, 1999). TCS is used to determine the critical gel time, t_c, and critical relaxation exponent, n. The critical relaxation exponent indicates the structure of the scaffold

and is a measure similar to a complex modulus, indicating how much energy the scaffold can store and dissipate. Although bulk rheology has been the classic way to collect data of gelling systems, microrheological characterization can also be used.

Microrheological characterization has been used extensively to characterize gelling materials (Freundlich and Seifriz, 1922; Heilbronn, 1922; Seifriz, 1924; Valentine et al., 1996, 2001; Crocker et al., 2000; Gardel et al., 2005; Panorchan et al., 2006; Slopek et al., 2006; Veerman et al., 2006; Caggioni et al., 2007; Wong Po Foo et al., 2009; Corrigan and Donald, 2009a; Mulyasasmita et al., 2011; Schultz and Furst, 2012; Schultz and Anseth, 2013; Furst and Squires, 2017). Our work focuses on passive microrheological characterization of gelling scaffolds. Multiple particle tracking microrheology (MPT), a passive microrheological technique, measures the Brownian motion of probe particles embedded in a material which is related to rheological properties using the Generalized Stokes-Einstein Relation (GSER) (Mason and Weitz, 1995; Crocker and Grier, 1996; Mason, 2000; Valentine et al., 2004; Savin and Doyle, 2005; Squires and Mason, 2010; Furst and Squires, 2017). Advantages of MPT that make it ideal for characterization of gelling scaffolds are: small sample size ($1 - 50\ \mu$L), measurement of a large frequency range (up to MHz), short acquisition time enabling measurement of steady state properties of an evolving material and sensitivity in the low moduli range enabling characterization of the fragile microstructure of a gel at the sol-gel transition (Mason et al., 1997; Waigh, 2005, 2016; Squires and Mason, 2010; Schultz and Furst, 2012; Wehrman et al., 2016; Furst and Squires, 2017; Daviran et al., 2018). Additionally, TCS has been adapted to determine the critical gelation time and critical relaxation exponent using MPT measurements (Larsen and Furst, 2008; Larsen et al., 2008; Corrigan and Donald, 2009a,b; Schultz et al., 2009a). Due to these advantages, we use MPT to characterize the critical transitions of PEG-acrylate gels as polymeric interactions are increased.

Previous work determined the overlap concentration, $c^* = 13 \pm 4$ wt%, of the PEG-acrylate backbone using bulk rheology (Wehrman et al., 2018). This previous investigation also characterized the change in material properties and structure when the PEG-acrylate backbone is below (3 wt%) and above (10 and 18 wt%) the overlap concentration. This work characterized a change in structure to a more tightly cross-linked scaffold as PEG-acrylate concentration is increased (Wehrman et al., 2018). The present work expands upon this work to determine if there is a gradual or step change in the structure of the material below and above c^*. Scaffolds are characterized changing the PEG-acrylate concentration below c^* from $4 - 9$ wt% and above c^* at 13 and 15 wt%. Data from the previous study is also included for comparison. First, the kinetics of gelation are measured with MPT. The logarithmic slope of the mean-squared displacement, α, quantifies the change in material properties during scaffold gelation. For this chain-growth gel, there is an initial step when polymers are adding to growing chains and there is no measurable change in the rheology. Once chains begin to cross-link and form the gel network, rapid gelation is measured. Normalization of the UV exposure time with the final time of gelation, defined as the time when $\alpha \approx 0.02$, results in all curves collapsing onto a master curve indicating that polymeric interactions do not change the kinetics of gelation. TCS is used to analyze MPT data at PEG-acrylate backbone concentrations above and below c^*. We calculate a critical relaxation exponent, n, and critical gelation time, t_c, for each scaffold. The critical relaxation exponent is constant above and below c^* with a step change at c^*. The normalized critical gelation time has no change as a function of PEG-acrylate concentration. Together, these results characterize a change in scaffold structure that is only dependent on the overlap concentration. This will enable the scaffold rheological properties to be tailored without changing the structure. This work provides additional information about scaffold properties and structure which can be used to tailor these materials for applications that include decreasing permeability during enhanced oil recovery, rheological modification of fabric and home care products and as synthetic implantable materials for wound healing.

MATERIALS AND METHODS

Hydrogel Scaffold

The hydrogel scaffold is composed of a four-arm star PEG-acrylate which is cross-linked with PEG-dithiol. PEG-acrylate has a molecular weight of $M_n = 20,000$ g mol^{-1} (JenKem Technology) and is end-functionalized with acrylates ($f = 4$ where f is functionality). The cross-linker is a PEG end-functionalized with thiols ($M_n = 1,500$ g mol^{-1}, $f = 2$, Aldrich). These two molecules undergo a chain-growth polymerization upon exposure to ultraviolet (UV) light (PhotoFluor LM-75, output range $340 - 800$ nm, 89 North, Inc.). The reaction is initiated by lithium phenyl-2,4,6 trimethylbenzoylphosphinate (LAP). LAP is synthesized using previously published protocols (Fairbanks et al., 2009a). Carboxylated polystyrene probe particles ($2a = 0.97 \pm 0.01\ \mu$m where a is the particle radius, Polysciences, Inc.) are added to the polymer precursor solution to enable multiple particle tracking microrheological measurements.

Hydrogel samples maintain an acrylate:thiol ratio of 1.4 : 1. The concentration of PEG-acrylate is changed by 1 wt% from $4 -$ 9 wt%. Higher PEG-acrylate concentrated samples are measured and are 13 and 15 wt%. Data from 3, 10 and 18 wt% are included from a previous study for comparison (Wehrman et al., 2018). During sample preparation, all concentrated stock solutions are kept on ice for 30 min prior to addition to the polymer precursor solution. This ensures that there are no reactions in the solutions, especially thiol-thiol reactions in the PEG-dithiol stock solution. The polymer precursor solutions consist of PEG-acrylate, PEG-dithiol, 1.5 mM LAP, 0.052% solids per volume probe particles and water. Solutions are well-mixed prior to injection into the sample chamber. Hydrogel samples are gelled by exposure to UV light and MPT data are collected.

Multiple Particle Tracking Microrheology

Multiple particle tracking microrheology (MPT) measures the change in rheological properties during scaffold gelation. In MPT, the Brownian motion of 1 μm fluorescently labeled probe particles (carboxylated polystyrene particles, $2a = 0.97 \pm$

0.01 μm, Polysciences, Inc.) is measured. Data are collected using video microscopy on an inverted fluorescent microscope (Zeiss Observer Z1, Carl Zeiss AG). A high numerical aperture water-immersion objective is used to capture data, which maximizes the pixels per probe particle (63× water-immersion objective, N.A. 1.3, 1× optovar, Carl Zeiss AG). Our equipment is calibrated to minimize static and dynamic particle tracking errors (Savin and Doyle, 2005). Data are collected at 30 frames per second and an exposure time of 1000 μs (Phantom Miro M120, 1024 × 1024 pixels, Vision Research Inc.).

After data acquisition, the brightness-weighted centroid of each probe particle is determined using classical tracking algorithms (Crocker and Grier, 1996; Crocker and Weeks, 2011; Furst and Squires, 2017). These algorithms determine the center of each particle in each frame. Those particle centers are linked together into trajectories using a probability distribution function that accounts for Brownian motion (Crocker and Grier, 1996; Crocker and Weeks, 2011; Furst and Squires, 2017). From the particle positions, the ensemble-averaged mean-squared displacement (MSD, $\langle \Delta r^2(\tau) \rangle$) is calculated from the two-dimensional data using $\langle \Delta r^2(\tau) \rangle = \langle \Delta x^2(\tau) \rangle + \langle \Delta y^2(\tau) \rangle$. From the MSD, rheological properties can be calculated using the Generalized Stokes-Einstein Relation

$$\langle \Delta r^2(\tau) \rangle = \frac{k_B T}{\pi a} J(\tau) \tag{3}$$

where k_B is the Boltzmann constant, T is the temperature, a is the particle radius and $J(\tau)$ is the creep compliance.

To measure gelation using MPT we first add probe particles into the polymer precursor solution. Briefly, 1 μm probe particles are washed 3× by dilution and centrifugation at 5,000 RPM for 5 min (Centrifuge 5425, Eppendrof) to remove any excess dye. Probe particles are then sonicated (40 kHz, Emerson Industrial Automation) for 15 min to ensure that there are no particle aggregates. We add probes at a final concentration of 0.052% solids per volume to the polymer precursor solution. We then inject our polymer precursor solution into a sample chamber. Sample chambers are made on a standard glass slide (75 × 25 × 1 mm, Thermo Fisher Scientific), with 0.16 mm thick spacers and a coverglass (22 × 22 × 0.16 mm) as the top of the chamber. After the polymer precursor solution has filled the sample chamber it is sealed with an air-curing epoxy (Gorilla Glue Company). During curing, sample chambers are kept in the dark and allowed to cure for 15 min.

Each sample is exposed to UV light and MPT data are collected. This is repeated until ≈30 min after complete gelation is measured. Neutral density filters (Chroma Technology) are used to lower the intensity of the UV light. This is done to slow the gelation reaction enabling acquisition of MPT data during the sol-gel transition. The neutral density filters used are 32 and 10% transmission (Chroma Technologies) for 4−15 and 18 wt% PEG-acrylate, respectively. Due to the arbitrary time of UV exposure, data are reported as a normalized UV exposure time which is UV exposure time divided by final time of gelation. The final time of gelation is the time when the logarithmic slope of the MSD, α, is ≤0.02. All MPT experiments are repeated at least 3× to ensure repeatability and critical values are reported as the average ± the standard deviation.

RESULTS AND DISCUSSION

This work characterizes the change in rheological properties and scaffold structure as polymeric interactions are increased. Previous work determined the overlap concentration, c^*, of this PEG-acrylate backbone using bulk rheology and MPT. The value of $c^* = 13 \pm 4$ wt% (Wehrman et al., 2018). We consider scaffolds with PEG-acrylate concentrations $c \leq 9$ wt% to be below c^* and $c > 9$ wt% to be above c^*. This uses the lower limit of c^* as the transition point. This value is chosen not only from the measurements of c^* but also from the characterization of scaffold properties presented here. We measure the same trend in gelation kinetics as a function of UV exposure, regardless of PEG-acrylate concentration. Previous work found that below the overlap concentration the material had a more open structure than samples at and above the overlap concentration. This work expands this initial study determining that there is a step change in the scaffold structure when the overlap concentration is reached. In the previous study, we hypothesized that there would be a gradual decrease in the value of n below the overlap concentration and a constant value above c^*. The gradual decrease in n below c^* would have indicated a more densely cross-linked structure as the concentration is increased. Instead, we measure no change in the dilute, $c < c^*$, and semi-dilute, $c > c^*$, concentration regimes, but there is a step change in the structure of the scaffold at the transition. This result indicates that the structure remains constant above and below the overlap concentration regardless of PEG-acrylate concentration. This information can lead to the design of new materials, where the moduli of the material can be tailored for applications, such as the mimic of a tissue or a material to reduce permeability in enhanced oil recovery without changing the scaffold structure.

Scaffold Gelation

Multiple particle tracking microrheology measures the scaffold properties during gelation. After UV exposure, MPT data are collected. From the MPT data, the ensemble-averaged mean-squared displacement is calculated for all the measured probe particles. Previous work that used MPT to measure this hydrogel scaffold determined that the scaffold evolves homogeneous during gelation with each particle probing the same material properties (Wehrman et al., 2018). The logarithmic slope of the MSD, $\alpha = \frac{d \log \langle \Delta r^2(\tau) \rangle}{d \log \tau}$, is a measure of the state of the material (Stauffer et al., 1982; Winter and Chambon, 1986; Adolf and Martin, 1990; Larsen and Furst, 2008; Corrigan and Donald, 2009a,b; Schultz et al., 2009a, 2012; Schultz and Furst, 2012; Wehrman et al., 2016; Daviran et al., 2018). When $\alpha = 1$ probe particles are freely diffusing and the material is a liquid. When $\alpha \to 0$ probe particles are completely arrested in the gel scaffold. This occurs at a low moduli value, $G' \approx 4$ Pa (Waigh, 2005; Schultz and Furst, 2011, 2012; Furst and Squires, 2017). Due to the low maximum moduli value, bulk rheology should be used to supplement MPT to measure the

equilibrated material properties. Finally, when $0 < \alpha < 1$ the material is a viscoelastic sol or gel and probe particle movement is restricted.

To quantitatively determine when the sol-gel transition occurs, time-cure superposition (TCS) is used to analyze the critical transition and will be discussed in detail below. From TCS, the critical relaxation exponent is determined, n. $\alpha = n$ is the sol-gel transition (Larsen and Furst, 2008; Corrigan and Donald, 2009a,b; Schultz et al., 2009a,b; Schultz and Anseth, 2013; Adibnia and Hill, 2016; Wehrman et al., 2016; Escobar et al., 2017; Daviran et al., 2018). This is when the first sample-spanning network cluster has formed and is the definition of a gel (Stauffer et al., 1982; Muthukumar and Winter, 1986; Winter and Chambon, 1986; Chambon and Winter, 1987; Winter, 1987; Adolf and Martin, 1990; Larsen and Furst, 2008; Corrigan and Donald, 2009a,b; Schultz et al., 2009a,b; Schultz and Anseth, 2013; Adibnia and Hill, 2016; Wehrman et al., 2016; Escobar et al., 2017; Daviran et al., 2018). To determine the state of the material α is compared to n. When $\alpha < n$ the material is a gel and when $\alpha > n$ the material is a sol (Larsen and Furst, 2008; Corrigan and Donald, 2009a,b; Schultz et al., 2009a,b; Schultz and Anseth, 2013; Adibnia and Hill, 2016; Wehrman et al., 2016; Escobar et al., 2017) ; (Daviran et al., 2018).

Figures 1A,B show the change in α as the polymer precursor solution is exposed to UV light. Upon initial exposure to UV light there is lag prior to scaffold gelation. This lag is due to radicals being formed in the polymer precursor solution and the growth of polymeric chains that are not cross-linking into a network structure. During chain-growth, cross-linking occurs by the addition of polymers to growing network chains. Those chains then cross-link together to form the scaffold network structure (Rubinstein and Colby, 2003; Tibbitt et al., 2013; Payamyar et al., 2016). This cross-linking of chains leads to the steep slope in α vs. normalized UV exposure. Prior to the decrease in α, probe particles are freely diffusing. During this time polymer chains are forming but are not large enough to restrict probe particle motion. When these chains start to cross-link, the network structure is forming and probe particle movement becomes restricted and, eventually, arrested in the gel scaffold. At the point of probe particle arrest, the network structure will continue to grow, but MPT can no longer measure the change in material properties.

For all PEG-acrylate samples the kinetics of gelation follow the same trend that is described above. **Figure 1A** shows PEG-acrylate samples with concentrations below c^* and **Figure 1B** are concentrations above c^*. This is further illustrated in **Figure S1**, where all concentrations are plotted together. In **Figures 1A,B**, UV exposure time is normalized by the UV exposure when complete gelation is measured, defined as $\alpha \leq 0.02$. This value is used because it is a slope where no probe particle movement is measured. Upon normalization, all data sets collapse and have a lag in gelation and then a steep slope, where the value of α decreases rapidly with time. Therefore, from these experiments, we can conclude that there is no change in the mechanism of gelation when polymeric interactions are added into the system by concentrating the PEG-acrylate backbone over c^*.

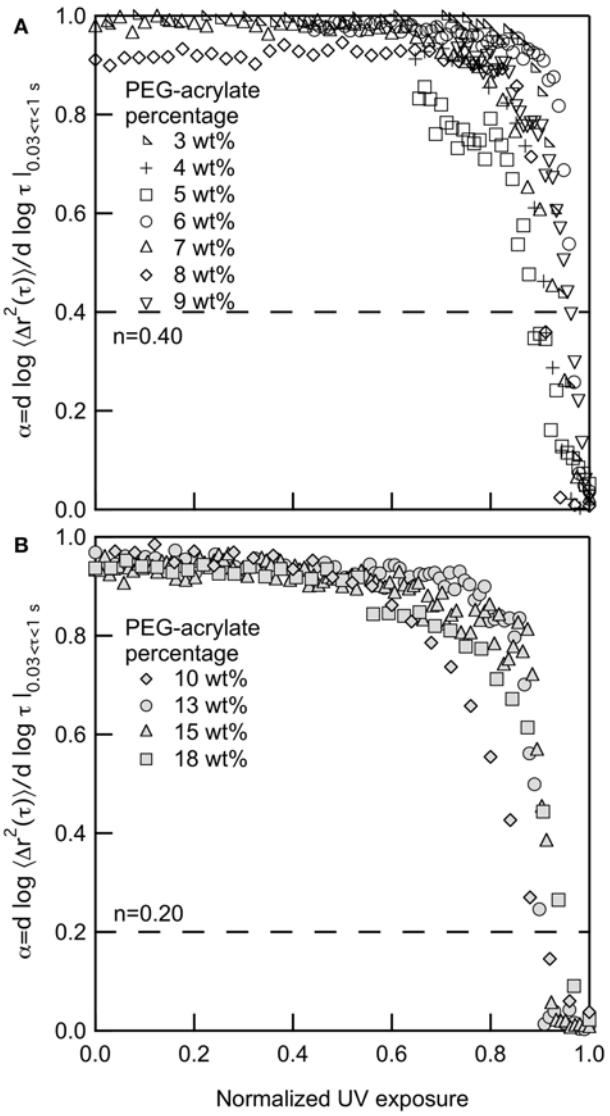

FIGURE 1 | Logarithmic slope of the MSD, α, for gelation of PEG-acrylate gels when the backbone concentrations is **(A)** below and **(B)** above the overlap concentration, c^*. The dotted line in both graphs is the critical relaxation exponent, n. 3, 10 and 18 PEG-acrylate wt% data originally appeared in Wehrman et al. (2018).

Time-Cure Superposition

Time-cure superposition (TCS) is used to analyze each scaffold gelation reaction and determine the critical relaxation exponent, n, and the critical gelation time, t_c. TCS is the superposition of viscoelastic functions at different extents of reaction (Muthukumar and Winter, 1986; Winter and Chambon, 1986; Chambon and Winter, 1987; Winter, 1987; Adolf and Martin, 1990; Larsen and Furst, 2008; Corrigan and Donald, 2009a,b; Schultz et al., 2009a,b; Schultz and Anseth, 2013; Adibnia and Hill, 2016; Wehrman et al., 2016; Escobar et al., 2017;

Daviran et al., 2018). This analysis exploits the self-similarity of measurements of the scaffold material properties prior to and after gelation to shift data onto master curves. In MPT, the shortest lag times, $0.03 \leq \tau \leq 1$s, measure the longest relaxation times, τ_R, of the material. This is because the short lag times are equivalent to high frequency measurements in bulk rheology. The longest relaxation times in the pre- and post-gel give distinct curvature to MSDs measured with MPT. In the pre-gel, the longest relaxation time of the polymers are measured. In the post-gel, the longest relaxation time of the gel network is being probed (Muthukumar and Winter, 1986; Winter and Chambon, 1986; Chambon and Winter, 1987; Winter, 1987; Adolf and Martin, 1990; Larsen and Furst, 2008; Corrigan and Donald, 2009a,b; Schultz et al., 2009a,b; Schultz and Anseth, 2013; Adibnia and Hill, 2016; Wehrman et al., 2016; Escobar et al., 2017; Daviran et al., 2018). Since these measurements are probing the same relaxation time, over a large time scale, the data can be shifted into pre- and post-gel master curves by shifting along the lag time and MSD axes.

The shift factors determine the critical values, namely the critical relaxation exponent and critical gelation time (Muthukumar and Winter, 1986; Winter and Chambon, 1986; Chambon and Winter, 1987; Winter, 1987; Adolf and Martin, 1990; Larsen and Furst, 2008; Corrigan and Donald, 2009a,b; Schultz et al., 2009a,b; Schultz and Anseth, 2013; Adibnia and Hill, 2016; Wehrman et al., 2016; Escobar et al., 2017; Daviran et al., 2018). The lag time shift factor, a, is related to the inverse of the longest relaxation time, τ_R, and the distance away from the critical gelation time, $\frac{|t-t_c|}{t_c}$, by a scaling factor y by

$$a \sim \tau_R^{-1} \sim \left(\frac{|t-t_c|}{t_c}\right)^y. \tag{4}$$

Similarly the MSD shift factor, b, is related to the inverse of the steady state creep compliance, J_e, and the distance away from the critical gelation time by a scaling factor z by

$$b \sim J_e^{-1} \sim \left(\frac{|t-t_c|}{t_c}\right)^z. \tag{5}$$

The critical relaxation exponent is the ratio of the two scaling exponent

$$n = \frac{z}{y}. \tag{6}$$

The critical relaxation exponent determines the state of the material as described in detail above. This is the value of α where the first sample-spanning network cluster forms during gelation. Additionally, n can be thought of as a complex modulus, G^*, with both a viscous and elastic component. When $n > 0.5$ the material is an open porous network which dissipates more energy than it stores. When $n < 0.5$ the scaffold is a tightly cross-linked network that stores more energy. When $n = 0.5$ the scaffold is a percolated network which stores and dissipates equal amounts of energy (Stauffer et al., 1982; Schultz et al., 2009a; Wehrman et al., 2018).

All data taken of PEG-acrylate gelation is analyzed with TCS to determine the value of the critical relaxation exponent, n, and the critical gelation time, t_c. TCS for a 4 wt% PEG-acrylate gelation is shown in **Figure 2**. An example of TCS for all other PEG-acrylate concentrations are in the Supplementary Material, **Figures S2–S8**. The ensemble-averaged MSD is calculated from MPT data, **Figure 2A**. The MSDs decrease in both magnitude and α as UV exposure time is increased. Initially, probe particles are freely diffusing in the polymer solution. As UV exposure increases the scaffold network grows and probe particle movement decreases. As mentioned above, at the sol-gel transition there is a change in the shape of MSD curves due to the change in the relaxation times measured from the relaxation of polymers to the relaxation of a network. This change in shape enables the MSD curves to be shifted into two master curves, a pre- and post-gel master curve, **Figure 2B**. The start of the pre-gel master curve is the polymeric solution with $\alpha = 1$. As the value of $a \cdot \tau$ decreases the value of α also decreases which is due to the growing polymer chains restricting the movement of the probe particles. Additionally, the curvature of the pre-gel curve shows that at short lag times the MSD curves up slightly, which is the measure of the polymeric longest relaxation time, τ_R (Furst and Squires, 2017; Wehrman et al., 2018). At $\alpha = n$ the pre- and post-gel master curves meet. In the pre-gel curve this is the last measurement before the sample-spanning network cluster forms and in the post-gel curve this is the first measurement after the sample-spanning network cluster has formed. In the post-gel master curve as $a \cdot \tau$ increases, there is a decrease in α until $\alpha \to 0$ and probe particles are completely arrested in the polymerized network scaffold. In the post-gel master curve, the curvature is reversed and at short lag times, the MSDs curve down, indicative of measurements of the longest relaxation time of a network.

The shift factors are used to determine the critical relaxation exponent and critical gelation time. In **Figure 2C** both the lag time and MSD shift factors diverge at the sol-gel transition. This is the divergence of the viscosity upon network formation and the emergence of the elastic modulus, $G^{'}$, as the network continues to grow. This divergence happens at the critical gelation time, which is $t_c = 11.6$ min for this 4 wt% PEG-acrylate network. The critical relaxation exponent is the ratio of scaling exponents. Scaling exponents y and z are calculated by fitting the $\log a$ and $\log b$ vs. the $\log \frac{|t-t_c|}{t_c}$, **Figure 2D**. The ratio of the scaling exponents determine the critical relaxation exponent, which is $n = 0.26 \pm 0.08$ for this hydrogel scaffold.

This analysis is done for all MSD data collected both above and below c^*. Since the absolute value of UV exposure can be dependent on the size of the sample, we normalize the critical gelation time by the final time of gelation $\left(t_{c,norm} = \frac{t_c}{t_{final}}\right)$. The critical gelation time, t_c, is defined as the time when the first sample-spanning network cluster is formed in the material. The final time of gelation, t_{final}, is again defined as the time when $\alpha \leq 0.02$. The normalized critical gelation time is $t_{c,norm} = 0.86 \pm 0.17$ and $t_{c,norm} = 0.96 \pm 0.06$ for PEG-acrylate concentrations below and above c^*, respectively. A plot of these values is provided in the Supplementary Material, **Figure S9**. These values are within error of each other, indicating that the critical gelation time

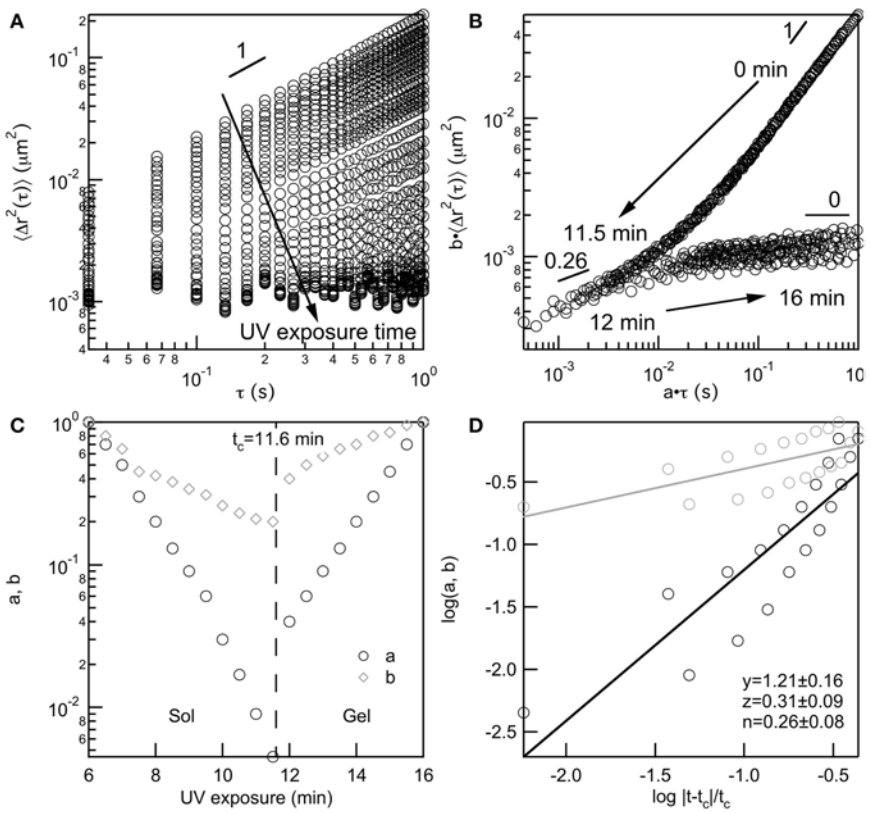

FIGURE 2 | Four wt% PEG-acrylate scaffold gelation analyzed using time-cure superposition. **(A)** Ensemble-averaged MSD data collected as UV exposure time is increased. **(B)** MSD curves shifted into pre- and post-gel master curves using shifting factors *a* and *b*, which **(C)** diverge at the critical gelation time, t_C, at the sol-gel transition. **(D)** The scaling exponents *y* and *z* are determined from the slope of $\log a$ and $\log b$ vs. the logarithm of the distance away from the critical gelation time, $\log \frac{|t-t_C|}{t_C}$. The critical relaxation exponent, *n* is calculated from the scaling factors.

occurs at the same point within the scaffold gelation reaction regardless of the backbone concentration. The first sample-spanning cluster will require a similar amount of cross-links regardless of polymeric interactions and, therefore, occurs at a similar point in the gelation process. This is also supported by the collapse of MPT measurements throughout gelation in **Figures 1A,B**. These results show that scaffold gelation proceeds through the same reaction mechanism regardless of polymeric interactions in the precursor solution.

Finally, the critical relaxation exponent is calculated for scaffolds above and below the overlap concentration of PEG-acrylate. **Figure 3** is a plot of the average value of *n* vs. PEG-acrylate concentration. As described previously, scaffold with $c \leq 9$ wt% are considered below c^* and $c > 9$ wt% are considered above c^*. The critical relaxation exponent indicates the scaffold structure and is a measure similar to a complex modulus, indicating how much energy the scaffold can store and dissipate. The value of *n* has a step change at the overlap concentration. Below c^* $n_{avg} = 0.40 \pm 0.03$ and above c^* $n_{avg} = 0.20 \pm 0.03$. This step change in the value of *n* indicates that there is a change in structure below and above the overlap concentration, but within the dilute and semi-dilute concentration regimes there is no structural change. For all concentrations, a tightly cross-linked network that stores more energy than it dissipates is measured.

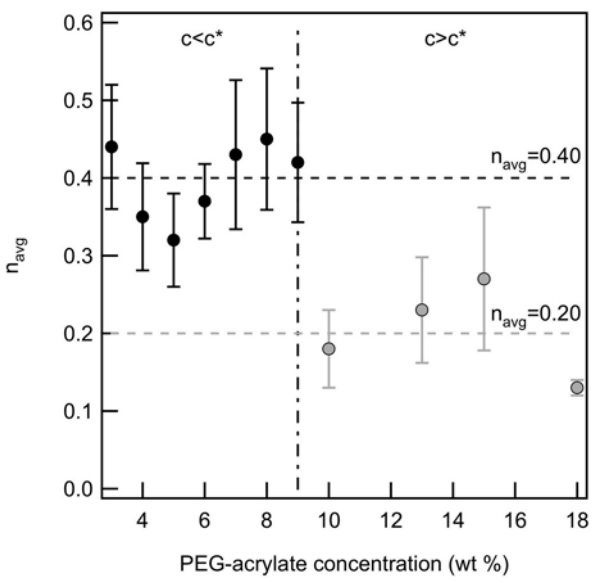

FIGURE 3 | The critical relaxation exponent below and above c^* for a PEG-acrylate:PEG-dithiol scaffold by increasing the backbone concentration above c^*. There is a step change in the value of *n* when the concentration is above c^*.

When $c > c^*$ the network is more tightly cross-linked with a smaller pore structure than when $c < c^*$. This is due to polymeric interactions. When $c > c^*$, polymers are interacting and are able to enter into the pervaded volume of other chains. Due to the polymers being physically closer during network formation there is a high likelihood of arm interpenetration during network formation. This leads to a scaffold with a smaller porous structure that can store energy. This result indicates that the scaffold structure is unchanged by the change in backbone concentration. The only factor that changes scaffold structure is whether the backbone concentration is above or below c^*. Therefore, this scaffold can be tailored to change the elastic moduli of the material without changing the structure of the scaffold enabling the material to be tailored for desired applications.

CONCLUSIONS

This work characterizes the change in rheological properties and scaffold structure during the photopolymerization of a four-arm star PEG-acrylate:PEG-dithiol hydrogel scaffold as polymeric interactions are added to the system. MPT is used to measure the change in scaffold properties as UV exposure time is increased. The gelation mechanism is the same for all scaffolds, regardless of polymeric interactions. The rheology of all scaffolds indicate that they follow a typical chain-growth polymerization. Upon UV exposure, chains of polymers begin to grow in the system and gelation is measured when these chains begin to cross-link into a network. Measured mean-squared displacements are further analyzed using time-cure superposition. The critical relaxation exponent and critical gelation time are determined. The normalized critical gelation time is independent of polymeric interactions. This result supports measurements that all scaffolds follow the same gelation mechanism. The critical relaxation exponent is sensitive to polymeric interactions. A step change in the value of the critical relaxation exponent is measured when polymeric interactions increase above the overlap concentration. This decrease in the value of n indicates that scaffolds made with backbone concentrations above c^* have a smaller porous network which stores more energy than scaffold made with PEG-acrylate concentrations below c^*. This is due to the increased physical interactions, which likely lead to an interpenetrated network structure when $c > c^*$.

The results of this work provide a predictability of material properties, structure and kinetics during gelation. This information can be used to determine the feasibility of these scaffolds for desired applications, particularly when these materials are made in a new environment and require a specific modulus and structure. A stable structure below and above c^* enables properties of the material to be tailored while the structure remains constant. The wide applicability of hydrogel scaffolds has lead to the need to more precisely design these materials. This work informs this design by building a knowledge base which can be exploited to minimize trial-and-error when a scaffold is used in a new application.

AUTHOR CONTRIBUTIONS

HZ was responsible for design of experiments and collection and analysis of data. MW was responsible for design of experiments. KS was responsible for design of experiments, data analysis and writing the manuscript.

FUNDING

Funding for this work was provided by the American Chemical Society Petroleum Research Fund (54462-DNI7). Acknowledgment is made to the Donors of the American Chemical Society Petroleum Research Fund for support of this research.

ACKNOWLEDGMENTS

The authors would like to acknowledge Stephanie Cook, Melissa J. Milstrey, and Danielle Rafanelli for their help with experiments. The authors would also like to acknowledge Nan Wu for carefully reading the manuscript.

SUPPLEMENTARY MATERIAL

The Supplementary Material for this article can be found online at: https://www.frontiersin.org/articles/10.3389/fchem.2019.00317/full#supplementary-material

Additional graphs for α vs. normalized UV exposure for all PEG-acrylate concentrations, TCS of each PEG-acrylate concentration and $t_{c,norm}$ for all PEG-acrylate concentrations are provided. Additionally, a table with the values of n and $t_{c,norm}$ are provided for each PEG-acrylate concentration and can be found in the Supplemental data.

One-hundred percent renewable triphenol—GTF—(glycerol trihydroferulate) and novel bisphenols—GDF_x–(glycerol dihydroferulate) were prepared from lignocellulose-derived ferulic acid and vegetal oil components (fatty acids and glycerol) using highly selective lipase-catalyzed transesterifications. Estrogenic activity tests revealed no endocrine disruption for GDF_x bisphenols. Triethyl-benzyl-ammonium chloride (TEBAC) mediated glycidylation of all bis/triphenols, afforded innocuous bio-based epoxy precursors GDF_xEPO and GTF-EPO. GDF_xEPO were then cured with conventional and renewable diamines, and some of them in presence of GTF-EPO. Thermo-mechanical analyses (TGA, DSC, and DMA) and degradation studies in acidic aqueous solutions of the resulting epoxy-amine resins showed excellent thermal stabilities ($T_d5\% = 282–310°C$), glass transition temperatures (T_g) ranging from 3 to 62°C, tunable tan α, and tunable degradability, respectively. It has been shown that the thermo-mechanical properties, wettability, and degradability of these epoxy-amine resins, can be finely tailored by judiciously selecting the diamine nature, the GTF-EPO content, and the fatty acid chain length.

Keywords: ferulic acid, glycerol, lipase, bio-based thermosets, wettability, degradability

INTRODUCTION

Thermoset polymers are widely used in industrial applications thanks to their versatile performance, good durability, and excellent chemical resistance provided by their highly cross-linked structure (Ellis, 1993; Auvergne et al., 2014; Ramon et al., 2018). It is therefore very common to find these polymers in a broad range of applications such as maintenance coating, adhesives for aerospace (Prolongo et al., 2009) and automobile (Holbery and Houston, 2006) industries, or binders in composites (Gojny et al., 2006). Epoxy resins are one of the most important thermoset materials and are usually synthesized by reacting (poly)phenolic compounds with epichlorohydrin under basic conditions (Bruins, 1968).

The thermoset polymers sector, and more generally the polymer industry, has adopted the current trend which consists in developing greener and more sustainable chemicals and technologies. For instance, Solvay or Dow Chemical have already initiated the transition with the commercialization of bio-based epichlorohydrin prepared from the chlorination of bio-based glycerol, a by-product of biodiesel production (Strebelle et al., 2001; Freddy, 2006). Furthermore, a number of renewable resources—including fatty acids (Biermann et al., 2000; Maisonneuve et al., 2013; Laurichesse et al., 2014), lignocellulosic biomass (Isikgor and Becer, 2015), and enzymatic products—have been reported as alternative feedstocks in polymers synthesis.

Bisphenol A (BPA) is commonly used to prepare commercial high-performance epoxy resins (aka DGEBA, DiGlycidylEther of Bisphenol A). Although DGEBA, upon curing with diamines, leads to cross-linked materials with exceptional properties such as strong adhesion, mechanical integrity and chemical resistance, BPA is recognized as an endocrine disruptive chemical and many studies have been conducted to replace it by innocuous bio-based chemicals. Lignans and lignin-derived chemicals that can be obtained through pyrolysis (Celikbag et al., 2017; Barde et al., 2018) or controlled depolymerization (Pandey and Kim, 2011; Shuai et al., 2016) are the most used biomass-derived chemical platforms for the design of bio-based BPA-substitutes, for the preparation of sustainable thermosets with high thermo-mechanical properties. Indeed, the aromatic moieties present in these bio-based chemicals confer rigidity to the resulting polymers (Wang et al., 2017; Feghali et al., 2018). For example, there have been many reports on epoxy resins from eugenol (Wan et al., 2016), vanillin (Fache et al., 2015a,b; Hernandez et al., 2016; Mauck et al., 2017; Nicastro et al., 2018; Savonnet et al., 2018; Zhao et al., 2018), ferulic and sinapic acids (Maiorana et al., 2016; Janvier et al., 2017; Ménard et al., 2017), guaiacols (Maiorana et al., 2015), and creosol (Meylemans et al., 2011) with promising performances capable of competing with current DGEBA-based materials. However, few researchers have considered the potential toxicity of these BPA substitutes, especially endocrine disruption, which remains a crucial health issue for both plastic sector workers and consumers (Jiang et al., 2018). The degradability of the resulting materials and their behavior regarding water are two other aspects that are also under-investigated. In fact, in most of the studies described above, the thermo-mechanical (e.g., T_g) and physico-chemical (e.g., wettability) properties of the materials cannot be finely tuned because of the lack of apolar moieties in the bio-based aromatic-epoxies.

Plant oil-derived fatty acids are highly valuable building blocks and are frequently used as renewable resources for the synthesis of thermoplastics/thermosets (Meier, 2018). Their long aliphatic chain and their double bond(s) allow a wide number of chemical modifications and provide materials with tunable properties, such as glass transition temperature (T_g), chemical resistance, (bio)degradability, and adhesion strength. Combining the rigidity of bio-based aromatic building blocks and the apolar moiety of the alkyl chain of a fatty acid in a single BPA-substitute thus appears as an interesting approach to finely tune the T_g, the wettability and the degradability of the resulting epoxy-amine resins, after curing with diamines.

In this present work, we aim at developing a series of bio-based epoxy resins, from naturally occurring ferulic acid and plant oils-derived components (i.e., glycerol and fatty acids), to access epoxy-amine thermoset materials with tunable thermo-mechanical properties, wettability and chemical degradation ability. Through highly selective chemo-enzymatic pathways, several polyphenolic compounds, named GDF_x and GTF, have been prepared with tunable flexibility and degree of functionality (i.e., 2 or 3). The determination of the toxicity of these compounds has been carried out by determining their binding to human hormone receptors (ERα, PXR, and AR) and was benchmarked against that of commercial and controversial BPA. GDF_x and GTF were then converted to their corresponding glycidyl ether by TEBAC-mediated glycidylation in presence of epichlorohydrin. Characterization studies were then performed on the corresponding epoxy resins formulations (i.e., molecular weight distribution and EEW). The latter were finally cured with three crosslinkers (i.e., IPDA, DA10, and DIFFA) and the thermo-mechanical properties as well as wettability and chemical degradation abilities of the resulting epoxy-amine resins were investigated.

EXPERIMENTAL

Material

Ferulic acid, lauric acid, palmitic acid, stearic acid, benzyl bromide, *N*,*N*-Dimethylpyridin-4-amine (DMAP), *N*,*N*-Diisopropylcarbodiimide (DIC), benzyltriethyl ammonium chloride (TEBAC), and palladium supported on carbon, were supplied by Sigma-Aldrich. Glycerol was purchased from Alfa Aesar. Epichlorohydrin was purchased from Acros Organics. Isophorone diamine (IPDA) and Decane diamine (DA10) were purchased from TCI. *Candida antarctica* Lipase B (CAL-B) immobilized on resin (LC200291, 10,000 propyl laurate units.g^{-1}) was obtained from Novozyme. All reactants were used as received. All solvents were bought either from ThermoFisher Scientific or VWR. Deuterated chloroform ($CDCl_3$) was purchased from Euriso-top.

Methods

Purification

Column chromatographies were carried out with an automated flash chromatography (PuriFlash 4100, Interchim) and pre-packed INTERCHIM PF-30SI-HP (30 μm silica gel) columns using a gradient of cyclohexane and ethyl acetate for the elution.

Characterization

FT-IR analyses were performed on Cary 630 FT-IR with ATR. NMR analyses were recorded on a Bruker Fourier 300. ^{1}H NMR spectra of samples were recorded in $CDCl_3$ at 300 MHz, chemicals shifts were reported in parts per million ($CDCl_3$ residual signal at $\delta = 7.26$ ppm). ^{13}C NMR spectra of samples were recorded at 75 MHz ($CDCl_3$ signal at $\delta = 77.16$ ppm). HRMS were recorded by the PLANET platform at URCA on a Micromass GC-TOF.

Gel Permeation Chromatography (GPC)

Gel permeation chromatography (GPC) was performed at 40°C on an Infinity 1260 system from Agilent Technologies with PL-gel 5 μM MIXED-D column in THF (flow rate 1 mL.min^{-1}) using conventional PS calibration and UV detection at 280 nm.

Thermo-Gravimetric Analyses (TGA)

Thermo-gravimetric analyses (TGA) were recorded on a Q500, from TA. About 10 mg of each sample was heated at 10°C.min^{-1} from 30 to 500°C under nitrogen or oxygen flow (60 mL.min^{-1}).

Differential Scanning Calorimetry (DSC)

Differential scanning calorimetry (DSC) thermograms were obtained using a DSC TA Q20, under inert atmosphere (N_2), with a calibration using indium, *n*-octadecane and *n*-octane standards. For each sample, about 10 mg was weighed in a pan which was then sealed and submitted to three heat/cool/heat cycles: heating from 30 to 200°C at 10°C.min^{-1}, cooling from 200°C to −50°C at 20°C.min^{-1}. Glass transition temperatures (T_g) were determined at the inflection value in the heat capacity jump.

Dynamical Mechanical Analyses (DMA)

Dynamical Mechanical Analyses (DMA) were performed on a DMA Q800 from the TA Instrument. The DMA samples had a rectangular geometry (length: 40 mm, width: 8 mm, thickness: 1.5 mm). Uniaxial stretching of samples was performed while heating at a rate of 3°C.min^{-1} from 30 to 200°C, keeping frequency at 1 Hz. Deformation was kept at 0.001% (amplitude of 7 μm) to stay in the linear viscoelastic region. The storage modulus (E') and tan δ curves as a function of the temperature, were recorded and analyzed using the TA Instruments Universal Analysis 2000 software. The temperatures T_α *(°C)* were determined as the temperatures at the peak maximum of the tan δ curves.

Synthesis of Resin Epoxy Precursors

Scheme 1 presents the complete synthetic pathway using the following molecules: ferulic acid (**a**), ethyl dihydroferulate (**b**), benzylated ethyl ferulate (**c**), benzylated glycerol diferulate (GDFoBn) (**d**), glycerol tri-dihydroferulate (GTF) (**e**) and lipophilic glycerol dihydroferulates (GDF_x) (**f**, **g** and **h**). Compound syntheses were carried out following procedures previously described in the literature (Ménard et al., 2017; Hollande and Domenek, 2018). Full characterizations and detailed procedures for new compounds are given in the **Electronic Supplementary Information** (ESI). ^{1}H & ^{13}C NMR spectra, FTIR spectrum as well as TGA trace of GTF-EPO can be found in a previous published work (Ménard et al., 2017).

Glycidylation

Phenolic precursors (GDF_x or GTF; 1 eq) were dissolved in epichlorohydrin (10 eq/OH). Triethyl benzyl chloride (TEBAC) (0.2 eq) was added and the suspension was stirred for 2 h at 80°C. The reaction medium was cooled down to room temperature and NaOH (5M, 2 eq/OH) was added. The biphasic solution was vigorously stirred for 4 h at room temperature then extracted with ethyl acetate (3 × 100 mL). The organic layers were washed with brine (80 mL), dried over anhydrous $MgSO_4$, filtered and concentrated *in vacuo*.

Epoxide Equivalent Weight (EEW)

Experimental values of EEW for the epoxide resins synthesized herein were determined by ASTM D1652. Samples were dissolved in dichloromethane (DCM) with tetraethylammonium bromide and titrated in triplicate, using perchloric acid solution in acetic acid (1 N). Crystal violet was used as an indicator and the end point was determined when the solution turned from blue to green for longer than 30 s. Detailed results are provided in the ESI.

Preparation of Cured Epoxy Materials

This method considers that the epoxy resins prepared herein contained small amounts of higher molecular weights fractions. The weight of the resins and cross-linkers were determined by using the EEW values and amine hydrogen equivalent weight (AHEW). Weights of reaction components for the formulated resin systems were determined using equation (1). Equations (2) and (3) were used to calculate the AHEW and to obtain the parts by weight of diamine per hundred parts resin (phr).

$$EEW\ of\ mix = \frac{Total\ Weight}{\frac{Weight\ of\ resin\ A}{EEW\ of\ resin\ A} + \frac{Weight\ of\ resin\ B}{EEW\ of\ resin\ B}} \quad (1)$$

$$AHEW = \frac{molecular\ weight\ of\ amine}{number\ of\ active\ hydrogens} \quad (2)$$

$$phr = \frac{AHEW\ x\ 100}{EEW} \quad (3)$$

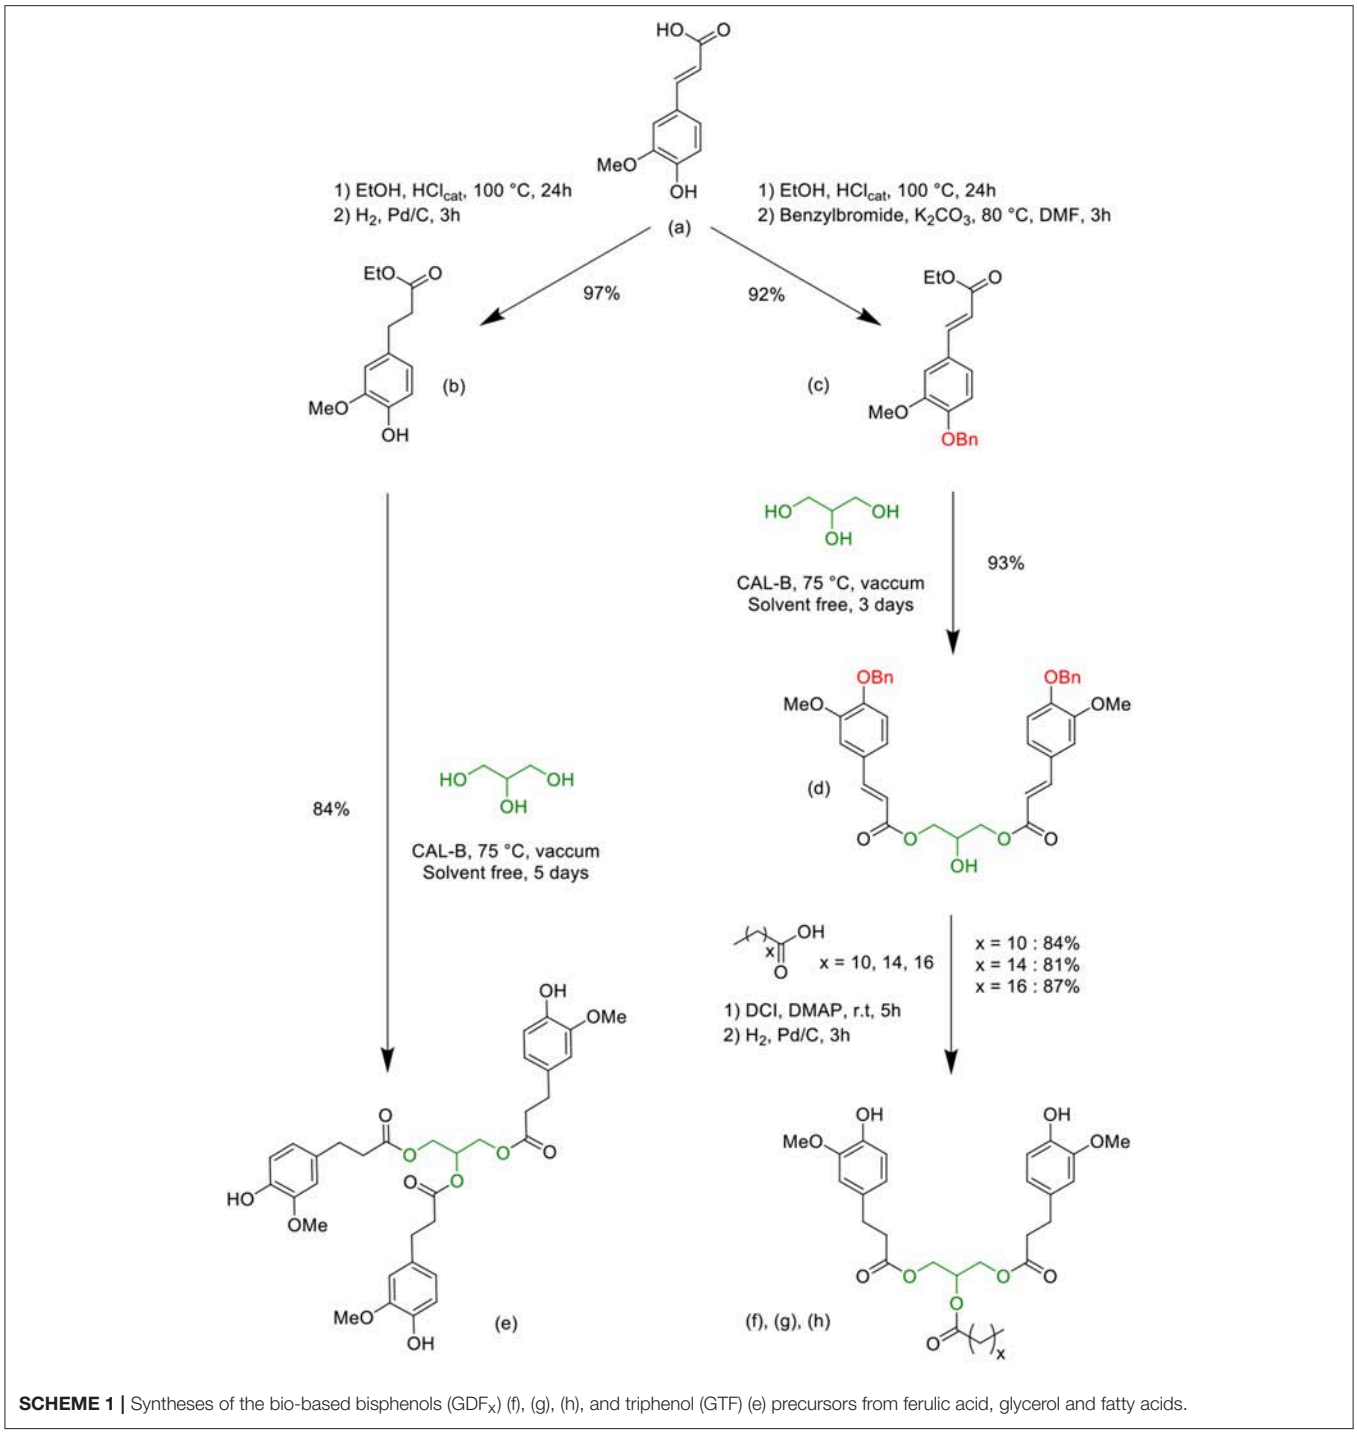
For instance, if phr = 20, then 20 g of diamine would be needed for 100 g of epoxy resin. Epoxy resins were vigorously mixed with the appropriate amount of crosslinker at room temperature in a disposable aluminum pan. In the case of the solid diamine DA10, an additional stirring time at 120°C was necessary to obtain a complete dissolution of the amine in the epoxy precursor. Mixtures were then transferred into rectangular stainless steel molds (length: 40 mm, width: 8 mm, thickness: 1.5 mm). The method of curing was adapted from a literature procedure (Janvier et al., 2017). In summary, the resins were maintained under ambient conditions in the molds for 2 h and then for 2 h at 60°C, for 20 h at 110°C and for 1 h at 150°C.

Hydrolytic Degradation Assays

Cured resin samples with dimensions about 4 × 8 × 1.5 mm, with weights ranging from 75 to 95 mg, were placed in a 10 mL sealed tube. An aqueous solution of HCl (3M) was added. The vials were heated at 60°C for 40 min for equilibration. Incubations were then continued for 5, 20, 26, 43, and 50 h. The residual solid was then washed with deionized water, dried then weighed to determine the mass loss.

Measurement of Contact Angle

The contact angle (θ) of liquid water against the cured epoxy resins was measured by the sessile drop method at room



SCHEME 1 | Syntheses of the bio-based bisphenols (GDF$_X$) (f), (g), (h), and triphenol (GTF) (e) precursors from ferulic acid, glycerol and fatty acids.

temperature with a drop shape analysis system (DIGIDROP and Visiodrop software). The contact angle was measured at three different locations for each thermoset and the average value was reported.

Estrogen Binding Affinity Testing

The agonistic and antagonistic potentials of bisphenols were analyzed following a literature method (Delfosse et al., 2012) in which ERα, PXR, and AR transcriptional activities were monitored by using corresponding reporter cells HELN ERα, U2OS AR, and HG5LN PXR cells, respectively. Activities were measured in relative light units (RLU) and 100% activities were assigned to the RLU value obtained with 10 nM agonist control (estradiol (E_2), R 1881, SR 12813). The vehicle (DMSO) was tested as a control without any compound.

RESULTS AND DISCUSSION

Synthesis of the Bio-Based Epoxy Resin

Chemo-Enzymatic Synthesis

Chemical esterification of *p*-hydroxycinnamic acids with alcohol is unselective and side reactions generally lead to an unwanted product that needs to be removed by purification steps, generating waste to dispose of. In opposition, the lipase-mediated enzymatic synthesis offers some advantages for synthesizing esters, such as milder reaction conditions and selectivity. Hence, the selective synthesis of the bis/tri-ferulate resin epoxy precursors **e**, **f**, **g** and **h**, involving glycerol linker group, was based on chemo-enzymatic methods recently published (**Scheme 1**) (Pion et al., 2013; Hollande and Domenek, 2018).

Ferulic acid was first transformed either in ethyl dihydroferulate (**Scheme 1**, b) or in benzylated ethyl ferulate (**Scheme 1**, c), through a two-step one-pot process. Afterwards, a specific affinity of *Candida antarctica* Lipase B (CAL-B) toward glycerol allowed controlling the degree of functionalization of the latter, giving access to the symmetric bisphenol (**Scheme 1**, d) or to the fully functionalized glycerol triferulate (**Scheme 1**, e) in excellent yields and purities. Fatty acids were then grafted onto the available secondary alcohol of the intermediary compound d, immediately followed by a palladium-catalyzed hydrogenation to simultaneously reduce unsaturation and cleave the benzyl group, thus providing the GDF_x compounds (**Scheme 1**, f, g, h. It is noteworthy to mention that all the syntheses described in **Scheme 1** have been performed at the multi-gram scale. Moreover, in a recent work, we have not only demonstrated the feasibility of the lipase-mediated transesterification of dihydroferulate ethyl ester at the kilo-scale (Teixeira et al., 2017), but also devised a sustainable and industrially relevant membrane-based technique, allowing both the purification of the targets and the recycling of solvents and unreacted reagents.

Endocrine Receptor Activities of GDF_x Bisphenols

Nowadays, the development of new platform chemicals is deeply regulated, especially for bisphenolic compounds—such as BPA—and other controversial endocrine disrupting chemicals (EDCs). Herein, endocrine activities of newly created GDF_x bisphenols were investigated by evaluating their ability to interact with three types of receptors ERα, PXR, and AR. ERα is a member of the nuclear hormone receptors family, and its activity is regulated by the steroid estrogen sex hormone 17β-estradiol (E2). PXR is a member of the steroid and xenobiotic sensing nuclear receptors family and AR is a nuclear type androgen receptor that is activated by binding with any of the androgenic hormones. In **Figure 1A**, sex hormone E2 induces a 100% ERα activity at 5.10^{-10} M, which plateaus at higher concentrations. For BPA, estrogenic activity was observed at molarities of 10^{-7} and slightly above 60% at concentrations of 10^{-5}. In contrast, all newly created GDF_x bisphenols, GDF_{10}, GDF_{14}, and GDF_{16}, exhibited an activity similar to that of the control, even with increasing concentrations. In addition, **Figure 1B** reveals that the highest concentration tested for GDF_x family (i.e., 10^{-5} M) did not induce any abnormal receptor activities on both PXR and AR. Finally, an endocrine disruption assay (ESI p22) indicated that phenolic structures were neither agonist nor antagonist ligands. Based on these results, that demonstrated the innocuousness of these newly created GDF_x bisphenols, we were encouraged to further explore their use for the production of epoxies and epoxy-amine resins.

Glycidylation

Epoxy resins synthesis consists in the glycidylation of the different GDF_x bisphenols, using the classical procedure, i.e., large excess of epichlorohydrin under alkaline conditions. However, to prevent the partial hydrolysis of the internal ester moieties observed by Maiorana et al. (2016) during classical glycidylation of bisferulate esters, milder temperatures, and shorter reaction times were applied. Thus, to offset this restriction, a catalytic amount of triethylbenzyl ammonium chloride (TEBAC) as phase transfer catalyst—well known for allowing higher epoxy functionality—was used (Fache et al., 2015a). Under such conditions, the phenolate formed is able to attack each one of the carbons of epichlorohydrin (**Scheme 2**), two of them, (b) and (c), leading to the epoxy ring opening. Thus, a basic treatment is necessary to close the open forms. Yet, not all the resulting species are diepoxies resins. Side reactions can occur, the most important being (b) the oxetane formation or (d) the formation of branched molecules due to the oligomerization of chlorinated intermediate (Ellis, 1993).

Resulting crude di/triglycidyl ether bis/triferulate epoxy resins, named GDF_xEPO, and GTF-EPO, respectively, were obtained in high isolated yields (>85%). All the resins prepared herein (see ESI, p18) showed the appearance of an epoxy vibrational band at 912 cm^{-1} characteristic of oxirane C-O group on their FT-IR spectra. ^{1}H NMR analyses showed the expected chemical shifts for the proton on the tertiary carbon of the oxirane ring at 3.40 ppm (see ESI, p17). However, signals were also observed between 3.75 and 3.95 ppm, which could be attributed to the oxetane or the oligomeric production epoxies pictured in **Scheme 2** (b) and (d). In order to investigate the potential side formation of such oligomeric epoxies, molecular weight distributions of GDF_xEPO and GTF-EPO resins were measured by gel permeation chromatography. The results are shown in **Figure 2** and the ESI (p20-21).

The distribution of molecular species (M_n) in epoxy resins was analogous for each sample. Experimentally determined values (GPC) described the normalized weight distribution of epoxy systems in two monodisperse fractions according to the M_w/M_n values closed to 1.0. The first corresponds to the monomeric glycidyl ether of GDF_{10}, GDF_{14}, GDF_{16}, and GTF, with M_n *of* 840, 970, 1,070, and 860 g/mol, respectively, whereas the second corresponds to M_n above 2,000 g/mol, suggesting the formation of oligomeric by-products through the dimerization of chlorinated intermediate depicted in **Scheme 2**. Nevertheless, the contribution of the high molecular weight tail to the cumulative molecular weight distribution is <5%. Considering the relatively low concentration of by-products estimated through ^{1}H NRM and GPC analyses, we decided to use these epoxy resins directly without further purification. **Table 1** displays values of experimental and theoretical epoxide

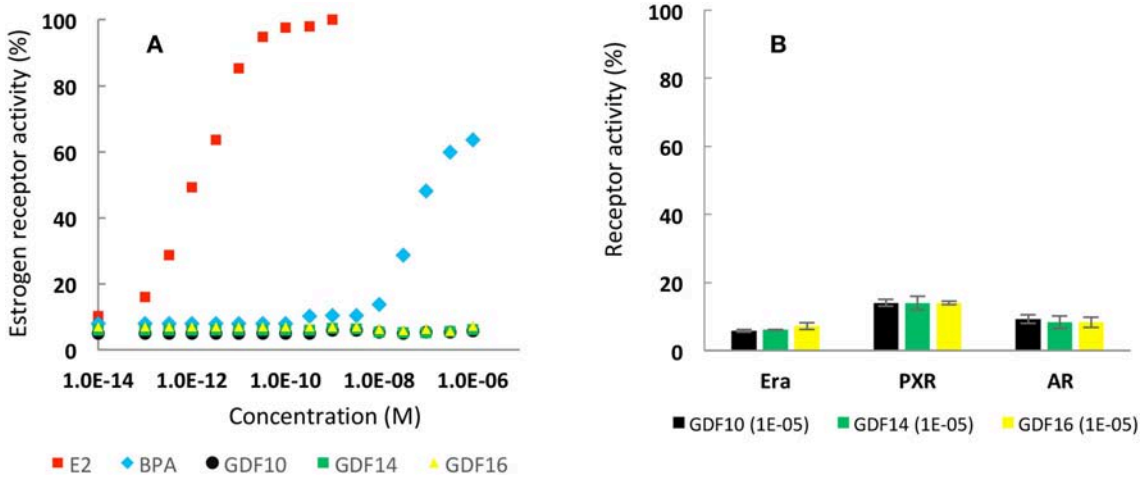


FIGURE 1 | (A) Estrogenic activity (%) as function of concentration of E2, BPA and synthesized bisphenols. **(B)** Activities (%) of Erα, PXR and AR induced by synthesized bisphenol at 10^{-5} molarity.

equivalent weights (EEW) where the latter assumes 100% conversion to the corresponding monomeric glycidyl ferulate structures. Experimental EEWs values are 11 to 15% greater than that of the corresponding theoretical values. This result is attributed to the formation of dimers which results in the increase of the EEW of the synthesized resins above the theoretical value. Finally, **Table 1** also reports on the thermal behaviors of uncured resins. TGA analysis revealed thermostability (T_d 5%) in the range of 311–340°C under an inert atmosphere, and 304–321°C under an oxidative atmosphere. Furthermore, the alkyl chain length does not significantly impact the degradation temperature.

Thermosets Synthesis

The chemical structures of all amine hardeners or curing agents are reported in **Figure 3**. Two bio-based (DA10 and DIFFA) and one extensively used fossil-based (IPDA), presenting different rigidities, were selected.

To ensure that epoxy resin has a good reactivity toward diamines, a DSC analysis of an equimolar mixture of resins and diamines was carried out (**Figure 4**). An exothermic peak was observed around 100°C corresponding to the epoxy ring-opening reaction to form the crosslinked polymer. In order to ensure chain mobility during gelation and to obtain optimal crosslinking content, a multistep temperature program was

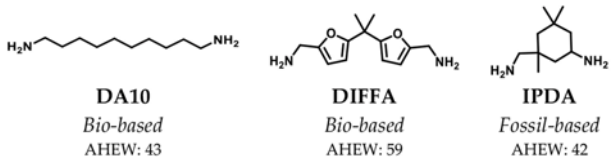

FIGURE 3 | Chemical structures of the curing agents used for thermoset formulation.

elaborated. Mixtures were first left for 2 h at room temperature followed by two additional hours at 60°C. Formulations were then cured at $T \approx T_{DSCcrosslinkingpeak}$ (20 h at 110°C), then at $T > T_{DSCcrosslinkingpeak}$ (1 h at 150°C). Each difunctionalized GDF_xEPO epoxy precursor was cured in presence of each curing agent leading to 9 formulations (**Table 2**, thermosets 1–9). In order to tune the properties of these thermosets, and as the formulations with diamines and difunctionalized GDF_xEPO (i.e., thermosets 1–9) did not provide materials rigid enough to perform DMA analyses, 1 formulation with GTF-EPO (**Table 2**, thermoset 15) as well as 5 co-formulations with IPDA, in variable ratios of difunctionalized ($GDF_{14}EPO$) and tri-functionalized (GTF-EPO) epoxy resin (**Table 2**, thermosets 10–14) were also prepared.

Characterization of the Thermosets

Thermogravimetric Analyses (TGA)

The thermal stability of cured thermosets was studied by thermal gravimetric analysis (TGA) under nitrogen flow. $T_d5\%$ was defined as the temperature at which the thermosets lost 5% of its initial mass, Td_{max} as the temperature at which the kinetic degradation of the thermoset occurs at the maximum rate and $W\%_{char}$ corresponds to the relative amount of stable residue at a high temperature. **Table 2** sums up the values for the thermosets prepared and all thermograms are displayed in ESI p23-25. The lowest $T_d5\%$ was obtained with DIFFA (**Table 2**; thermosets 4–6), which might be explained by the initiation of the degradation by rupture of the curing agent segment, as reported by Ménard et al. (2017). Overall, higher $T_d5\%$ and Td_{max}were measured with IPDA- and DA10-containing resins. Concerning the high temperature stable char content ($W\%_{char}$), values were around 10% for GDF_xEPO resins; moreover, the higher the GTF-EPO ratio in epoxy resin system, the higher the char content. This parameter would be particularly interesting for the development of flame-retardant materials.

Differential Scanning Calorimetric Analyses (DSC)

The degree of cure of the resins and glass transition temperatures were both determined through DSC. Analyses of post-cured resins showed no residual exothermic peak above or below the glass transition corresponding to further curing reactions (ESI, p26-28). These results indicate that if additional cure ever occurred during DSC heating, it is below the instrument level of detection. Therefore, consumption of epoxy moieties and concurrent events of cross-linking during the curing cycle

adopted herein results in a degree of cure that closely approaches its upper limit. Furthermore, the curing of difunctionalized resins (**Table 2**, entries 1–9 and 15) with hardeners presenting various rigidities (DA10 < DIFFA < IPDA due to their aliphatic, aromatic, and cyclic configuration), respectively, lead to a restricted range of T_g values (from 3 to 23°C). Hence, the most flexible amine (DA10) provided the lowest T_g values, while the IPDA-containing thermosets led to the highest T_g. Nevertheless, for a given diamine, thermosets exhibit quite similar T_g, meaning that the impact of the diamine on the rigidity of the network outweighs that of the alkyl chain length (**Figure 5A**), Entries 1–3; 4–6; 7–9).

When IPDA reacted with tri-functionalized resins, i.e., GTF-EPO, the T_g value increased up to 60°C due to the higher epoxy functionally (2 vs. 3) and higher cross-link density (**Figure 5A**, 15). Moreover, as shown in **Figure 5B**, it is noteworthy to

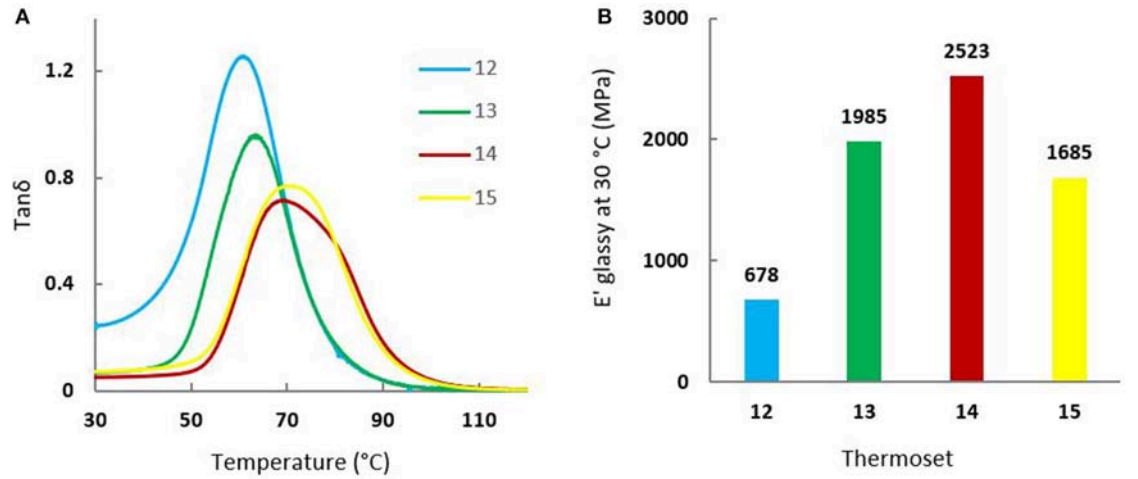

FIGURE 6 | (A) Tan δ curves of (blue) 12, (green) 13, (red) 14, and (yellow) 15 thermosets; **(B)** Storage modulus (E'_{glassy}) at 30°C of (blue) 12, (green) 13, (red) 14, and (yellow) 15 thermosets.

mention that the T_g increased linearly with the tri-functionalized resin GTF-EPO content ($R^2 = 0.9898$).

Dynamic Mechanical Analyses (DMA)

Mechanical properties of the cured resins were evaluated by DMA on each sample with a glass transition upwards of 30°C (thermoset 12–15). **Figure 6** and **Table 2** provide (a) tan δ values as a function of temperature and (b) storage modulus values at the glassy state at 30°C. Similar to the previous linear relationship observed for T_g and GTF-$EPO_{wt\%}$, the same trend was observed for tan δ that increased with the increasing incorporation of the GTF-EPO to the $GDF_{14}EPO$ system. As discussed previously, the thermal behaviors observed with the addition of GTF-EPO was a consequence of the decrease of EEWs of the co-formulated systems relative to the GDF_xEPO resin. In other words, co-formulated resins will lead to thermosets with relatively higher crosslink densities. On the other hand, when the ratio of $GDF_{14}EPO$ in GTF-EPO does not exceed 25 wt%, thermosets exhibit a higher storage modulus than that of the GTF-EPO resin (**Figure 6B**; entries 13 and 14 vs. 15). It is worth mentioning that the storage modulus at 30°C of epoxy systems which contain 10 wt% of $GDF_{14}EPO$ is 50% higher than that of the GTF-EPO thermoset (2,523 vs. 1,685 MPa). This rather unexpected outcome may be explained by the more efficient interaction/distribution of lipophilic GTFxEPO epoxies during the gelation/curing induced by their "surfactant" properties.

Degradation and Wettability Behavior

To gain further insight on how surface hydrophobicity varies as a function of the alkyl chain length, contact angles were measured (**Table 3**). Whatever the curing agent, increasing the alkyl chain length from 12 to 18 carbons (i.e., lauric acid -> palmitic acid -> stearic acid) resulted in an increase of the contact angle (**Table 3**; thermosets 1 vs. 3, 4 vs. 6, and 7 vs. 9). However, it is worth mentioning that the nature of the curing agent does not significantly impact the hydrophilicity of thermosets as for a same resin GDF_xEPO cured with the three different curing agents (i.e., DA10, DIFFA, and IPDA) contact angles differ by $< \pm 7°$.

TABLE 3 | Characterization of weight loss plots and contact angle.

Thermoset	Resin type	Curing agent	Weight loss/hour 10^{-3} ($mg.h^{-1}$)	Least squares fitting value for weight loss plots (R^2)	Contact angle (°)
1	$GDF_{10}EPO$	DA10	−17.1	0.965	66 ± 2
2	$GDF_{14}EPO$	DA10	−15.8	0.997	75 ± 5
3	$GDF_{16}EPO$	DA10	−2.2	0.990	82 ± 6
4	$GDF_{10}EPO$	DIFFA	−17.3	0.997	63 ± 8
5	$GDF_{14}EPO$	DIFFA	−12.8	0.983	76 ± 6
6	$GDF_{16}EPO$	DIFFA	−5.2	0.939	83 ± 5
7	$GDF_{10}EPO$	IPDA	−20.1	0.981	79 ± 3
8	$GDF_{14}EPO$	IPDA	−14.7	0.854	82 ± 1
9	$GDF_{16}EPO$	IPDA	−10.6	0.947	88 ± 4

In addition, thermosets weight loss, determined as a function of the incubation time in acidic aqueous solutions, was plotted (**Figure 7**). Data showed a decrease in mass upon incubation with linear behavior, according to the R^2 values for weight loss plots (**Table 3**). Finally, it is noteworthy to mention that the length of the fatty acid chain grafted onto GDF_x epoxies had a significant effect on the hydrolytic degradation rate of cured thermosets. Indeed, an increase in hydrophobicity of the thermoset, by increasing the length of the fatty acids graft, was consistent with a corresponding decrease of the degradation rate measured in $mg.h^{-1}$ and the susceptibility of that surface to hydrolysis.

CONCLUSION

Herein, the chemo-enzymatic synthesis, thermo-mechanical properties, wettability and acidic hydrolysis of 100% renewable

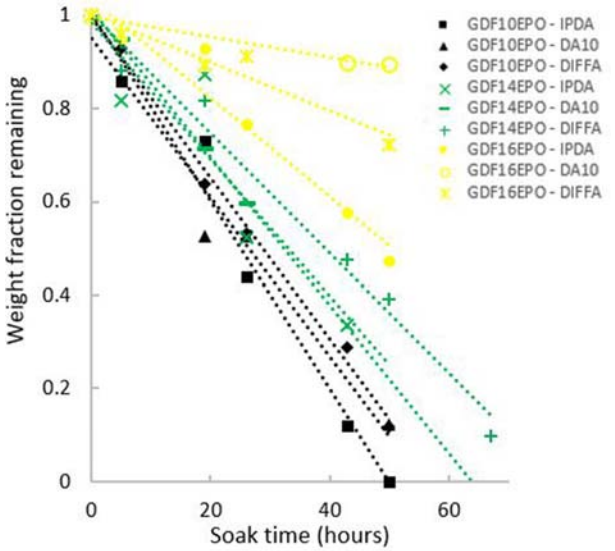

FIGURE 7 | Analyses of thermoset weight loss as function of incubation time at 60°C in acid aqueous solutions.

ferulic-, glycerol- and fatty acids-based bis- and triphenols - GDF_x and GTF - are described. The estrogenic activity of GDF_x with fatty acid chain lengths of 12, 16, and 18-carbons was quantified and compared to bisphenol A and 17β-estradiol and showed no significant activity for ERα, PXR, and AR receptors. Bio-based GDF_x and GTF bis/triphenols were then successfully converted to their corresponding di- and triglycidyl ether epoxy resins (i.e., GDF_xEPO and GTF-EPO, respectively) through a TEBAC-mediated glycidylation. GDF_xEPO was then cured with DIFFA, DA10 and IPDA diamines; GDF_{14}EPO was also co-formulated with tri-functionalized GTF-EPO and IPDA. All the resulting epoxy-amines exhibited relatively high thermostability with $T_d5\%$ ranging from 282 to 310°C and T_g between 3 and 62°C. Surprisingly, in the case of GDF_xEPO-diamine resins, for a given diamine, the chain length of the fatty acid moiety did not significantly impact the T_g. However, one can tailor the T_g by playing with the diamine nature and achieve T_g up to 23°C with IPDA and GDF_{14}EPO. To further tailor the T_g and to reach higher values, GTF-EPO must be added to the formulation. In such formulations, DSC and DMA analyses showed that the T_g and the storage modulus can also be modulated by finely adjusting the GTF-EPO content. Finally, with regards to wettability and degradability, the chain length of the fatty acid was found to provide a simple but powerful approach to tailor the wettability and the susceptibility to hydrolysis of the GDF_xEPO-based epoxy-amine resins. Indeed, the shortest fatty acid provided the highest wetting and hydrolysis rate, and *vice-versa*. This study therefore demonstrates the great potential of combining ferulic acid, glycerol and fatty acids using chemo-enzymatic processes for the preparation of epoxies and epoxy-amine networks with tunable properties.

AUTHOR CONTRIBUTIONS

FA and RG conceived the research. FA and SD managed the research. LH and ID performed the chemo-enzymatic reactions and the characterizations. PB performed the endocrine disruption assays. FA and LH provided the technical guidelines, reviewed the results, wrote, and drafted the article. FA, RG, and SD reviewed and approved the article.

ACKNOWLEDGMENTS

The authors are grateful to Région Grand Est, Conseil Départemental de la Marne and Grand Reims for financial support.

Xerogels are defined as porous structures that are obtained by evaporative drying of wet gels. One challenge is producing xerogels with high porosity and large specific surface areas, which are structurally comparable to supercritical-dried aerogels. Herein, we report on cellulose xerogels with a truly aerogel-like porous structure. These xerogels have a monolithic form with porosities and specific surface areas in the ranges of 71–76% and 340–411 m^2/g, respectively. Our strategy is based on combining three concepts: (1) the use of a very fine type of cellulose nanofibers (CNFs) with a width of ∼3 nm as the skeletal component of the xerogel; (2) increasing the stiffness of wet CNF gels by reinforcing the inter-CNF interactions to sustain their dry shrinkage; and (3) solvent-exchange of wet gels with low-polarity solvents, such as hexane and pentane, to reduce the capillary force on drying. The synergistic effects of combining these approaches lead to improvements in the porous structure in the CNF xerogels.

Keywords: cellulose nanofiber, xerogel, aerogel, porous material, ambient pressure drying

INTRODUCTION

Aerogels are defined from a processing perspective as porous structures that are obtained by supercritical drying of wet gels (Hüsing and Schubert, 1998). In general, aerogels are mesoporous and combine a high porosity and large specific surface area (SSA). Owing to their specific porous structure, aerogels can excellently function as thermal, acoustic, and electrical insulators as well as catalyst supports, separators, and adsorbents. Some aerogels can be optically transparent yet thermally insulating, and have drawn interest as transparent insulators that might reduce thermal energy loses from windows in offices and automobiles (Hayase et al., 2014; Zu et al., 2018). Aerogels were first reported in 1931 (Kistler, 1931); however, it remains difficult to put aerogels to practical use because of two problems: one is the mechanical brittleness of aerogels; and the other is the process of supercritical drying, which limits productivity and scalability. Therefore, much effort has recently been made to overcome these problems.

In terms of the brittleness, one approach is to use cellulose nanofibers (CNFs) as the skeletal units of aerogels. CNFs are wood-derived emerging materials, which have excellent mechanical strength (∼3 GPa) (Saito et al., 2013) and solvent tolerance. CNFs are thus suitable building blocks for aerogels. Pääkkö et al. (2008) demonstrated the flexibility of structurally aerogel-like CNF cryogels, and Kobayashi et al. (2014) have reported on mechanically tough aerogels with good optical transparency and thermal insulating properties, based on a very fine type of CNFs with a width of ∼3 nm.

One approach to addressing the processing problem is to switch focus from aerogels to xerogels. Xerogels are defined as porous structures that are obtained by evaporative drying of wet gels. However, producing structurally aerogel-like xerogels under ambient conditions remains particularly challenging. Even thick block-like hydrogels shrink considerably during evaporative drying owing to capillary forces; hence, the resulting xerogels inevitably become thin films with a very low porosity. One approach is to exchange the solvent of the wet gels, which is typically water, to a solvent of lower polarity, such as hexane and pentane, to reduce the capillary force. This concept was reported in a paper by Prakash et al. (1995), in which aerogel-like silica xerogels were formed as a thin film with a high porosity (∼99%) through solvent exchange after chemically modifying the silica skeleton to be hydrophobic. Later, Kanamori et al. (2007) further developed the idea and reported that monolithic xerogels can be optically transparent and even exhibit rubbery compression with the use of organosilicons as the skeletal precursor.

In the field of cellulose science, Toivonen et al. (2015) reported a landmark study of CNF xerogels, which were similarly produced through a solvent exchange process. Here CNFs were formed into a wet cake by vacuum filtration of their water dispersion, followed by drying under ambient conditions after solvent exchange with octane. The resulting xerogels were mesoporous and in a film form with a thickness of ∼25 μm. Their porosity and SSA were ∼60% and 200 m^2/g, respectively, which are high characteristics among xerogels but still not within the structural range of supercritical-dried CNF aerogels (porosity 60–99%, SSA 300–600 m^2/g) (Sehaqui et al., 2011; Kobayashi et al., 2014; Sakai et al., 2016). In another route to xerogel formation, freeze-thawing of aqueous CNF dispersions has been used to form block-like hydrogels, followed by solvent exchange. The resulting xerogels were monolithic with a high porosity of over 98% but were macroporous. Their SSA values were ∼30 m^2/g (Li et al., 2017; Erlandsson et al., 2018). Furthermore, a non-CNF skeletal, different type of cellulosic xerogels with a high porosity (∼90%) has been produced by a molecular dissolution-regeneration process; however, the SSA values of these materials were ∼10–30 m^2/g (Pour et al., 2016).

Here we report on CNF xerogels with a truly aerogel-like porous structure. The xerogels are in a monolithic form with high porosities and SSA in the ranges of 71–76% and 340–411 m^2/g, respectively. Our strategy is based on three ideas: (1) the use of a very fine type of CNFs with a width of ∼3 nm; (2) increasing the stiffness of precursor hydrogels by reinforcing inter-CNF interactions; and (3) solvent exchange as described above. To our knowledge, these ideas have not yet been combined, and the synergistic effects of these factors lead to the development of porous structure in CNF xerogels.

MATERIALS AND METHODS

Materials

A softwood bleached kraft pulp (Nippon Paper Industries, Japan) was used as the starting sample. The pulp was maintained in an undried state after bleaching. Before use, the pulp was demineralized by stirring in an aqueous HCl solution at pH 2 for 1 h, followed by washing with deionized water. All chemicals and solvents were of laboratory grade (Wako Pure Chemicals, Japan) and used as received.

Preparation of CNFs

CNF dispersions were prepared according to our previous reports (Saito et al., 2006; Sakai et al., 2016). In brief, the pulp was oxidized by a TEMPO/NaBr/NaClO system with 10 mmol of NaClO added per gram of pulp. The carboxylate content of the oxidized pulp was ∼1.6 mmol/g. The oxidized pulp was then suspended in water at a concentration of 0.5% w/w, and disintegrated into CNFs by passing the suspension through a high-pressure water jet system (HJP-25005X, Sugino Machine) five times.

Xerogel Formation via Acid-Induced Gelation

The 0.5% w/w CNF dispersion (20 g) was poured into a plastic mold with an inner dimension of 6 × 5.5 × 1 cm^3. A 1 M HCl solution (6 mL) was spread over the dispersion and allowed to stand for 1 h. The resulting hydrogel was removed from the mold and cut into pieces of ∼10 × 10 × 5 mm^3 in size with a sharp blade. Some pieces were immersed into 0.01 M HCl (150 mL) and shaken at ambient conditions for 1 day using an orbital shaker at 50 rpm, followed by rinsing out the HCl with distilled water over 2 days. The hydrogels were then dried at 23°C under ambient pressure. The resulting xerogels are denoted as *w*-xerogels. For reference, supercritical-dried CNF aerogels were also prepared from the same lot of hydrogel according to our previous report (Sakai et al., 2016).

The remaining pieces of the hydrogel were immersed in a mixed solution of 0.01 M HCl (75 mL) and ethanol (75 mL) and shaken under ambient conditions for 1 day using an orbital shaker at 50 rpm. The gel pieces were then shaken in an ethanol bath (280 mL) at 40°C for 3 days, accompanied by replacement of the bath with fresh ethanol twice a day. Some of the alcogel pieces were further shaken in a bath of acetone, hexane or pentane (280 mL) at 40°C for 3 days, accompanied by replacement of the bath with each fresh solvent twice a day. Each of the ethanol-, acetone-, hexane-, and pentane-exchanged gels was dried at 23°C under ambient pressure in an airtight desiccator containing silica gel at the bottom; the resulting xerogels are denoted as *e*-, *a*-, *h*- and *p*-xerogels, respectively.

Xerogel Formation via Metal Ion-Induced Gelation

The 0.5% w/w CNF dispersion (20 g) was poured into the same plastic mold as for that used for the acid-induced gelation (see section Xerogel Formation via Acid-Induced Gelation). A 0.1 M solution of $MgCl_2$, $CaCl_2$, or $AlCl_3$ (6 mL) was spread over the dispersions, which were then allowed to stand for 24 h. Similar to the case of the acid-induced gelation, the resulting hydrogel was cut into pieces with dimensions of ∼10 × 10 × 6 mm^3. The gel pieces were shaken in a 0.01 M solution of $CaCl_2$, $MgCl_2$, or $AlCl_3$ (150 mL) for 1 day and then successively in a mixed solution of water (75 mL) and ethanol (75 mL) for 1 day each. The subsequent processing after solvent exchange with the mixed

solutions involved the same steps as for the acid-induced gelation with ethanol and hexane. The xerogels resulting from evaporative drying of hexane are denoted as *h-Mg-*, *h-Ca-*, and *h-Al-*xerogels.

Membrane Xerogel Formation

An 0.5% w/w CNF dispersion (27 g) was poured into a glass dish with an inner diameter of 7 cm. A 0.1 M $AlCl_3$ solution (8 mL) was spread over the dispersion, which was then allowed to stand for 24 h. The originally air-exposed, top surface of the resulting hydrogel was cut off using a sharp blade to obtain a columnar gel with a thickness of ∼6 mm. The shaped gel was shaken in a 0.01 M $AlCl_3$ solution (150 mL) for 1 day and successively in a mixed solution of water (75 mL) and ethanol (75 mL) for 1 day each. The subsequent process involved the same solvent-exchange steps with the use of ethanol and hexane for the acid-induced gelation. The hexane-exchanged gel was then sandwiched with flat PTFE plates and allowed to dry at 23°C under ambient pressure in an airtight desiccator containing silica gel at its bottom. The top PTFE plate was 34 g in weight.

Analyses

Scanning electron microscope (SEM) images were acquired with a Hitachi S-4800 field-emission microscope operated at 1 kV. Prior to SEM observations, the xerogels were split using tweezers, and the exposed cross-sections were thinly coated with osmium with the use of a Meiwafosis Neo osmium coater at 5 mA for 10 s. Nitrogen adsorption–desorption isotherms were measured with a Quantachrome NOVA 4200e at −196°C after degassing of the samples in the system at 105°C for 3 h. The SSA values and pore size distributions of the xerogels were estimated from the isotherms following Brunauer–Emmett–Teller (BET) theory and the Barrett–Joyner–Halenda (BJH) model, respectively. The porosity values (%) of the xerogels were calculated using the

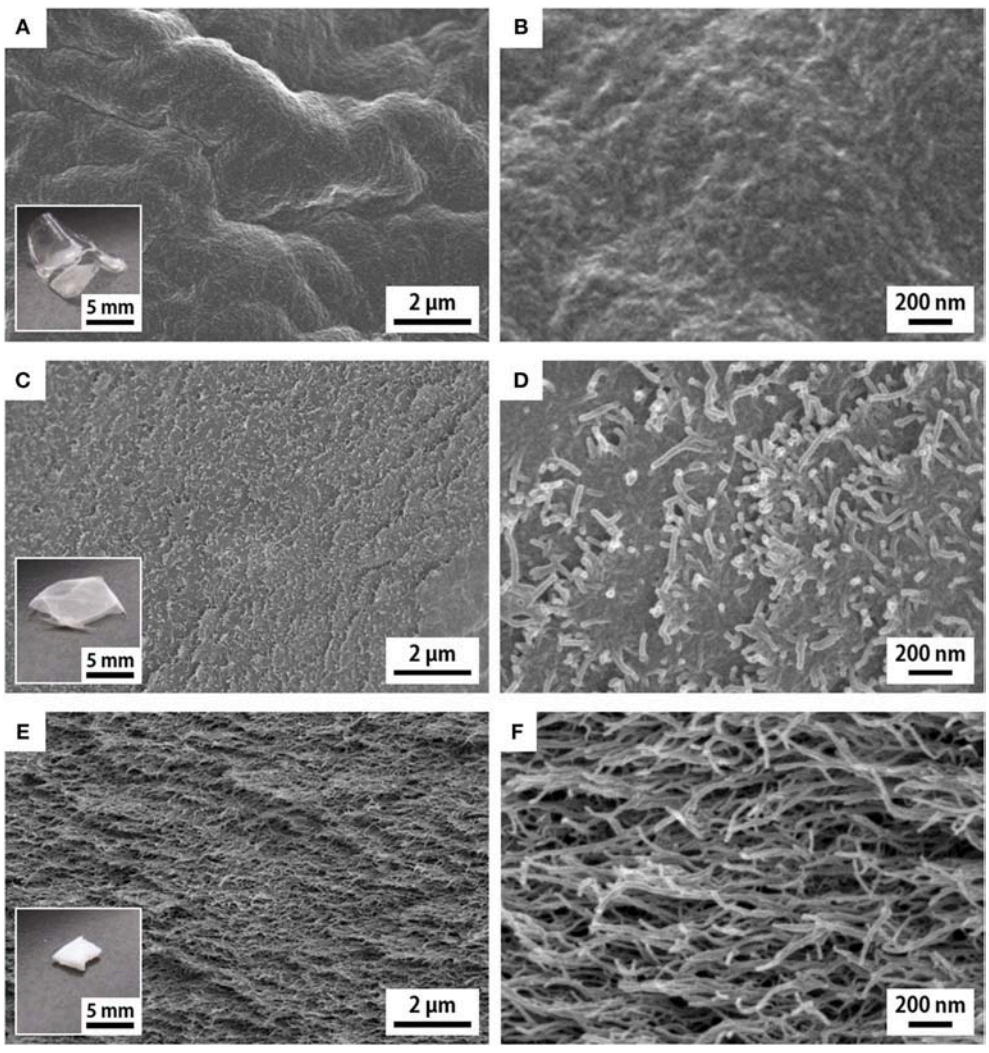

FIGURE 1 | SEM images of the cross sections of the **(A,B)** *w*-xerogel, **(C,D)** *a*-xerogel, and **(E,F)** *h*-xerogel. Insets show the appearances of the respective xerogels.

following equation,

$$Porosity = \frac{V_p}{V_p + 1/\rho_t} \times 100,$$

where V_p is the pore volume (cm^3/g) of the corresponding xerogel, and ρ_t is the true density of the CNF (1.64 g/cm^3). The pore volumes V_p of the xerogels were estimated from the maximum amounts of N_2 adsorbed into the respective xerogels by converting the adsorbed amount expressed as a gas volume at 273 K and 1 atm into pore-filling volumes as liquid nitrogen at −196°C. The porosity of the reference aerogel was calculated in the usual manner from its apparent volume and weight. Fourier transform infrared (FTIR) spectra of the xerogels were obtained with a JASCO FT/IR-6100. Tensile testing of the membranous xerogel was performed at 23°C and 50% relative humidity with the use of a Shimadzu EZ-TEST equipped with a 500 N load cell. The specimens were ∼2 mm wide and 20 mm long. Ten specimens were measured with a span length of 10 mm at a rate of 1.0 mm/min. The thermal conductivity k of the membranous xerogel was estimated based on the following equation,

$$k = \rho\alpha c,$$

where ρ, α and c are the bulk density, thermal diffusivity, and specific heat capacity of the xerogel, respectively. The thermal diffusivity α (9.02×10^{-8} m^2/s) was measured at 23°C and 50% relative humidity using an ai-Phase Mobile 1U device. The specific heat capacity c at 23°C (1.23 J/g·K) was measured using a Perkin-Elmer DSC 8500 instrument.

RESULTS AND DISCUSSION

The CNF in the present study was chemically modified by a TEMPO-oxidation process (see section Materials and Methods). The TEMPO-oxidized CNFs are characterized by a uniform width of ∼3 nm (Daicho et al., 2018), and by a high density of surface carboxyl groups (1–1.7 groups/nm^2). The carboxyl groups are in the form of sodium salts and are well-dissociated in water. Accordingly, electric double layer repulsion is induced between the CNFs in water, and these CNFs are stably dispersed. Their dispersibility strongly depends on the pH of the system and the presence of co-existing salts (Tanaka et al., 2014, 2016). The CNFs start to attractively interact by lowering of the pH below the pK_a value 3.6 for the carboxyl group and form a stiff hydrogel (Saito et al., 2011). Here, the sodium carboxylates (-COO^-Na^+) turn into carboxylic acids (-COOH). The inter-CNF repulsion is lost, and the CNFs are partially assembled or networked through hydrogen bonding and other van der Waals interactions. For this sol-gel transition, the storage modulus G′ of the system increases by several orders of magnitude. Similar behavior is observed when multivalent metal ions, such as Ca^{2+} and Al^{3+}, are added into the system (Goi et al., 2018). The inter-CNF interactions are dominated by ionic bonds in this case, such that the resulting hydrogels are thereby stiffer than the acid-type gels.

Xerogels via Acid-Induced Gelation

Initially, the acid type hydrogels were solvent-exchanged with ethanol, acetone, hexane, and pentane, followed by evaporative drying at 23°C under ambient pressure. For reference, some of the hydrogel samples were directly subjected to evaporative drying. Although all the hydrogels were shaped

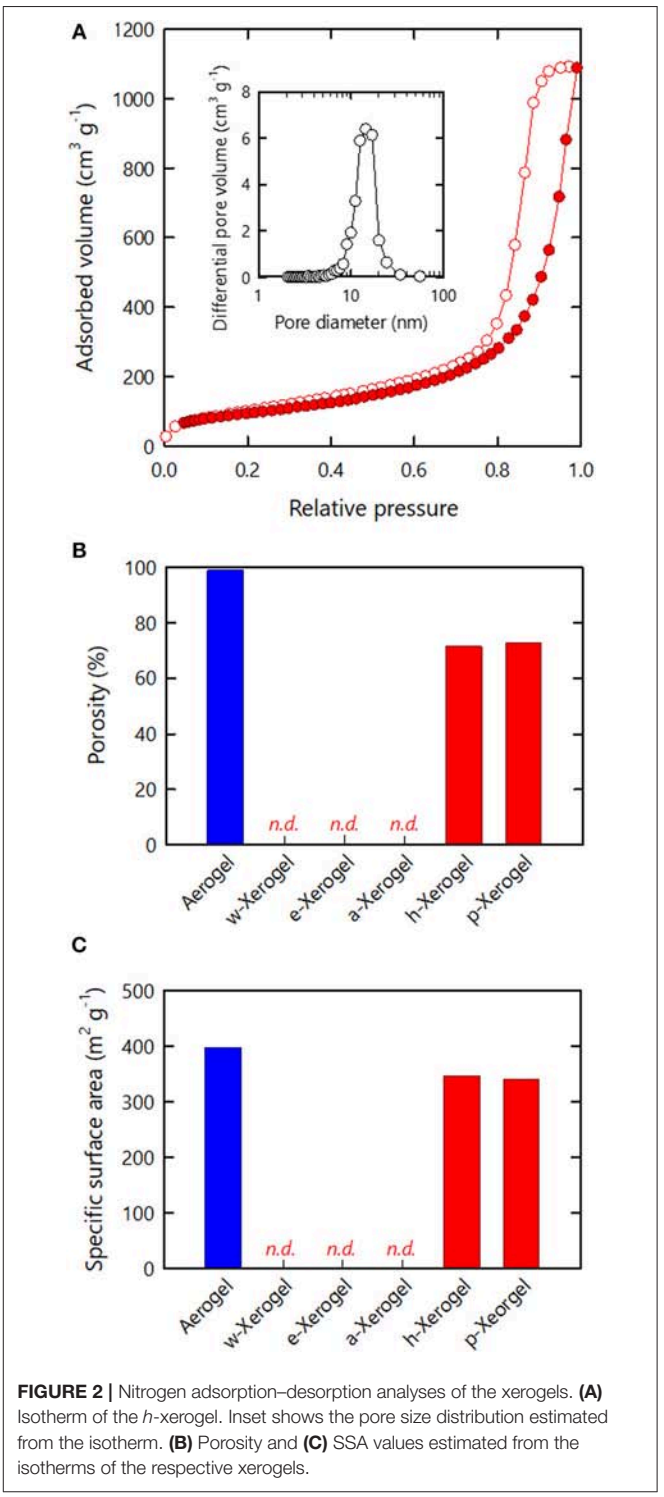

FIGURE 2 | Nitrogen adsorption–desorption analyses of the xerogels. **(A)** Isotherm of the *h*-xerogel. Inset shows the pore size distribution estimated from the isotherm. **(B)** Porosity and **(C)** SSA values estimated from the isotherms of the respective xerogels.

in block-like pieces with a size of ~10 × 10 × 6 mm^3 (**Supplementary Figure S1**), the resulting xerogels through solvent exchange differed from each other in both appearance and skeletal structure (**Figure 1**).

The reference *w*-xerogels, obtained by evaporation of water, formed thin and optically transparent films (the inset of **Figure 1A**). The CNF morphology was invisible at the cross sections of the *w*-xerogel films by SEM (**Figures 1A,B**). We explain this result by the close assembly of CNFs, which was induced by the strong capillary force of water (surface tension $\gamma \approx 72$ mN/m). The *e*- and *a*-xerogels obtained by evaporation of ethanol ($\gamma \approx 22$ mN/m) and acetone ($\gamma \approx 24$ mN/m) also formed thin films but had a hazy appearance (the inset of **Figure 1C**). The CNF morphology at their cross sections became visible, although the CNFs remained closely assembled (**Figures 1C,D**). Ethanol and acetone are also likely to interact strongly with the polar groups on the CNF surfaces, such as hydroxyl and carboxyl groups, resulting in the close assembly of CNFs at a meniscus on the solvent evaporation. Notable cases were found for the *h*- and *p*-xerogels, which were obtained by evaporation of hexane ($\gamma \approx 18$ mN/m) and pentane ($\gamma \approx 16$ mN/m), respectively. These xerogels had a block-like, monolithic shape (~1 mm thick) and were optically opaque (the inset of **Figure 1E**). The CNF assembly on drying was sufficiently suppressed, such that a network-like CNF skeleton was formed within the xerogels (**Figures 1E,F**). There might exist a threshold at $\gamma \approx 20$ mN/m for the solvent developing a porous structure within the xerogels, in the case when no further hydrophobization or stronger cross-linking was applied to the TEMPO-oxidized CNFs.

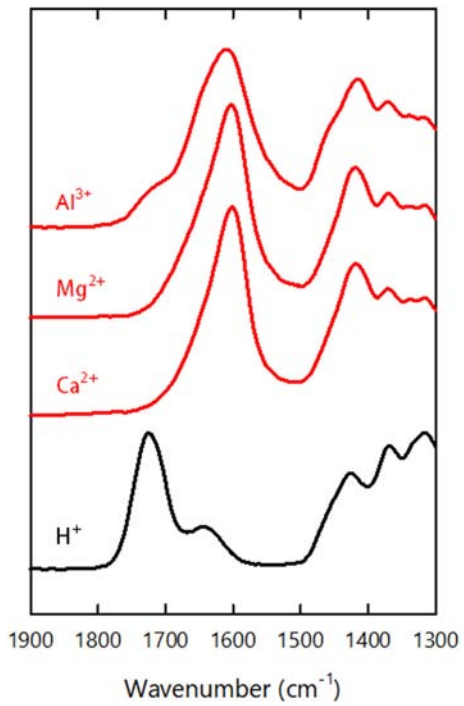

FIGURE 3 | FTIR spectra of the *h*-xerogel, *h-Ca*-xerogel, *h-Mg*-xerogel, and *h-Al*-xerogel.

Nitrogen adsorption–desorption analyses were performed on the series of xerogels (**Figure 2**). For reference, we also analyzed aerogels obtained from the acid type CNF hydrogels via supercritical drying (**Supplementary Figure S2**). Although the *w*-, *e*- and *a*-xerogels were non-porous, as shown in **Figure 1**, and could not be analyzed, both the *h*- and *p*-xerogels exhibited typical isotherms of mesoporous structures (**Figure 2A**). The isotherms were characterized by hysteresis at a high relative pressure, caused by capillary condensation of nitrogen gas in pores. The pore sizes estimated from the isotherms of the *h*- and *p*-xerogels ranged from a few nm to ~30 nm (the inset of **Figure 2A**). Note that the capillary pressures on nitrogen sorption can be of order 1 MPa (Reichenauer and Scherer, 2001) and thus shrinkage of the xerogels should be inevitable at a high relative pressure; the pore sizes in the present study are lower estimates.

The porosity values of the xerogels were also estimated from the isotherms (**Figure 2B**), where the maximum amounts of nitrogen adsorbed were regarded as the pore filling volumes of liquefied nitrogen through capillary condensation (see section Materials and Methods). The resulting values thus reflect the lower limit of the porosity. Although the porosity of materials

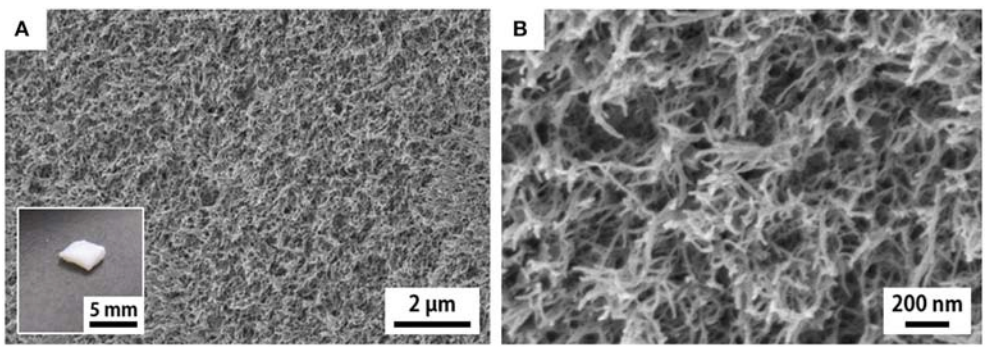

FIGURE 4 | SEM images of the cross section of the *h-Al*-xerogel. **(A,B)** show the images taken at low and high magnifications, respectively. Inset shows appearance of the *h-Al*-xerogel.

is commonly evaluated from their dimensions, mass, and true density, in the present study it was difficult to reliably measure the dimensions of the series of xerogels, which had distorted shapes and rough surfaces. The porosities of the *w*-, *e*-, and *a*-xerogels, evaluated on this basis, were below the limit of detection. The porosity values of the *h*- and *p*-xerogels were found to be as high as 70%. A value of 70% is within the porosity range of CNF aerogels reported to date (>60%) (Sehaqui et al., 2011; Sakai et al., 2016), but was lower than the porosity of the reference aerogel, as shown in **Figure 2B** (∼99%). Note that the reference aerogels in the present study were prepared by acid-induced gelation of TEMPO-oxidized CNFs; their structural profiles as porous materials, including porosity and SSA, are among the highest reported for cellulosic porous structures (Kobayashi et al., 2014).

The SSA results of the xerogels are shown in **Figure 2C**. Similar to the porosity, the SSA values of the *w*-, *e*- and *a*-xerogels were below the limit of detection (∼2 m^2/g). The SSA values of both the *h*- and *p*-xerogels were as high as 340 m^2/g. Although the value of 340 m^2/g was lower than the SSA of the reference aerogels (∼400 m^2/g), it is the highest SSA value ever reported for an ambient pressure-dried xerogel of cellulose or its derivatives. These results justify our combined strategy of: 1) the use of 3 nm-wide TEMPO-oxidized CNFs; 2) stiffening the inter-CNF interaction; and 3) solvent exchange.

Xerogels via Metal Ion-Induced Gelation

We examined further reinforcing the inter-CNF interactions by ionically cross-linking carboxylate groups via multivalent metal ions, namely Mg^{2+}, Ca^{2+}, and Al^{3+} (Goi et al., 2018). The resulting hydrogels were solvent-exchanged with hexane based on the results in the previous section, followed by evaporative drying at 23°C under ambient pressure.

Figure 3 shows FTIR spectra of the xerogels formed through metal ion-induced gelation (*h-Mg*-, *h-Ca*-, and *h-Al*-xerogels). For reference, the spectrum of the acid-type one (*h*-xerogel) is also shown. In the spectra, the carboxyl-related IR adsorptions were as follows (Fujisawa et al., 2011): the C=O stretch of the carboxylic acid groups was at 1,720 cm^{-1}, the C=O stretch of carboxylate groups was at 1,600 cm^{-1}, and the C–O symmetric stretching of carboxylate groups was at 1,410 cm^{-1}. An adsorption peak was also present from bending of adsorbed water molecules at 1,630 cm^{-1}. The reference *h*-xerogel showed no peaks at 1,600 and 1,410 cm^{-1} but had a clear adsorption at 1,720 cm^{-1}. Meanwhile, the *h-Mg*-, *h-Ca*-, and *h-Al*-xerogels showed little or no adsorption at 1,720 cm^{-1} but had distinct peaks at 1,600 and 1,410 cm^{-1}, regardless of the ionic species present. The small adsorption at 1,720 cm^{-1} for the *h-Al*-xerogel indicated the presence of carboxylic acid groups. This result is explained by the pH of the gelling agent; a 0.01 M $AlCl_3$ solution that has a pH value of 3.8 was used in the gelation process for the *h-Al*-xerogel, and some of the carboxyl groups will be protonated because their pK_a value is 3.6. We estimated the ratio of the carboxylic acid groups to the total carboxylate content to be ∼15% based on the peak area. For *h-Mg*- and *h-Ca*-xerogels, $MgCl_2$ and $CaCl_2$ solutions with pH values of ∼6 were used, such that no protonation occurred in the gelation process. Furthermore, neither Na^+ ions in the starting CNF dispersion nor Cl^- ions in the gelling agents were detected by energy-dispersive X-ray (EDX) spectroscopy (data not shown). In fact, each multivalent metal ion in the xerogel electrostatically interacted with two or three carboxylate anions on the same or two different CNF surfaces. Otherwise, hydroxide ions would be coupled to electrically neutralize the remaining charges of the metal salts of carboxyl groups, for example, $-COO^- Al(OH)_2^+$.

As for the case of the *h*-xerogels, all the *h-Mg*-, *h-Ca*-, and *h-Al*-xerogels possessed a monolithic shape (roughly 1 mm in thickness), and a network-like CNF skeleton formed within the xerogels (**Figure 4**, **Supplementary Figure S3**). These xerogels showed similar nitrogen adsorption–desorption isotherms to those for the *h*-xerogels (see **Figure 2A**). The porosity values,

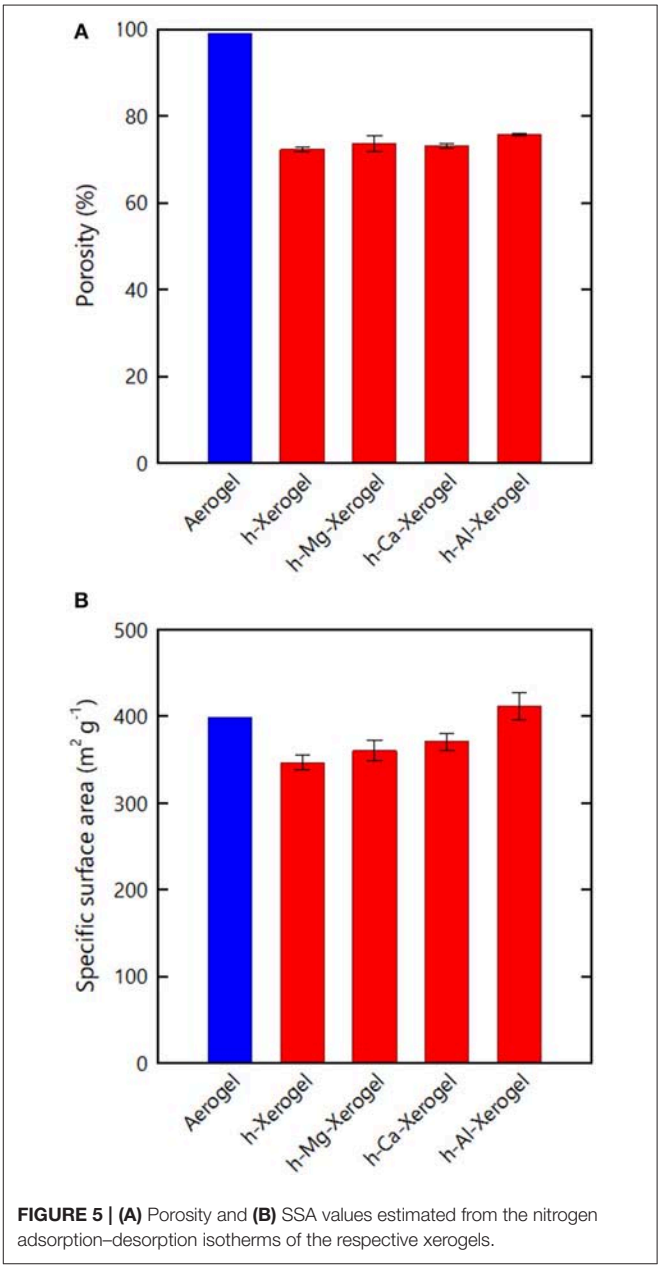

FIGURE 5 | (A) Porosity and **(B)** SSA values estimated from the nitrogen adsorption–desorption isotherms of the respective xerogels.

which were estimated from the isotherms, increased slightly from 71% for the *h*-xerogel to 76% for the *h-Al*-xerogel (**Figure 5A**). The SSA significantly increased from a high value of ∼340 m^2/g for the *h*-xerogel to 410 m^2/g for the *h-Al*-xerogel (**Figure 5B**). This value of 410 m^2/g is truly comparable to the SSA of the reference aerogels (∼400 m^2/g). Considering the electrostatic interactions with the carboxylate anions, the trivalent ions of Al^{3+} were likely more effective than the divalent ions of Mg^{2+} and Ca^{2+}, in improving the porosity and SSA.

Membrane Xerogels

The *h-Al*-xerogels were optically opaque as shown in **Figure 4**, despite their high porosity and SSA. We attribute this result to their surface roughness. Thus, we tried to reduce the surface roughness of the *h-Al*-xerogels by sandwiching the precursor organogels with flat PTFE plates during drying (see section Materials and Methods). The compression force imposed on the organogels by sandwiching was estimated to be ∼87 Pa. Although the resulting *h-Al*-xerogels formed films (∼74 μm), their optical transmittance improved greatly (**Figure 6A**) (see **Supplementary Figure S4** for a light transmittance spectrum). In addition, the nitrogen adsorption–desorption isotherms of the film-like *h-Al*-xerogels were as categorized as type IV IUPAC physisorption, similar to the monolithic *h*- and *h-Al*-xerogels (**Figure 6B**). The porosity and SSA values were then estimated from the isotherm to be ∼60% and 270 m^2/g, respectively. These values are lower than those of the *h-Al*-xerogels but still high as those of cellulosic xerogels.

Unlike the other xerogels in the present study, the film-like *h-Al*-xerogels had sufficiently flat surfaces that their specimen sizes could be reliably measured. Next, we analyzed the tensile properties and thermal conductivity of the film-like *h-Al*-xerogels. In the tensile tests, the film-like xerogels exhibited a high Young's modulus E and tensile strength σ of ∼3 and 49 MPa, respectively (see **Supplementary Figure S5** for a typical stress–strain curve). These values are within the range of the E and σ values of practically applicable plastic films (Ashby et al., 2009), which is surprising because of the high porosity and a large SSA of the xerogels. We explain this result by the high strength of the CNFs and their strong interactions at the contacting surfaces. The thermal conductivity k of the film-like xerogels was measured to be 0.095 W/m·K in the out-of-plain direction. This value is intermediate between those of highly-compacted CNF films (0.11–0.14 W/m·K) (Zhao et al., 2018) and insulating CNF aerogels (0.02–0.04 W/m·K) (Sakai et al., 2016). The porosity and SSA of the xerogels (∼60% and 270 m^2/g) were both higher than those of the compacted films (10–18% and < 2 m^2/g) but lower than those of the insulating aerogels (>97% and > 300 m^2/g). Therefore, the drying conditions should be further explored to obtain heat-insulating yet optically-transparent CNF xerogels with a truly aerogel-like porous structure.

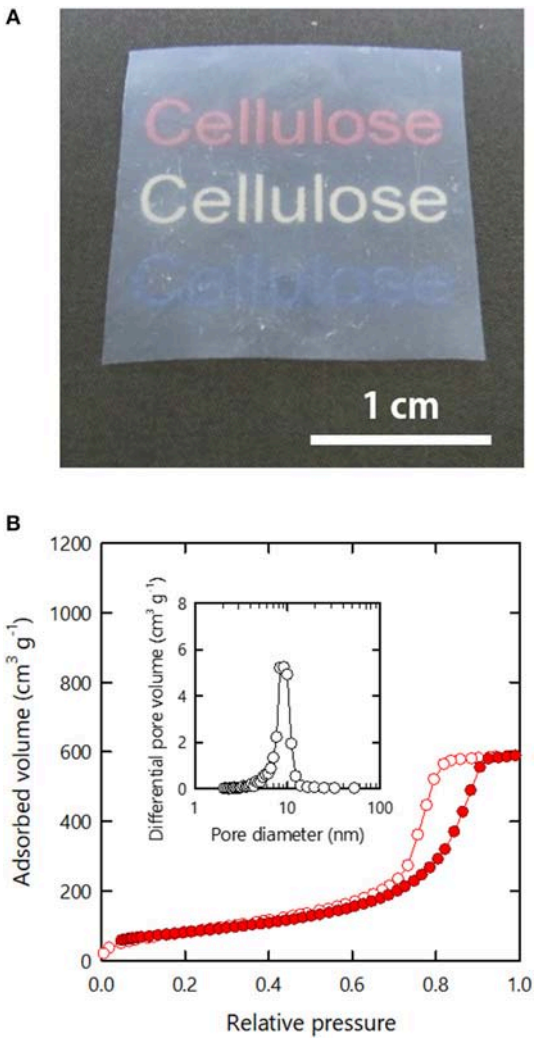

FIGURE 6 | (A) Appearance and **(B)** nitrogen adsorption–desorption isotherm of the membranous *h-Al*-xerogel. Inset in **(B)** shows the pore size distribution estimated from the isotherm.

CONCLUSIONS

Monolithic CNF xerogels with high porosities and large SSAs in the ranges of 71–76% and 340–411 m^2/g, respectively, were prepared via evaporative drying under ambient conditions. These characteristics fall within the structural range of supercritical-dried CNF aerogels reported to date. These materials were achieved by a combination of three concepts: (1) the use of TEMPO-oxidized CNFs with a uniform width of ∼3 nm to exploit the potential SSA of CNFs; (2) stiffening the inter-CNF interactions in the hydrogels by, for example, ionic cross-linking to withstand their dry shrinkage; and (3) solvent exchange with low-polarity solvents such as hexane and pentane to reduce the capillary forces during drying. All the monolithic xerogels had distorted shapes and rough surfaces. Accordingly, these materials were opaque despite having high porosity and SSA. Therefore, further exploration of the drying conditions might enable monolithic yet optically-transparent CNF xerogels. Such trials should also look to optimize the inter-CNF interactions and make the CNF surfaces more hydrophobic.

DATA AVAILABILITY

The datasets for this manuscript are not publicly available because the raw data supporting the conclusions of this manuscript will be made available by the authors, without undue reservation, to any qualified researcher. Requests to access the datasets should be directed to TS, asaitot@mail.ecc.u-tokyo.ac.jp.

AUTHOR CONTRIBUTIONS

TS conceived the concept of the study. SY and TS designed the experiments with the help of KK. SY performed most of the experiments with the help of WS, HY, and KD. All the authors analyzed the data. SY and TS mainly wrote the manuscript with the contributions of all the authors.

FUNDING

This research was supported by the JST-Mirai R&D Program (JPMJMI17ED) and in part by the JSPS Grant-in-Aid for Young Scientists B (17K15298).

SUPPLEMENTARY MATERIAL

The Supplementary Material for this article can be found online at: https://www.frontiersin.org/articles/10.3389/fchem.2019.00316/full#supplementary-material

Chemical Biology

Ryo Okamoto

Ryo Okamoto received his BSc in 2004, MSc in 2006 and his PhD in 2009 from Yokohama City University under the supervision of Prof. Yasuhiro Kajihara. From 2009, he joined the Stephen B. H. Kent lab at the University of Chicago as a Postdoctoral Fellow for research abroad as part of the Japan Society for the Promotion of Science (JSPS). He joined Kajihara's group at Osaka University as an Assistant Professor in 2010 and was promoted to Associate Professor in 2017. His current research interest is the chemical synthesis of artificial proteins that surpass the functions of native proteins.

Xiaojun Peng

Xiaojun Peng obtained his PhD from Dalian University of Technology in 1989, after which he was a postdoctoral researcher in organic chemistry at Nankai University from 1990 to 1992. In 1992, he returned to the School of Chemical Engineering of Dalian University of Technology, and also held positions as a visiting scholar at Stockholm University and Northwestern University. He has received several prestigious awards including the Cross-Century Excellent Talents award, awarded by the Ministry of Education in 2000. He was also noted as one of the leading talents in Liaoning Province in 2010.

Jiangli Fan

Jiangli Fan obtained her PhD from Dalian University of Technology in 2005 in China. In 2010 she attended the University of South Carolina as a visiting scholar. She is currently a Professor at the State Key Laboratory of Fine Chemicals at Dalian University of Technology. Her research interests focus on small-molecule fluorescent probes for bioimaging and sensing, photosensitizers based photodynamic therapy, and targeted nanodrug delivery.

Zhiqian Guo

Prof. Zhiqian Guo obtained his BSc degree in Fine Chemicals from Zheng Zhou University in 2002. He then obtained his PhD degree in Applied Chemistry from East China University of Science & Technology (ECUST) in 2010. (Advisor: Professor Wei-Hong ZHU). From 2011 to 2012, he worked with Prof. Dr Juyoung Yoon (Ewha Woman's University/Korea) on organic chemistry. He became a full Professor at the School of Chemistry and Molecular Engineering at ECUST in 2017. He was a recipient of NSFC for Excellent Young Grants (2016), and Cheung Kong Young Scholar (Younger Project) (2017). His current research interests focus on functional chromophores, including fluorescent sensors, molecular imaging, drug delivery systems, and molecular logic devices.

Yimon Aye

Born and raised in Burma, Yimon Aye obtained her undergraduate and PhD degrees in Chemistry at Oxford (UK) and Harvard (USA), respectively. She received her postdoctoral training in Biochemistry at MIT (USA). In her independent career that began in mid-2012, she set out to understand the detailed mechanisms of electrophile signaling. This impetus culminated in the development of "REX" technologies (T-REX™ delivery and G-REX™ profiling). In a parallel research program, she studies pathways involved in genome maintenance, including the mechanisms of anticancer drugs in clinical use. In mid-2018, she established the Laboratory of Electrophiles And Genome Operation (LEAGO) at EPFL (Switzerland).

Mehdi Mobli

Associate Prof. Mehdi Mobli (PhD 2004, University of Liverpool) is a Principal Research Fellow at the University of Queensland's Centre for Advanced Imaging. His research involves understanding the mechanisms of ion-channel function in health and disease, and his group is well known for fundamental contributions to the field of nuclear magnetic resonance (NMR) spectroscopy. He has over 100 publications including 13 book chapters and two books. His research has been recognized through a number of awards including the Sir Paul Callaghan Medal (ANZMAG - NMR research), the Tregear Award (Australian Peptide Society - peptide research), and the MERCK medal (ASBMB - biochemistry).

N,N-Dimethylaminoxy Carbonyl, a Polar Protecting Group for Efficient Peptide Synthesis

Ryo Okamoto, Emiko Ono, Masayuki Izumi and Yasuhiro Kajihara*

Department of Chemistry, Osaka University, Toyonaka, Japan

Peptide coupling with minimal protection is one of the desired methods for the synthesis of peptides and proteins. To achieve regioselective amide bond formation, side chain protection is often essential; however, protecting groups potentially diminish peptide solubility and render the polar polyamide chain amphipathic due to their apolar nature. In this manuscript, we describe a new protecting group, *N,N*-dimethylaminoxy carbonyl (Dmaoc), and its use in peptide coupling reactions. The Dmaoc group has a relatively polar character compared to the Boc group, which is a conventional protecting group for the N^{ε}-amine of Lys residues. This polar protecting group is removable by reduction in the buffer containing (±)-dithiothreitol (DTT). Furthermore, the Dmaoc group proved compatible with peptide ligation strategies featuring the activation of *N*-acyl diaminobenzamides (Dbz) with sodium nitrate to generate the respective benzotriazole leaving group. The Dmaoc/Dbz strategy described in this manuscript provides a new method for the chemical synthesis of peptides.

Keywords: *N,N*-dimethylaminoxy carbonyl, Dmaoc, Dbz, peptide coupling, solid phase peptide synthesis, chemical ligation, thioester, protecting group

INTRODUCTION

Peptide coupling reactions are essential for the chemical synthesis of polypeptides and proteins (Kricheldorf, 2006; Kent, 2017). Considerable efforts have been devoted to the development of chemical ligation for the chemoselective coupling of unprotected peptides. Many proteins have been synthesized using a variety of chemical ligation techniques, including native chemical ligation (Bode, 2011, 2017; Jin and Li, 2018; Liu and Li, 2018). These methodologies are generally based on site-specificity, which limits the amino acid sites for ligations. Consequently, chemical ligation often requires the preparation of suitable building blocks for peptide coupling at desired sites, depending on the amino acid sequence of target polypeptides.

Strategies are desired for the coupling of peptide fragments possessing diverse chemical structures using minimal functional group protection (Aimoto, 1999; Hojo, 2014). To achieve regioselective amide bond formation, side chain protection is often essential; however, many protecting groups diminish peptide solubility and render the polar polyamide chain amphipathic due to their nonpolar nature. A strategy involving minimal use of protection on the N^{ε}-amine of Lys residues and the *N*-terminal α-amine may circumvent the solubility problem and avoid undesirable amide bond formation. The utility of the minimum protection strategy for peptide coupling was demonstrated in the chemical synthesis of proteins using the thioester leaving group (Aimoto, 1999). However, this strategy used Boc protection on the N^{ε}-amine of Lys, which increases the risk of poor solubility, depending on the number of protecting groups in the target peptide sequence.

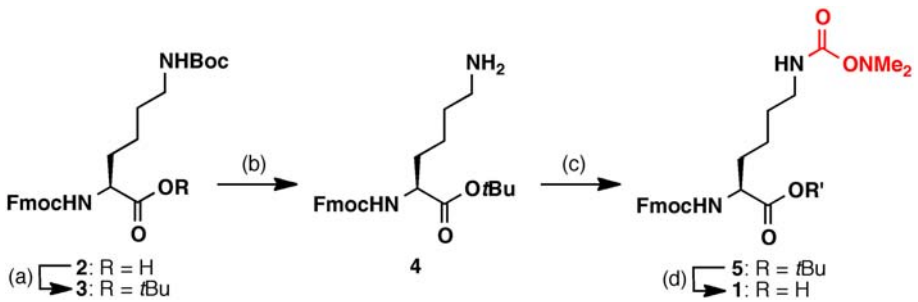

FIGURE 1 | Synthesis of Fmoc-Lys(Dmaoc)-OH **1**. Reagents and conditions: **(a)** Boron trifluoride diethyl ether complex, *tert*-butyl 2,2,2-trichloroacetimidate; **(b)** TFA, dichrolomethane (y = 86%, over 2 steps); **(c)** *N,N'*-carbonyldiimidazole, *N,N*-dimethyl hydroxylamine hydrochloride (y = 46%); **(d)** 6 M hydrochloric acid, 1,4-dioxane (y = 91%).

The isonicotinyloxycarbonyl (iNoc) group has been used to circumvent the intrinsic low solubility of protected peptides (Veber et al., 1977). Recently, the protection of the N^{ε}-amine of Lys residues with the iNoc group has also demonstrated its utility during peptide synthesis (Asahina et al., 2015). These reports suggest the potential of polar protecting groups for the chemical synthesis of peptides. However, much effort has not been paid to the development of new polar protecting groups that are stable but efficiently removable under mild reaction conditions.

Herein, we present a polar protecting group *N,N*-dimethylaminooxy carbonyl (Dmaoc) for the N^{ε}-amine of Lys and its use in peptide synthesis. This protecting group can be removed by reduction in a buffer containing thiol. The Dmaoc group proved compatible with peptide ligation strategies featuring the activation of *N*-acyl diaminobenzamides (Dbz) with sodium nitrate to generate the respective benzotriazole (Bt) leaving group (Wang et al., 2015; Weidmann et al., 2016), as further demonstrated by the synthesis of Sunflower trypsin inhibitor.

RESULTS AND DISCUSSION

Firstly, Fmoc-Lys(Dmaoc)-OH **1** was synthesized from commercially available Fmoc-Lys(Boc)-OH **2** for the preparation of Dmaoc protected peptide by Fmoc solid phase peptide synthesis (SPPS) (**Figure 1**). The Lys derivative **2** was esterified using *tert*-butyl trichloroacetimidate. The Boc group was removed selectively by treatment with trifluoroacetic acid (TFA)/dichloromethane solution. The Dmaoc group was then incorporated onto the N^{ε}-amine of Lys of **4** by treatment with *N,N'*-carbonyldiimidazole, followed by the addition of *N,N*-dimethylhydroxylamine. After optimizing the conditions for removing the *t*Bu ester moiety, we found that the treatment of the fully protected Lys derivative **5** with the mixed solution of 6 M HCl and 1,4-dioxane (1: 1 vol/vol) afforded Fmoc-Lys(Dmaoc)-OH **1** in good yield.

In order to perform a peptide coupling reaction, we focused on the Dbz group that was known as a precursor of the Bt group. Thioesters have been utilized as an efficient leaving group for peptide coupling reactions. However, the synthesis of peptide-thioesters is still difficult in Fmoc SPPS, and thus several thioester surrogates have been developed. Recently, the Dawson and Liu groups have independently reported the synthesis of peptide-thioester from peptide-Dbz through the formation of peptide-Bt (Wang et al., 2015; Weidmann et al., 2016). These synthetic methodologies were based on previous studies by Katritzky et al. (1992, 2000, 2004), in which *N*-acyl-Bt was used as an efficient acylating agent. We envisaged that peptide-Bt, prepared from peptide-Dbz, could be used as a *C*-terminal activated peptide for peptide coupling reactions.

The Dmaoc-protected peptide having the Dbz group was synthesized by standard Fmoc SPPS (**Figure 2**). The synthesis was performed on the commercially available Fmoc-Dbz-polystyrene resin, according to the protocol reported by Dawson et al. (Blanco-Canosa and Dawson, 2008). Coupling of Fmoc-amino acids including **1** was performed by using standard coupling reagents such as HATU or HBTU, together with *N,N*-diisopropylethylamine (DIEA) (see **Supplementary Material** for the detail). Removal of the Fmoc group was also performed under standard conditions using 20% piperidine/*N,N*-dimethylformamide (DMF). After complete assembly, the peptide was detached from the solid support by use of a TFA cocktail. This Fmoc SPPS successfully yielded the Dmaoc-protected peptide-Dbz (peptide(Dmaoc)-Dbz **6**, 66% isolated yield).

The Dmaoc group includes the dimethylamino moiety that can be a proton acceptor and this structural property allowed us to anticipate the polar nature of the Dmaoc group. The polarity of the Dmaoc group was compared with the Boc group, a conventional protecting group for the N^{ε}-amine of Lys. The peptide(Dmaoc)-Dbz **6** and corresponding Boc-protected peptide **7** were subjected to reversed-phase high-performance liquid chromatography (**Figure 3**). This analysis revealed that the retention time for the peptide(Dmaoc)-Dbz **6** was shorter than that of the peptide(Boc)-Dbz **7**. This result indicates that the Dmaoc group has essentially higher polarity than that of Boc group.

We found that the Dmaoc group could be removed under reductive conditions (**Figure 4**). The removal of

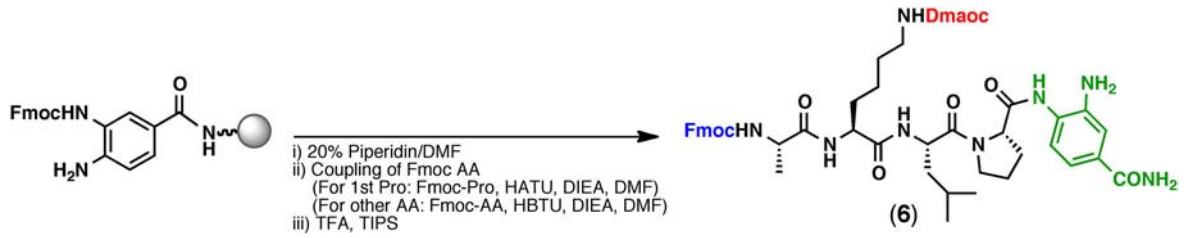

FIGURE 2 | Fmoc SPPS of Dmaoc-protected peptide (**6**).

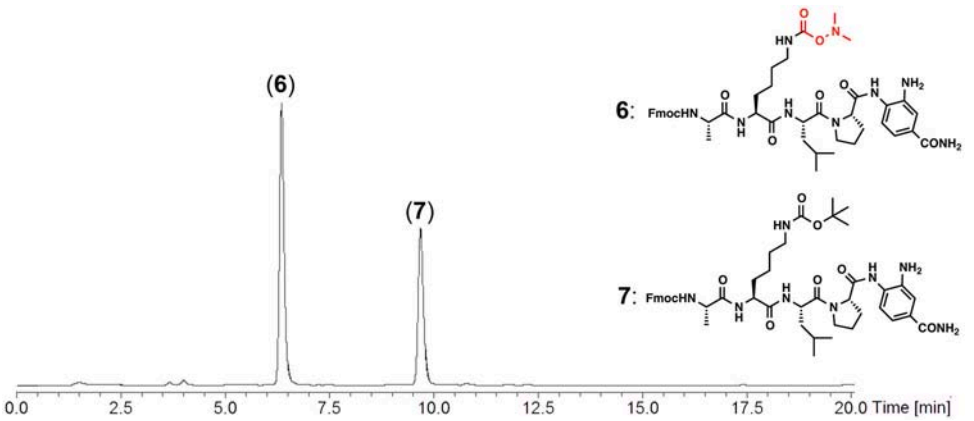

FIGURE 3 | RP-HPLC chromatogram for the analysis of Dmaoc-protected peptide (**6**) and Boc-protected peptide (**7**). Chromatographic separation was performed by using a linear gradient of 0.1% HCOOH aq.: 90% acetonitrile aq. containing 0.09% HCOOH from 60:40 to 30:70 over 20 min at a flow rate of 0.3 mL/min. C4 silica gel with column dimension 2.0 × 150 mm was used for this analysis. The eluent was monitoring by UV-absorbance at 280 nm with on-line ESI-MS.

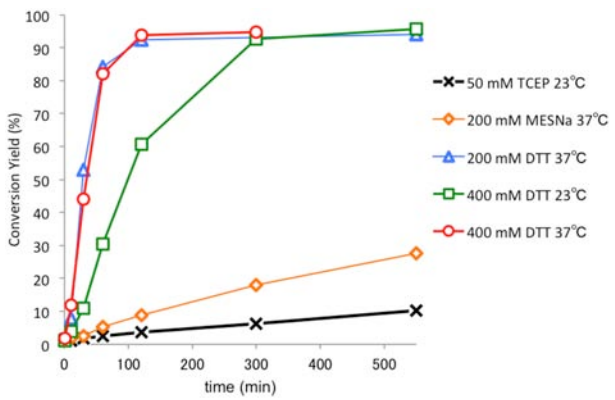

FIGURE 4 | Investigation of the reaction rate for the removal of Dmaoc group of peptide **6**. The reaction was performed using 4 mM of the peptide (0.5 mg) in 0.1 M sodium phosphate buffer containing 6 M guanidine hydrochloride and reducing agents at pH 7.0. At each time point, the fraction conversion was determined by HPLC peak area intensities.

the Dmaoc group on peptide **6** was conducted in a buffer at pH 7.0 in the presence of reducing agents such as sodium 2-mercaptosulfonate (MESNa), (±)-dithiothreitol (DTT) or tris(2-carboxyethyl)phosphine (TCEP). Consequently, the Dmaoc group was efficiently removed within a few hours in the presence of DTT. In contrast, the deprotection rate was slow in the presence of MESNa or TCEP, and no deprotection was observed without reducing agents. These results suggested that a suitable reducing potency as well as the nucleophilicity of the thiol group contributed to the removal of Dmaoc group; however, a detailed investigation of the reaction mechanism is still underway.

We then tested the peptide coupling between the peptide(Dmaoc)-Dbz **6** and the heptapeptide **8** (**Figure 5A**, **Figures S-1**,**S-4**). The Dbz group was converted into Bt by treatment with sodium nitrate ($NaNO_2$) in acidic DMF at −17°C (**Figure 5B**a). Subsequently, peptide **8**, 3-hydroxy-1,2,3-benzotriazine-4(3*H*)-one (HOOBt) and DIEA were added to initiate the peptide coupling via the conversion of peptide-Bt (**9**) into an active peptide-ester. This reaction gave Dmaoc-protected undecapeptide **10** within 14 h (**Figure 5B**c). After separating the crude peptide **10** from DMF by ether precipitation, the resultant material was dissolved in phosphate buffer (pH 7.0) containing DTT to remove the Dmaoc group. This reaction proceeded to completion within 2 h and gave peptide **11** (**Figure 5B**d). To remove the *N*-terminal Fmoc group, piperidine was subsequently added to the reaction mixture (**Figures 5B**e,f). As a result, these sequential reactions efficiently yielded undecapeptide **12** (60% isolated yield over four steps).

Encouraged by the result of the peptide coupling reaction, we conducted the synthesis of a cyclic peptide using the Dmaoc/Dbz

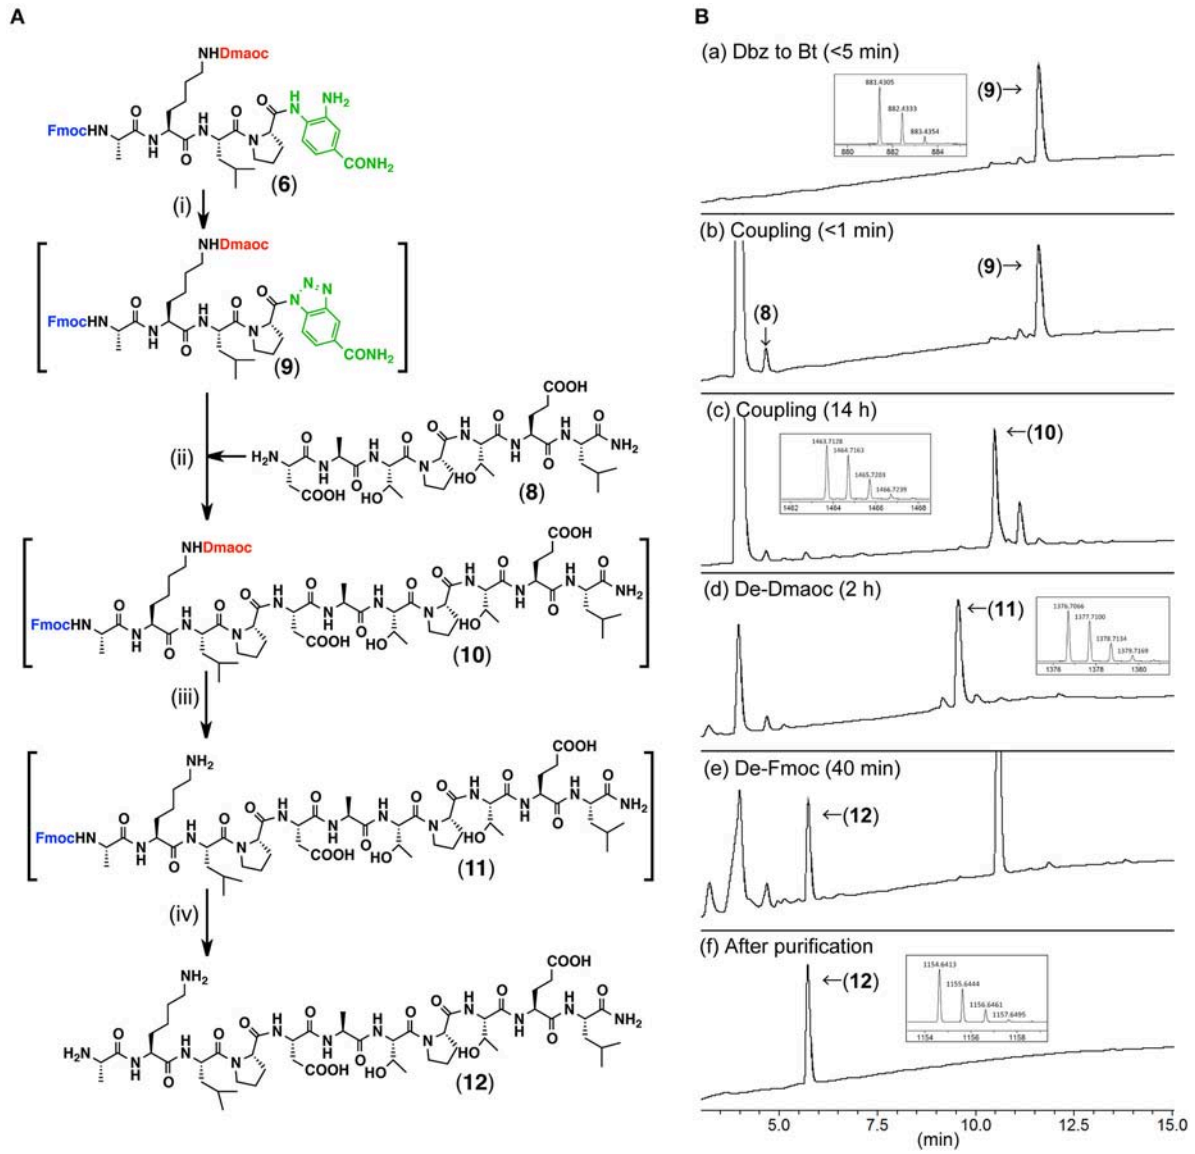

FIGURE 5 | The coupling of the Dmaoc-protected peptide-Dbz **6** and the heptapeptide **8**. **(A)** Reaction scheme for the peptide coupling followed by the deprotections; Reagents and conditions: (i) $NaNO_2$, DMF/4 M HCl in 1,4-dioxane (39: 1 vol/vol); (ii) DIEA, HOOBt, DMF; (iii) Ether precipitation then 0.1 M sodium phosphate buffer containing 6 M guanidine-hydrochloride and 0.2 M DTT (pH 7.0) at 37°C; (iv) piperidine. **(B)** LC data for the monitoring of the sequential reactions. Analytical condition: Linear gradient of 0.1% HCOOH aq.: 90% acetonitrile aq. containing 0.09% HCOOH from 90:10 to 30:70 over 15 min at a flow rate of 0.3 ml/min. The eluent was monitoring by UV-absorbance at 218 nm with on-line ESI-MS. Insets are expanded view of $[M+H]^+$ ion peak acquired by on-line ESI-HRMS from each UV peak labeled with compound number. m/z calculated mono isotopic $[M+H]^+$ for compound **9** $C_{45}H_{57}N_{10}O_9^+$ 881.4304; for compound **10** $C_{69}H_{103}N_{14}O_{21}^+$ 1463.7417; for compound **11** $C_{66}H_{98}N_{13}O_{19}^+$ 1376.7096; for compound **12** $C_{51}H_{88}N_{13}O_{17}^+$ 1154.6416.

strategy. Sunflower trypsin inhibitor (SFTI) is one of the smallest cyclic peptides that has a head-to-tail ring structure consisting of 14 amino acids, including one Lys residue. The chemical synthesis of SFTI has been achieved using native chemical ligation, which requires an *N*-terminal cysteine residue (Daly et al., 2006). In our present research, the Dmaoc/Dbz strategy was applied to the construction of the cyclic-structure of SFTI. We expected that this result would provide us with a new synthetic route for cyclic peptides that do not have Cys residues.

Linear Dmaoc-protected SFTI-Dbz prepared by Fmoc SPPS was subjected to an intramolecular peptide bond formation followed by the removal of the Dmaoc group (**Figure 6**, **Figures S-2**,**S-3**). The sequential reactions in the conversion of Dbz to Bt and the subsequent coupling steps resulted in the formation of disulfide bonded cyclic SFTI(Dmaoc) **15** and a cyclic SFTI(Dmaoc)-NO adduct **16**. These products were afforded because the starting peptide **13** had free thiols, which could be oxidized by $NaNO_2$. We expected that the NO group

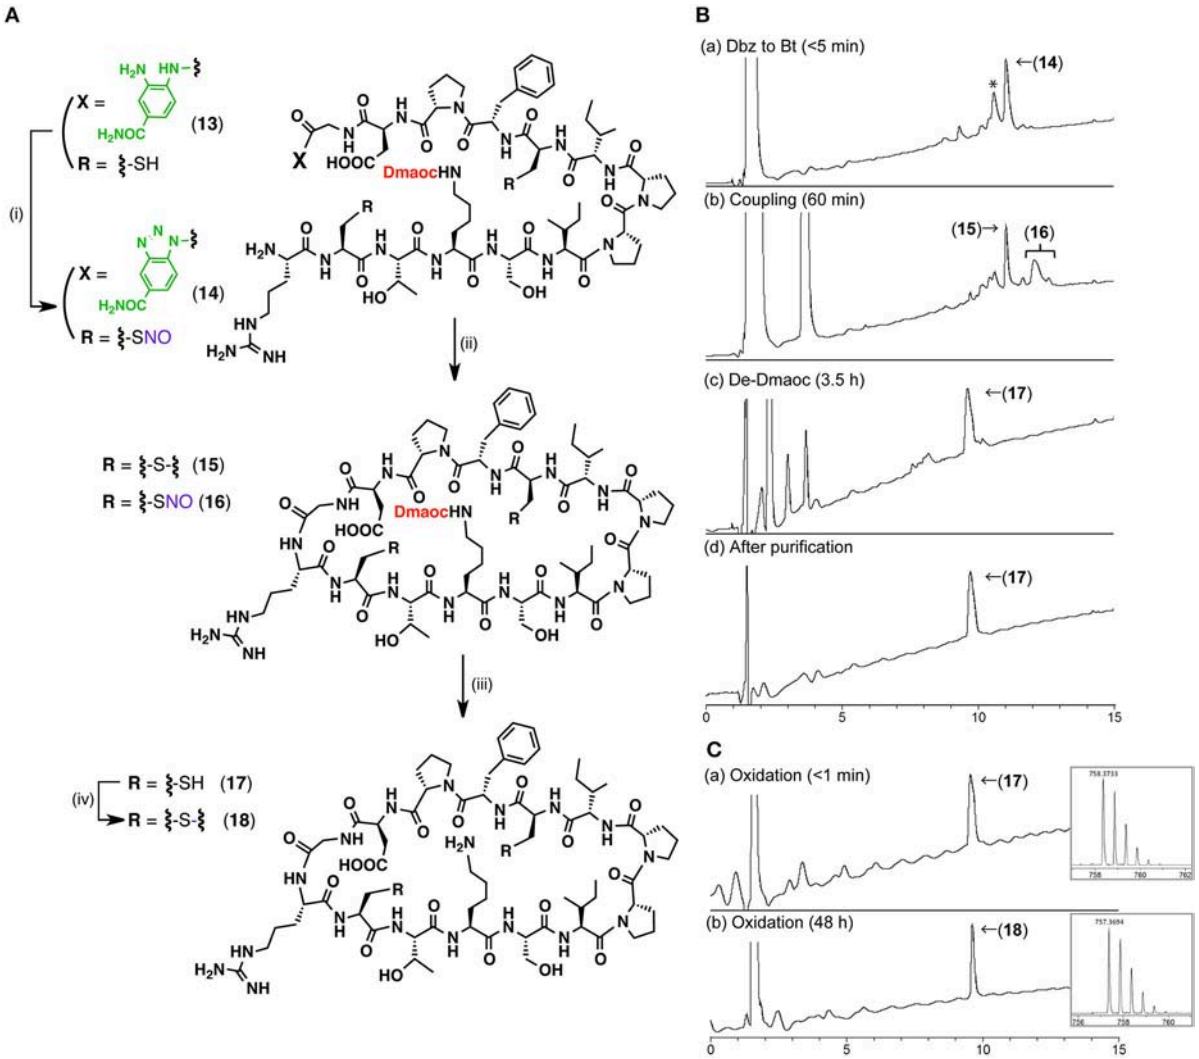

FIGURE 6 | The synthesis of cyclic peptide, SFTI using the Dmaoc protected peptide-Dbz (**13**). **(A)** Reaction scheme for the synthesis of SFTI; Reagents and conditions: (i) $NaNO_2$, DMF / 4 M HCl in dioxane (39: 1, vol/vol); (ii) DIEA, HOOBt, DMF; (iii) Ether precipitation then 0.1 M sodium phosphate buffer containing 6 M guanidine-hydrochloride and 0.2 M DTT (pH 7.0) at 37°C; (iv) 20 % DMSO aq. **(B)** LC data for the monitoring of the sequential reactions and **(C)** LC data for the formation of disulfide bond; Analytical condition: Linear gradient of 0.1% HCOOH aq.: 90% acetonitrile aq. containing 0.09% HCOOH from 90:10 to 30:70 over 15 min at a flow rate of 0.3 ml/min. The eluent was monitoring by UV-absorbance at 218 nm with on-line ESI-MS. Peak labeled with asterisk in the chromatogram of **(Ba)**, was corresponding to the hydrolyzed form of peptide **14** judged by on-line MS analysis (see **Supplementary Material**). This was plausibly afforded in LC-MS analysis and not from reaction mixture, since this product was not observed in the following coupling step; Insets are expanded view of $[M+H]^+$ ion peak acquired by on-line ESI-HRMS from each peak labeled with compound number. m/z calculated mono isotopic $[M+2H]^{2+}$ for **17** $C_{67}H_{108}N_{18}O_{18}S_2$ 758.3760 and oxidized form **18** $C_{67}H_{108}N_{18}O_{18}S_2$ 758.3760.

would be removed simultaneously during the deprotection of the Dmaoc group with thiol. The subsequent deprotection of Dmaoc using DTT successfully yielded the reduced form of cyclic SFTI **17** (43% isolated yield over three steps). This product was converted into the corresponding oxidized form of SFTI **18** quantitatively by treatment with DMSO (**Figure 6C**, **Figure S-3**). The synthesis of cyclic peptide SFTI demonstrated the utility of our peptide coupling strategy using the Dmaoc and Dbz groups for the chemical synthesis of peptide derivatives.

CONCLUSION

We reported the Dmaoc as a polar protecting group and its use in peptide coupling reactions. The polarity of Dmaoc is higher than that of the Boc group, which is a conventional protecting group of the N^{ε}-amines of Lys. The Dmaoc-protected peptides could be synthesized by standard Fmoc-SPPS straightforwardly and were successfully used for the synthesis of Sunflower trypsin inhibitor peptide. The Dmaoc group was stable during the synthesis but

removable in a buffer containing thiol, thereby achieving the facile deprotection of Dmaoc after the peptide coupling reactions. The unique character of the Dmaoc group would expand the chemical toolbox for the synthesis of peptides and proteins, which would contribute to the development of next-generation drugs.

For the precision resection, development of near-infrared (NIR) fluorescent probe based on specificity identification tumor-associated enzyme for lighting-up the tumor area, is urgent in the field of diagnosis and treatment. Overexpression of γ-glutamyltranspeptidase, one of the cell-membrane enzymes, known as a biomarker is concerned with the growth and progression of ovarian, liver, colon and breast cancer compared to normal tissue. In this work, a remarkable enzyme-activated NIR fluorescent probe NIR-SN-GGT was proposed and synthesized including two moieties: a NIR dicyanoisophorone core as signal reporter unit; γ-glutamyl group as the specificity identification site. In the presence of γ-GGT, probe NIR-SN-GGT was transformed into NIR-SN-NH_2, the recovery of Intramolecular Charge Transfer (ICT), liberating the NIR fluorescence signal, which was firstly employed to distinguish tumor tissue and normal tissues *via* simple "spraying" manner, greatly promoting the possibility of precise excision. Furthermore, combined with magnetic resonance imaging by T2 weight mode, tumor transplanted BABL/c mice could be also lit up for first time by NIR fluorescence probe having a large stokes, which demonstrated that probe NIR-SN-GGT would be a useful tool for assisting surgeon to diagnose and remove tumor in clinical practice.

Keywords: enzyme-activated, NIR fluorescent probe, spraying, large stokes shift, diagnose, clinical practice, tumor, γ-Glutamyltranspeptidase

INTRODUCTION

With the improvement of economic level, diagnose and treatment of cancer is getting more and more attention (Cheng et al., 2011; Chen et al., 2016, 2018; Cong et al., 2018; Jung et al., 2018; Lee et al., 2018; Yang et al., 2018; Zhang et al., 2018). The traditional clinical detection techniques, such as positron emission tomography (PET) (Mileshkin et al., 2011; Xiao et al., 2012), magnetic resonance imaging (MRI) (Sardanelli et al., 2010; Pinto et al., 2011) and X-ray imaging (Huang et al., 2011; Shi et al., 2014), are widely used to the medical examination of humans. Unfortunately, the fatal flaw in these techniques is the inability to diagnose early tumors, especially for flat or depressed lesions (Park et al., 2018). Although histopathological biopsy could provide the accurate diagnose result, it is suffered from the possibility of real-time diagnosis *in situ* due to the complex

processing and time-consuming of the sample separation (Kozlowski et al., 2006). Indeed, surgical specialists urgent need an effective tool to easily distinguish between tumor and normal tissue during surgery. Fluorescence technology has been paid unprecedented attention (Blum et al., 2007; Paulick and Bogyo, 2008; Asanuma et al., 2015; Ofori et al., 2015; Cheng et al., 2016; Gu et al., 2016a,b; Hu et al., 2016; Chen et al., 2017; He et al., 2017; Liu et al., 2017a,b,c; Wang et al., 2017a, 2018; Yin et al., 2017; Kuriki et al., 2018; Li et al., 2018b; Llancalahuen et al., 2018; Miao et al., 2018; Sedgwick et al., 2018; Shang et al., 2018; Verwilst et al., 2018), especially for medical diagnosis and treatment system (Kim et al., 2017; Li et al., 2017b; Verwilst et al., 2017), owing to efficient identification without destructive *in vivo*. Thus, it is of great medical significance to develop fluorescent probe that can assist clinician for imaging and resection of tumor.

γ-glutamyltranspeptidase (γ-GGT; EC 2.3.2.2), an over-expression enzyme associated with the growth and progression of ovarian, liver, colon and breast cancer compared to normal tissue (De Young et al., 1978; Shinozuka et al., 1979; Rao et al., 1986), plays important roles in many physiological and pathological processes (Pompella et al., 2006; Strasak et al., 2010), which is regarded as an important target for analysis and imaging *in vitro* or *in vivo* (Li et al., 2015b, 2016c; Wang et al., 2015, 2017b; Park et al., 2016a,b; Zhang et al., 2016a,b; Liu et al., 2018). However, rarely related fluorescent probe could be qualified for the identification tumor by tracking the activity of γ-GGT enzyme *in vivo* (Urano et al., 2011), especially for NIR emission property, possessing good performances of avoiding auto-fluorescence and deeper tissue penetration (Gu et al., 2016a). In addition, large stokes shift could effectively avoid self-absorbing for beneficial to fluorescence imaging. Till to now, there is no fluorescence probe visualized tracking the activity of γ-GGT enzyme in various organs. More importantly, by "spraying" manner, tumor tissue could be conveniently and efficiently lighted up from normal tissue, which is urgent need for precision medicine.

In this work, based on our previous research (Li et al., 2018a), through installing γ-GGT enzyme-activable unit on photo-stability; large stokes shift and controllable NIR chromophore, probe NIR-SN-GGT was successfully proposed and synthesized for monitoring the activity of γ-GGT *in vitro* and *in vivo*. NIR fluorescence emission was strictly modulated through the electron donor capability of amino. Upon addition γ-GGT into solution, obvious NIR fluorescence emission signal was observed after activable group cut off, which attributed to the enhancement of electronic capacity of product NIR-SN-NH_2. By layer scanning and 3D imaging construction of tissue slices, the probe NIR-SN-GGT was breakthrough employed to evaluate the content of γ-GGT enzyme in different organs. To the best of our knowledge, tumor tissue could be distinguished from normal through "spraying" NIR fluorescence probe style for the first time.

Experimental Section

General Information and Materials

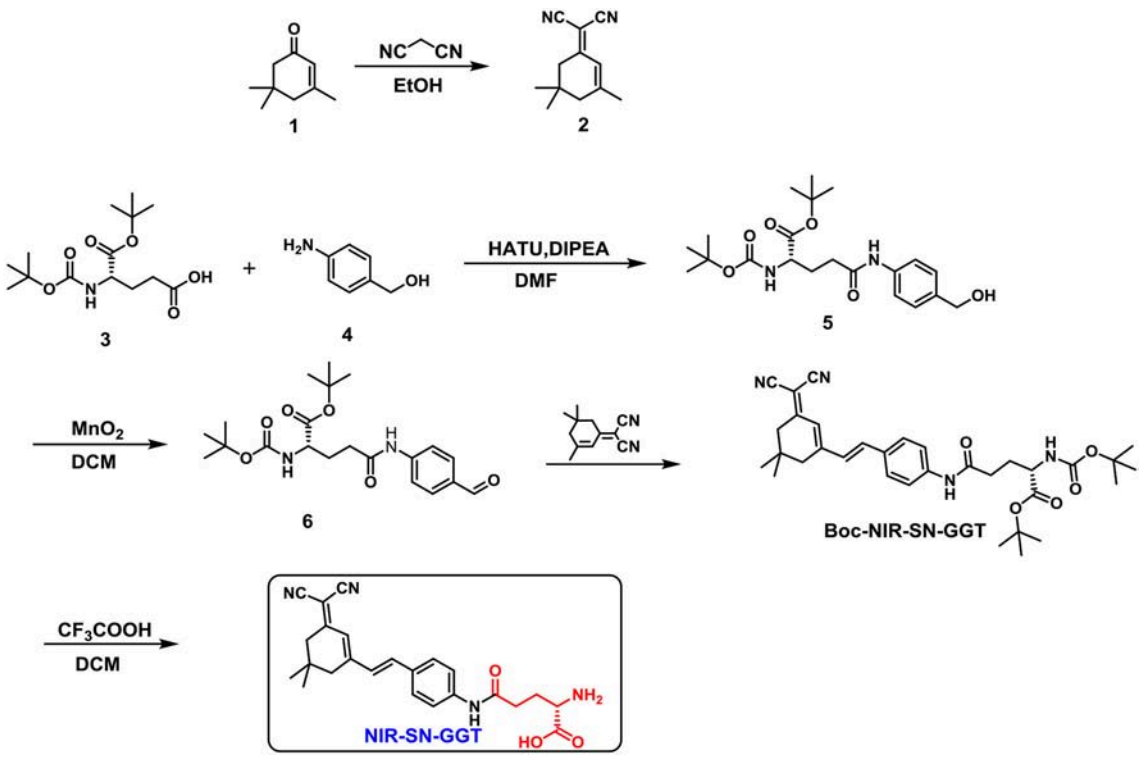
All reagents used were obtained from commercial suppliers and were used without further purification unless otherwise stated. Solvents used were purified *via* standard methods. Twice-distilled purified water used in all experiments was from Milli-Q systems. ^{1}H-NMR and ^{13}C-NMR spectra were recorded on a Bruker Avance II 400 MHz spectrometer. Chemical shifts (δ) were reported as ppm (in MeOD or DMSO-d_6, with TMS as the internal standard). Fluorescence spectra were performed on a VARIAN CARY Eclipse fluorescence spectrophotometer (Serial No.MY15210003) in 10 × 10 mm quartz cell. Excitation and emission slit widths were modified to adjust the fluorescence intensity to a suitable range. Absorption spectra were measured on Agilent Technologies CARY 60 UV-Vis spectrophotometer (Serial No.MY1523004) in 10 × 10 mm quartz cell. Mass spectrometric data were achieved with HP1100LC/MSD MS and an LC/Q-TOF-MS instruments. Mito-Tracker Green, Lyso-Tracker Green and Hoechst 33342 were purchased from Life Technologies Co. (USA). Nitroreductase, transglutaminase, γ-glutamyltranspeptidase, and 6-Diazo-5-oxo-L-norleucine (DON) were purchased from Sigma-Aldrich. All pH measurements were performed using the Ohaus Starter 2100 pH meter. The fluorescence quantum yields for compounds with Absolute PL Quantum Yield Spectrometer (HAMAMATSU C11347). Instruments used in cell imaging tests were carried out on Olympus FV1000 and FV1000-IX81 confocal microscopy (Olympus, Japan). Slight pH variations in the solutions were achieved by adding the minimum volumes of HCl or NaOH (1 M). Flash column chromatography was performed using silica gel (200–300 mesh) obtained from Qingdao Ocean Chemicals. Flow cytometry analysis was carried out on cytometer (Attune NxT). MRI imaging of mice was carried out on NIUMAG analytical instrument (MesoMR23-060H-I). Tumor tissue slices were prepared from freezing microtome (LEICA CM1860 UV). All the interferential reagents were prepared based on published literatures (Li et al., 2015a, 2016a,b, 2018a; Fan et al., 2017).

Detection Limit

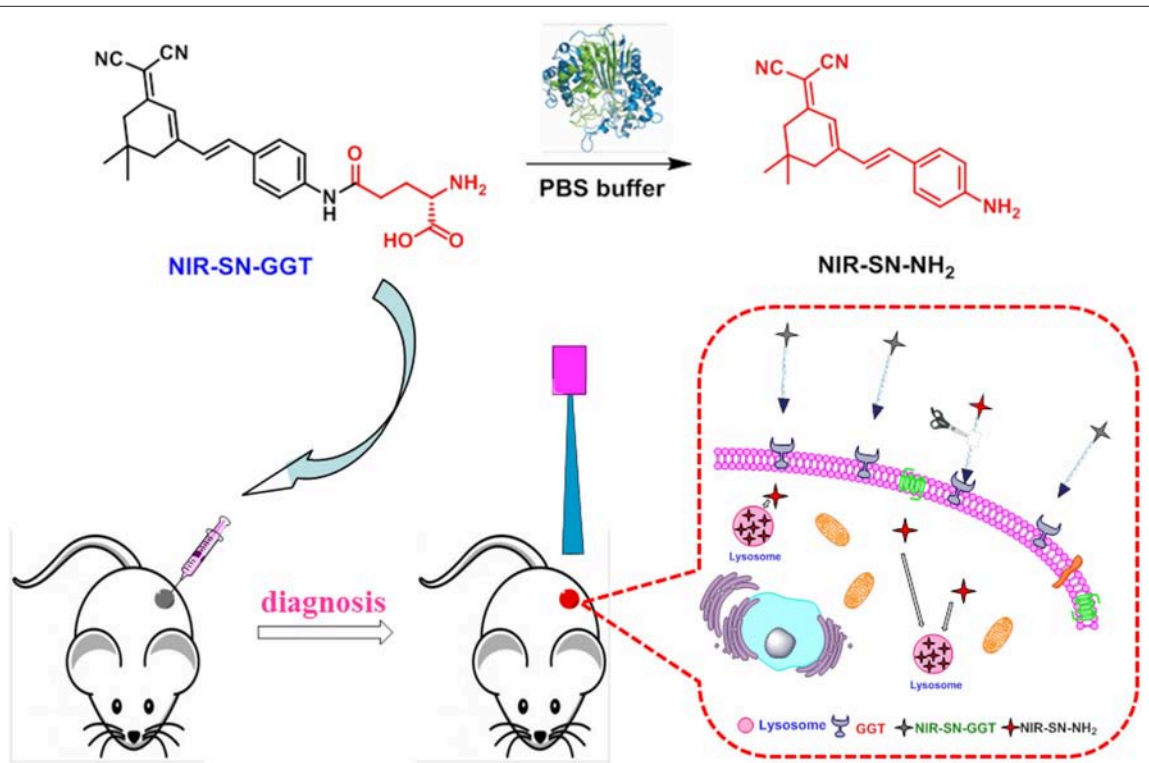
The detection limit (DL) was calculated based on the fluorescence titration of probe NIR-SN-GGT (10 μM) in the presence of γ-GGT (0-10 mU/mL). The fluorescence intensity of probe NIR-SN-GGT was measured and standard deviation of the blank measurement was achieved. The detection limit was calculated with the following equation: Detection limit $= 3\sigma/k$. Where σ is the standard deviation of the blank measurement, k is the slope between the fluorescence intensity (F_{650} nm) versus various γ-GGT concentrations.

Determination of the Quantum Yield

The fluorescence quantum yields for compounds with Absolute PL Quantum Yield Spectrometer (HAMAMATSU C11347). Operating this system is simple. Load a sample and press the start button to measure the photoluminescence quantum yields, excitation wavelength dependence, PL excitation spectrum and other properties in a short time. The PL Quantum Yield (Φ) is expressed as the ratio of the number of photons emitted from molecules (PNem) to that absorbed by molecules (PNabs). As following equation: Φ = PNem/PNabs.



SCHEME 1 | The synthesis route of probe NIR-SN-GGT.



SCHEME 2 | Recognition mechanism of probe NIR-SN-GGT for γ-GGT enzyme *in vivo*.

Cell Incubation

Ovarian cancer cells (A2780 cells), breast cancer 4T1 cells (4T1 cells) and human umbilical vein endothelial cells (HUVEC cells) were purchased from Institute of Basic Medical Sciences (IBMS) of the Chinese Academy of Medical Sciences. Except for A2780 cells treated with Dulbecco's modified Eagle's medium (DMEM, Invitrogen), others cells were cultured in RPMI medium 1640 supplemented with 10% fetal bovine serum (Invitrogen). The cells were seeded in confocal culture dishes and then incubated for 24 h at 37°C under a humidified atmosphere containing 5% CO_2.

Cytotoxicity Assays

Measurement of cell viability was measured by reducing of MTT (3-(4, 5)-dimethylthiahiazo (-2-yl)-3, 5-diphenytetrazoliumromide) to formazan crystals using mitochondrial dehydrogenases. A2780 and HUVEC cells were seeded in 96-well microplates (Nunc, Denmark) at a density of 1×10^5 cells/mL in 100 μL medium containing 10% FBS. After 24 h of cell attachment, the plates were then washed with 100 μL/well PBS buffer. The cells were then cultured in medium with 0, 1, 2, 5, and 10 μM of probe NIR-SN-GGT for 24 h. Cells in culture medium without probe NIR-SN-GGT were used as the control. Six replicate wells were used for each control and test concentration. 10 μL of MTT (5 mg/mL) prepared in PBS was added to each well and the plates were incubated at 37°C for another 4 h in a 5% CO_2 humidified incubator. The medium was then carefully removed, and the purple crystals were lysed in 200 μL DMSO. Optical density of solutions was determined on a microplate reader (Thermo Fisher Scientific) at 490 nm. Cell viability was expressed as a percent of the control culture value, and it was calculated using the following equation: Cells viability (%) = $(OD_{dye} - OD_{blank})/(OD_{control} - OD_{blank}) \times 100$

Imaging Endogenous γ-GGT Activity in Living Cells

A2780 and HUVEC cells were seeded in glass-bottom culture dishes at approximately concentration of 2×10^4 cells/mL and allowed to culture for 24 h at 37°C in a 5% CO_2 humidified incubator. For the detection of endogenous γ-GGT activity, A2780 and HUVEC cells were incubated with probe NIR-SN-GGT (10 μM) 37°C for 30 min, followed by washing thrice with free DMEM. Under the confocal fluorescence microscope (Olympus FV1000-IX81) with a 60 × objective lens, probe NIR-SN-GGT was excited at 488 nm (one-photon) and 800 (two-photon), next, fluorescence emission at 655–755 nm channel and 575–630 nm channel were gathered, respectively.

Time-Dependent Cell Imaging

The time-dependent cell imaging of probe NIR-SN-GGT (10 μM) monitoring endogenous γ-GGT activity in A2780 cells and HUVEC cells were investigated on Olympus FV1000-IX81 with the excitation at 488 nm. Fluorescent signals were recorded as time went on. After that, quantitative image analysis of the

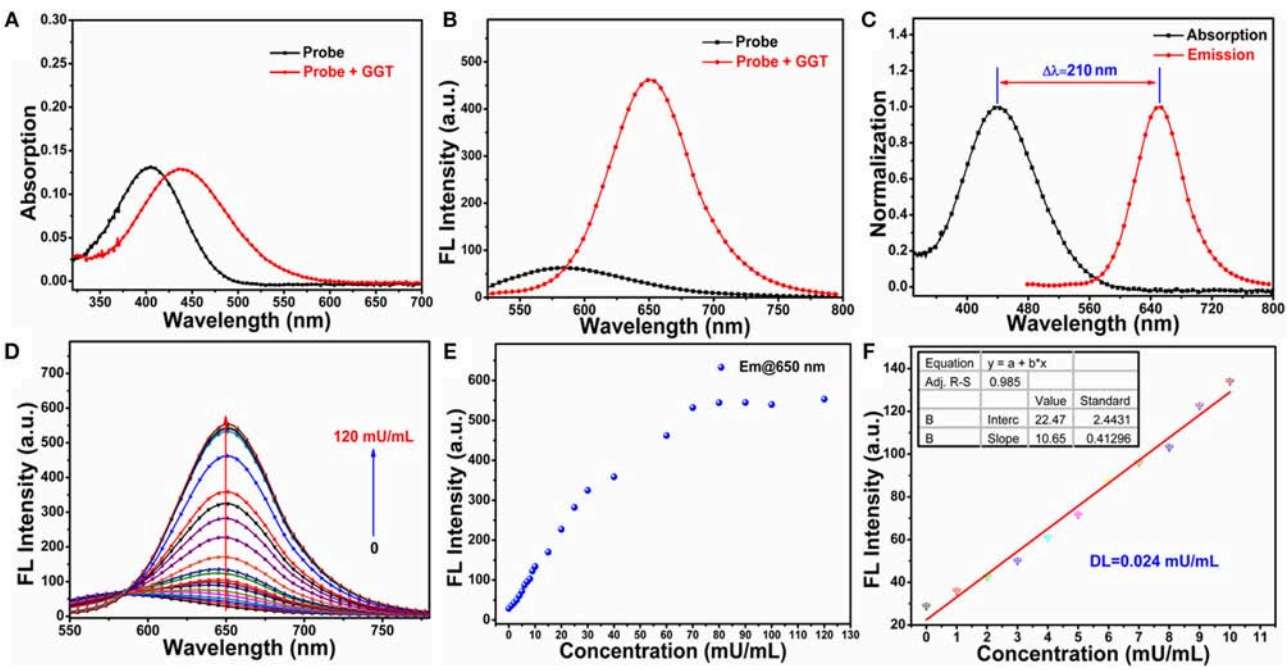


FIGURE 1 | (A) UV-Vis and **(B)** fluorescence spectra changes of probe NIR-SN-GGT (10 μM) toward adding 60 mU/mL γ-GGT enzyme in PBS buffer solution (0.01 M, pH 7.4). **(C)** Normalization UV-Vis (blank line) and fluorescence spectrum (red line) of NIR-SN-NH_2 in PBS buffer solution (0.01 M, pH 7.4). **(D)** Fluorescence titration experiments of probe NIR-SN-GGT (10 μM) toward different concentrations of γ-GGT enzyme (titration concentrations: 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 15, 20, 25, 30, 40, 60, 70, 80, 90, 100, 120 mU/mL). **(E)** Fluorescence intensities of probe NIR-SN-GGT (10 μM) around 650 nm toward various concentrations of γ-GGT enzyme (0-120 mU/mL). **(F)** The linearity of F_{650nm} vs. low concentration of γ-GGT ranging from 0 to 10 mU/mL. The experiments were repeated three times and the data were shown as mean (±S.D.). λ_{ex} = 445 nm, slit: 10/10 nm.

average fluorescence intensity of cells, determined from analysis of 9 regions of interest (ROIs) across cells.

Concentration-Dependent Cell Imaging

The concentration-dependent cell imaging of probe NIR-SN-GGT for monitoring endogenous γ-GGT activity in A2780 cells was investigated on Olympus FV1000-IX81 with the excitation at 488 nm. In the experiment, the concentration of probe NIR-SN-GGT was set 0, 5, 10, and 15 μM, respectively. Before cell imaging, A2780 cells were pre-treated with probe NIR-SN-GGT for 30 min at 37°C in the incubator. After that, quantitative image analysis of the average fluorescence intensity of cells, determined from analysis of 9 regions of interest (ROIs) across cells.

Flow Cytometry Analysis

A2780 cells and HUVEC cells gathered in logarithmic growth phase were incubated in 6-well with DMEM medium or RPMI 1640 medium at 37°C in a 5% CO_2 humidified incubator. The density of 1×10^5-5×10^5 was cultured and dilution with 500 μL PBS buffer. A2780 cells and HUVEC cells were pre-treated with probe NIR-SN-GGT (10 μM) 37°C for 30 min, followed by centrifugation (1000 r/min, 5 min) and dispersion with PBS buffer solution for twice. After that, cells were finally suspended in 0.5 ml PBS buffer and analyzed through flow cytometer (Attune NxT), and each sample was terminated with 10,000 target cells.

Visualization of γ-GGT Activity in Tissue and Mice Xenograft Tumor Model

All procedures were carried out in compliance with the guide for the care and use of laboratory animal resources and the national research council, and were approved by the institutional animal care and use committee of the NIH. For establishing a mouse tumor model, the 4T1 mammary carcinoma cells were chose to transplant under the armpit of approximately 15–20 g male BABL/c mice. After 10 days inoculation, the xenograft tumor mice were given with 50 μM 100 μL probe NIR-SN-GGT through *in-situ* injection within the period of mice anesthesia. After that, the imaging of mice was carried out on the NightOWL II LB983 small animal *in vivo* imaging system (Germany) with a 475 nm excitation and a 665 nm emission filter. Tumor tissue slices of 100 or 500 μm were prepared from freezing microtome (LEICA CM1860 UV). As a comparison, normal slices were chose from muscle tissue of hind legs. Next, these tissues were incubated with probe NIR-SN-GGT (10 μM) at 37°C for 45 min, followed by washing thrice with phosphate buffer saline (0.01 M, pH 7.4). Under the confocal fluorescence microscope (Olympus

FV1000-IX81) with a 60 × objective lens, probe TCF-GGT was excited at 800 (two-photon), next, fluorescence emissions at 575–630 nm of red channel were gathered. In tissue depth imaging, the 3D images were constructed *via* every 5 μm as a step under the same condition. Quantitative image analysis of the average fluorescence intensity of cells, determined from analysis of 9 regions of interest (ROIs) across cells.

Synthesis of Probe NIR-SN-GGT

Synthesis of compound 2

Compound **1** (2.76 g, 20 mmol), malononitrile (3.30 g, 50 mmol) and catalytic dose of piperidine (0.05 mL) were dissolved in 50 mL dry ethanol. The mixture was stirred at 80°C for 6 h. After removing the solvent by reduced pressure distillation, fuscous solid was obtained finally. The solid was with ethyl acetate three times. The organic phase was dried with anhydrous Na_2SO_4 for overnight and vacuum filter. Following, the crude product was purified through silica gel column chromatography to obtain 1.93 g white crystal compound **2** (yield 52%). ^{1}H NMR (400 MHz, DMSO-d_6) δ 6.56 (d, J = 1.3 Hz, 1H), 2.54 (s, 2H), 2.24 (s, 2H), 2.05 (s, 3H), 0.96 (s, 6H). ^{13}C NMR (100 MHz, DMSO-d_6) δ 171.91, 162.98, 119.87, 113.92, 113.12, 76.48, 45.28, 42.43, 32.42, 27.74, 25.43, ESI-MS: m/z calculated for $C_{12}H_{13}N_2^-$ $[M\text{-}H]^-$: 185.25, found: 185.12.

Error bar = RSD (n = 9). λex = 488 nm and λem = 655–755 nm. Scale bar = 20 μm.

Synthesis of compound 5 and 6

The synthesis of compound **5** and **6** were referred from the reported literature (Li et al., 2018a).

Synthesis of compound Boc-NIR-SN-GGT

Compound **6** (406 mg, 1 mmol) and compound **2** (186 mg, 1 mmol) were dissolved in 5 mL dry EtOH solution. Then, catalytic dose of piperidine (0.05 mL) was added into the above solution. The reaction system was stirred at 80°C for overnight under N_2 protection. After removing the solvent by reduced pressure distillation, crude jacinth solid was obtained finally without further purification for the next step. ESI-MS: *m/z* calculated for $C_{33}H_{42}N_4NaO_5^+$ $[M+Na]^+$: 597.30, found: 597.32.

Synthesis of probe NIR-SN-GGT

Compound **Boc-NIR-SN-GGT** (56 mg, 0.1 mmol) was dissolved in 2 mL dry CH_2Cl_2 and stirred at room temperature for 10 min. Next, 2 mL CH_2Cl_2-TFA (v/v 1:1) was added into above mixture *via* drop by drop style. When add was completed, the mixture system continued to stir overnight. After that, the crude product was purified through silica gel column chromatography to obtain 23 mg bright red probe **NIR-SN-GGT** (yield 54%)0.1H NMR (400 MHz, MeOD/TFA, 0.60 mL/0.05 mL) δ 7.62 (d, J = 8.7 Hz, 2H), 7.56 (d, J = 8.8 Hz, 2H), 7.17 (d, J = 16.1 Hz, 1H), 7.07 (d, J = 16.1 Hz, 1H), 6.81 (s, 1H), 4.07 (t, J = 6.5 Hz, 1H), 2.71 (t, J = 7.0 Hz, 2H), 2.60 (s, 2H), 2.53 (s, 2H), 2.27 (m, 2H), 1.06 (s, 6H). ^{13}C NMR (125 MHz, MeOD-TFA) δ 171.19, 170.11, 169.85, 155.21, 139.67, 136.70, 131.90, 128.13, 122.47, 119.77, 116.62, 113.78, 112.46, 76.98, 52.07, 42.52, 38.45, 31.47, 26.63, 25.48. ESI-HRMS: *m/z* calculated for $C_{24}H_{27}N_4O_3^+$ $[M+H]^+$: 419.2078, found: 419.2074.

RESULTS AND DISCUSSION

Design Probe NIR-SN-GGT

The synthetic procedure of probe NIR-SN-GGT was described in **Scheme 1**, which was fully validated through ^{1}H, ^{13}C-NMR and ESI-HRMS in the Supplementary Data (**Figures S20–S22**). In consideration of γ-glutamyl group as the recognition, it was installed on the framework of near-infrared emission. When γ-GGT encounter probe NIR-SN-GGT, it is cut off by specificity, liberating bare amino in the D-π-A structure. Then, NIR fluorescence signal of around 650 nm was observed through the modulation of Intermolecular Charge Transfer (ICT), where the recognition procedure of probe NIR-SN-GGT for target was shown in **Scheme 2**.

Spectroscopic Characteristics of Probe NIR-SN-GGT

With probe NIR-SN-GGT in hand, firstly, we studied the basic spectral properties of probe NIR-SN-GGT in different solvents

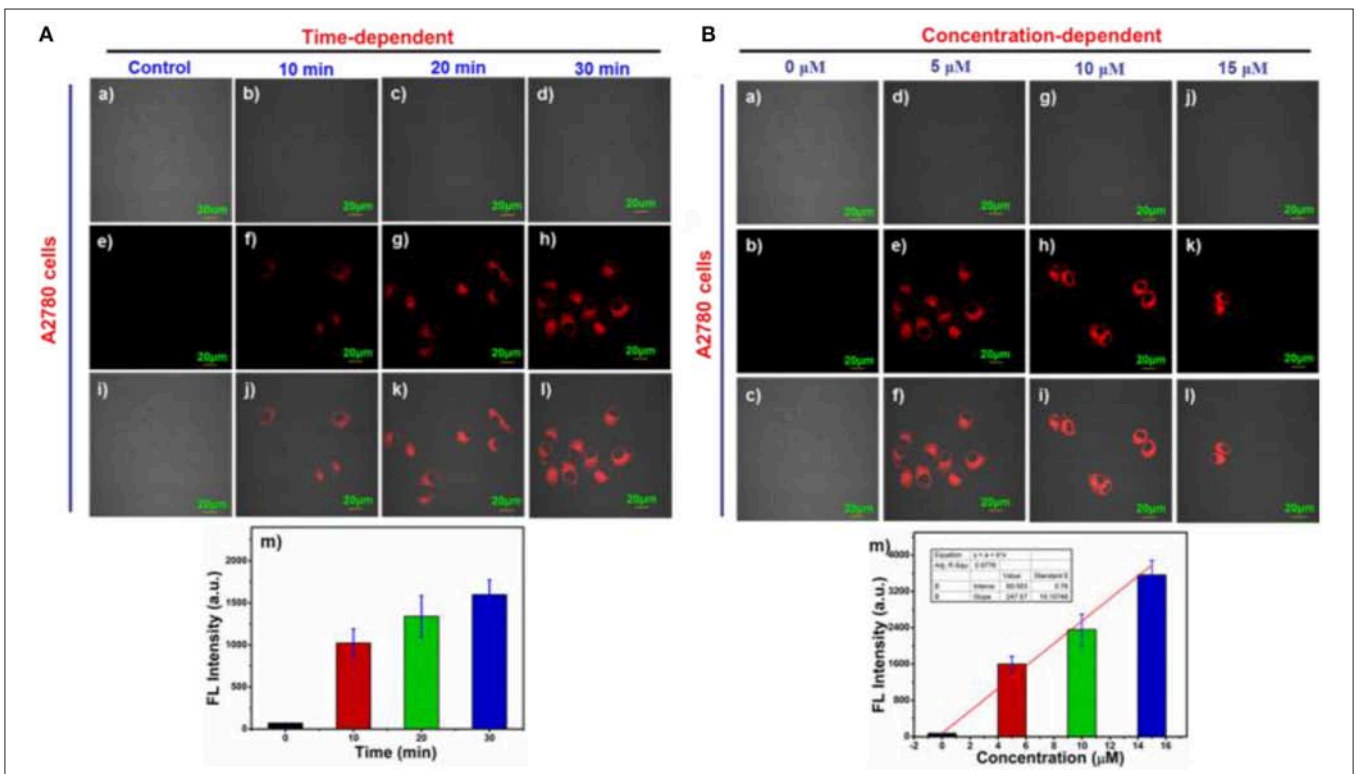

FIGURE 4 | (A) Time and **(B)** Concentration-dependent imaging of probe NIR-SN-GGT in A2780 cells. (a–d) bright imaging; (e–h) fluorescence imaging; (i–l) merged imaging; (m) fluorescence emission intensities of NIR channel were measured as averages of 9 regions of interest (ROIs) from different treated A2780 cells. Error bar = RSD (n = 9). λex = 488 nm and λem = 655–755 nm. Scale bar = 20 μm.

(**Figures S1, S2**). UV-Vis titration experiments of probe NIR-SN-GGT in PBS buffer solution (0.01 M, pH 7.4) demonstrated that probe had considerable solubility in aqueous solution (**Figure S3**). In addition, probe NIR-SN-GGT showed good stability (**Figure S4**), which laid the foundation for practical application of biology. As is seen in **Figure 1A**, adding 60 mU/mL γ-GGT enzyme in PBS buffer solution, and the absorption peak around 405 nm of probe NIR-SN-GGT (10 μM) reduced accompanied by the appearance of new absorption peak around 440 nm. The color of solution ranging from light green to yellowish-brown (**Figure S5**), which made the recognition of γ-GGT enzyme, was through the naked eyes. In the fluorescent spectra, obvious NIR signal emission was gathered (**Figure 1B**) accompanied by the quantum yield varying from 0.012 to 0.038 in PBS buffer solution. Notably, such a large stokes shift of $\Delta\lambda = 210$ nm effectively avoiding self-absorption is more conducive to fluorescence imaging (**Figure 1C**). With the increase of γ-GGT concentration (0-120 mU/mL), the fluorescence intensity around 650 nm of probe NIR-SN-GGT (10 μM) gradually enhanced (**Figure 1D**) and reached a plateau needing 70 mU/mL γ-GGT with a remarkable 21.84-fold enhancement (**Figure 1E**). In order to explore the sensitivity of probe NIR-SN-GGT, the low concentration (0–10 mU/mL) titration experiments were carried out in PBS buffer solution (0.01 M, pH 7.4). As is depicted in **Figure 1F**, there was an excellent linear relationship ($R^2 = 0.9851$) between the fluorescence intensity of 650 nm and various concentrations. Subsequently, the detection limit (DL) of probe NIR-SN-GGT versus γ-GGT was calculated to be 0.024 mU/mL, and proved that probe had the ability to quantitatively detect trace γ-GGT *in vitro*.

Response Speed and Selectivity

The reaction speed of probe NIR-SN-GGT toward γ-GGT is an important indicator for evaluating the availability of probe. As is seen in **Figure 2A**, it took approximately 30 min to reach equilibrium which showed that probe NIR-SN-GGT possessed the ability to recognize γ-GGT activity in real-time. Next, biological interferences including ions, amino acid, reductive species, reactive oxygen and enzymes were also investigated the influence on probe. To our delight, except for γ-GGT, none of the others interfered with probe NIR-SN-GGT (**Figures 2B,C**); clearly indicating that probe NIR-SN-GGT has outstanding selectivity in a variety of biologically related species.

Effects on Micro-Environment and Sensing Mechanism

The influences of micro-environment factors (e.g., pH and temperature) on the recognition of probe NIR-SN-GGT toward γ-GGT were performed. As is demonstrated in **Figures S6, S7**,

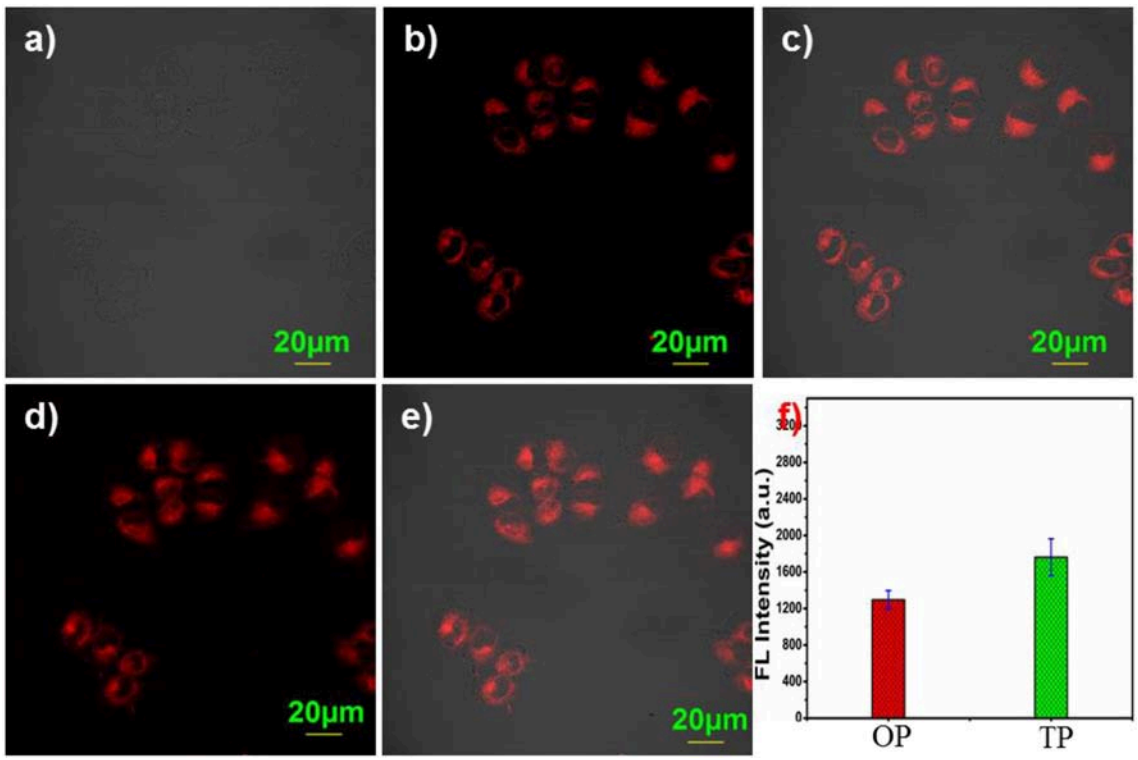

FIGURE 5 | Two-photon fluorescence imaging of probe NIR-SN-GGT in A2780 cells. **(a)** bright imaging; **(b)** one-photon imaging; **(c)** merged imaging from **(a,b)**; **(d)** two-photon imaging; **(e)** merged imaging between **(a)** and **(d)**; **(f)** fluorescence emission intensities of NIR channel were measured as averages of 9 regions of interest (ROIs) from different treated A2780 cells. Error bar = RSD ($n = 9$). (OP mode) λex = 488 nm and λem = 655-755 nm; (TP mode) λex = 800 nm and λem = 575–630 nm. Scale bar = 20 μm.

the related-parameters (pH = 7.4 and T = 37°C) are especially suitable for probe NIR-SN-GGT to track the activity of γ-GGT *in vivo*. Subsequently, we explored the enzyme-activation mechanism of probe for γ-GGT through HPLC and ESI-HRMS experiments. Only probe showed an obvious signal peak with retention time at 13.426 min (**Figure S8**, blue line). Upon addition γ-GGT into solution for incubation 30 min, a new distinct signal peak appeared at 18.018 min (**Figure S8**, red line), and the corresponding ESI-HRMS spectra was shown in **Figure S9**. There was an obvious peak at m/z 290.1658 corresponding to the positive ion mode of product NIR-SN-NH_2 (calcd. 290.1652 for $[M+H]^+$). Besides, the ability catalytic of γ-GGT for probe was largely suppressed (**Figure 2D** and **Figure S10**) after adding 30 μM 6-Diazo-5-oxo-L-norleucine (DON, an inhibitor for γ-GGT enzyme). Based on above results, γ-GGT-intervened enzymatic reactions at specific site of probe NIR-SN-GGT was verified shown in **Scheme 2**.

MTT Assays and Cell Imaging

In order to study the biocompatibility of probe NIR-SN-GGT, standard 5-diphenyltetrazolium bromide (MTT) assays in A2780 cells and HUVEC cells were carried out, respectively. As is observed in **Figures 2E,F**, experimental results indicated that probe NIR-SN-GGT was almost no cytotoxicity toward living cells.

Ovarian cancer cells (cancer cells) were selected as research object because of γ-GGT overexpression on the surface of its membrane. After A2780 cells incubated with 5 μM probe NIR-SN-GGT for 30 min, NIR fluorescence signal (655–755 nm) was obtained from **Figure 3e**. By contrast, no-treated A2780 cells were basically no fluorescence signal (**Figures 3a–c**). In addition, pre-treated A2780 cells with 30 μM DON (inhibitor) for 1 h, and then incubated with 5 μM probe NIR-SN-GGT for 30 min, we found that the intensity of NIR fluorescence signal became very weaker (**Figures 3g–i**) compared to **Figures 3d,e**. Hence, based on the above experiments confirmed that probe

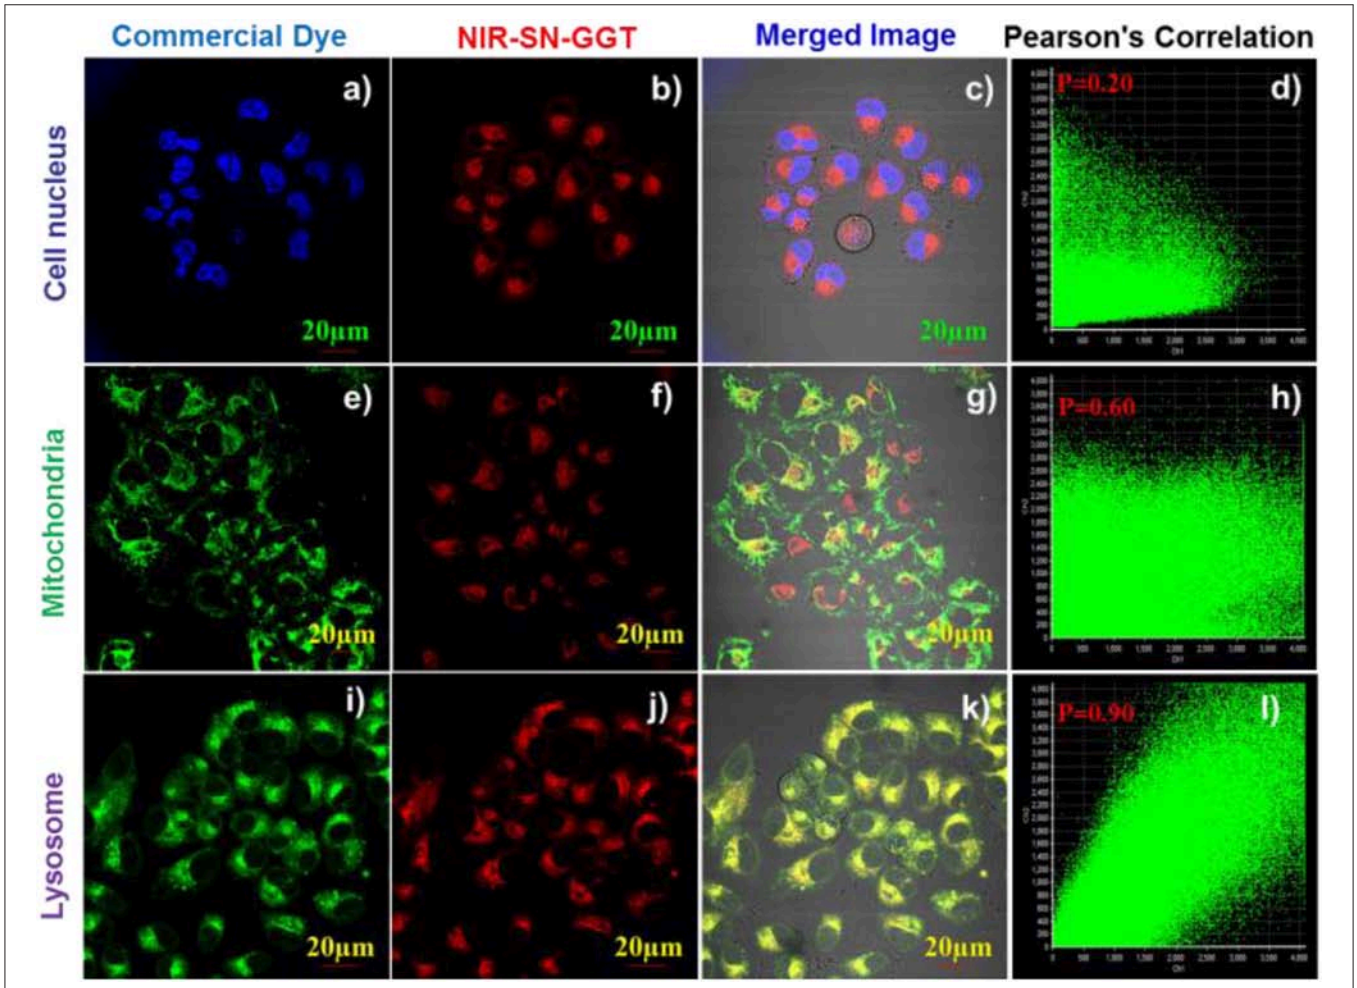

FIGURE 6 | Fluorescence imaging of subcellular localization in living A2780 cells. A2780 cells were treated with 5 μM probe NIR-SN-GGT for 20 min and the co-incubated 0.1 μM Hoechst 33342 **(a–d)**, 0.5 μM Mito-Tracker **(e–h)**, 0.5 μM Lyso-Tracker **(i–l)** for another 15 min at 37 °C. The blue channel of Hoechst 33342 dye was collected at 410-480 nm with the excitation at 405 nm. The green channel of Mito-Tracker and Lyso-Tracker dyes were collected at 500-560 nm with the excitation at 488 nm. The red channel of probe NIR-SN-GGT was collected at 655-755 nm with the excitation at 488 nm. Scale bar = 20 μm.

NIR-SN-GGT was used to monitor the activity of γ-GGT through NIR channel. Moreover, the ability of probe for differentiating tumor cells from normal cells was further confirmed. HUVEC cells (normal cells, **Figures 3j–l**) were used as negative control owing to low expression of γ-GGT. Upon addition 5 μM probe NIR-SN-GGT, negligible fluorescence signal was observed, as expected in **Figures 3m,n**. Subsequently, flow cytometry assays (FCM) demonstrated that HUVEC cells (**Figure 3o**) were distinguishable from A2780 cells (**Figure 3f**) through high throughput data analysis. So, this probe was successfully employed to track γ-GGT enzyme for the identification cancer cells. Besides, three-dimensional (3D) imaging of A2780 cells and HUVEC cells treated with probe NIR-SN-GGT was also investigated *via* *z*-scan (**Figures 3p–r**, and **Figures S11a–c**). Fluorescence emission intensities of NIR channel were measured as averages of 9 regions of interest (ROIs) from different treated cells (**Figure 3s**). Above results undoubtedly verified that probe NIR-SN-GGT possessed the ability for distinguishing cancer cells from normal cells through 2D&3D imaging, which was beneficial for clinician to the early diagnosis and resection operation of the tumor.

Time/Concentration-Dependent Imaging

Time-dependent response of 5 μM probe NIR-SN-GGT in living A2780 cells was carried out. As is seen in **Figure 4A**, after incubating for 10 min with this probe, there was obvious fluorescence signal from **Figures 4Af**. As time went on, the fluorescence intensity of NIR channel gradually increased (**Figures 4Ae–h,m**). By comparison, weak fluorescence signal of HUVEC cells pretreated with 5 μM probe NIR-SN-GGT for 30 min was observed (**Figures S12a–i**). In addition, concentration-dependent experiments of ovarian cancer

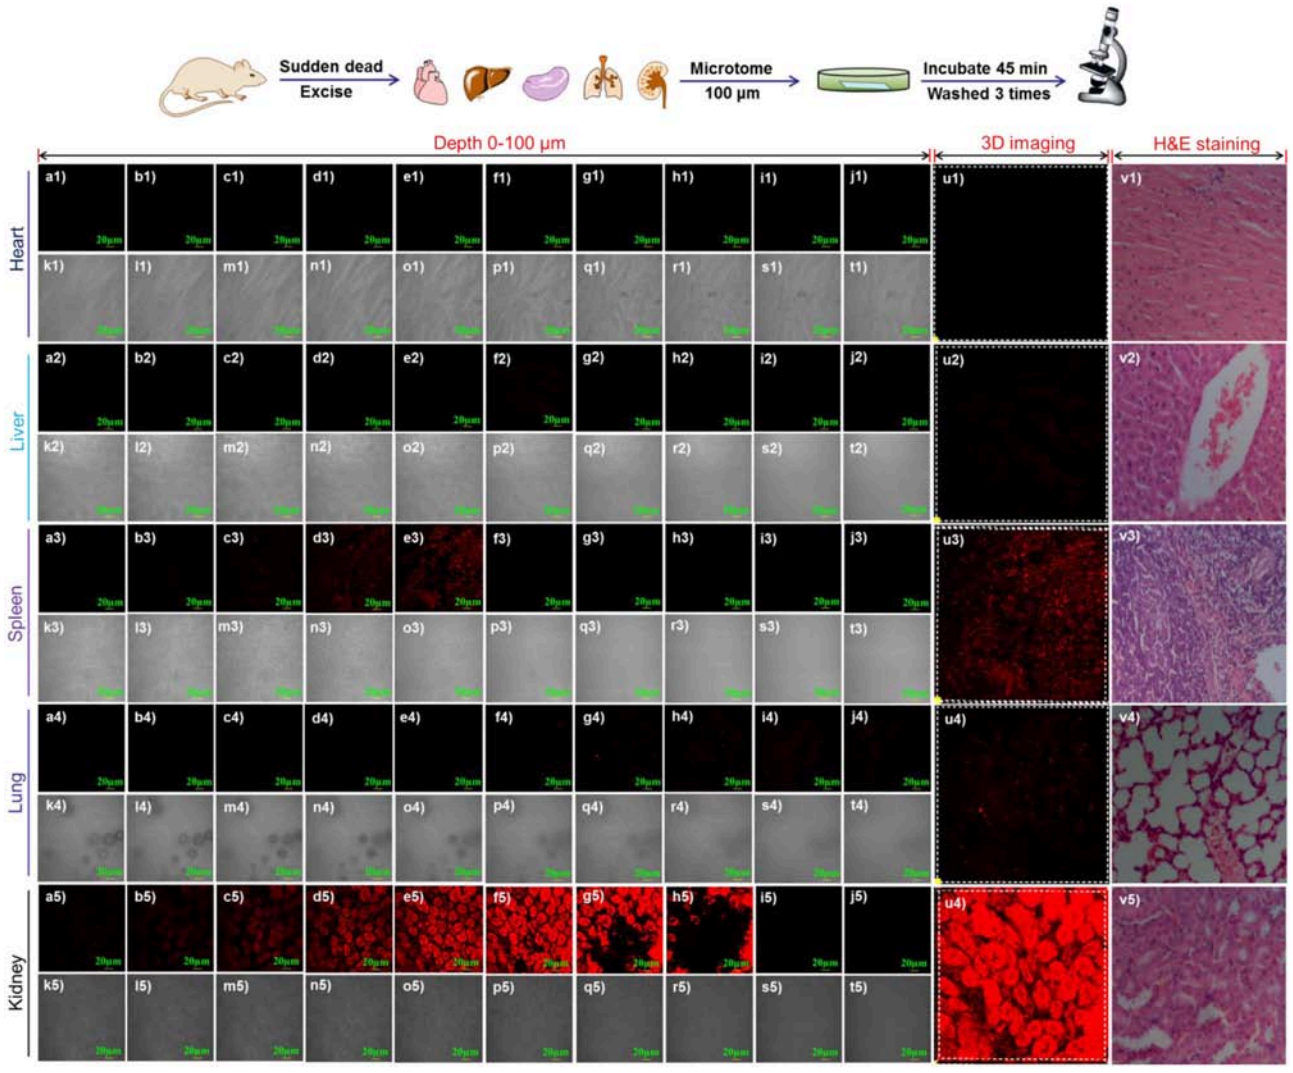

FIGURE 7 | Confocal fluorescence imaging of endogenous γ-GGT activity in various organs including heart, liver, spleen, lung and kidney. Tissue slices of 100 μm were prepared by freezing microtome (LEICA CM1860 UV). 3D-depth images of different tissue were obtained through *z*-scan pattern with step size 10 μm. (a-j) fluorescence channel; k-t bright channel; u) 3D-restruction imaging; v) HandE staining. λex = 488 nm and λem = 655-755 nm. Scale bar = 20 μm.

cells were also investigated (**Figure 4B**). With the increase of probe concentration, the fluorescence intensity increased (**Figures 4Bb–k**) and showed a good linear relationship (R^2 = 0.9776, **Figure 4Bm**), which verified that probe NIR-SN-GGT could be used to detect the endogenous γ-GGT activity with semi-quantitative detection.

Two-Photon Imaging Evaluation

Considering the advantages of two-photon fluorescence probes, such as long excitation wavelength, deep tissue penetration, and less photo-bleaching etc., are widely used in the field of chemical biology (Li et al., 2017a). Therefore, two-photon (TP) imaging experiments were performed in living A2780

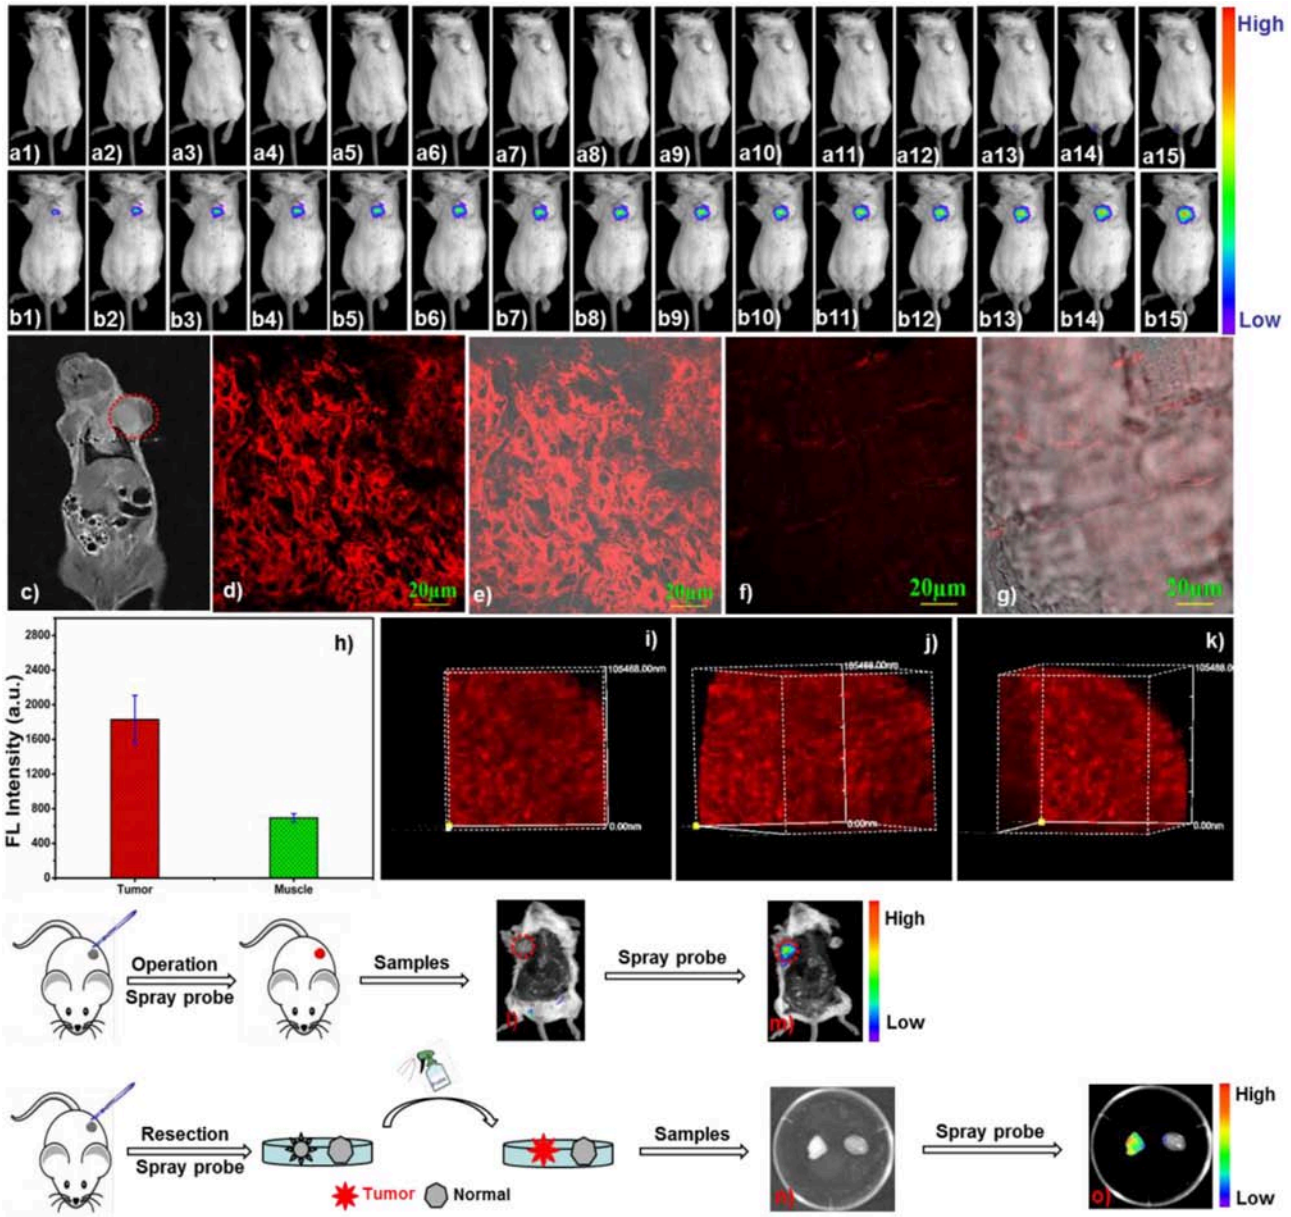

FIGURE 8 | (a,b) *In vivo* fluorescence imaging of γ-GGT activity in BABL/c mice bearing xenograft tumor. Probe NIR-SN-GGT (50 μM, 100 μL) was intratumoral injected, subsequently, fluorescent photographs (insert: b1) 2 min; (b2) 5 min; (b3) 10 min; (b4) 15 min; (b5) 20 min; (b6) 25 min; (b7) 30 min; (b8) 40 min; (b9) 50 min; (b10) 60 min; (b11) 70 min; b12 80 min; b13) 90 min; (b14) 100 min; (b15) 120 min) were gathered with excitation at 475 nm (fwhm 20 nm) and emission at 655 nm (fwhm 20 nm). (a1–a15) the corresponding control group was injected equivalent PBS buffer (pH 7.4, 0.01 M) solution. **(c)** MRI imaging (MesoMR23-060H-I) *via* T2 weighted imaging (red dotted line represents the tumor). **(d–g)** Tissue imaging of tumor tissue (**d**-fluorescence channel, **e**-merged channel) and normal (**f**-fluorescence channel, **g**-merged channel) pre-incubated with 10 μM probe NIR-SN-GGT in PBS buffer solution, and washed thirce by PBS buffer. **(h)** The fluorescence intensities of tumor and normal were gathered as averages of 21 regions of interest (ROIs) from NIR channel. **(i–k)** 3D-depth imaging (500 μm) of tumor tissue under the two-photon excitation at 800 nm. Fluorescence imaging of mouse (before **l**) and after **(m)** was sprayed with probe NIR-SN-GGT (100 μM, 150 μL). Fluorescence imaging of tumor tissue (left side) and normal tissue (right side) *via* "spraying" style (**n**: bright image; **o**: fluorescence image). λex = 488 nm, λem = 655–755 nm. Scale bar = 20 μm.

cells. Upon addition 5 μM probe NIR-SN-GGT, obvious two-photon fluorescence signal was obtained (**Figures 5d,e**) as well as one-photon (OP) imaging (**Figures 5a–c,f**), indicating that probe NIR-SN-GGT had a two-photon recognition capability for γ-GGT enzyme. Photo-stability is one of the important factors in biological imaging. To our satisfaction, the NIR fluorescence intensity of probe was not apparent changes under continuous two-photon of 800 nm irradiation (**Figure S13**). Taken together, probe NIR-SN-GGT is an excellent two-photon tool for monitoring the activity of γ-GGT enzyme in living cells with outstanding photo-stability, as we expected.

Subcellular Localization

To research the distribution of probe NIR-SN-GGT triggered by γ-GGT in living A2780 cells, thus, co-location experiments were carried out. As is observed in **Figure 6**, the red signal of probe NIR-SN-GGT (**Figure 6j**) and the green signal of Lyso-Tracker (**Figure 6i**) overlay well (**Figure 6k**) with the outstanding Pearson's correlation of 0.90 (**Figure 6l**), which showed that the product of enzyme catalytic probe was mainly clustered in lysosomes rather than nucleus ($P = 0.20$, **Figure 6d**) and mitochondria ($P = 0.60$, **Figure 6h**). Faced the above results, we speculated that this distribution was caused by the alkalization effect of the exposed amino products (**Scheme 2**).

Imaging of Endogenous γ-GGT Activity in Various Organs

Endogenous γ-GGT enzyme (Crystal structure, **Figure S14**) generated from the precursor protein *via* posttranslational processing, catalyzing the cleavage of the γ-glutamyl unit in the important biological species (Okada et al., 2006). Thus, it indicated that γ-GGT plays a very vital role in different tissues and organs. Until now, to the best of our knowledge, there is no literature report to use visualization tool for monitoring the activity of γ-GGT enzyme in various organs. Based on it, we had tried to investigate the applicability of probe NIR-SN-GGT for meeting the above requirements. Tissue sections of the experiment were immediately prepared from isolated organs including heart (**Figures 7a1–u1**), liver (**Figures 7a2–u2**), spleen (**Figures 7a3–u3**), lung (**Figures 7a4–u4**), and kidney (**Figures 7a5–u5**) through freezing microtome (LEICA CM1860 UV), and the above organizations biopsy were confirmed through H&E staining (**Figures 7v1–v5**). Each tissue of 100 μm was pre-treated with 10 μM probe NIR-SN-GGT for 45 min at indoor environment, and washed thrice by PBS buffer to removing excess probe. As shown in **Figure 7**, the confocal fluorescence imaging of step size 10 μm of tissue slice was performed. Apparent fluorescence signal of nephridial tissue was observed (**Figures 7a5–t5**), and 3D-reconstructed imaging was shown in **Figure 7u5**, which clearly visual displayed the content of γ-GGT enzyme more than other organs (heart, liver, spleen, and lung). According to medical research reported glomerulonephritis could increase the γ-GGT enzyme level (Malyszko, 2010). Thus, probe NIR-SN-GGT can be employed for helping secretory doctor to diagnose acute glomerulonephritis. In addition, the content of γ-GGT enzyme in spleen was also abundant (**Figures 7a3–u3**). Various fluorescence intensity of tissues represented different the content of γ-GGT *in situ*. As far as we know, this is the first NIR fluorescence probe for visualizing the contents of different organs by monitoring the activity of γ-GGT enzyme, which is useful for the detection of γ-GGT-related diseases.

In vivo Fluorescence and MRI Imaging of γ-GGT Activity in Xenograft Tumor Mode

In view of its high selectivity, sensitivity, photo-stability as well as NIR fluorescence emission, avoiding background interference and reducing light scattering, has been laid the foundation for *in vivo* application. Then, we explored the availability of probe NIR-SN-GGT in the transplanted tumor of BABL/c mice. As demonstrated in **Figure 8b**, after probe NIR-SN-GGT (50 μM, 100 μL) was directly *in-situ* injected, the NIR fluorescence signal of 655-755 nm on the tumor area enhanced gradually (**Figures 8b1–b15**), which attributed to the tracking over-expression γ-GGT on tumor site. In comparison, fluorescence intensity of control group injected equivalent PBS buffer solution was not gathered up to 2 h (**Figures 8a1–a15**). Combined with magnetic resonance imaging (MRI) through T2 weighted imaging (**Figure 8c**), probe NIR-SN-GGT could light up tumor relying on tracking endogenous γ-GGT enzymes, which would help surgeon real-time to the diagnosis *in situ* and treatment of cancer. Besides, tissues imaging of probe NIR-SN-GGT were also performed on laser confocal fluorescence microscopy (FV1000-IX81). Various tissues samples were prepared by freezing-microtome (Leica CM1860 UV), and pretreated with 10 μM probe NIR-SN-GGT for 45 min at room temperature. Obvious NIR fluorescence signal of 655-755 nm was gathered from tumor tissue, as we expected in **Figures 8d,e**. By comparison, weak fluorescence signal of normal tissue was observed due to lacking of γ-GGT overexpression (**Figures 8f,g** and **Figure S16b**). Their fluorescence intensity statistics were shown in **Figure 8h**, which were consistent with layer scanning of tissue imaging (**Figure S15**). In consideration of its excellent two-photon performance, 3D imaging of 500 μm was also studied under the excitation 800 nm by *z*-scan pattern with step size 5 μm. As depicted in **Figures 8i–k**, remarkable 3D-imaging clearly demonstrated probe NIR-SN-GGT had excellent deep tissue permeability. More interestingly, tumor could be lighted up (**Figures 8l,m**) after "spraying" probe NIR-SN-GGT (100 μM, 150 μL) 30 min, greatly promoting the possibility of precise excision. In addition, compared to normal tissue (**Figures 8n,o**, right side), isolated tumor tissue (**Figure S16a**, H&E staining) was also easily lighted up through "spraying" probe NIR-SN-GGT (100 μM, 50 μL) on the surface (**Figures 8l,m**, left side). Based on above results, to our satisfaction, probe NIR-SN-GGT was used to the identification tumor transplanted in BABL/c mice and deep tissue (up to 500 μm) accompanied by MRI imaging, which would be in favor of early diagnosis and treatment of tumor in clinical practice.

CONCLUSION

In summary, a smart fluorescent probe NIR-SN-GGT was successfully developed through rational design. After γ-GGT

accurately cleaving activated unit, liberating bare amino, NIR fluorescence emission signal of 650 nm strengthen gradually, which attributed to the recovery of Intramolecular Charge Transfer (ICT) mechanism. Only γ-GGT made the probe fluorescence spectrum clear change, and low detection limit of probe was calculated to be 0.024 mU/mL, undoubtedly verified that probe NIR-SN-GGT would employed to detect trace γ-GGT in complex system. Owing to its good biocompatibility and photo-stability, probe NIR-SN-GGT was also used to the identification cancer cells (A2780 cells) from normal cells (HUVEC cells) by fluorescence imaging and high throughput flow cytometry. Through "spraying" manner, to the best of our knowledge, tumor tissue could be lighted up compared to normal tissue for first time. We hope that enzyme-activated NIR fluorescent probe NIR-SN-GGT can be a potential functional molecular tool for inhibitor development, early diagnosis and resection of cancer.

ETHICS STATEMENT

This study was carried out in accordance with the recommendations of Dalian Medical University Animal Care and Use Committee. The protocol was approved by the Dalian Medical University Animal Care and Use Committee.

AUTHOR CONTRIBUTIONS

HL was responsible for performing the experiments and writing manuscript. QY was responsible for carrying out animal experiments. FX and NX were responsible for providing cells. Formaldehyde (FA), a highly reactive carbonyl species, plays significant role in physiological and pathological functions. However, elevated FA will lead to cognitive impairments, memory loss and various neurodegenerative diseases due to its potent DNA and protein cross-linking mechanisms. In this work, a fluorescence probe, **BD-CHO**, based on benz-2-oxa-1, 3- diazole (**BD**) skeleton, was designed and synthesized for detection of FA via Aza-Cope reaction with high selectivity and large Stokes shifts (about 118 nm). **BD-CHO** was successfully applied to monitor the changes FA level in living cells, and kidney tissues of mice. Importantly it was the first time that **BD-CHO** was used for visualizing exogenous FA changes in *Daphnia magna* through fluorescence microscopy, demonstrating its potential application for studies of biological processes associated with FA.

Keywords: fluorescence probe, formaldehyde, *Daphnia magna*, large Stokes shifts, Aza-Cope reaction, bioimaging

INTRODUCTION

Formaldehyde (FA) is a common environmental toxin but also endogenously produced through metabolism of amino acids or xenobiotics catalyzed by demethylases and oxidases, such as lysine-specific demethylase 1 (LDS1) (Shi et al., 2004) and semicarbazide-sensitive amine oxidase (SSAO) (O'Sullivan, 2004). The physiological FA levels ranging from 0.1 mM in blood to 0.4 mM intracellular (Andersen et al., 2010; Tong et al., 2013b) and is a well-established neurotoxin that affects memory, learning, and behavior (Tong et al., 2013a; Tulpule and Dringen, 2013). However, due to the rapidly growing list of modified DNA (Jones, 2012; Kohli and Zhang, 2013) and RNA (Jia et al., 2011) bases, elevated of FA are implicated in numerous disease pathologies, including neurodegenerative diseases, (Tong et al., 2011, 2013b) diabetes, heart disorders (Tulpule and Dringen, 2013), and Alzheimer's disease (Unzeta et al., 2007). Hence, the development of effective method for detecting FA in biosystem is urgent to understand the roles and metabolism process of FA.

Comparing to conventional detection approach, including colormetric assays (Luo et al., 2001), GC analyses (Bagheri et al., 2009; Chen et al., 2009), HPLC (Nash, 1953; Soman et al., 2008), fluorescence probes are considered as one of the most powerful tools due to their simplified operation, high selectivity and sensitivity, real-time detectability, and biocompatibility

(Tang et al., 2015; Zhou et al., 2015; Bruemmer et al., 2017a; Xu et al., 2017). To date, a number of fluorescent probes for FA visualization have been reported based on the fluorophores of silicon rhodol, 1,8-naphthalimide, resorufin and so forth (Brewer and Chang, 2015; Roth et al., 2015; He et al., 2016; Bruemmer et al., 2017b; Liu et al., 2017; Xie et al., 2017a,b; Bi et al., 2018; Zhou et al., 2018). However, some of them suffered from disadvantages including time-consuming and rigorous synthetic procedure, high background fluorescence and small Stokes shifts which restricted their widely applications in biological system. In the presence of FA, partial probes encounter relatively small Stokes shifts which is not conducive to separating excitation and emission bands, in turn, cannot effectively minimize the interferences caused by self-absorption or auto-fluorescence (Abeywickrama et al., 2017; Chen et al., 2017). Meanwhile, low background fluorescence is beneficial for improving signal to noise ratio (SNR), facilitating to clearly visualize FA in complex biological environment. Hence, it is urgent to develop a FA-selective fluorescence probe with large Stokes shifts and low basal fluorescence.

Herein, we report an Aza-Cope reaction-based fluorescence probe (**BD-CHO**) for FA (**Figure 1**). The core structure of the probe was benz-2-oxa-1, 3- diazole (**BD**), an excellent fluorophore with facile modified and good stability which has been widely used to design fluorescence sensors (Taliani et al., 2007; Liu et al., 2011; Chen et al., 2012; Jiang et al., 2017), and homoallylic amine as FA-recognized group. **BD-CHO** shows good selectivity and sensitivity toward FA over other reactive carbonyl species (RCS) *in vitro* and is subsequently applied to visualize endogenous or exogenous FA in living cells and tissues. Significantly, to the best of our knowledge, **BD-CHO** is the first fluorescence probe for imaging FA in *Daphnia magna*.

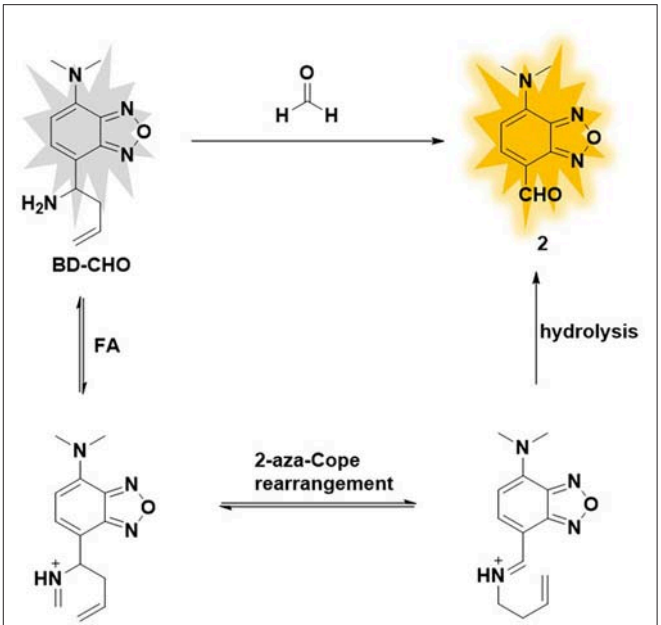

FIGURE 1 | Design of formaldehyde probe BD-CHO.

EXPERIMENTAL SECTION

Materials and Instruments

Unless otherwise stated, all chemicals were purchased from commercial suppliers and used without further purification. The solvents were purified by conventional methods before used. All analytes were obtained by traditional methods. 4-Chloro-2, 1, 3-benzoxadiazole was purchased from TCI chemical. Silica gel (200–300 mesh) used for flash column chromatography was purchased from Qingdao Haiyang Chemical Co., Ltd. ^{1}HNMR and ^{13}CNMR spectra were determined by 400 MHz and 100 MHz using Bruker NMR spectrometers. Chemical shifts (δ) were expressed as parts per million (ppm, in $CDCl_3$ or DMSO, with TMS as the internal standard). Meanwhile, high-resolution mass spectrometry was achieved with ESI-TOF and FTMS-ESI instrument. Fluorescence measurements were performed on an Agilent Technologies CARY Eclipse fluorescence spectrophotometer, and absorption spectra were measured on a PerkinElmer Lambda 35 UV–vis spectrophotometer. The pH values of sample solutions were measured with a precise pH-meter pHS-3C. Fluorescence quantum yield was achieved from a C11347-11 Absolute PL Quantum Yield Spectrometer. MTT assays were conducted on the Varioskan LUX Multimode Microplate Reader. The instrument used for imaging living cells and tissues of mice was an Olympus FV 1000 confocal microscopy purchased from Olympus.

Determination of Detection Limits

According to the fluorescence titration data, a linear relationship between the fluorescence intensity ($F_{578\ nm}$) and FA concentrations was observed, the detection limit was calculated with the following equation: Detection limit = 3σ/k. Where σ is the standard deviation of blank measurements ($n = 10$), k is the slop between the fluorescence intensity vs. the concentrations of FA.

Cytotoxicity Assays

The MTT method was employed to assess the cellular cytotoxicity of **BD-CHO**. Before experiments, MCF-7 cells at a density of 1×10^4 cells/well were seeded into 96-well plates and cultured for 24 h. Then the fresh culture contained **BD-CHO** over a range of concentrations (0–30 μM) ($n = 6$) to substitute the previous media, and further incubation for 24 h. After that, 10 μL of MTT (5 mg/mL in PBS) was added into per well and incubated another 4 h. Finally, 100 μL of DMSO was then added to dissolve formazan. The absorbance at 490 and 570 nm was measured in a microplate reader, and the cell viability (%) was calculated according to the following equation: Cells viability (%) = [OD570 (sample)—OD490 (sample)] / [OD570 (control)—OD490 (control)] × 100.

Living Cells Incubation and Imaging

MCF-7 cells, HepG2 cells and HeLa cells were purchased form Institute of Basic Medical Sciences (IBMS) of the Chinese Academy of Medical Sciences. MCF-7 cells were cultured in

90% Dulbecco's Modified Eagle Medium (DMEM, Gibico) supplemented with 10% FBS (Gibico) and 1% antibiotics (100 U/mL penicillin and 100 μg/mL streptomycin, Hyclone) in an atmosphere of 37°C and 5% CO_2. One day before imaging, the cells were detached and were replanted on glass-bottomed dishes and allowed to adhere for 24 h. For imaging exogenous FA, the culture media of HepG2 cells was replaced with 2 mL of serum-free DMEM containing 10 μM fluorescent probe (from 2 mM stock in DMSO) and the cells were incubated for 30 min. Cells were then washed once with 2 mL PBS and then incubated further with FA (0.5 mM) for 3 h prior to imaging. For inhibition tests, FA-treated cells were incubated with DMEM containing sodium bisulfite (1 mM) and washed with PBS, then incubated with 10 μM fluorescent probe for 3 h before imaging. For imaging endogenous, MCF-7 cells were pretreated with or without (control) the inhibitor tranylcypromine (TCP) or GSK-LSD 1 for 20 h, followed by exchange into serum-free DMEM containing 10 μM fluorescent probe for 3 h.

Fluorescence Imaging of in Kidney Slices

Kidney slices were surgically exposed in Balb/c mice, which was approved by the Dalian Medical University Animal Care and Use Committee. The fresh kidney tissues were incubated with 10 μM **BD-CHO** for 30 min, and then, 1 mM FA was added for another 3 h. Before imaging, the tissues were washed with PBS three times. Olympus FV 1000 confocal microscopy with 20× objective lens was used for fluorescence imaging. All of these experiments were carried out in accordance with the relevant laws and guidelines.

Fluorescence Imaging in *Daphnia magna*

The *D. magna* (age < 72 h) were cultured in clean non-chlorinated tap water under cool-white fluorescence light with light (14 h)-dark (10 h) photoperiod (Du et al., 2018). The animals were incubated with **BD-CHO** (10 μM) for 1 h, followed by washing twice with PBS and then incubated further with or without FA for 3 h. Olympus FV 1000 confocal microscopy with 4× objective lens was used for fluorescence imaging.

Synthesis of BD-CHO

The synthetic procedure was illuminated in **Figure 2**. Compound **1**: 4-Chloro-2,1,3-benzoxadiazole (1.0 g, 6.5 mmol), ethanol (10 mL), dimethylamine hydrochloride (3.0 g, 36.7 mmol), and triethylamine (6.0 mL) were mixed in a 25 mL autoclave at room temperature and followed by quick closure. Then, the bomb was heated with stirring at 150°C for 48 h. The mixture was cooled to room temperature and the solvent was removed under reduced pressure. After the addition of NaOH solution (2 M, 20 mL) to the residue, the mixture was extracted with ethyl acetate (30 Ml × 3). The combined organic layer was dried with anhydrous magnesium sulfate. After the removal of solvent, the product was purified by silica gel column chromatography with dichloromethane: petroleum ether (1:1) as the eluent to afford the desire product to yield red solid (965 mg, 91.0%). ^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm): δ 7.18 (d, J = 7.3 Hz, 1H), 7.02 (s, 1H), 6.06 (s, 1H), 3.25 (s, 6H). ^{13}C NMR (101 MHz, $CDCl_3$) δ (ppm): 150.87, 145.72, 139.87, 133.36, 104.86, 102.13, 41.99, 1.01. MS (ESI-TOF): calculated for $C_8H_{10}N_3O^+$, $[M+H]^+$, m/z, 164.08, found: 164.05.

Compound **2:** $POCl_3$ (2 mL, 21 mmol) and anhydrous DMF (10 mL, 128 mmol) are mixed slowly with stirring in a round-bottomed flask at 0°C. Then, an anhydrous DMF (5 mL) containing compound **1** (960 mg, 5.9 mmol) was added into the mixture. Finally, the obtained mixture was stirred at room temperature about 6 h. The reaction was quenched by pouring the mixture into the ice water (50 mL). After pH was adjusted to pH ∼ 9 by 10% NaOH, the mixture was extracted by ethyl acetate (30 mL × 3). The combined organic layer was dried with anhydrous magnesium sulfate. After the removal of solvent, the product was purified by silica gel column chromatography with petroleum ether: ethyl acetate (1:1) as the eluent to afford

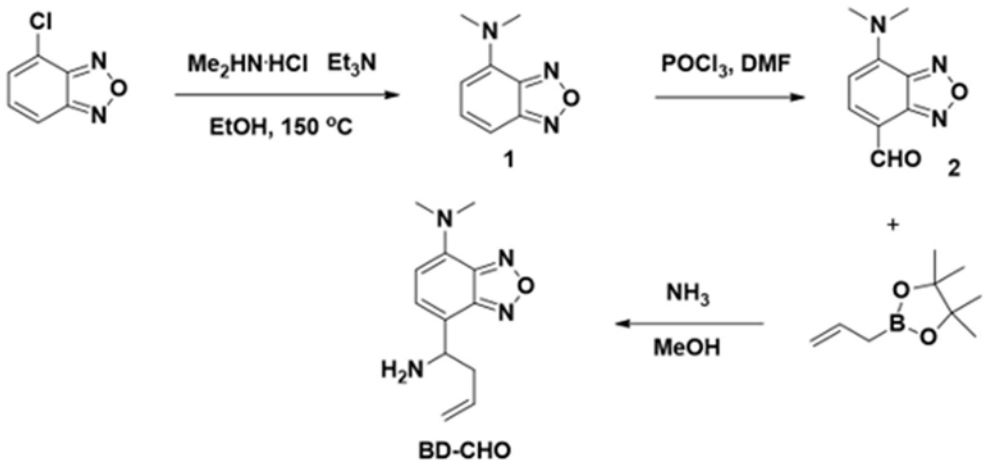

FIGURE 2 | Synthetic procedure of BD-CHO.

the desired product to yield red solid (743 mg, 65.8%). ^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm): 10.03 (s, 1H), 7.89 (d, J = 8.2 Hz, 1H), 6.15 (d, J = 8.2 Hz, 1H), 3.58 (s, 6H). ^{13}C NMR (101 MHz, $CDCl_3$) δ (ppm): 185.93, 147.71, 145.08, 144.87, 142.15, 111.46, 102.35, 42.90, 1.01. HRMS (ESI-TOF): calculated for $C_9H_{10}N_3O_2^+$, $[M+H]^+$, m/z, 192.0773, found: 192.0767.

BD-CHO

To a solution containing compound **2** (192 mg, 1.0 mmol) in 20 mL of CH_3OH, 6 mL of NH_3 solution (7.0 M in CH_3OH, 42 mmol) was added at 0°C under argon atmosphere and stirred 30 min. After that, allylboronic acid pinacol ester (0.48 mL, 2.5 mmol) was added, the mixture was warmed to ambient temperature and stirred overnight. The solvent was removed

under reduced pressure, and the residue was purified by silica gel column chromatography with dichloromethane: methanol (50:1) as the eluent to afford probe **BD-CHO** as yellow solid (101 mg, 43.4%). ^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm): 7.06 (d, J = 7.5 Hz, 1H), 5.94 (d, J = 7.6 Hz, 1H), 5.68 (dd, J = 17.0, 9.7 Hz, 1H), 4.99 (dd, J = 19.8, 13.8 Hz, 2H), 4.20 (t, J = 6.6 Hz, 1H), 3.19 (s, 6H), 2.71–2.54 (m, 1H), 2.48 (dd, J = 14.2, 7.2 Hz, 1H), 2.09 (s, 2H). ^{13}C NMR (101 MHz, $CDCl_3$) δ (ppm) 149.25, 146.08, 138.78, 135.27, 129.21, 120.35, 117.72, 105.15, 52.63, 41.94, 41.81. HRMS (ESI-TOF): calculated for $C_{12}H_{12}N_3O^-$, $[M\text{-}NH_2]^-$, m/z, 216.1137, found: 216.1134.

RESULTS AND DISCUSSION

Design and Synthesis of BD-CHO

To design selective and sensitive fluorescence probe for the FA detection, we focus on homoallylamine trigger which can specially react with FA and produce an electron-withdrawing aldehyde group via an Aza-Cope rearrangement reaction. Benz-2-oxa-1, 3- diazole (**BD**) was chosen as fluorophore core due to easily regulated intramolecular charge transfer (ICT) and excellent photophysical property. In this probe, dimethylamine group was introduced as an electron-donating group (EDG) and homoallylic amine as FA-recognized group. The original **BD-CHO** exhibits almost no fluorescence due to the poor electron withdrawing ability of the homoallylamine moiety. After addition of FA, the amine reacts selectively with FA to form an imine intermediate, which simultaneously undergoes 2-Aza-Cope rearrangement and final hydrolysis to produce an aldehyde group with power electron withdrawing ability (**Figure 1**) (Brewer et al., 2017; Dou et al., 2017). As a result, the intramolecular charge transfer (ICT) process from π-conjugated electron donor (dimethylamine group) to the aldehyde group is opened, showing a "turn-on" fluorescence response.

The probe **BD-CHO** was readily prepared by coupling compound **2** with allylboronic acid pinacol ester in the presence of NH_3 solution. The intermediates and target compound were well characterized by ^{1}H NMR, ^{13}C NMR, HR-MS (**Figures S11–S16**).

Spectral Properties of BD-CHO

All the spectra of **BD-CHO** were investigated in HEPES buffer containing DMSO (V/V = 1:1, 20 mM, pH 7.4). Upon addition of FA, the maximum absorption wavelength shifted from 450 to 460 nm (**Figure S1**). The probe exhibited almost no fluorescence in the absence of FA, which made **BD-CHO** more favorable probe for highly sensitive detecting FA. In the presence of 5 mM FA, however, the fluorescence intensity sharp enhanced about 55-fold at 578 nm with excited at 460 nm (**Figure 3A**)

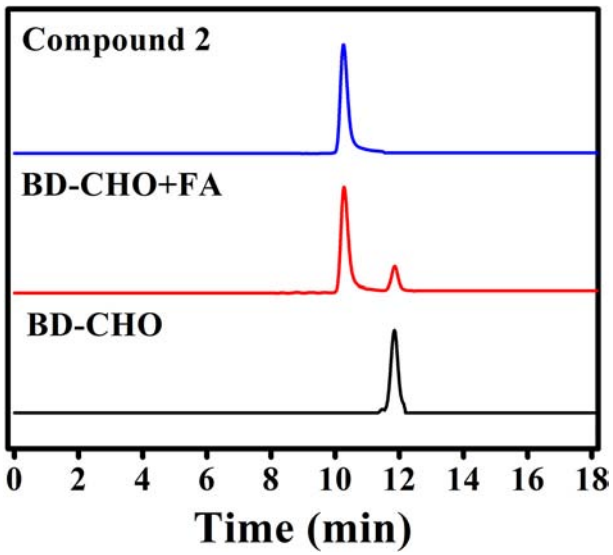

FIGURE 6 | HPLC analysis of compound 2, probe BD-CHO before (black) and after (red) incubation with FA (5 mM) at 37°C for 2 h.

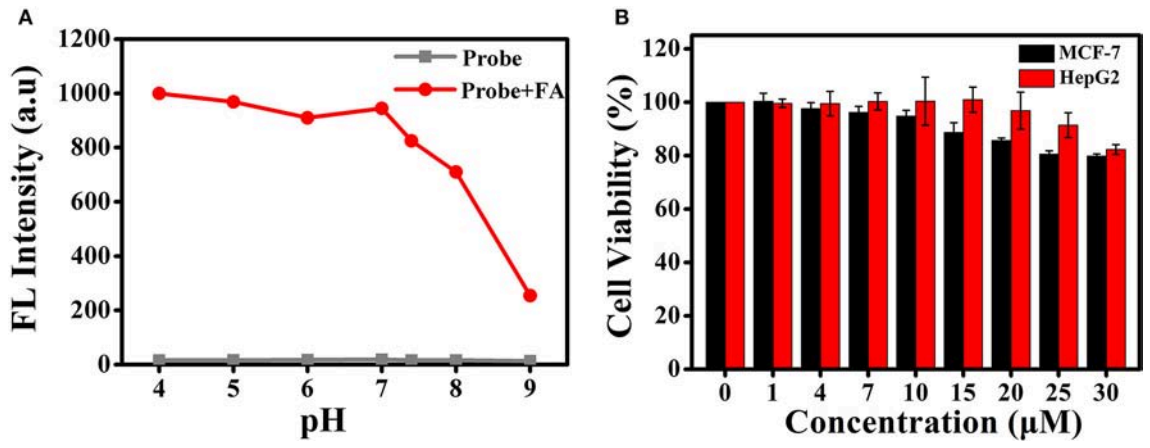

FIGURE 5 | (A) Fluorescence responses of BD-CHO (10 μM) in the presence (red) and absence (blank) of FA in HEPES buffer (20 mM, pH 7.4, 50% DMSO) with different pH values. λ_{ex} = 460 nm, slit: 10/10 nm **(B)** The cell cytotoxicity of BD-CHO in MCF-7 and HepG2 cells.

and the fluorescence quantum yield increased from 0.015 to 0.080. Importantly, **BD-CHO** displayed a large Stokes shifts (118 nm) in response to FA (**Figure S2**), which is beneficial for fluorescent detection in view of reduction of self-absorption. Upon addition of 5 mM FA, the fluorescence intensity of **BD-CHO** increased dramatically over 50 min and reaches a plateau after approximately 3 h (**Figure S3**). There was a linear concentration-dependent fluorescent response with **BD-CHO** toward FA ranging from 0 to 0.8 mM, with a high correlation coefficient $R^2 = 0.991$ (**Figure 3B**). Thus, the detection limit was calculated to be around 9.7 μM, allowing its applicability for the detection of the intracellular FA (100–400 μM) (Andersen et al., 2010).

Selectivity and pH Influence

High selectivity is necessary and crucial for evaluating the applicability of the fluorescent probe. Therefore, we investigated the ability of **BD-CHO** to distinguish FA from various relevant species, including benzaldehyde (BA), acetaldehyde (AA), glutaraldehyde (GA), *o*-phthalaldehyde (OPA), glyoxal (GO), methylglyoxal (MGO), biothiols (Cys, Hcy, and GSH), H_2O_2, HClO. As shown in **Figure 4A**, negligible fluorescence intensity changes of **BD-CHO** were obtained in the presence of possible interfering analytes but a 55-fold fluorescence enhancement with FA. The fluorescence change can also be observed with naked eyes under illumination with a 365 nm UV lamp (**Figure 4C**). To further evaluate the selectivity, competitive experiments were performed in the presence of 5 mM FA and various other species (**Figure 4B**). **BD-CHO** still responded to FA with turn-on fluorescence signal in the presence of competitive species. These results demonstrate that the ability of **BD-CHO** to specifically recognize FA over others relative analytes in complexed biological system. Subsequently, we investigated the effect of pH on the recognition of FA. As shown in **Figure 5A**, fluorescence response of **BD-CHO** to FA is independent of pH in the range 5.0–8.0, indicating its suitability for imaging under physiological conditions.

Recognized Mechanism

The possible sensing mechanism was shown in **Figure 1**. Firstly, homoallylamine moiety in **BD-CHO** reacted with FA to afford 2-aza-1,5-dienes, and then the 2-Aza-Cope rearrangement occurred via [3,3]-migration to form α, β-ene, which was hydrolyzed in aqueous solution to release highly fluorescent compound **2**. In order to verify the proposed hypothesis, we compared the absorption and fluorescence spectra of **BD-CHO** in the presence of FA with that of the compound 2. As shown in **Figure S4**, the absorption and fluorescence spectra of **BD-CHO** + FA were almost identical to that of compound **2**, indicating that compound **2** might be the final reaction product of the **BD-CHO** with FA. Meanwhile, HPLC analysis was used to further confirm the detected product. As shown in **Figure 6**, the chromatographic peak of compound **2** and **BD-CHO** were found at 10.27 and 11.85 min, respectively. Additionally, upon addition of FA (5 mM) and incubation with **BD-CHO** for 2 h, the reaction product exhibited a chromatographic peak at 10.27 min, which matched

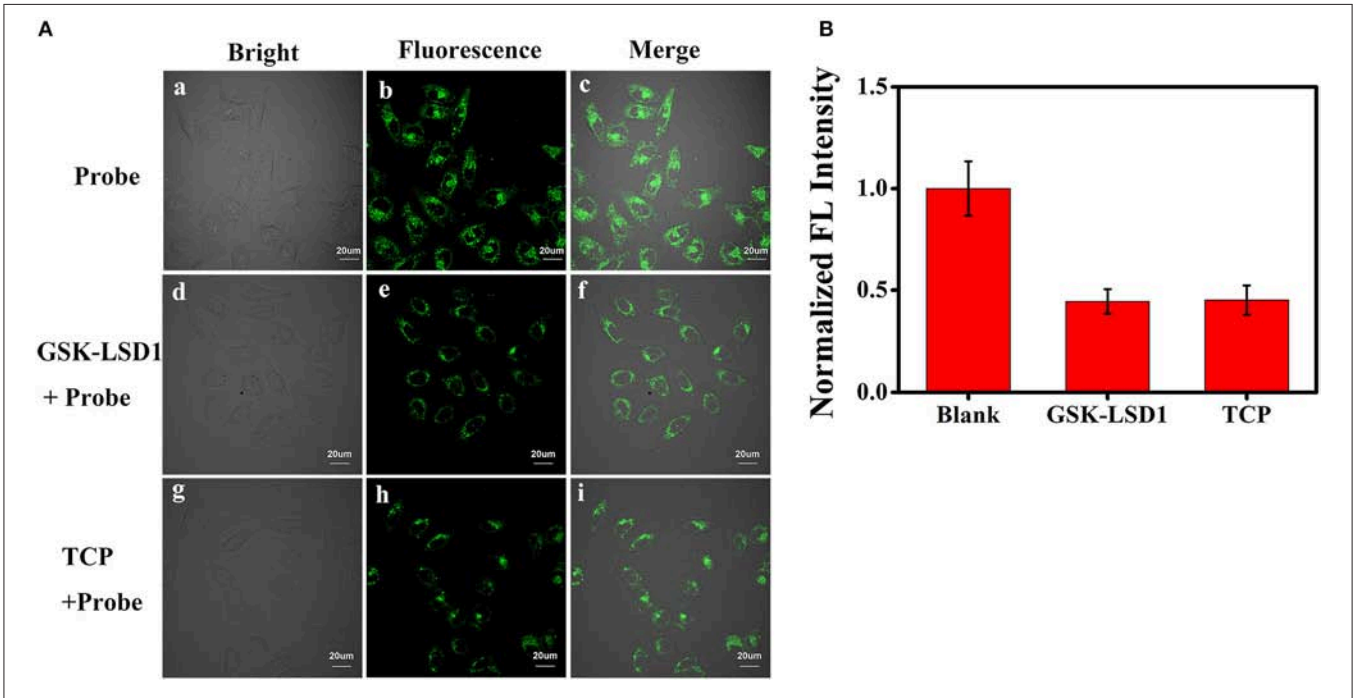

FIGURE 7 | (A) Fluorescence image for BD-CHO in GSK-LSD1 and TCP treated MCF-7 cells. (a-c) blank, (d-f) Cells were pre-treated with 1 μM GSK-LSD1 for 20 h and then with BD-CHO (10 μM) for 3 h, (g-i) Cells were pre-treated with 20 μM TCP for 20 h and then with BD-CHO (10 μM) for 3 h. $\lambda_{ex} = 488$ nm, collected 550–600 nm. **(B)** Mean fluorescence intensity of MCF-7 cells treated with blank, GSK-LSD1 and TCP. Scale bar: 20 μm.

perfectly with compound 2; a weak peak was also observed at 11.85 min, corresponding to probe **BD-CHO**. Furthermore, HR-MS confirmed this result, where a noticeable signal peak at m/z = 214.0584 was assigned to $[M + Na]^+$ (compound **2**, calculated for 214.0592) (**Figure S5**). This is consistent with the previously reported mechanism (Xu et al., 2016; Yang et al., 2018).

Fluorescence Imaging of Exogenous and Endogenous FA in Living Cells

Encouraged by the excellent photophysical properties of **BD-CHO** and its selective response to FA *in vitro*, we attempted to assess the suitability of **BD-CHO** for monitoring FA in living cells. Accordingly, the cytotoxicity of **BD-CHO** was established using MTT assays with MCF-7 cells and HepG 2 cells. It was found that the cell viabilities exceed 94% when incubated cells for 24 h with 10 μM **BD-CHO**, demonstrating the low cytotoxicity of **BD-CHO** (**Figure 5B**). The probe has good stability in biological medium (**Figure S6**).

Subsequently, we evaluated the ability of **BD-CHO** to visualize changes of FA in living cells using confocal microscopy. HepG2 cells were treated with 10 μM **BD-CHO** for 30 min at 37°C, it showed almost invisible fluorescence signal when excited at 488 nm (**Figures S7a–c**). When probe loaded cells were treated with 0.5 mM FA for another 3 h, obvious green fluorescence signal was observed (**Figures S7d–f**). $NaHSO_3$ was used for negative experiments, because it can efficiently react with FA to destroy the central carbonyl group (Tang et al., 2016). When the cells were pre-treated with 0.5 mM FA and 1 mM $NaHSO_3$ for 30 min, and then cultured with **BD-CHO** for 3 h, the green fluorescence became faint (**Figures S7g–i**). Owing to overexpression of LSD1, MCF-7 cells were known to showed elevated FA levels (Liu et al., 2013). When the LSD1 was pharmacological inhibited, the FA levels significantly decreased (Brewer and Chang, 2015). The MCF-7 cells were treated with **BD-CHO** and the cells exhibited strong green fluorescence signal (**Figure 7Ab**), which indicated a high level of FA in MCF-7 cells. However, when MCF-7 cells were incubated with 1 μM GSK-LSD1 (Munoz, 2015) (an LSD1 inhibitor with an IC_{50} of 42 nM) and then with **BD-CHO**, a decrease in **BD-CHO** fluorescence signal compared to control cells was observed (**Figure 7Ae**). Additionally, treatment with 20 μM tranylcypromine (Lee et al., 2006) (TCP, an LSD1 inhibitor

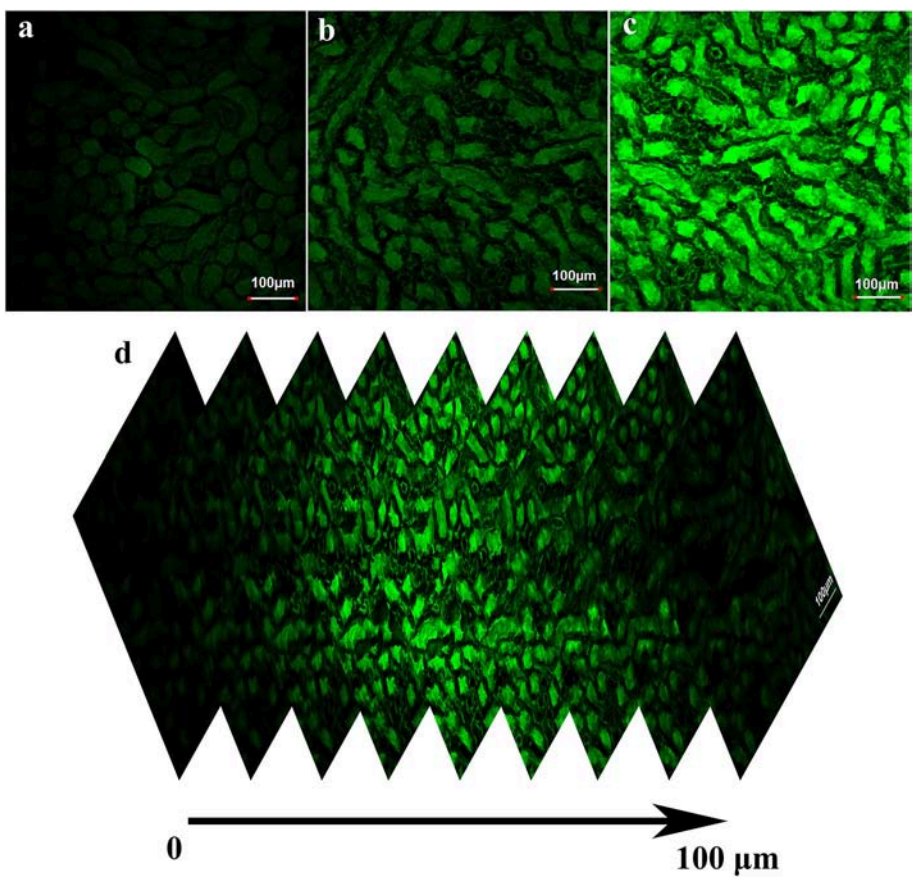

FIGURE 8 | Fluorescence image of fresh kidney tissue slices stained with 10 μM BD-CHO for 1 h and then treated without **(a)** and with **(b)** 0.5 mM **(c)** 1 mM FA for further 3 h. **(d)** Fluorescence image of kidney tissue slices incubated with BD-CHO and FA at different depths (0–100 μm). λ_{ex} = 488 nm, collected 550–600 nm. Scale bar: 100 μm.

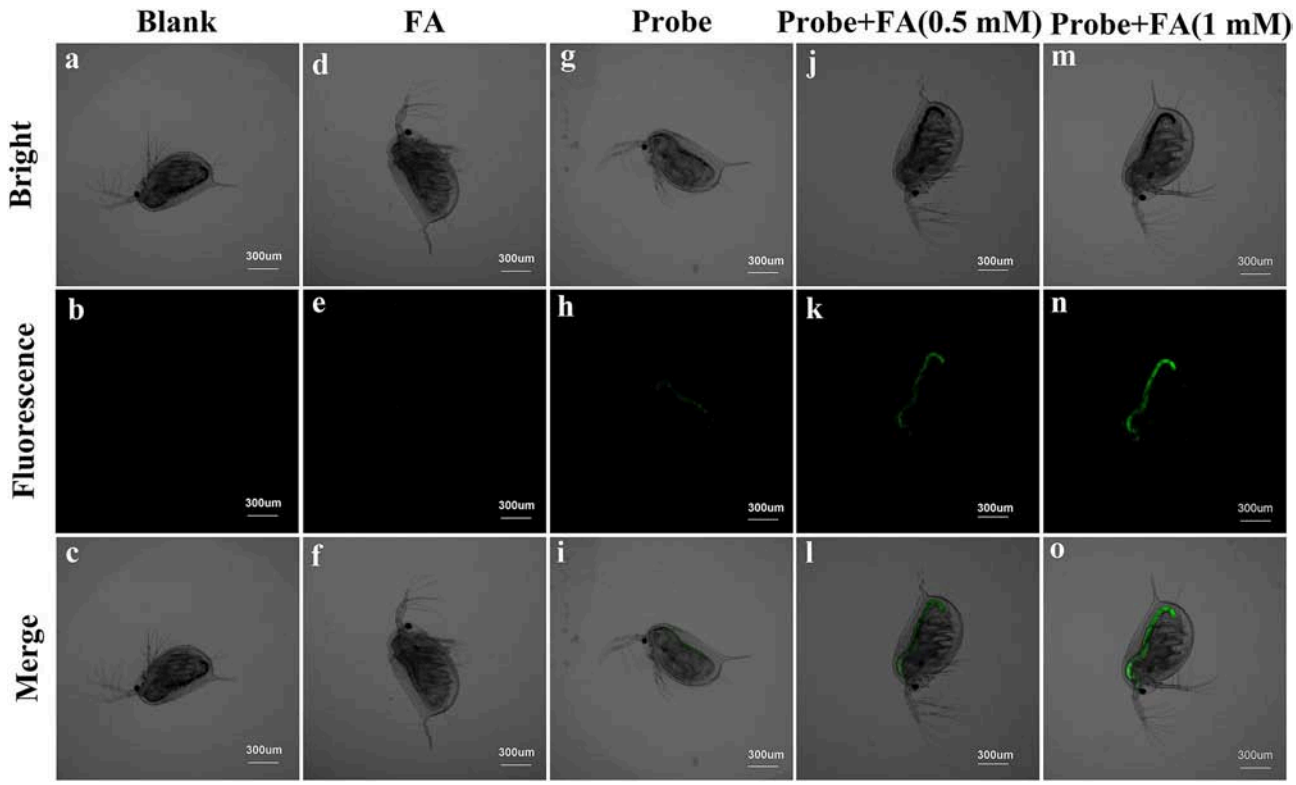

FIGURE 9 | Fluorescence imaging of living *Daphnia magna*. *Daphnia magna* treated with PBS **(a–c)**, FA **(d–f)** and probe **(g–i)** independently. *Daphnia magna* were incubated with 10 μM BD-CHO for 1 h and then with 0.5 mM **(j–l)** and 1 mM **(m–o)** FA for another 3 h before imaging. $\lambda_{ex} = 488$ nm, collected 550–600 nm. Scale bar: 300 μm.

with an IC_{50} of 2 μM), also attenuated **BD-CHO** fluorescence (**Figures 7Ah,B**). Meantime, the detection of endogenous FA changes in HeLa cells were also carried out (**Figure S8**). Take together, the data showed that **BD-CHO** is capable of detecting exogenous and endogenous produced FA in living cells.

Fluorescence Imaging in Kidney Tissues

We further investigated whether **BD-CHO** could image FA in living kidney tissue slices. The kidney tissue slices only soaked in 10 μM **BD-CHO** solution for 3 h showed negligible fluorescence signal (**Figure 8a**, **Figure S9**). By contrast, when the mice kidney tissue slices were soaked in 10 μM **BD-CHO** solution for 30 min, and then soaked in the FA solution for another 3 h, the strong green fluorescence signals were observed (**Figures 8b,c**) with the penetration depth of up to about 100 μm (**Figure 8d**, **Figure S10**). These results indicated that **BD-CHO** was capable of imaging FA in the kidney tissue slices.

Fluorescence Imaging in *Daphnia magna*

The ability of **BD-CHO** for detecting FA *in vivo* was evaluated in living *Daphnia magna*, a widely used animal as a standard Environmental Protection Agency test organism (Lovern and Klaper, 2006), using fluorescence imaging. The untreated and FA-treated *Daphnia magna* showed no fluorescence signal (**Figures 9a–f**). It exhibits faint green fluorescence signal when the *Daphnia magna* were incubated with 10 μM **BD-CHO** for 3 h at 25°C (**Figures 9g–i**). By contrast, upon in the succession treated with **BD-CHO** and different concentration FA, the *Daphnia magna* displays noticeable fluorescence enhancement in green channel (**Figures 9j–o**), indicating that **BD-CHO** could be used for the fluorescence imaging of FA in living *Daphnia magna*.

CONCLUSIONS

In summary, an efficient fluorescent probe, **BD-CHO**, for selective detection of FA via 2-Aza-Cope reaction with large Stokes shifts has been designed and synthesized. In the presence of FA, the fluorescence intensity was significantly increased (about 55-fold) and exhibited large Stokes shifts (about 118 nm). The recognition mechanism of **BD-CHO** to FA was confirmed by HPLC and MS analysis. The probe was used for the fluorescence imaging of exogenous and endogenous FA in living cells with low cytotoxicity and autofluorescence. In addition, **BD-CHO** could also detect FA in living kidney tissue slices with a penetration depth of up to about 100 μm. More importantly, **BD-CHO** was successfully applied to monitor exogenous FA changes in *Daphnia magna* for the first time. All the results indicated that **BD-CHO** could potentially serve as a useful tool

for studying the pathology and physiology role of FA in complex biosystem.

High-fidelity tracking of specific enzyme activities is critical for the early diagnosis of diseases such as cancers. However, most of the available fluorescent probes are difficult to obtain *in situ* information because of tending to facile diffusion or inevitably suffering from aggregation-caused quenching (ACQ) effect. In this work, we developed an elaborated near-infrared (NIR) aggregation-induced emission (AIE)-active fluorescent probe, which is composed of a hydrophobic 2-(2-hydroxyphenyl) benzothiazole (HBT) moiety for extending into the NIR wavelength, and a hydrophilic β-galactosidase (β-gal) triggered unit for improving miscibility and guaranteeing its non-emission in aqueous media. This probe is virtually activated by β-gal, and then specific enzymatic turnover would liberate hydrophobic AIE luminogen (AIEgen) QM-HBT-OH. Simultaneously, brightness NIR fluorescent nanoaggregates are *in situ* generated as a result of the AIE-active process, making on-site the detection of endogenous β-gal activity in living cells. By virtue of the NIR AIE-active performance of enzyme-catalyzed nanoaggregates, QM-HBT-βgal is capable of affording a localizable fluorescence signal and long-term tracking of endogenous β-gal activity. All results demonstrate that the probe QM-HBT-βgal has potential to be a powerful molecular tool to evaluate the biological activity of β-gal, attaining high-fidelity information in preclinical applications.

Keywords: fluorescent probe, near-infrared, aggregation-induced emission, β-galactosidase, *in situ*, long-term tracking

INTRODUCTION

Specific enzymes play vital roles in a wide range of biological processes. Among them, β-galactosidase (β-gal) is overexpressed in primary ovarian cancers, which has been regarded as an important biomarker for cell senescence and ovarian cancer diagnosis (Dimri et al., 1995; Spergel et al., 2001). In view of this importance, real-time tracking of β-gal activity has become a powerful tool for accurate disease diagnostics. Recently, fluorescent probes have gained ever-increasing attention owing to its noninvasiveness to tissue and high sensitivity (Sun et al., 2016; Xu K. et al., 2016). However, current strategy for enzyme probes is generally based on fluorophores that are soluble in the cytoplasm (Bhuniya et al., 2014; Li X. et al., 2014; Zhang et al., 2014, 2018; Wang F. et al., 2015; Xu et al., 2015; Makukhin et al., 2016; Wu et al., 2016; Chen X. et al., 2017). These responsive probes

largely suffer from inaccurate *in situ* information about biocatalytic activity, because the products of small molecules by enzyme conversion quickly diffuse away from the site of their generation (Kamiya et al., 2011; Yang et al., 2013; Li L. et al., 2014; Yin et al., 2014; Xu Q. et al., 2016; Zhou et al., 2016; Zhu et al., 2016; Wu et al., 2017). These released fluorophores even tend to translocate out of cells, thus making long-term tracking in living subjects difficult (Taylor et al., 2012; Wang et al., 2013; Liu H. W. et al., 2017). On the other hand, it is still far from achieving *in situ* accurate information, owing to the distorted signal from inevitable aggregation-caused quenching (ACQ) effect (Sun et al., 2014; Wu et al., 2014; Li et al., 2015; Gu et al., 2016; Liu Z. et al., 2017; Qi et al., 2018). Therefore, it is an urgent demand to overcome the dilemma of the released fluorophores between aggregation requirement for diffusion-resistant and ACQ effect resulting from aggregation.

With this in mind, we envisioned that near-infrared (NIR) aggregation-induced emission (AIE) probes (Qin et al., 2012; Leung et al., 2013; Mei et al., 2015; Guo et al., 2016; Wang et al., 2016; Yan et al., 2016; Liu L. et al., 2017; Shi et al., 2017; Yang et al., 2017; Zhang F. et al., 2017; Feng and Liu, 2018; Wang Y.-L. et al., 2018; Xie et al., 2018) can provide reliable opportunities to address the aforementioned intractable dilemma. The design of the AIE fluorophores extending into NIR wavelength for decreased autofluorescence and high penetration depth is essentially required for attaching additionally a hydrophobic π-conjugated bridge (Guo et al., 2014; Lim et al., 2014; Chevalier et al., 2016; Andreasson and Pischel, 2018; Li et al., 2018; Yan et al., 2018a,b,c). Impressively, nanoaggregates of the released fluorophores ideally meet the hydrophobic requirements for long-term tracking, and the AIE character of the aggregates can well solve the notorious ACQ effect. Furthermore, we anticipate that AIE-active β-gal probes integrating light-up NIR characteristic in synergy with tunable aggregation behavior could make a breakthrough to detect endogenous β-gal with high-fidelity imaging in living subjects. During the response to β-gal, the aggregation behavior of the AIE probe altered from the molecular dissolved state into the aggregated state, achieving AIE-active NIR mode. In this case, the more AIEgens aggregate, the brighter their NIR emission becomes, making them suitable for *in situ* sensing and long-term tracking of biomolecules in living systems (Kwok et al., 2015; Peng et al., 2015; Yuan et al., 2016; Nicol et al., 2017). However, as far as we know, AIE-active β-gal probes possessing the characteristics of both localizable NIR fluorescence signal and long-term tracking mode are scarcely reported.

Herein, we developed an elaborated NIR AIE-active β-gal probe for enabling *in situ* and long-term tracking of endogenous enzyme activity (**Scheme 1**). Firstly, we focus on our group-developed AIE building block of quinoline-malononitrile (QM) to overcome the enrichment quenching effect (Shi et al., 2013; Shao et al., 2014, 2015; Wang M. et al., 2018). Then, the lipophilic 2-(2-hydroxyphenyl) benzothiazole (HBT) moiety is covalently attached as an external π-conjugated backbone for extending the NIR emission. Furthermore, the masking of the phenolic hydroxyl group prohibits the excited-state intramolecular proton transfer (ESIPT) process and thus largely suppresses fluorescence (Kwon and Park, 2011; Thorn-Seshold et al., 2012; Hu et al., 2014; Zhou et al., 2015; Cui et al., 2016; Chen L. et al., 2017; Chen Y. H. et al., 2017; Zhang P. et al., 2017; Sedgwick et al., 2018a,b; Zhou and Han, 2018). Finally, we utilized the hydrophilic galactose moiety as the β-gal-triggered unit for keeping probes in the fluorescence-*off* state with minimal background. When converted by β-gal, the probe releases free QM-HBT-OH, which is found to be nearly insoluble and aggregated in water and shows bright NIR fluorescence owing to the AIE building block with extended π-conjugated structure. By virtue of the NIR AIE-active performance of enzyme-catalyzed nanoaggregates, QM-HBT-βgal is capable of affording a localizable fluorescence signal and long-term tracking of endogenous β-gal activity. Our results demonstrate that the probe QM-HBT-βgal has potential to be a powerful molecular tool to evaluate the biological activity of β-gal.

EXPERIMENTAL SECTION

Materials and General Methods

Unless especially stated, all solvents and chemicals were purchased from commercial suppliers in analytical grade and used without further purification. β-Galactosidase (β-gal) was supplied by *J&K* Scientific Ltd (Beijing, China). The ^{1}H and ^{13}C NMR spectra were recorded on a Bruker AM 400 spectrometer, using TMS as an internal standard. High-resolution mass spectrometry data were obtained with a Waters LCT Premier XE spectrometer. Absorption spectra were collected on a Varian Cary 500 spectrophotometer, and fluorescence spectra measurements were performed on a Varian Cary Eclipse fluorescence spectrophotometer. The time-dependent fluorescence measurements were conducted upon continuous illumination (Hamamatsu, LC8 Lightningcure, 300 W). Dynamic light scattering (DLS) experiments were conducted with Zetasizer Nano-ZS (Malvern Instruments, Worcestershire, UK), and scanning electron microscope (SEM) images were operated on a JEOL JSM-6360 scanning electron microscope. Confocal fluorescence images were taken on a confocal laser scanning microscope (CLSM, Leica confocal microscope TCS SPS CFSMP).

General Procedure for *in vitro* Monitoring β-gal Activity

Probes were dissolved in dimethyl sulfoxide (DMSO, AR) to obtain 1-mM stock solutions. All UV–vis absorption and fluorescence spectra measurements were carried out in PBS/DMSO buffer solution (7:3, v/v, pH = 7.4, 50 mM). In a 3-mL tube, PBS buffer (2.1 mL) and DMSO (900 μL) solution were mixed, and then the probe (30 μL) was added to obtain a final concentration of 10 μM. β-Gal was dissolved in a PBS buffer, and an appropriate volume was added to the sample solution. After rapid mixing of the solution, it was transferred to a 10 × 10-mm quartz cuvette and incubated at 37°C for *in vitro* detection.

Cell Experiment

Cell Lines

This study was performed in strict accordance with ethical standards including ethics committee approval and consent procedure, and adhered to standard biosecurity and institutional safety procedures. This study was performed in strict accordance with the NIH *Guidelines for the Care and Use of Laboratory Animals* (NIH Publication No. 85-23 Rev. 1985) and was approved by the Institutional Animal Care and Use Committee of National Tissue Engineering Center (Shanghai, China).

The human ovarian adenocarcinoma cell line SKOV-3 cells and the human epithelioid cervical carcinoma cell line HeLa cells were purchased from the Institute of Cell Biology (Shanghai, China). Cells were all propagated in T-75 flasks cultured at 37°C under a humidified 5% CO_2 atmosphere in RPMI-1640 medium or DMEM medium (GIBCO/Invitrogen, Camarillo, CA, USA), which were supplemented with 10% fetal bovine serum (FBS, Biological Industry, Kibbutz Beit Haemek, Israel) and 1% penicillin–streptomycin (10,000 U mL^{-1} penicillin and 10 mg mL^{-1} streptomycin, Solarbio Life Science, Beijing, China).

In vitro Cytotoxicity Assay

The cell cytotoxicity of QM-HBT-βgal to SKOV-3 cells and HeLa cells was measured by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay. Cytotoxicity was evaluated by Cell Counting Kit-8 (Dojindo, Tokyo, Japan) according to the factory's instruction. Cells were plated in 96-well plates in 0.1-mL volume of DMEM or RPMI-1640 medium with 10% FBS, at a density of 1×10^4 cells/well, and added with desired concentrations of SKOV-3. After incubation for 24 h, absorbance was measured at 595 nm with a Tecan GENios Pro Multifunction Reader (Tecan Group Ltd., Maennedorf, Switzerland). Each concentration was measured in triplicate and used in three independent experiments. The relative cell viability was calculated by the following equation: cell viability (%) = $(OD_{treated}/OD_{control}) \times 100\%$.

Cells Imaging

Cells were seeded onto glass-bottom petri dishes in culture medium (1.5 mL) and allowed to adhere for 12 h before imaging. Probe QM-HBT-βgal at a final concentration of 10 μM (containing 0.1% DMSO) was added into culture medium and incubated for different times at 37°C under a humidified 5% CO_2 atmosphere. Cells imaging was captured by using a confocal laser scanning microscope (Leica confocal microscope TCS SPS CFSMP) with a 60 × oil immersion objective lens. The fluorescence signals of cells incubated with probes were collected at 650–700 nm under excitation wavelength at 460 nm.

Synthesis of Probe QM-HBT-βgal

Synthesis of Compound 1

A mixture of 2-aminobenzenethiol (2 g, 16.0 mmol) and 2-hydroxy-3-methylbenzoic acid (2 g, 16.0 mmol) in polyphosphoric acid (15 mL) was heated in an oil bath at 180°C for 10 h under an argon atmosphere and then was cooled at room temperature. The mixture was then poured into ice, filtered, and the resulting solid product was washed with water, dried in air, and finally purified by column chromatography using dichloromethane/petroleum ether (v/v, 2:1) as the eluent to afford a white solid product (1 g): yield 26%. ^{1}H NMR (400 MHz, $CDCl_3$, ppm): $\delta = 2.36$ (s, 3H, C***H***$_3$-H), 6.87 (t, $J = 8.0$ Hz, 1H, phenyl-H), 7.27 (s, 1H, phenyl-H), 7.41 (t, $J = 8.0$ Hz, 1H, phenyl-H), 7.50 (t, $J = 8.0$ Hz, 1H, phenyl-H), 7.56 (d, $J = 8.0$ Hz, 1H, phenyl-H), 7.90 (d, $J = 8.0$ Hz, 1H, phenyl-H), 7.97 (d, $J = 8.0$ Hz, 1H, phenyl-H), 12.8 (s, 1H, -O***H***). ^{13}C NMR (100 MHz, $CDCl_3$, ppm): δ 169.81, 156.29, 151.83, 133.69, 132.71, 126.63, 126.07, 125.43, 122.07, 121.49, 119.00, 116.02, 16.08. Mass spectrometry (ESI-MS, *m/z*): $[M + H]^+$ calcd. for $[C_{14}H_{11}NOS + H]^+$ 242.0640; found 242.0636.

Synthesis of Compound 2

Compound 1 (200 mg, 0.83 mmol) was dissolved in 10 mL of trifluoroacetic acid, and then, hexamethylenetetramine (174.5 mg, 1.25 mmol) was added. The mixture was heated in an oil bath at 90°C for 20 h under an argon atmosphere. The reaction mixture was then cooled to room temperature and poured into 6 M HCl (30 mL) and extracted with CH_2Cl_2. The combined organic extracts were washed with saturated brine. Next, purification was done by column chromatography using dichloromethane as the eluent to afford the pure product as a whiteness solid (100 mg): yield 45%.^{1}H NMR (400 MHz, $CDCl_3$, ppm): δ 2.42 (s, 3H, C***H***$_3$-H), 7.47 (t, $J = 8.0$ Hz, 1H, phenyl-H), 7.55 (t, $J = 8.0$ Hz, 1H, phenyl-H), 7.80 (s, 1H, phenyl-H), 7.95 (d, $J = 8.0$ Hz, 1H, phenyl-H), 8.01 (d, $J = 8.0$ Hz, 1H, phenyl-H), 8.11 (d, $J = 8.0$ Hz, 1H, phenyl-H), 9.92 (s, 1H, C***H***O-H), 13.6 (s, 1H, -O***H***). ^{13}C NMR (100 MHz, $CDCl_3$, ppm): δ 190.29, 168.63, 161.12, 151.27, 133.98, 132.62, 128.95, 128.18, 126.98, 126.02, 122.20, 121.67, 116.17, 16.06. Mass spectrometry (ESI-MS, *m/z*): $[M - H]^-$ calcd. for $[C_{15}H_{11}NO_2S - H]^-$ 268.0432; found 268.0436.

Synthesis of QM-HBT-OH

Compound 2 (100 mg, 0.37 mmol) and 2-(1-ethyl-2-methylquinolin-4(1*H*)-ylidene)malononitrile (132 mg, 0.56 mmol) were dissolved in acetonitrile (20 ml) with piperidine (0.5 ml). Then, the mixture was refluxed for 10 h under an argon atmosphere. The solvent was removed under reduced pressure, and then, the crude product was purified by silica gel chromatography using dichloromethane as the eluent to afford QM-HBT-OH as a red solid (50 mg): yield 28%. ^{1}H NMR (400 MHz, DMSO-d_6, ppm) δ1.45 (t, $J = 8.0$ Hz, 3H, NCH_2C***H***$_3$-H), 2.18 (s, 3H, C***H***$_3$-H), 4.59 (q, $J = 8.0$ Hz, 2H, NC***H***$_2CH_3$-H), 7.09 (d, $J = 16.0$ Hz, 1H, alkene-H), 7.15 (s, 1H, phenyl-H), 7.29 (t, $J = 8.0$ Hz, 1H, phenyl-H), 7.42 (d, $J = 8.0$ Hz, 1H, phenyl-H), 7.50 (d, $J = 16.0$ Hz, 1H, alkene-H), 7.56 (d, $J = 8.0$ Hz, 1H, phenyl-H), 7.73(s, 1H, phenyl-H), 7.87 (t, $J = 8.0$ Hz, 1H, phenyl-H), 7.92 (d, $J = 8.0$ Hz, 1H, phenyl-H), 8.00 (d, $J = 8.0$ Hz, 1H, phenyl-H), 8.04 (t, $J = 8.0$ Hz, 1H, phenyl-H), 8.24 (d, $J = 8.0$ Hz, 1H, phenyl-H), 8.90 (d, $J = 8.0$ Hz, 1H, phenyl-H). ^{13}C NMR (100 MHz, DMSO-d_6, ppm): δ 165.84, 151.86, 150.47, 150.34, 143.33, 138.18, 135.37, 132.98, 130.47, 128.51, 124.97, 124.23, 122.31, 121.25, 120.70, 120.40, 117.76, 104.59, 43.02, 17.53, 13.63. Mass spectrometry (ESI-MS, *m/z*): $[M - H]^-$ calcd. for $[C_{30}H_{22}N_4OS - H]^-$ 485.1436; found 485.1439.

Synthesis of QM-HBT-βgalAc

QM-HBT-OH (100 mg, 0.21 mmol) and tetra-O-acetyl-α-D-galactopyranosyl-1-bromide (150 mg, 0.36 mmol) were dissolved in acetonitrile (15 ml) with Cs_2CO_3 (359 mg, 1.10 mmol) and Na_2SO_4 (125 mg, 0.88 mmol) under argon protection at room temperature. The mixture then was stirred at room temperature for 4 h. After filtration, the solvent was removed under reduced pressure. The residue was taken up in sat.NH_4Cl and extracted with CH_2Cl_2. Next, the solution was dried over anhydrous Na_2SO_4, and the solvent was removed by evaporation again. Finally, the crude product was purified by silica gel chromatography using dichloromethane/methanol (100:1) to afford the desired product QM-HBT-βgalAc as a red solid (30 mg): yield 18%. ^{1}H NMR (400 MHz, DMSO-d_6, ppm) δ 1.41 (t, J = 8.0 Hz, 3H, $NCH_2C\boldsymbol{H}_3$-H), 1.76 (s, 3H, acetyl-H), 1.94 (s, 3H, acetyl-H), 1.99 (s, 3H, acetyl-H), 2.08 (s, 3H, acetyl-H), 2.46 (s, 3H, $C\boldsymbol{H}_3$-H), 3.56 (m, 2H, $C\boldsymbol{H}_2OCOCH_3$), 4.06 (t, J = 8.0 Hz, 1H, galactose-H), 4.62 (q, J = 8.0 Hz, 2H, $NC\boldsymbol{H}_2CH_3$-H), 5.16 (s, 1H, galactose-H), 5.24 (s, 1H, galactose-H), 5.34 (s, 1H, galactose-H), 5.48 (m, 1H, galactose-H), 7.06 (s, 1H, phenyl-H), 7.47 (t, J = 8.0 Hz, 1H, phenyl-H), 7.54 (t, J = 8.0 Hz, 1H, phenyl-H), 7.60 (d, J = 16.0 Hz, 2H, alkene-H), 7.65 (d, J = 8.0 Hz, 1H, phenyl-H), 7.95 (t, J = 8.0 Hz, 1H, phenyl-H), 8.01(s, 1H, phenyl-H), 8.11 (m, 2H, phenyl-H), 8.19 (d, J = 8.0 Hz, 1H, phenyl-H), 8.37(s, 1H, phenyl-H), 8.95 (d, J = 8.0 Hz, 1H, phenyl-H). ^{13}C NMR (100 MHz, DMSO-d_6, ppm): δ 169.67, 169.45, 163.39, 167.27, 152.34, 151.67, 149.11, 138.43, 137.75, 135.94, 133.74, 132.40, 132.29, 129.09, 127.67, 126.03, 125.12, 122.78, 121.61, 120.61, 118.12, 107.28, 99.94, 91.56, 70.10, 69.77, 69.18, 68.22, 67.00, 64.11, 61.19, 60.60, 47.20, 43.84, 20.52, 20.11, 16.21, 13.69. Mass spectrometry (ESI-MS, m/z): $[M + H]^+$ calcd. for $[C_{44}H_{40}N_4O_{10}S + H]^+$ 817.2543; found 817.2548.

Synthesis of QM-HBT-βgal

QM-HBT-βgalAc (50 mg, 0.06 mmol) was added to MeONa (70 mg, 1.3 mmol) in methanol (10 ml), and the mixture was stirred at room temperature for 4 h. Then, the reaction mixture was neutralized with Amberlite IR-120 plus (H^+). After Amberlite IR-120 plus (H^+) was filtered off, the solvent was removed by evaporation. Finally, the crude product was purified by silica gel chromatography using dichloromethane/methanol (40:1) to afford the desired product QM-HBT-βgal (16 mg): ^{1}H NMR (400 MHz, DMSO-d_6, ppm) δ 1.41 (t, J = 8.0 Hz, 3H, $NCH_2C\boldsymbol{H}_3$-H), 2.53 (s, 3H, $C\boldsymbol{H}_3$-H), 3.07-3.26 (m, 4H, -O$\boldsymbol{H}$), 3.27(m, 2H, -$C\boldsymbol{H}_2$OH), 3.28 (m, 2H, galactose-H), 3.61 (d, J = 8.0 Hz, 1H, galactose-H), 3.87 (d, J = 8.0 Hz, 1H, galactose-H), 4.62 (q, J = 8.0 Hz, 2H, $NC\boldsymbol{H}_2CH_3$-H), 4.77 (d, J = 8.0 Hz, 1H, galactose-H), 7.07 (s, 1H, phenyl-H), 7.44 (t, J = 8.0 Hz, 1H, phenyl-H), 7.52 (d, J = 8.0 Hz, 1H, phenyl-H), 7.58 (d, J = 16.0 Hz, 2H, phenyl-H), 7.64 (d, J = 8.0 Hz, 1H, phenyl-H), 7.95 (d, J = 8.0 Hz, 1H, phenyl-H), 7.97 (s, 1H, phenyl-H), 8.09 (d, J = 16.0 Hz, 1H, alkene-H), 8.11 (d, J = 8.0 Hz, 1H, phenyl-H), 8.12 (d, J = 16.0 Hz, 1H, alkene-H), 8.39 (d, J = 8.0 Hz, 1H, phenyl-H), 8.95 (d, J = 8.0 Hz, 1H, phenyl-H). ^{13}C NMR (100 MHz, DMSO-d_6, ppm): δ 163.97, 153.87, 152.25, 151.58, 149.12, 138.67, 137.72, 136.00, 133.68, 132.49, 132.05, 131.29, 128.18, 127.56, 125.08, 125.01, 124.95, 122.52, 121.71, 120.89, 120.58, 119.15, 118.07, 107.19, 104.47, 75.48, 73.11, 71.11, 67.66, 59.79, 47.10, 43.85, 16.81, 13.71. Mass spectrometry (ESI-MS, m/z): $[M + H]^+$ calcd. for $[C_{36}H_{32}N_4O_6S + H]^+$649.2121; found 649.2123.

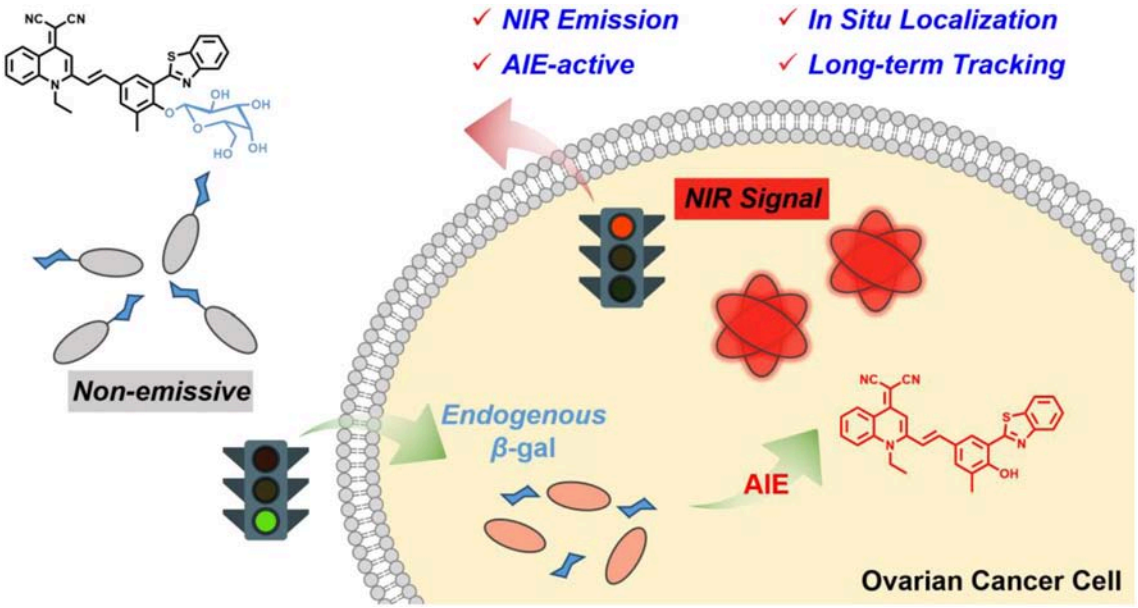
RESULTS AND DISCUSSION

Design and Synthesis

In our strategy, QM is employed as the AIE building block along with generating modifiable sites for functionalization, which could perform controllable NIR emission via tuning electron–donor ability (Shi et al., 2013; Shao et al., 2014, 2015; Wang M. et al., 2018). Particularly, neighboring HBT moiety is covalent attached as hydrophobic π-conjugated backbone, efficiently extending emission wavelength to the NIR region. Finally, a β-gal activatable unit is grafted at the position of phenolic hydroxyl group, blocking the ESIPT process and endowing the elaborated probe QM-HBT-βgal with moderate water solubility. In consequence, the molecular dissolved state in the aqueous system renders the probe almost non-fluorescent. After being specifically hydrolyzed by β-gal, hydrophobic QM-HBT-OH can be released and aggregated with a remarkable light-up AIE-active fluorescent signal, which could be well retained in the reaction site and emit strong fluorescence for long-term tracking endogenous β-gal activity. The synthetic route for the probe is depicted in the Materials and General Methods (**Scheme S1**), which was fully characterized by ^{1}H and ^{13}C NMR and high-resolution mass spectrometry (HRMS) (**Figures S10–S24**).

Aggregation-Induced Emission Properties of QM-HBT-βgal and QM-HBT-OH

Initially, the AIE properties of QM-HBT-βgal and QM-HBT-OH were investigated in the water/THF mixed solvents with different water volume fractions (f_w = 0–90%) in **Figure 1**. Actually, both compounds showed two absorption peaks at 360 and 440 nm, respectively. The absorption spectrum of QM-HBT-βgal displayed only slight changes with the increasing f_w (**Figure 1A**), but that of QM-HBT-OH significantly descended when the f_w exceeded 70% (**Figure 1D**), resulting from the light scattering effect of the well-formed nanoaggregates. As expected, the hydrophilic galactose group makes QM-HBT-βgal in the molecular dissolved state in water, which exhibits non-emission in various water/THF mixtures (**Figures 1B**,**C**), with a quantum yield (Φ) of 0.1 using Rhodamine B as a reference compound. In contrast, QM-HBT-OH showed distinct light-up AIE characteristics. By increasing the f_w from 0 to 60%, the emission intensity increased slowly, accompanied by an obvious bathochromic shift (**Figure 1E**). Further addition of water leads to a sharp and dramatic enhancement in fluorescence intensity (Φ = 3.6%), which correlates well with the formation of nanoaggregates in poorer solvents (**Figure 1F**). Here, the initial fluorescence-*off* state of QM-HBT-βgal and significant AIE-active NIR fluorescence of QM-HBT-OH in aggregated state made it as an ideal candidate for tracking β-gal.



SCHEME 1 | Schematic illustration of an enzyme β-gal-regulated liberation strategy for on-site sensing and long-term tracking.

Spectroscopic Properties and Optical Response to β-gal

A smart AIE-active β-gal NIR fluorescent probe should significantly alter its fluorescence characteristic upon response to β-gal. With the probe QM-HBT-βgal in hand, we investigated the optical response of the probe to β-gal in the aqueous solution (PBS/DMSO = 7:3, v/v, 50 mM, pH = 7.4) at 37°C. QM-HBT-βgal has a broad absorption band at 440 nm, and the absorbance peak decreased gradually with the addition of β-gal (**Figure S1**). As shown in **Figures 2A**,**B**, a distinct NIR fluorescence enhancement at 650 nm was observed from QM-HBT-βgal upon the addition of 10 U β-gal, accompanied by a significant bathochromic shift in emission spectra. It could be interpreted that the QM-HBT-βgal can be specifically hydrolyzed by β-gal and then spontaneously form nanoaggregates QM-HBT-OH with a remarkable AIE-active fluorescent signal, which is confirmed by **Figures S2, S3**, and we observe *in situ* generation of about 200-nm nanoaggregates by DLS and SEM characterization. In addition, the enhancement of fluorescence intensity is dependent on the incubation time with β-gal, leveling off at around 6 h. In contrast, negligible fluorescence intensity change of QM-HBT-βgal was observed without the addition of β-gal, indicative of the moderate and efficient enzyme response rate toward β-gal. Further, we performed the titration to study the enzymatic fluorescence response of QM-HBT-βgal (**Figure 2C**). With the increase of β-gal concentration (0–12 U),

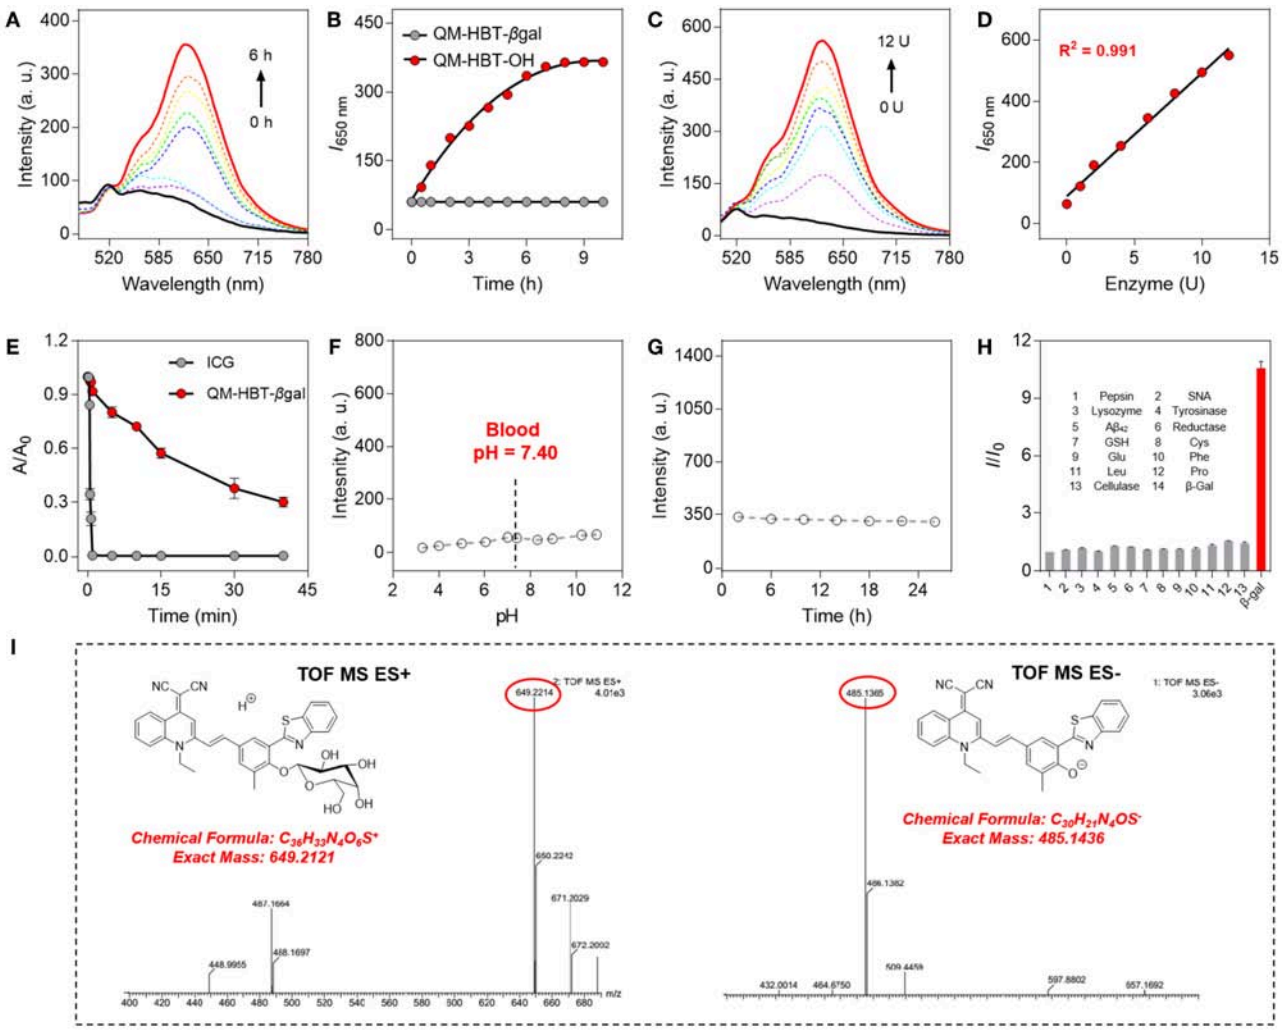

FIGURE 2 | (A) Time-dependent fluorescence spectra of QM-HBT-βgal (10 μM) with 10 U β-gal in aqueous solution (PBS/DMSO = 7:3, v/v, 50 mM, pH = 7.4) at 37°C. **(B)** Time dependence of I_{650} nm for QM-HBT-βgal before (black) and after (red) adding β-gal, λ_{ex} = 460 nm. **(C)** Fluorescence spectra of QM-HBT-βgal (10 μM) upon treatment with increasing concentrations of β-gal (0–12 U) after incubation for 6 h. **(D)** Fluorescence intensity I_{650} nm as a function of β-gal concentration after incubation for 6 h. **(E)** Time-dependent fluorescence intensity of ICG (10 μM, monitored at 812 nm, and λ_{ex} = 780 nm) and QM-HBT-βgal (10 μM, monitored at 650 nm, and λ_{ex} = 460 nm) under sustained illumination. **(F)** Fluorescence intensity at 650 nm of QM-HBT-βgal remaining stable in various pH values and **(G)** fresh mouse serum over 24 h at 37°C. **(H)** Fluorescence responses of QM-HBT-βgal (10 μM) upon incubation with β-gal (10 U) and various other analytes (100 equiv.) in aqueous solution (PBS/DMSO = 7:3, v/v, 50 mM, pH = 7.4) at 37°C, λ_{ex} = 460 nm. **(I)** High-resolution mass spectrometry (HRMS) demonstrating the enzyme-activatable mechanism and showing the cleavage product QM-HBT-OH.

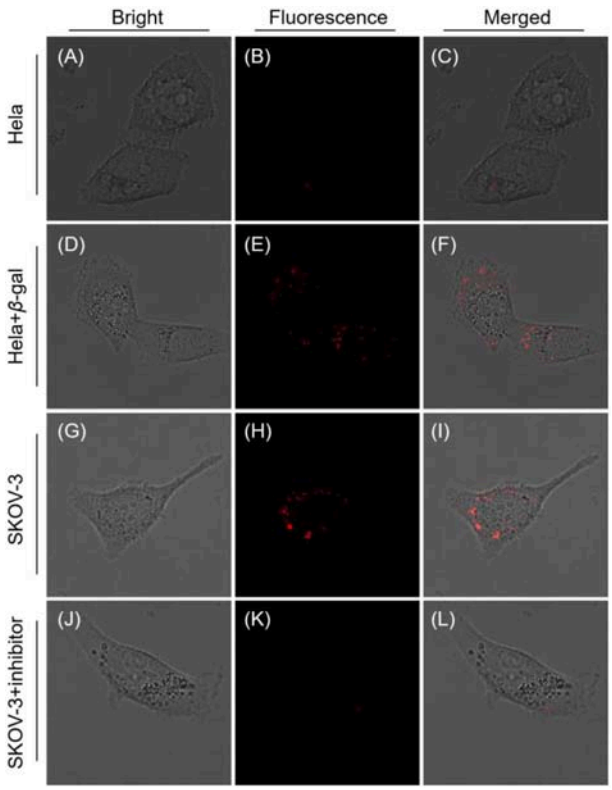

FIGURE 3 | Confocal laser scanning microscopy (CLSM) images of Hela and SKOV-3 cells incubated with QM-HBT-βgal (10 μM) for 4 h: **(A–C)** Hela cells, **(D–F)** Hela cells pretreated with 1 mM β-gal for 0.5 h. **(G–I)** SKOV-3 cells, and **(J–L)** SKOV-3 cells pretreated with 1 mM inhibitor for 0.5 h. The window of fluorescence emission collection is 650–700 nm, $\lambda_{ex} = 460$ nm.

the fluorescence intensity around 650 nm of QM-HBT-βgal gradually enhanced and showed a linear correlation vs. the concentration of β-gal in the range of 0–12 U with a correlation coefficient of 0.991 (**Figure 2D**). Obviously, these remarkable characteristics of QM-HBT-βgal indicated that it could be capable of detecting β-gal activity.

Photostability and Selectivity

The high photostability of QM-HBT-βgal is very crucial to perform long-term tracking and high-fidelity imaging of enzyme activity in preclinical applications. Compared with the commercial FDA-approved NIR contrast agent ICG, the time-dependent absorbance measurements were also conducted to evaluate the photostability of QM-HBT-βgal upon continuous illumination (Hamamatsu, LC8 Lightningcure, 300 W) in aqueous solution (**Figure 2E**). As calculated, the half-life of QM-HBT-βgal (∼1,500 s) is 60-fold longer than that of ICG (∼25 s), suggestive of excellent photostability of QM-HBT-βgal, which further confirmed its potential application in long-term tracking.

We further study the stability of the probe QM-HBT-βgal in different pH values. **Figure 2F** indicates excellent stability of QM-HBT-βgal in various pH values (3–11), and its excellent stability remained in fresh mouse serum over 24 h (**Figure 2G**). In addition, the probe QM-HBT-βgal exhibits excellent pH stability in the medium of FBS (**Figures S4, S8** and **S9**). Furthermore, prior to investigating endogenous β-gal activity in living cells, the specificity of QM-HBT-βgal toward β-gal was also evaluated with potential competitive species including amino acids, enzymes, serum markers, and metabolic substances. As shown in **Figure 2H**, compared with β-gal, nearly negligible fluorescence change of QM-HBT-βgal makes it a promising candidate to achieve accurate detection under practical applications.

Sensing Mechanism

For gaining insight into the activation mechanism of probe QM-HBT-βgal for enzyme β-gal, and then *in situ* release of QM-HBT-OH as NIR AIEgens, we acquired high-resolution mass spectrometry to confirm this proposed mechanism. In the electrospray ionization (ESI)-MS spectra of QM-HBT-βgal with β-gal, the peaks of QM-HBT-βgal and QM-HBT-O^- were found at *m/z* 649.2214 and 485.1365 (**Figure 2I**), respectively. The result clearly indicated that QM-HBT-βgal could be specifically activated by enzyme β-gal, and release QM-HBT-OH as NIR AIEgens.

Imaging of Endogenous β-gal in Living Cells

In order to study the biocompatibility of probe QM-HBT-βgal, standard 5-diphenyltetrazolium bromide (MTT) assays in human ovarian carcinoma cells (SKOV-3 cells) and human epithelioid cervical carcinoma cells (Hela cells) were carried out, respectively. As is observed in **Figure S5**, experimental results verified that probe QM-HBT-βgal has almost no cytotoxicity toward living cells.

Taken all together, the probe QM-HBT-βgal is anticipated to be capable of accurately detecting the endogenous enzyme activity in living cells with *in situ* formation of AIEgen nanoaggregates. To demonstrate this potential, SKOV-3 cells were used as a model, because they overexpress β-gal (Asanuma et al., 2015), while Hela cells without expressed β-gal were used as a negative control model. As depicted in **Figures 3A–C**, no fluorescence was observed at the Hela cells, in accordance with the weak fluorescence spectrum of QM-HBT-βgal. In contrast, by adding an exogenous 10 U β-gal to Hela cells, a significant enhancement of fluorescence (**Figures 3D–F**) was observed due to further the enzyme conversion process. As demonstrated, the enzyme-catalyzed AIE-active NIR fluorescent probe QM-HBT-βgal can be used to detect β-gal in cancer cells. Impressively, SKOV-3 cells, which were treated with QM-HBT-βgal for 3 h, exhibit strong fluorescence in its NIR fluorescent channel (**Figures 3G–I**), suggesting its possible reaction with endogenous β-gal in the cells. These AIE-active signals were interpreted as being insoluble aggregates of released QM-HBT-OH, only occurring at the site where the probe is reacted with β-gal. To verify that the fluorescence change was caused by endogenous β-gal, 1 mM D-galactose (an inhibitor of β-gal; Portaccio et al., 1998) was used to pretreat the cells for 0.5 h. Negligible fluorescence signal was observed in the NIR channel (**Figures 3J–L**), indicating that the enhancement in SKOV-3 cells indeed results from the endogenous β-gal activity.

To establish the precise intracellular localization, co-staining experiments of QM-HBT-βgal were performed with SKOV-3 cells. The AIE-active probe QM-HBT-βgal co-staining with commercially available Golgi-Tracker Green, LysoTracker Red, ER-Tracker Red, and Mito-Tracker Red shows an obvious co-localization characteristic (**Figure 4**). Specifically, the red channel

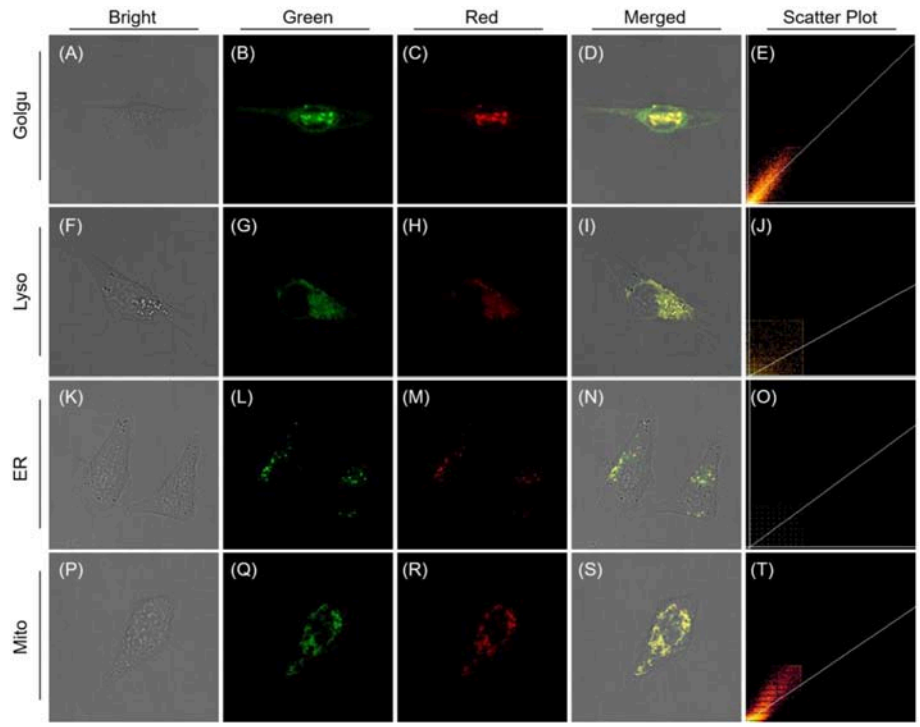

FIGURE 4 | CLSM images for intracellular localization of QM-HBT-βgal in SKOV-3 cells. Cells were incubated with QM-HBT–βgal (10 μM) for 2 h and then co-stained with 1 μM Golgi-Tracker Green (BODIPY FL C5-Ceramide) **(A–E)**, 100 nM Lyso-Tracker Red DND-99 **(F–J)**, 1 μM ER-Tracker Red (BODIPY TR Glibenclamide) **(K–O)**, and 200 nM Mito-Tracker Red for 30 min **(P–T)**, respectively. The green channel at 510–530 nm for Golgi-Tracker Green **(B)**, λ_{ex} = 505 nm; 610–630 nm for ER-Tracker Red **(L)**, 590–610 nm for Lyso-Tracker Red DND-99 **(G)** and Mito-Tracker Red **(Q)**, λ_{ex} = 561 nm. The red channel at 650–700 nm, λ_{ex} = 460 nm.

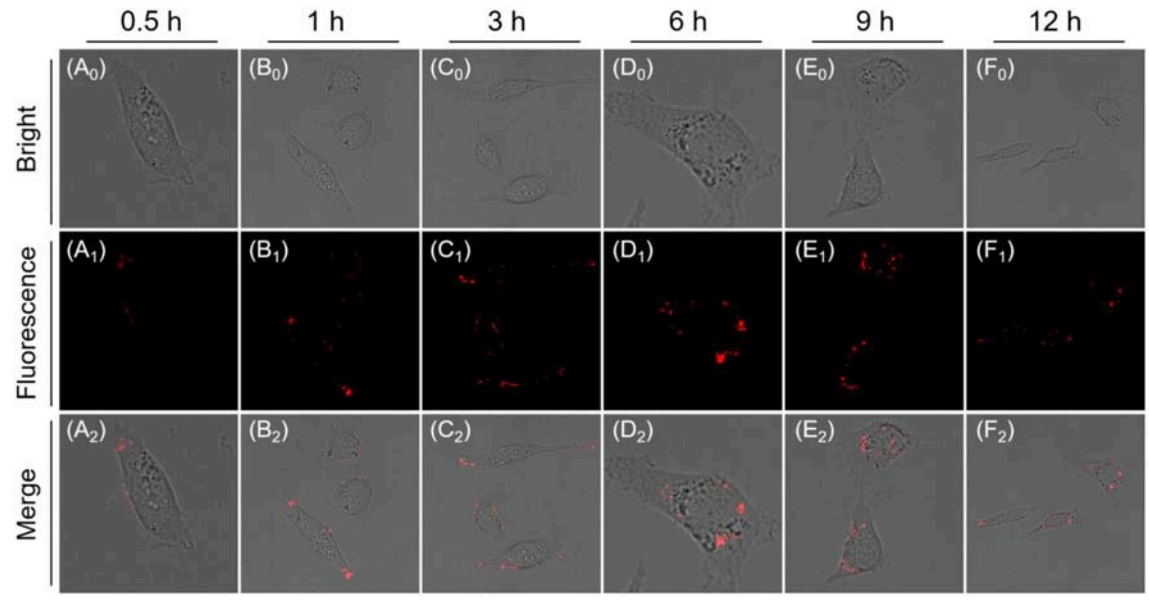

FIGURE 5 | Time-dependent CLSM images of SKOV-3 cells incubated with QM-HBT-βgal (10 μM) (**A_0-F_0**: Bright field, **A_1-F_1**: Fluorescence channel) and (**A_2-F_2**: Merge channel). The window of fluorescence emission collection is 650–700 nm (λ_{ex} = 460 nm).

from AIEgen nanoaggregates largely overlaps with the green channel from Mito-Tracker Red and Golgi-Tracker Red, with Pearson's correlation coefficients of 0.8977 and 0.8522 (**Table S1**). These results indicate that enzyme-catalyzed AIEgen QM-HBT-OH tends to mainly accumulate in the mitochondria and Golgi body.

Furthermore, long-term tracking of endogenous β-gal experiments also conducted in living cells. Indeed, its fluorescence intensity slowly increases and reaches a plateau at 3 h, which does not change significantly over the next 3 h ($t = 6$ h; **Figure 5**), suggesting the AIE-active NIR fluorescent signal is ascribed to nanoaggregate formation, which could amplify the fidelity signals because of emitting stronger during concentration enrichment of AIEgen nanoaggregates. Most importantly, AIEgen nanoaggregates do not easily leak out of cells during prolonged incubation, due to its lipophilicity of extending π-conjugated backbone. When the incubation time was increased to 12 h, the intracellular fluorescence intensity was slightly attenuated and was fixed in the local region (**Figure 5**). In addition, we use the commercial non-*in situ* fluorescent probe (ICG) and the reported probe DCM-βgal by introducing ACQ fluorophore dicyanomethylene-4*H*-pyran (DCM) as control compounds (**Figures S6, S7**), demonstrating the long-term tracking capability of NIR AIE-active QM-HBT-βgal.

Altogether, all these experiment results verified that the AIE-active NIR probe QM-HBT-βgal can overcome intracellular diffusion and attain high-fidelity enzyme information, enabling *in situ* and long-term tracking of β-gal in SKOV-3 cells.

CONCLUSIONS

In summary, we have developed an enzyme-responsive NIR AIE-active probe QM-HBT-βgal for *in situ* and long-term tracking of endogenous β-gal activity, overcoming the dilemma of the requirement for released molecular fluorophores between diffusion-resistant and ACQ effect. Notably, QM-HBT-βgal is almost non-emissive in aqueous media, and upon the addition of β-gal, the masking groups at the hydroxyl moieties of QM-HBT-βgal were removed, thus recovering ESIPT and strong AIE-active NIR fluorescent signal in the aggregate states. Compared with other available β-gal probes, the AIE-active NIR probe QM-HBT-βgal not only provides localization signal of the β-gal at the reaction site but also avoids self-quenching when accumulated in cells, making obvious the advance in high-fidelity detection of endogenous enzyme activity. This study provides a promising strategy for the design of NIR AIE-active probes, paving a new pathway for *in situ* and long-term tracking of enzyme activity in preclinical applications.

Chemical Biology Gateways to Mapping Location, Association, and Pathway Responsivity

Marcus J. C. Long[1†], *Xuyu Liu*[2†] *and Yimon Aye*[2*]

[1] *Independent Researcher, Beverley, United Kingdom,* [2] *École Polytechnique Fédérale de Lausanne, Institute of Chemical Sciences and Engineering, Lausanne, Switzerland*

Here we discuss, how by applying chemical concepts to biological problems, methods have been developed to map spatiotemporal regulation of proteins and small-molecule modulation of proteome signaling responses. We outline why chemical-biology platforms are ideal for such purposes. We further discuss strengths and weaknesses of chemical-biology protocols, contrasting them against classical genetic and biochemical approaches. We make these evaluations based on three parameters: occupancy; functional information; and spatial restriction. We demonstrate how the specific choice of chemical reagent and experimental set-up unite to resolve biological problems. Potential improvements/extensions as well as specific controls that in our opinion are often overlooked or employed incorrectly are also considered. Finally, we discuss some of the latest emerging methods to illuminate how chemical-biology innovations provide a gateway toward information hitherto inaccessible by conventional genetic/biochemical means. Finally, we also caution against solely relying on chemical-biology strategies and urge the field to undertake orthogonal validations to ensure robustness of results.

This article is intended to be a primer for the use of chemical biology. We focus on processes that are limited kinetically by reactive chemistry or that use reactive short-lived molecules to perturb and/or monitor individual-protein- or locale-specific function in living systems. We begin by discussing the need for chemical biology and the underlying design/execution of chemical-biology experiments, including ways to avoid pitfalls. We subsequently highlight some of the latest, and what we consider most interesting, chemical-biology approaches and evaluate their benefits and limitations. These methods are contrasted against classical genetic and chemical/biochemical techniques.

THE NEED FOR CHEMICAL BIOLOGY: *BEYOND GENETICS AND BIOCHEMISTRY*

Chemical biology occupies a niche that is not adequately filled by traditional biological sciences. Biochemistry/enzymology are suited to understand proteins in isolation, or in lysates. Using these methods, functions of individual proteins have been divined (Knowles and Albery, 1977), rates of specific steps of enzyme-catalyzed reactions have been elucidated, and development of tools to modulate a specific enzymatic process has been established. For instance, inhibition experiments directly impact physiological studies because inhibitors can downregulate specific enzymatic

function expediently. Such events can in turn impact cellular pathways/processes rapidly, without the system being given the chance to compensate for the signaling changes incurred upon activity loss (as can occur during genetics experiments, *vide infra*). By measuring time-dependent effects, one can observe how the system responds to loss of the target protein's function. Such inhibition studies are of course also directly applicable to drug design and discovery. Perhaps Daniel Bovet's award of the 1957 Nobel Prize for physiology or medicine is the best example of the use of inhibitors for both academic and industrial pursuits[1]. The Nobel Prize in Physiology or Medicine 1957 was awarded to Daniel Bovet "for his discoveries relating to synthetic compounds that inhibit the action of certain body substances, and especially their action on the vascular system and the skeletal muscles." Inhibitors continue to be used to study age- or context-specific loss of protein function for comparison to genetic knockout studies or to better model diseases (Ogasawara et al., 2018). Of equal importance, since knockout and chemical inhibition are not necessarily the same in terms of percentage of loss of function and the effect on global protein function, such chemical-biology experiments require careful consideration and data interpretation (Hedstrom, 2017).

Biochemistry/enzymology also are often used to study *robust complexes or* individual protein function, such as by immunoprecipitation, or activity assays. However, these experiments are typically carried out in lysates or on purified proteins. Cellular compartmentalization is lost under these conditions, and several other contextual factors are also perturbed. Such biochemistry experiments were instrumental in unraveling many fundamental processes, like the nature of triplet codons (Matthaei et al., 1962). But in many instances, the loss of context that occurs upon lysis or upon isolation incurs artifacts or loss of activity/structure, due to, for example, incorrect preparation techniques (Darling and Reid, 1979; Wang et al., 2011), or expression conditions (Osz-Papai et al., 2015). Furthermore, these assays also require large amounts of protein, thereby losing track of information on cell-to-cell variation, for example. Small-molecule bulk-exposure regimens tend to lack resolution at the sub-cellular and organ/tissue scales, unless cell-surface behaviors are investigated using cell-impermeable molecules, or deploying, as we see below, chemical-biological tricks. It is worth noting that the intracellular concentration of a small molecule is not necessarily the concentration of the molecule in the media. Especially for reactive small molecules (Liu et al., 2019), there is often a concentration gradient across the cell.

On the other hand, genetic tools have proven powerful for studying the functions and necessities of genes, pathways, and specific-protein functions. Such studies can often be carried out in the subcellular locale or organ/tissue of choice. High-throughput screening approaches to find specific genetic associations, that are difficult to identify otherwise, have been applied to global analysis of protein stability (Yen et al., 2008), cell-to-cell variation (Livet et al., 2007), and pathway intersections. Genetics—often guided through biochemical/structural studies, random mutation of putatively-important mutants, or genomic sequencing of selected mutants showing resistance to an inhibitor, or rescue of a specific phenotype—offers ways to manipulate *steady-state* information flow. Oftentimes, these experiments can be carried out at the single-cell level. However, genetic techniques often lack dynamic range and precise temporal control, especially in higher eukaryotes, in all but a few instances. Thus, new methods were required to deliver high-resolution information on transient associations, to enable investigations of rapid gain of function, to effect localized perturbation, or to zoom-in on the signaling behavior of individual proteins/pathways.

These questions above have all been tackled to varying success by chemical biology. Chemical biology offers the ability to generate reactive chemical signals at will, or modulate chemical properties of specific proteins at a preordained time, often in specific locales for a specific duration. In many of the most pertinent and informative scenarios, chemical-biology methods offer insight because they can generate "on demand" highly-reactive small molecules, whose half-lives and diffusion distances are short (Parvez et al., 2018). Localization or duration control are often achieved in conjunction with genetically-encodable elements that can serve as frameworks for biocompatible processes. Thus, although a simplification, chemical biology exists to some extent to: (1) bring the power of *in vitro* analysis to the cell, and ideally to the whole organism; and to (2) extend genetically-encodable functions beyond those accessible through the use of canonical amino acids. Indeed, much of the advances of chemical biology have been made by researchers that seek to perform work on questions at a "triple point," i.e., the intersection of multiple fields, such as chemistry, enzymology, and cell signaling; or enzymology, bioinorganic chemistry, and genetics.

As chemical biology straddles several spheres of life sciences, we begin by discussing some intrinsic issues with chemical biology, and how they can be limited. We further discuss pitfalls and how to surmount them and aspects of good experimental design.

UTILITY TO MODEL ORGANISMS

One key benefit of genetic methods/analysis is applicability to model organisms and humans (e.g., through heredity maps, lineage information). Indeed, simply examining if a mutant or disease is dominant vs. recessive, and other simple hereditary patterns, can give clues to disease mechanisms that are informative (Wilkie, 1994). Most enzymology/biochemistry techniques are less applicable to model-organism studies. Ultimately many inhibitors/small-molecule-probes are either too toxic, metabolically unstable, or administered in cell/tissue-penetrable "prodrug" forms, yielding limited information to link a precise chemotype/target-engagement to phenotype. Of course, there are some excellent small-molecule modulators/probes applicable to numerous model organisms. Indeed, 92% of approved drugs targeting the human proteome are small molecule-derived as opposed to biologics (Santos et al., 2017). Ideal chemical-biology methods should be applicable to model

[1]https://www.nobelprize.org/prizes/medicine/1957/summary/

organisms; however, at the moment, few are generally applicable to much beyond cell culture. This limitation is in part because many methods require non-biocompatible chemical manipulations and/or use reagents either too toxic and/or impermeable to live models on the order of the experiment, thereby limiting the experiments to cultured cells or isolated organelles. Studies in lysates also remain a go-to strategy in proof-of-concept chemical-biology methods development, although these conditions provide little or no information on subcellular regulation or reflect close-to "real-world" conditions with respect to intracellular concentrations/assemblies/activities of specific macromolecules or metabolites. It is our hope that more model organism-based investigations with precise control in space, time, and context will surface in the future.

DEFINING ON-TARGET SPECIFICITY: NECESSITATING ORTHOGONAL VALIDATIONS

Generally, a small molecule used for chemical biology should be as non-invasive as possible. Thus, it should not ideally cause cell death, cell-cycle stall, or adversely affect relevant pathways. Thus, changes in the aforementioned parameters induced by the small molecule should all be assessed. Such assessments should be made early in methods development. Since most cells in culture are grown in high-serum media, ideally the compound should not interact strongly with serum. Should serum be an issue, low-serum media is available, or cells can be switched to serum-free conditions during compound exposure. Ideally, in model organisms, the molecule should also not affect growth, development, or fecundity, among other easily-measurable parameters. Should a molecule/regimen satisfy the above criteria, one can consider it biocompatible. However, it should be noted that most genes are in excess and are not absolutely required for growth/survival, especially in the rich conditions that we culture cells and organisms. These rich conditions may mask negative effects that could be observed under the intended experimental conditions, or when other stresses are added to the system. This is an ongoing issue for all research that is not easily addressable. We will elaborate on some ways chemical biologists have practically obviated these issues below.

Based on our current understanding of the number of proteins, protein-modified states, and protein-protein/protein–nucleic acid interactions, as well as the sheer number of non-protein molecules in cells, it seems highly unlikely that any molecule is "100% selective." Thus, there should always be concerns levied regarding off-target or artefactual effects arising due to use of small molecules, regardless of methods used to evaluate binding promiscuity 1962; Feldwisch-Drentrup, 2017. How binding promiscuity could impact a chemical-biology process depends on what the intended measurements are. Furthermore, observation of binding/labeling alone does not necessitate changes in enzyme activity/protein function, protein—protein/nucleic-acid interactions, or any process relevant to the intended experiment. Since the scope of this review does not warrant an extended discussion on IDing small-molecule targets, we focus here on methods aimed at assessing to what extent a specific output measured following a small-molecule treatment can be ascribed to a specific protein under study.

Integrating siRNA/shRNA-Knockdowns to Small-Molecule Experiments

One of the most common ways to use small molecules for mechanistic analysis is to assess whether a specific protein's activity is required for a process. Proteasome inhibitors are, for instance, commonly used to investigate degradation mechanisms (Goldberg, 2012). When using small-molecule inhibitors that are well characterized to validate if the activity of protein of interest (POI) or pathway is required for a specific function, it is responsible to assay more than one inhibitor targeting the POI or pathway (Zhang et al., 2013; Coffey et al., 2016; Conciatori et al., 2018; Smith et al., 2019) (**Figure 1A**). The use of inactive structural/regioisomeric analogs of a single inhibitor to verify "on-target" effects is inadequate, since if a modification manifested within the analog silences an on-target binding event, it may also silence off-target binding events, or affect permeation/stability, and overall negative data could be misinterpreted as "proving" on-target specificity (**Figure 1B**). However, in cases where there is high enantiospecificity shown by a chiral ligand, inactive epimers of the inhibitor that are inactive are useful (Bondeson et al., 2015).

An alternative way to validate inhibition assays is siRNA, or knockout technologies. Knockdown/knockout and inhibition are not necessarily identical to small molecules in terms of overall effect (Weiss et al., 2007). However, if the POI's chemical activity is required for a specific process, the effects of knockdown/knockout and inhibition should often be similar. To rule out off-target effects of the siRNA, at least two siRNAs are best deployed, separately per experiment. If all conditions, or the majority of conditions, agree with the postulate, this is good evidence that the POI is involved in the pathway. The logic of such experiments runs that the off-target binding of structurally-dissimilar inhibitors, or sequence-dissimilar siRNAs, is unlikely to converge at a point other than the desired target. As the number of different components of the comparison, and indeed the chemical difference across the different comparisons, increases, the robustness of such a conclusion also increases.

Finally, we note that cell-line validation is critical for genetic processes. This process must include both antibody validation and functional validation of knockdown, but may need to be extended to genotyping genes of interest, especially in cultured cells (Long et al., 2017a). Rigorous literature searches are also helpful to uncover other known issues surrounding generated/evolved lines (Princiotta et al., 2001), or species-specific effects (Gupta et al., 1986) that can potentially cause confounding results.

Integrating Resistant Cell Lines

If the mode of action of a compound is unknown, target-specificity validations are not as simple. One classic method to assess on-target effects of toxic drugs is to develop resistant cell

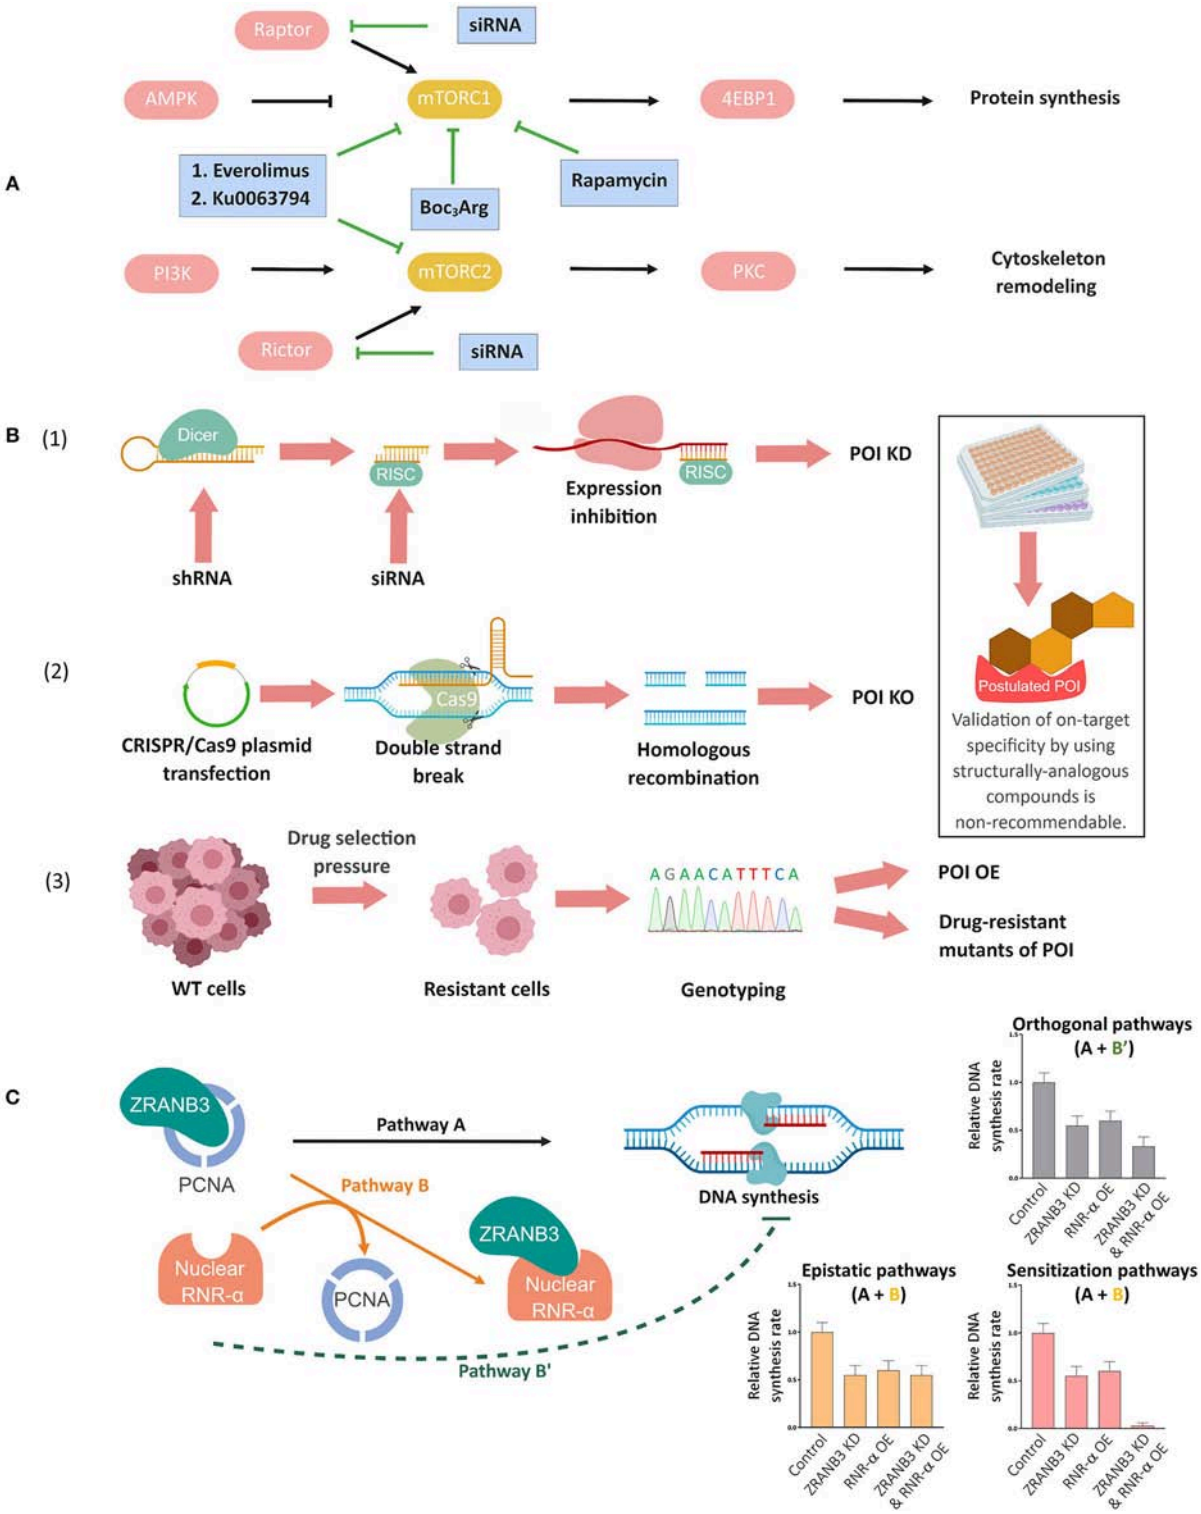

FIGURE 1 | Complementary genetic methods to validate chemical biology outcomes. **(A)** Deconvolution of mammalian target of rapamycin complex (mTORC)-1 and-2 signaling pathways using mTORC-1 selective small-molecule inhibitors, dual inhibitors of mTORC-1 and-2, and specific knockdown of the respective companion (Raptor or Rictor) of each mTORC (Conciatori et al., 2018). **(B)** Orthogonal validations to confirm on-target specificity of small-molecule probes/inhibitors. (1) siRNA/shRNA knockdown (KD), (2) targeted knockout (KO) through CRISPR/Cas9 or other gene-editing techniques, and (3) genotyping in resistant cell lines. In (1), Dicer, a ribonuclease-(RNase)-III converts shRNAs into siRNAs. The cleaved double-stranded RNA is incorporated into the RNA-induced silencing complex (RISC) and the resulting strand complementary to mRNA subsequently inhibits mRNA expression. In (2), mammalian cells are transfected with a plasmid containing desired

(Continued)

FIGURE 1 | sgRNA/Cas-9 combination, which results in the formation of a ribonucleoprotein complex of the Cas9 protein and the sgRNA upon expression. Upon the complementation between sgRNA and the target sequence, the Cas9 protein undergoes allosteric activation and cleaves the double-stranded DNA. This double-strand break (DSB) will lead to either non-homologous end joining (not shown, but the most commonly employed strategy to make a genetic knockout) or homologous recombination with an ectopic DNA repair template containing a deletion sequence (shown in figure). Upon cell colony selection, the desired KO will be confirmed experimentally**.** In (3) continued exposure, typically to escalating concentrations of a drug, can lead to selection of resistant cells that may overexpress the target protein (POI OE), or express drug resistant mutants, amongst other possibilities discussed in the text and elsewhere. Inset: Note that on-target validation using different analogs of the compounds is non-recommendable (see text). **(C)** *Concept of epistasis exemplified by nuclear RNR-α and ZRANB3 in DNA synthesis.* RNR-α, once inside nucleus, binds to ZRANB3 nuclear protein, displacing ZRANB3's cognate binding partner, PCNA, *in vitro* and in cell lysates. But this data alone does not prove that such a mechanism occurs in an intact cell. Cells deficient of ZRANB3 (i.e., ZRANB3-KD) suppresses DNA-synthesis by ∼30−40%, supporting the previous data on ZRANB3—PCNA binding-dependent DNA-synthesis (Pathway A). Overexpression (OE) of nuclear RNR-α suppresses DNA-synthesis to a similar extent but this result does not prove that ZRANB3 is a target of nuclear RNR-α in DNA-synthesis downregulation. By examining how nuclear RNR-α affects DNA-synthesis in ZRANB3-KD cells, the requirement of ZRANB3 for nuclear-RNR-α-dependent effects on DNA synthesis can be assessed. Indeed, in the absence of ZRANB3, nuclear-RNR-α-promoted DNA-synthesis suppression is ablated, supporting Pathway B (epistatic regulation via ZRANB3) over Pathway B'(direct downregulation, independent of ZRANB3), and also indicating that ZRANB3 is only a promoter of DNA synthesis (otherwise, the combination treatment would likely lead to a synergistic suppression of DNA synthesis). This analysis was also backed up by the fact that expression of RNR-α-binding-defective but otherwise functional ZRANB3-mutants renders cells resistant to nuclear-RNR-α-driven DNA-synthesis inhibition (Fu et al., 2018).

lines, as these may overexpress the drug target (**Figure 1B**). Thus, there are known lines resistant to inhibitors such as hydroxyurea, MK2206, and methotrexate overexpressing their target protein, namely, ribonucleotide reductase(RNR)-subunit-β (Eriksson et al., 1984; Aye et al., 2015), Akt3 (Stottrup et al., 2016), and dihydrofolate reductase (Schimke, 1988), respectively.

However, it should be noted that there are multiple mechanisms to effect resistance, aside from direct upregulation of the target. Examining methotrexate resistance as an example, beyond target-gene upregulation, upregulation of efflux and altered drug metabolism are common routes to resistance (Bertino et al., 1996; Ercikan-Abali et al., 1997; van der Heijden et al., 2007). Indeed, transcription and translation of specific genes are often responsive to their products inhibition, meaning that cells actively work to countermand suppression of activity, and also that protein-upregulation often accompanies small-molecule inhibition. Thus, assessment of protein expression of the intended target following inhibition should be routine.

Protein overexpression itself can have unexpected consequences. An overexpressed protein can achieve micro-molar concentrations in mammalian cells (Zhao et al., 2018). Thus, particularly in instances where binding efficacy is moderate-to-high (a situation that can easily render concentrations of compound administered similar to, or significantly lower than, the overexpressed protein), the overexpressed protein could significantly reduce concentrations of active compound, sacrificially protecting other important targets, without it actually ever being a biologically-relevant target. Furthermore, protein overexpression can rewire signaling networks such that a drug may no longer be effective due to hyper-stimulation of a compensatory pathway.

Integrating Functional Mutants

In some instances, overexpression of a resistant mutant—ideally with kinetic properties similar to that of the wild-type-protein—can also occur upon drug exposure. For instance, the discovery of RNR-α(D57N) mutant of the enzyme RNR that has similar *in vitro* kinetic activity (Aye and Stubbe, 2011) but is not inhibited by the native nucleotide dATP was discovered through such experiments (Ullman et al., 1980; Weinberg et al., 1981; Caras and Martin, 1988). These mutants can also be used to evaluate on-target specificity through overexpression, or better yet, through close-to-endogenous expression (**Figure 1B**; Wisitpitthaya et al., 2016). Under these conditions, mass action effects discussed above are much less likely, rendering the conclusions more incontestable.

Integrating Epistasis Concepts

Modern approaches toward on-target specificity have focused on knockdown or knockout of the postulated target. Knockdown of a target typically sensitizes cells to a drug, because one can consider that some of the drug's "work" has been done for it, so it is easier for the drug to take effect. This sort of sensitization is most-commonly observed under conditions where there is little phenotypic output due to the knockdown. In some instances, knockdown of the protein is so acute that there is essentially a knockout of protein function. Under these conditions (or with true knockouts), one may expect there to be essentially no impact of the drug, as there is no target. This condition is termed *epistasis* (Cordell, 2002; Miko, 2008). If the drug functions through processes not associated with the proposed target, then similar fold effects will still be seen in the knockdown/knockout line. This sort of analysis applies equally to protein-based inhibitors and small molecules.

Our laboratory recently used such arguments to elucidate the pathway through which nuclear-translocated RNR-subunit-α suppresses DNA synthesis (Fu et al., 2018; **Figure 1C**). Our data showed that RNR-α is able to bind to a nuclear-localized protein called ZRANB3. We hypothesized that this interaction may inhibit ZRANB3-function because ZRANB3—RNR-α interaction also led to disruption of PCNA binding to ZRANB3, and it is known that the ZRANB3—PCNA complex plays a role in DNA damage response (Poole and Cortez, 2017). Our data revealed that robust (∼85%) knockdown of ZRANB3 by three different siRNAs suppressed DNA-synthesis rate by 30–40% (Fu et al., 2018), showing that ZRANB3 is a promoter (although not necessarily required) for DNA synthesis, and that in the knockdown states, ZRANB3's activity is significantly depleted. Overexpression of RNR-α (which raises nuclear RNR-α levels, allowing ZRANB3 to bind RNR-α) also suppressed DNA-synthesis rate. Thus, there were several possible scenarios: (assuming ZRANB3 were a promoter of DNA

synthesis and RNR-α inhibits ZRANB3) we would see that ZRANB3-knockdown cells (that have significantly lost ZRANB3's DNA synthesis promoting function) are resistant to RNR-α overexpression; (assuming ZRANB3 were *required* for DNA synthesis and RNR-α inhibits ZRANB3) we would see a large fold increase in fold suppression of DNA synthesis upon RNR-α overexpression in the knockdown lines as the minimal ZRANB3 remaining would be overwhelmed by the influx of the inhibitor RNR-α; (assuming ZRANB3 does not mediate the nuclear-RNR-α-promoted DNA-synthesis suppression) there would be a drop in DNA-synthesis rate when RNR-α was overexpressed in the ZRANB3-knockdown cells of the same fold to what was seen in the control cells. The first of these outcomes was observed (Fu et al., 2018), consistent with nuclear-RNR-α acting as an inhibitor of ZRANB3-function and ZRANB3 being a promoter of DNA synthesis. We validated these experiments by showing similar outcomes upon dATP treatment, a situation that causes RNR-α to translocate into the nucleus. We were also able to derive a functional point mutant of ZRANB3 (that cannot bind RNR-α but can promote DNA synthesis), and this mutant was resistant to RNR-α-overexpression (Fu et al., 2018).

Of course, one must be careful to interpret how knockdown, and especially knockout, affects cells. For instance, in some cases even 85% knockdown of the target protein is not sufficient to observe significant pathway flux change (Lew and Tolan, 2012), thus it may not be possible to obtain significant sensitization using siRNA. Furthermore, since knockout of a target protein should ideally mimic saturating drug behavior, knockout may not be tolerated. Thus derived knockout lines can suffer from change of flux through necessary pathways, likely suppressing growth rates, or selecting for cells with modified survival responses, etc. Such residual knockout cells can appear resistant, solely because a few outliers from the population have been selected. However, the observance of resistance in knockout lines still remains good evidence for an on-target mechanism (Chauhan et al., 2012). Accordingly, the use/derivation of resistant point mutants as performed above are highly useful for mechanistic studies.

DEALING WITH ECTOPIC PROTEINS: JUDICIOUS CHOICES FOR MINIMAL INTERFERENCE

Aside from employing ectopic small molecules, many chemical-biology methods employ unnatural (often fusion) proteins ectopically expressed in the system under study. The effect of these non-native elements must be considered when evaluating each specific method and the data each method produces. Any perturbation imposed by the ectopic protein on the basal levels of pathway signal and the responsivity of the pathway must be assessed.

Transient Expression vs. Stable Integration

Considerations should also be made on how such transgenes will be introduced (**Figure 2A**). For cell culture, transient transfection is common. This procedure tends to give high levels of expression that are significantly variable across individual cells. Thus, single-cell analysis must be performed carefully such that expression of transgene is normalized, or at least accounted for. Furthermore, bulk phenotypic outputs could be derived from a subset of cells from the transfected pool (Parvez et al., 2016). Transfection also requires large amounts of plasmid, and chemical treatment of cells with lipid or other reagents.

An alternative is the use of cells containing integrated copies of the plasmid, or integrated ectopic DNA. Integration can be achieved under conditions of prolonged selection post transfection (Lin et al., 2015), through viral integration, or through transposases, all of which typically give "random" incorporation usually at multiple loci. Targeted integration (which limits chances of integration incurring off-target effects) using FLIP-recombinase (Schlake and Bode, 1994; Fu et al., 2018) or similar setups has also become popular (**Figure 2A**). Overall benefits of integration approaches include: obviating the need to transfect, which gives increased reliability, and reduced variations across experiments. Furthermore, single clones of lines can be chosen to ensure uniform expression of the transgene. If several clones are picked, a range of expressions can be chosen. Alternatively, inducible lines can be used that give calibrated expression.

Model organisms vary in their analogies to cell culture in these respects. Some are routinely manipulated transiently or through modification at the genome level during experiments. Zebrafish is a good example of such a system (**Figure 2B**). Others are almost exclusively manipulated through heritable manipulations, such as *C. elegans*. There are also some species-specific quirks, such as the ability of worms to form stable extrachromosomal arrays. We have shown that this system can prove very useful for chemical biology as the array-containing worms can be selected using a visual marker (e.g., fluorescence), and give a predictable percentage of transgenic progeny vs. wildtype progeny (Hall-Beauvais et al., 2018; Long et al., 2018a). Thus, experiments ultimately contain both wildtype and transgenic animals derived from the same founders that have been exposed to identical experimental conditions.

Knock-Out/Knock-In Lines

There are several issues that need to be considered when planning to derive knockout or knock-in lines. There are important differences between implementing these approaches in cancer cell lines vs. model organisms. Indeed, the aneuploidy of cancer cells renders knock-in generation difficult to achieve currently. Some cancer cells lines are "near diploid," such as HCT116, which has enabled homozygous and heterozygous knock-ins to be made by several methods we describe below (Duncan et al., 2012). The issue of aneuploidy in cancer cell lines could also potentially contribute to difficulty in generating knockout lines in cancer cells, although this does not appear to be a huge factor for CRISPR-Cas9 technologies (Yuen et al., 2017). Notably, the on- vs. off-target effects of all genetic manipulation strategies are hotly debated (Gallagher and Haber, 2018; Wang et al., 2018). These issues in whole organisms can be overcome by outcrossing, but this issue is not possible to "fix" in cultured cells.

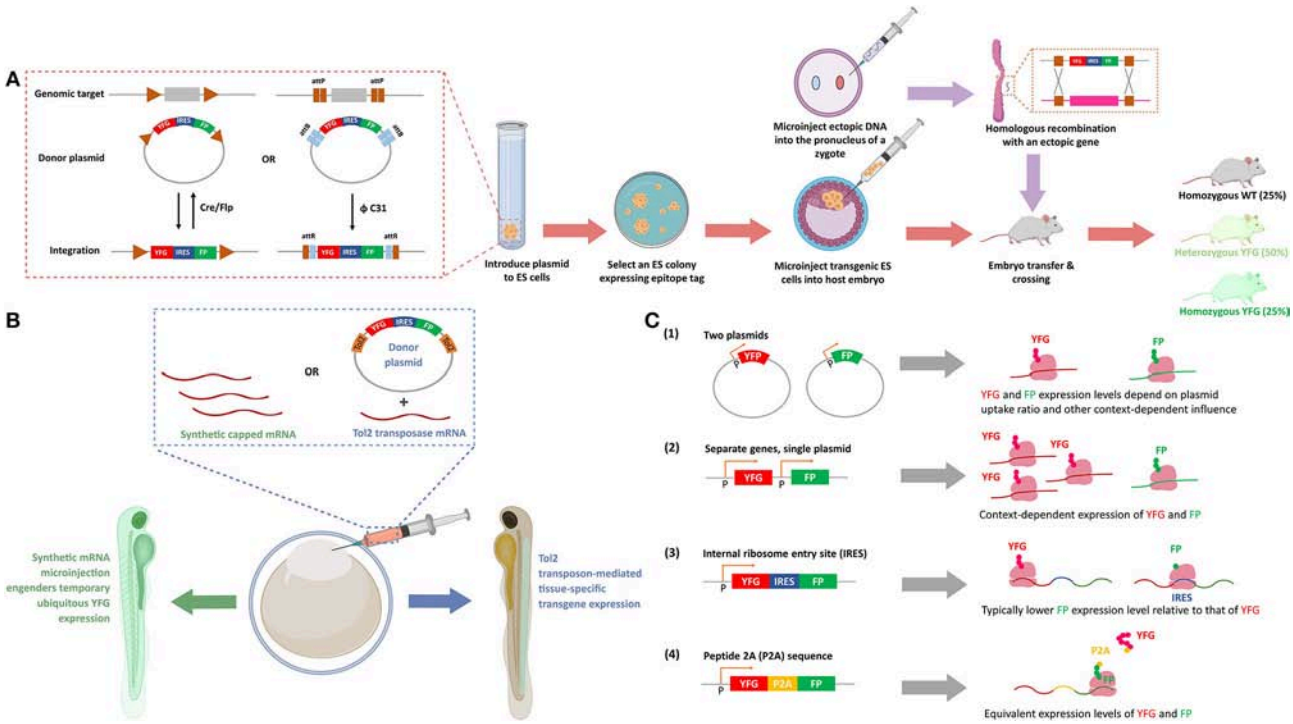

FIGURE 2 | Methods to express ectopic protein through introduction of ectopic nucleic acids. **(A)** Genetic integration of POI in cell lines and transgenic (Tg) mice. Inset: The recombinases [Cre and Flipase (Flp)] can be used to exchange genomic DNA with plasmid DNA to promote targeted integration of your favorite gene (YFG) into specific cell lines, or a suitable host. The bacteriophage ΦC31 integrase can perform a similar function in mouse. ΦC31 enables site-specific integration of the genes flanking phage attB-sites into the locus of host genome that is pre-engineered with up- and down-stream phage attP-sites. This recombination is irreversible because the resultant attR-flanked genes in host genome is not recognized by ΦC31 integrase. (FP, fluorescence protein; IRES, internal ribosomal entry site, that enables bicistronic expression of, in this figure, YFG and FP). To create a Tg mouse, a suitable embryonic stem (ES) cell line is prepared, and post integration of YFG-IRES-FP, colonies that have undergone insertion are selected and subsequently injected into a fertilized cell, giving rise to mosaic progeny that can be further manipulated. After multiple crossing with wild-type (WT) mice, 25% and 50% of the progeny have homozygous and heterozygous YFG knock-in, respectively (lower row, arrows in salmon). Alternatively, DNA with homology arms overlapping with the target site of interest can be injected into the pro-nuclei of fertilized embryos, and post-recombination, targeted-knock-in of the specific allele is created (top row, arrows in purple). **(B)** Transient expression and stable integration of POI in zebrafish. The eggs of zebrafish, which undergo external fertilization, can be injected with synthetic mRNA, to give ubiquitous, transient expression of YFG. Alternatively, a number of other random- or targeted-insertion protocols can be used. In this case, the transposon Tol2 is shown that gives random-integration of YFG—IRES—FP construct. Depending on the promoter driving the transgene (here, YFP and FP), locale-specific or ubiquitous expression can be achieved. **(C)** Different methods of POI expression in cultured cells. (1) Transfection of two plasmids gives a population of cells that express both genes (YFG and FP), with expression levels of each gene varying widely from cell to cell, with little correlation in the relative expression levels of each gene. (2) Separate genes on single plasmids can give standardized amounts of each protein, although the ratio of each protein is context-dependent, as transcription, mRNA stability and translation are independent between each protein (YFG and FP). (3) In IRES-driven bicistronic expression systems, transcription and mRNA stability of each protein are the same, but translation of the two genes (YFG and FP) can be considerably different. Typically, the protein downstream to IRES is expressed to a lower level than the one upstream to IRES. (4) In P2A-driven systems, transcription, mRNA stability, and translation are all the same (see text for details). (P designates promoter-binding site in **B,C**).

In general, targeted genome modification involves introducing a specific targeted DNA double-stranded break (DSB), which is then fixed either by homologous recombination (HR) or through non-homologous end joining (NHEJ). Indeed, the ability to induce specific DSBs is a critical factor of these experiments, explaining why targeted nucleases are such "big news." DSB can be achieved by expression of a nuclease that will specifically cut at an intended locus. In the modern era, DSB is most-readily introduced using CRISPR-Cas9, although other nucleases, including TALENs (Joung and Sander, 2013), have been and are still used. If there is no DNA with which to undergo recombination, the cell can repair the damage through NHEJ. This is an error-prone method that leads to formation of an "indel" (insertion/deletion polymorphism). Ideally, the indel creates a premature stop codon in the protein of interest (POI), yielding a truncated POI, although clearly frameshifts often also occur. It is important to appreciate that such systems create a "non-functional" protein, although typically mRNA-production still occurs and a gene product is often still generated, which could retain some bioactivity.

Knock-in is a particularly useful method to study the consequences of unnatural gene-products. Classic methods involve injection of linearized ectopic DNA into pro-nuclei of zygotes, and rely upon spontaneous HR (an error-free process) to introduce the gene of interest. Often times, the ectopic DNA contains a selection cassette, which can

be removed post selection by standard methods. In more modern approaches, a DSB is induced consequentially with the introduction of the DNA (either short single-stranded DNA with short overlapping regions, or longer double-stranded DNA) to promote recombination. Thus, the ectopic DNA can be incorporated into the locus of the break more efficiently.

Recently, CRISPR-Cas9 has become a method of choice for generation of DSBs to assist in generation of knock-in lines (Platt et al., 2014), in a range of organisms including mice (Singh et al., 2015), worms (Dickinson and Goldstein, 2016), and parasites (Cui and Yu, 2016). This requires the expression of Cas9, which can be achieved through the injection of protein, DNA, or mRNA. Although numerous factors intrinsic to the protein affect protein expression (such as protein stability), typically, a knock-in line is the most likely to lead to a set-up where protein expression (and protein translational/transcriptional regulation) are unperturbed compared to wild type. Unfortunately, as alluded to above, we currently lack the ability to generate knock-in lines of most cancer cells. Thus, knock-in cell lines are derived from genetically-engineered organisms, whose cells are harvested and then adapted into cell lines. This approach can work well, even if the knock-in is unable to survive to adulthood, as all that is required are relatively early embryos (Fu et al., 2018).

Cre-Lox has been used to perform context- or stage-specific manipulation of numerous organisms (**Figure 2A**), and similar concepts using CRISPR-Cas9 are also being introduced (Katigbak et al., 2018). Critically, CRISPR-Cas9 editing can be conducted in adult mice, under correct conditions. Such strategies are particularly relevant to knockout/mutation of essential genes and generation of targeted disease models.

Fluorescent Proteins and Epitope Tags

Regardless of the model system and expression system, ideally, all non-canonical/ectopic sequences, or protein domains should be removed from the expressed POI. For instance, it is common to express ectopic POIs as fusions with fluorescent proteins (FPs) or other chemically reactive domains, like Halo or SNAP, etc. Our subsequent discussion focuses on FPs, which are arguably most commonly used and for which several issues have been raised. However, protein-specific caveats likely apply to all ectopic protein domains and to a lesser extend linker regions and epitope tags. Efforts to assess validity (e.g. activity, localization, response)/rule out artifacts (unexpected effects on critical pathways, unexpected growth defects, etc.) in the specific system of use should always be made. FPs are certainly not bio-inert (Koelsch et al., 2013; Coumans et al., 2014; Ansari et al., 2016; Ganini et al., 2017); their use should be restricted where possible, especially in cell culture, unless, for instance, single live cell analysis is required. If FPs are required, whenever possible, fusion of FP to the POI can be circumvented through the use of separate promoters, plasmids, or, more reliably, through the use of bicistronic systems, such as IRES, or self-splicing peptides, like P2A. IRES/P2A also allow relative protein expression to be assessed across different cells (Jang et al., 1988; Pelletier and Sonenberg, 1988; Trichas et al., 2008; **Figure 2C**). It is important to note that IRES and P2A, are cell-type and organism dependent in terms of their effectiveness. Furthermore, P2A gives similar levels of each protein post translation (assuming each protein has similar stabilities Liu et al., 2017), but IRES biases expression against the protein downstream of the IRES (Mizuguchi et al., 2000). These nuances have been judiciously employed in experimental designs (Wang et al., 2015). The excitation and emission wavelength of the FP should be chosen to be as far away from background fluorescence and from any other photochemistry/redox-chemistry that is being conducted. Typically, red fluorescence gives better signal to noise.

In model organisms, such as *C. elegans* and *D. melanogaster*, the use of FPs as reporters of transgenicity are common, although dominant phenotypic markers, such as *rol-6* ("roller") or *ro+* ("rough"), are also used (Lockett et al., 1992). These phenotypic markers tend to be derived from known dominant mutants, leading to obvious physical deformities, and hence are "hard-wired," and as they affect, for instance, motility, they may pose undesired impacts on physiology. By contrast, for FP's, the locale of expression can be defined by the user. One can consider restricting fluorescence to a small number of cells (e.g., touch neurons, via the *C. elegans* promoter *Mec7*, in worms), or to cells that are not intended for the specific chemical-biology experiments (such as pharynx expression, via the *C. elegans* promoter *Myo2*, and gut expression of the key transgene, via the *C. elegans* promoter, *Ges-1*). If it is necessary to mark the specific transgenic cells with FPs, IRES, or likely better P2A fusions of the required gene with an FP, are best deployed (**Figure 2C**).

Furthermore, directing subcellular localization of the FP to a region that is not intended to be studied can also be useful, such as fusing the FP to a nuclear-localization sequence (NLS), if studying cytosolic processes with the specific POI. Finally, expressing POIs with epitope tags (FLAG, HA, V5, etc.) is often useful in cell culture for enrichment of specific proteins, but it is almost essential in model organisms, especially those for which homology with humans is only moderate, e.g., *C. elegans*. If the POI is fused to another protein-tag, such as Halo-Tag, for which highly-specific, low cross-reactivity antibodies are available (*vide infra*), such antibodies can often substitute. However, the background labeling of the antibody for the proteome from the species of interest should be evaluated, prior to design of the fusion construct, and the requirements of the whole experiment should be considered.

Additional Considerations

Ideally, activity/function of any fusion-POI expressed should be compared against the non-fused/non-tagged POI. This assessment can be done *in vitro*, or by measuring expected phenotypes/responses in cells/organisms in which the native protein has been depleted (by RNAi, or genetic knock out) and the fusion-POI exogenously supplemented. Knock-in lines are ideal, especially when the gene in question is essential, although for most purposes, simultaneous knockdown of a specific gene and plasmid transfection is operationally similar (provided the knockdown leads to a measurable effect on the cells that can be rescued). In cases where simultaneous siRNA knockdown and re-expression of the modified target POI is performed, the ectopic POI typically should have a synonymous mutation of the siRNA

target sequence. The re-expressed protein should be shown to occur at close to endogenous levels.

Because most chemical-biology approaches are multi-parameter, and these parameters often interact to make a new state that is not a simple "sum" of the individual parts, it can be argued that there is no "ideal" chemical-biology method. Hence, we emphasize that all chemical-biology approaches should be validated orthogonally. However, we also stress that close-to-ideal chemical-biology methods lend themselves to the development of as careful-and-as-close-to-"real" controls as possible. For our purposes, this means that assay conditions can be modulated such that *a single variable* is changed at a time (e.g., using a point mutant that does not process the chemistry/signal-propagation as intended). In fact, when such controls are available or built into the design, results tend to transpose well to real-life and any small-molecule-induced perturbations to the resting state of the cell can usually be tolerated.

PERTURBATION STRATEGIES: *COMPLEMENTING BIOSENSORS*

Most chemical-biology perturbation methods begin with the system at a "basal state" followed by a rapid jump to a new state induced by some form of chemical perturbation. The time taken to reach the new state/or the reactivity of the molecules generated, is often a key parameter that must be optimized such that genuine dynamics of cell responses can be measured on their relevant timescales. Thus, just as in classic kinetics experiments, the speed of the perturbation must be faster than other ensuing processes intended to be measured, so that a true readout of the chronology of the responses is established. In many instances, chemical-biology perturbations can elicit a shift to a "new state," or generate a reactive small molecule in minutes or even seconds.

By contrast, the length of time required to synthesize RNA and protein, and indeed the half-lives of most proteins are typically hours (Vogel and Marcotte, 2012; Liu et al., 2016; Mathieson et al., 2018) in higher eukaryotes, although precise values are species- and protein-dependent. Indeed, genetic techniques, like LOX/tet/RNAi/Flip/CRISPR-Cas9, also have a long latency. Arguably the "fastest-responding" genetically-encodable element is modulation of protein degradation (either positive or negative). The fastest responding of these strategies are mostly chemical genetic in nature. Such perturbation methods include: SHIELD (Banaszynski et al., 2006), auxin-initiated decay (Nishimura et al., 2009), HyT (and derivative stress induction methods) (Neklesa et al., 2011), Boc3Arg (Shi et al., 2016) and PROTACs (Lai and Crews, 2017). There are also some systems based on heat-shock that can be applied to organisms such as yeast (Dohmen et al., 1994), but one must consider the pleiotropic effects of temperature on the system in these instances as well. Despite these methods being considered rapid, 1–3 h is still required to have a significant effect (assumed to occur around 50% protein depletion, although much greater degradation than that can be required Lew and Tolan, 2012), and the slow step is almost certainly the change in stability of the protein target, not the engagement of the small molecule with its protein target, or the thermal unfolding of the protein (further underlining the relative slowness of biological recognition processes; Shamir et al., 2016).

Recently, photoactivatable cell signaling has also become common. This overall strategy represents another rapid response genetic unit. Importantly, this strategy has proven applicable to multiple different biological problems (Zhang and Cui, 2015), often (although not always) where oligomerization, dimerization, or recruitment are required for changes of cellular protein activity. In many instances, the system is also reversible, rendering these systems ideal for measuring signal-induced changes. Another group of rapid genetically-encodable methods involves chemical-induced dimerization (Stanton et al., 2018), a strategy that dates back to the earliest years of chemical biology (Spencer et al., 1993), but has found applications to modern genetic approaches, such as split-Cas9 (Zetsche et al., 2015). Using Cas9 as a specific example, intended outputs (e.g., transcriptional regulation, gene "deletion" or DNA damage) occur post Cas9 binding to its target DNA-sequence, meaning they are inherently controlled by factors with relatively long latency, such as mRNA stability or recruitment of transcriptional apparatus. Furthermore, Cas9 target engagement can take hours (Jones et al., 2017), even in *E. coli*. Finally, genetically-encodable sensors: such as the ROS-sensors: HYPER (Belousov et al., 2006) and roGFP (Meyer and Dick, 2010), the calcium sensor: m-GECO (Zhao et al., 2011); as well as the fleet of biosensors for kinase-activity (Mo et al., 2017) or metabolite sensing (Litke et al., 2016; Tao et al., 2017), are also rapidly-responsive elements, although these are not perturbation/labeling tools. However, use of these established visualization/activity-monitoring methods in conjunction with perturbation strategies—such as inhibition, integration of dominant-negative or gain-of-function alleles, or other targeted chemical-biology perturbation approaches that we outline below—offers a gateway to study cell responsivity and pathway architecture.

PARAMETERS

In this section, we discuss a few representative chemical-biology techniques (chosen for illustrative purposes from the much larger armory of methods these days available to researchers) in terms of the following parameters: (1) occupancy, i.e., whether these techniques are intended to saturate their targets or label only a subset of available targets based on some parameter; (2) spatial restriction, i.e., how constrained the techniques can be to a specific macromolecule, organelle, or interactome; and (3) functional information, i.e., what can we learn about the consequences of localization/reactivity/labeling using the technique. We further discuss the overall invasiveness of the methods and controls that are built in to the methods and orthogonal validation of the data. We will also evaluate how compatible and comparable these methods are with genetic/biochemical techniques.

Target Saturation Methods to Probe Protein Localization and Associations

These methods are not strictly direct perturbation methods. However, they ideally employ reactive small molecules, generated

on demand to chemically tag a specific set of proteins present in a chosen locale, or interactome, at a specific time (**Table 1**). These tagging processes thus reveal proteins either localized within a specific region or associating with a specific protein, even if they are present in low amounts, or if the interactions occur for a short period of time. Optimal parameters for these methods typically involve minimizing diffusion distance of the reactive molecule (Parvez et al., 2018), restricting membrane permeability (Yang and Hinner, 2015), and controlling the exposure time of the reactive entity to the native environment (Long et al., 2017c; Parvez et al., 2018).

APEX

APEX is an extremely useful method to profile protein localizations and associations. The key to this method is deployment of an engineered soybean ascorbate peroxidase protein that creates a reactive biotinylated phenoxyl radical, which has a short half-life (1 ms), giving APEX a labeling range of around 40 nm (Rhee et al., 2013; **Figure 3A**). The generation of this molecule within a defined compartment/region gives high resolution for assigning localizations and associations, which can be carried out in a multiplex manner (Cruz-Lopez et al., 2018). For instance, novel mitochondrial-associating proteins have been identified using APEX. Recent successes of APEX include profiling of associations at specific genomic loci (Myers et al., 2018) (through fusion to a binding-competent but catalytically-inactive mutant of Cas9, dCas9) and identifying new protein-protein associations (Xue et al., 2017). APEX has also recently been applied to RNA immuno-precipitation (Kaewsapsak et al., 2017). Thus, APEX was one of the most-widely used chemical biology methods in 2017–2018. Soybean peroxidase, from which both APEX-based probes are derived, is also known to be relatively robust to pH and temperature (Henriksen et al., 2001), although it does require a metallocofactor, and hence activity is dependent on correct loading of the cofactor, which could be context dependent.

Because of the short half-life and ectopic nature of the phenoxyradical (Rhee et al., 2013), APEX is unable to probe, for instance, downstream signaling. It is noteworthy that APEX outputs, although internally subject to not much more than 20% variability run to run, are subject to significant variability dependent upon the comparison used (Markmiller et al., 2018). Thus, multiple cross comparisons may be required to build up a complete picture of the interactome. Furthermore, APEX tends to favor labeling of unfolded proteins (Minde et al., 2018), so there is certainly the possibility for biased outcomes. Soybean peroxidase is known to generate spontaneous reactive oxygen species under certain conditions, and hence APEX could confer context specific changes to cellular redox levels that are difficult to address (Kimura and Kawano, 2015). How the ectopic overexpression of peroxidase may alter signaling/interactome architectures and redox homeostasis, etc., has not yet been assessed. Furthermore, APEX requires stimulation with peroxide (∼1 mM) to form the phenoxy radical. This requirement likely restricts the use of this technique to 2D-cell culture/isolated organs (Chen et al., 2015), as it is unlikely whole organisms will take up peroxide equally. Peroxide treatment is only for a relatively short time (minutes), but even brief pulses of peroxide can alter signaling pathways, elicit translocation, and affect protein stability/integrity (Parvez et al., 2018). Many small molecules can also be inactivated/compromised by peroxide treatment. APEX has, however, proven to be compatible with some important methods, including EM (Martell et al., 2017; Mavlyutov et al., 2017). Control for the peroxide is an intrinsic challenge of the peroxidase-based platform. The bioactivity of the phenoxy-radical-precursor that cells are treated with for significant dose (0.5 mM) and exposure-time (0.5 h) prior to oxidation as well as the post-treatment quenching regimen (5 mM Trolox and 10 mM ascorbate performed 3 times), also remains untested.

BioID

BioID uses an engineered promiscuous *E. coli* biotin ligase. This protein generates a reactive biotinylated molecule, biotin-AMP, *in situ* (**Figure 3B**). Biotin-AMP is a type of acyl phosphate, which are short-lived species whose hydrolysis liberates around as much energy as ATP hydrolysis (Meyerhof and Shatas, 1952; Di Sabato and Jencks, 1961). Acylphosphates are kinetically

TABLE 1 | Comparison of the representative chemical-biology techniques discussed in this review.

	PROTAC	APEX	BioID	(mini) Turbo ID	si/shRNA knockdown[a]	T-REX	G-REX
Effective time ($t_{1/2}$)	1–3 h	1 min	∼18 h	10 min−2 h	Variable (hours to days)	1 min	1 min
Occupancy	High	Proximity-dependent	Proximity-dependent	Proximity-dependent	Time-dependent	Target-dependent	Low
Spatio-temporal control	Low	High	Medium	Medium	Low	High	n.d.[b]
POI-specific functional information	High	Low	Low	Low	Variable (dependent on target intrinsic stability)	High	Low
Organismal applications	High	Low	Medium	Medium	Medium	Medium	Medium

[a] *RNAi is highly species dependent. It is extremely efficacious in worms, where effects can also be heritable. In higher eukaryotes, RNAi delivery is a significant challenge, although there are some drugs that have entered trials. Yeast and other lower eukaryotes and prokaryotes lack RNAi machinery.*
[b] *Not yet determined.*

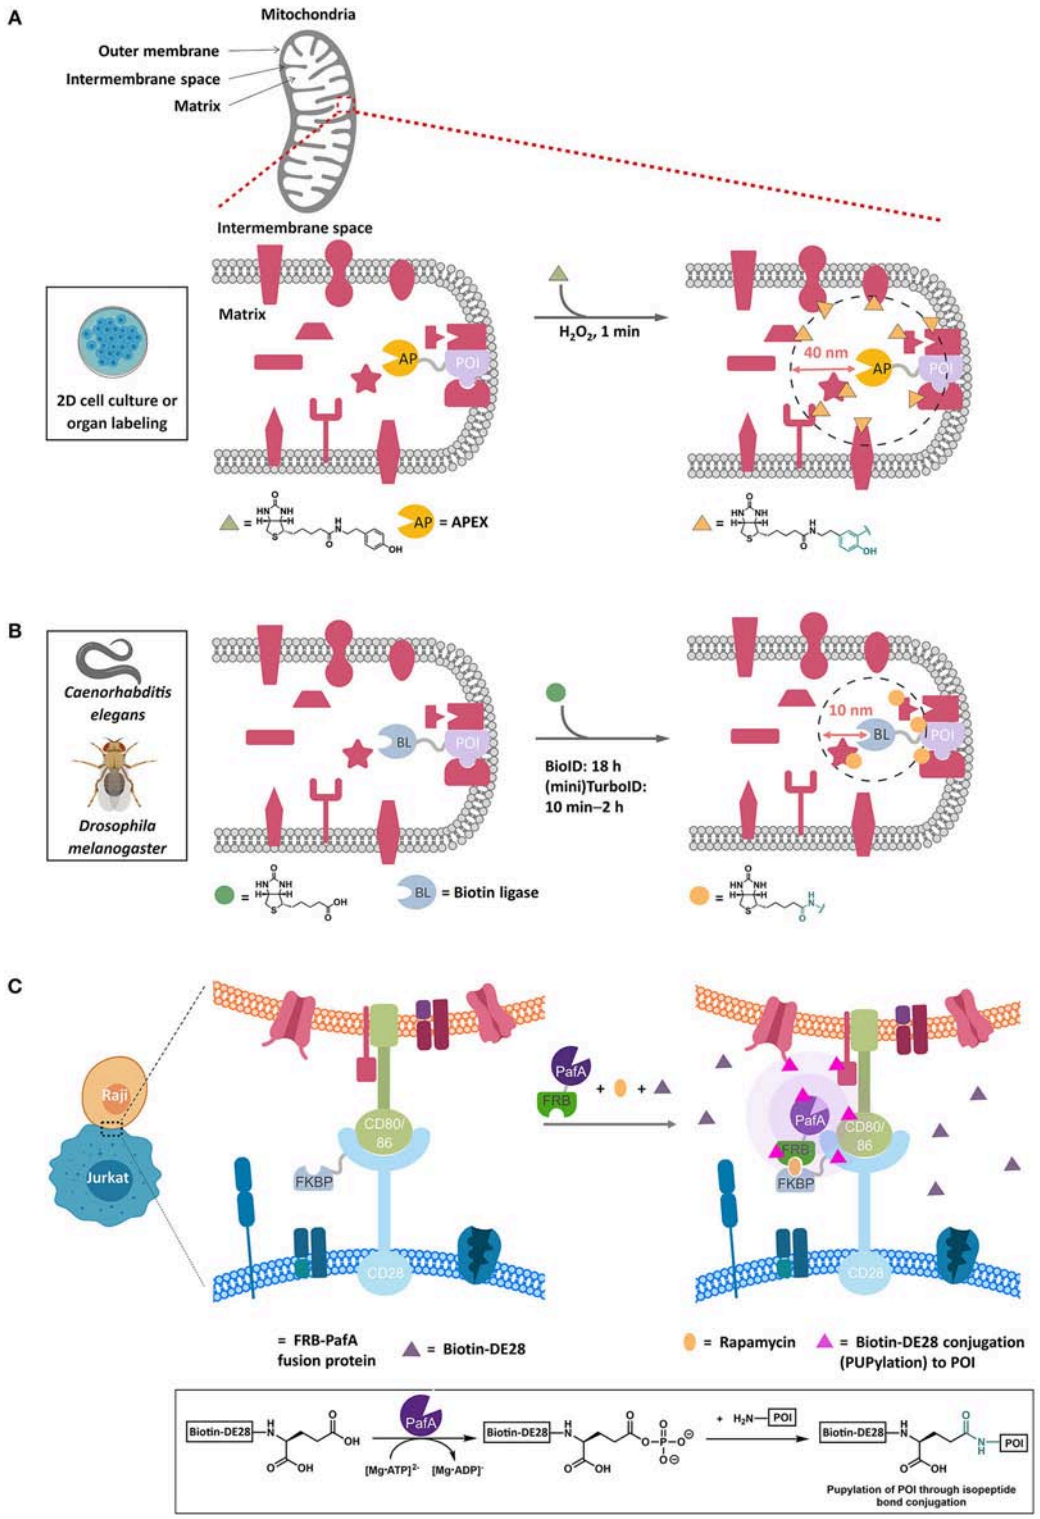

FIGURE 3 | Representative proximity-based target ID platforms. **(A)** APEX method. APEX-fused POI is overexpressed in live cells and targeted to the compartment of interest, such as the mitochondrial intermembrane in this example. The typical experimental procedure involves incubating cells with biotin-phenol (30 min, 0.5 mM) followed by a brief exposure to H_2O_2 (1 min, 1 mM) to initiate the biotinylation of the proteins proximal to the POI (within ~40 nm). After quenching the oxidants, cell lysis and streptavidin enrichment, the biotinylated proteins can be ID'ed by trypsin-digest and LC-MS/MS analysis. Currently, APEX's application is limited to 2D-cell culture and isolated organs. **(B)** BioID method. In this proximity-biotinylation catalyzed by promiscuous biotin ligases (BLs), various forms of BirA mutants have been employed, with TurboID and miniTurboID as the latest, leading to biotinylation of proteins spatially close to the POI (fused to BL). These biotin ligases catalyze the

(Continued)

FIGURE 3 | formation of biotin-5′-AMP ester, which diffuses out of the active site and is captured by the accessible nucleophilic residues (primarily lysine) of the POI and those of the proteins within 10 nm on average from the POI. BioID experiment typically requires 18 h or longer periods of time to achieve significant biotinylation of the proteins. TurboID and miniTurboID have significantly improved the biotinylation efficiency (10 min – 2 h) with little difference in labeling output. TurboID and miniTurboID have been successfully applied to tissue-specific protein ID using *D. melanogaster* and *C. elegans* as model organisms, although the optimized biotinylation conditions of TurboID and miniTurbo in human cells may not be transposable to these organisms, owing to the differences in growth temperature and time scale. **(C)** PUP-IT method. This method IDs protein–protein interactions through proximity-PUPylation on cell surface; e.g., PUP-IT has been applied to mark the cell–cell recognition events between Raji and Jurkat cells. The FKBP fusion of CD28 is stably expressed on cell-surface membrane in Jurkat cells. Upon addition of rapamycin (orange oval) and PafA(PUP ligase)-FRB fusion protein to the growth media, a functional PUP-IT complex proximal to CD28 receptor is formed. The addition of biotin-DE28 (purple triangle)—the truncated PUP protein that remains active in PUPylation reaction catalyzed by PafA—enables PUPylation of Raji cell-surface proteins CD80 and CD86 rapidly (magenta triangle), which are known to interact with the CD28 receptor in Jurkat cells. Inset shows the underlying chemistry. FKBP, FK506 binding protein. FRB, FKBP-rapamycin binding domain.

less stable than ATP, although they are more stable than the phenoxy radical generated by APEX in water (Long et al., 2016). However, in the biological milieu, biotin-AMP is ephemeral and has a diffusion distance of around 10 nm (Kim et al., 2014) (i.e., is likely more spatially restricted than APEX and may ultimately give protein-level resolution Rees et al., 2015), and is capable of labeling proximal lysines. One critical difference between APEX and BioID is that BioID does not require stimulation with peroxide to generate the intermediate, and as such BioID has been applied to multiple model organisms including mice, *Toxoplasma gondi* (Long et al., 2018b), and slime molds. Recently, there have been some extensions to this method to improve the context dependence, including split-BioID (De Munter et al., 2017; Schopp et al., 2017). Critically, two different split proteins have been reported, testifying to the versatility of BioID. Finally, BioID has recently been coupled with affinity purification MS, using Strep-II tag to allow more quantitative analysis of interaction distances across large complexes (Liu et al., 2018b).

One of the major issues with BioID is the slow kinetics of formation of biotin-AMP, which can particularly restrict use in organisms that are not grown at 37°C. This issue was recently overcome by engineering ligases with heightened kinetic proficiencies. TurboID and miniTurbo (a truncated version of TurboID) allow substantial biotinylation of the proteome in a few hours, as opposed to the typical 18 h in BioID (Branon et al., 2018). Although, little difference in the labeled proteins detected was observed between the two conditions in cultured cells, several important applications were shown in model organisms. For instance, the embryonic development of *C. elegans* is approximately 14 h and its optimal development temperature is 16–20°C (Zhang et al., 2015). Thus, a rapid labeling strategy is required to enable sufficient build-up of labeled protein in the embryonic stages. As may have been predicted, BioID did not label embryos well, but TurboID and miniTurbo yielded robust labeling.

BioID requires ATP to generate the reactive species. Thus, one could consider BioID to be more cellular context-dependent than APEX. Although this question has not been systematically addressed, and despite ATP being a critical component of the cell, it is known that ATP levels are fluxional (Imamura et al., 2009; Tantama et al., 2013) and time-(Schneider and Gourse, 2004) and locale-dependent (Suzuki et al., 2015) and variable cell-to-cell (Yaginuma et al., 2014). Furthermore, although many of the issues of BioID were solved by Turbo/miniTurbo-ID, it is worth noting that these proteins are not inert and can potentially stress cells/deplete cellular resources. Evidence for this was provided as TurboID-expressing worms were developmentally delayed, although this was not observed in miniTurboID-expressing worms; the reasons for these differences are unknown. It is possible that split TurboID would obviate some of these issues.

Reactive Ubiquitin Analogs

Another recent innovation aimed at mapping the cellular interactome exploits the enzymatic formation of acylphosphate intermediates on ubiquitin-like small protein domains, namely, prokaryotic ubiquitin-like protein (PUP) (Pearce et al., 2008) and Nedd8 in eukaryotes (Kamitani et al., 1997). PUP and Nedd8, upon activation by specific enzymes, PafA and Ubc12, respectively, form acylphosphates. By fusing proteins capable of forming PUP-acylphosphate or Nedd8-acylphosphate to a POI, proteins that associate with the POI have been identified. Since Nedd8 is an endogenous modification process in cultured mammalian cells, evaluation of the specificity of the tagging process is more complex than PUP. Furthermore, it remains unknown how elevated Nedd8-modification of individual proteins may impinge on native signaling/protein-association networks.

An extension to the Nedd8 approach has also been applied to identification of ligand—protein interactions. In this case, SNAP tag, an epitope tag that reacts irreversibly with a benzyl guanidine (Hill et al., 2016), was fused to an engineered Nedd8-conjugating enzyme Ubc12 that is capable of conjugating a biotinylated Nedd8 to proximal proteins. When a benzyl guanidine tag was fused to a small molecule of interest, such as Dasatinib, a Bcr-Abl/Src kinase inhibitor, known binders of Dasatinib were modified by Nedd8.

The PUP-based method can identify interactions that are very low affinity *in vitro* (maximum $K_d \sim 250\,\mu M$). Cell-based studies focused on the interactome of membrane proteins including CD28 (Liu et al., 2018a). Critically, modification by PUP was exclusively at lysine. Furthermore, several new interactions were identified, and these interactors were dependent on the presence of the CD28 C-terminal tail (**Figure 3C**). The experiments were carried out over a period of 24–36 h, timescale to similar to those used in Bio-ID.

The PUP/Nedd8 methods have strengths and weaknesses similar to Bio-ID as the intermediate formed is an acylphosphate (similar to the acyl-AMP intermediate Di Sabato and Jencks, 1961) and the protein turnover mechanism and kinetics may be similar. However, it is noteworthy that acylphosphate half-lives are variable in solution and biological systems (being dependent

likely on enzymatic and metal-catalyzed hydrolysis, to name two variables Di Sabato and Jencks, 1961; Parvez et al., 2018). Thus, careful considerations must be placed on the cellular backgrounds used when comparing the half-lives/diffusion distances of these systems. Although a similar concern applies to phenoxy radicals, such as are generated by APEX, the interaction preferences and modes of interaction/destabilization are different between acyl phosphates and radicals (Parvez et al., 2018). Thus, factors affecting longevity, diffusivity and off-target interactions are likely different between the methods. Interestingly, although both Bio-ID and PafA are ATP-hydrolyzing proteins whose kinetics are readily assessable *in vitro*, these have not been quantitatively compared. It has been shown that PafA is more readily auto PUPylated than BirA is auto-biotinylated (Liu et al., 2018a), but these outputs could be dependent on multiple factors not necessarily intrinsically linked to the activities of the enzymes.

There is also a significant difference in sizes between Nedd8/PUP and biotin. These differences clearly affect several biophysical aspects of the reactive intermediates, including: (1) the diffusion properties of the two molecules (diffusion distances decrease rapidly in cells as a function of size Parvez et al., 2018); (2) how the modified proteins may behave, in terms of association and stability over the long duration required for the experiment; (3) how the cell is affected; (4) the intrinsic reactivity biases of each probe; and yet (5) mean that for Nedd8/PUP both the activating protein AND the substrate's locale can be controlled to zero-in on associations/effects in specific locales.

Finally, it is noteworthy that immediately post synthesis, PafA is able to activate PUP and label interacting proteins. Maturation of T cells (and T-cell receptors, such as CD28) is complex (Wucherpfennig et al., 2010), and it is unknown precisely where upon this maturation process PUP is most readily able to label the CD28 interactome. Almost certainly, PUP is available at the membrane surface where CD28 ultimately resides, but it is unknown if PUP is present at points along the CD28 maturation process. Furthermore, because the dwell time of CD28 is relatively short during its maturation compared to its final localization (Stoops et al., 2015), and PUP-IT is relatively slow to label proteins, it is likely some chaperones are missed even if PUP were to be available at all points along the maturation pathway. APEX, with its faster labeling kinetics and small molecule substrate would likely be able to ID more potential interacting proteins (especially from locales where CD28 does not ultimately reside), especially if used in conjunction with inhibitors. Of course, unlike the small molecule substrate of APEX, PUP can be specifically targeted to specific locales along the CD28 maturation pathway. For instance, attempting to ID CD28 associating proteins using cells expressing ER-localized PUP, would illuminate "only" ER-specific interactors, provided PafA and PUP are functional in the ER.

Other Reactive-Molecule-Based Methods and Extensions

Other reactive-molecule-generation methods have recently been disclosed that function similarly to those discussed above, such as reactive N-arylation by N-acyl transferases (Kleinpenning et al., 2018). Although, so far these new techniques have not particularly expanded the repertoire of reactive molecule-based probes, they do have different requirements/cofactors needed for activity. Thus conditions where deployment of these probes is more informative than APEX and BioID may thus not yet have been discovered/assayed. Extensions to APEX and BioID have focused on trying to extract more data from the labeling reactions than simple protein ID using BioID and APEX (Udeshi et al., 2017; Kim et al., 2018). The logic of these extensions goes that a more detailed idea of the interaction region can be gained using such strategies. However, in order for such experiments to work well, the resolution would have to be less than the size of a protein domain 2–5 nm—a scenario unlikely to be easily achievable based on reported diffusion distances (Parvez et al., 2018). There would also have to be assumptions that all residues react equally with these high-energy probes.

COMPARISON WITH CLASSICAL METHODS TO UNDERSTAND LOCALIZATION AND ASSOCIATION

Protein localization is a critical parameter governing protein function. For instance, many proteins gain new associations, or functions upon translocation leading to important cellular responses. In some cases, the amount of translocation or partitioning of a protein between different organelles can be minimal. For instance, only a 2- to 3-fold *increase* in nuclear RNR-α levels can elicit suppression in DNA synthesis (Fu et al., 2018). Whether such small fold changes could be reliably detected by APEX localization studies and similar methods, in our opinion, remains to be conclusively proven.

The question of where proteins localize has been studied traditionally by immunofluorescence (IF) and fractionation. Both methods are powerful and often give consistent outcomes. These methods are ostensibly quantitative and so in principal can give an idea of relative amounts of protein in one locale over another and can measure even quite small changes.

However, it is worth remembering that traditional methods tend to suffer from limited spatial resolution and low sensitivity. This is for a number of reasons. First, both readouts are typically made by antibodies, so validating specificity through the use of clear controls (knockout/siRNA) are important and in reality in IF and western blotting, background labeling can limit signal to noise. Both methods suffer from intrinsic artifacts: for IF fixing can affect protein localization antigen presentation, whereas use of fluorescent proteins can affect target protein localization; during fractionation proteins can leak from membranes or there can be contamination from unintended structures. Thus, in our opinion at least, perhaps the biggest improvement that reactive labeling methods bring to localization studies is the ability to couple an unambiguous readout (MS) to stringent tagging protocol that is strongly spatially restricted.

There is estimated to be 650,000 protein-protein interactions (PPIs) in human cells, although this number reflects only a fraction of a percent of the total number of possible pairwise interactions (Stumpf et al., 2008). There are likely many more

possible associations when one considers protein-DNA/protein-RNA interactions and non-degenerate higher order complexes. Many of these PPIs are robust, with relatively long half-lives and K_d's in the nanomolar range. Such interactions can be readily assessed by classic methods such as co-IP, native gel, or 2D-PAGE gels. These methods have benefits in that they can be carried out in native cells, tissue, etc. However, requirement for lysing of the cells can introduce artifacts due to dysregulation of cellular compartmentalization, allowing interactions that do not happen in the cell to occur (Fu et al., 2018), or loosing weaker interactions (French et al., 2016). Weaker/more transient associations can be studied by semi-classical methods such as cross-linking (either chemical or UV). Crosslinking methods have the benefit of "trapping" the complex in the cell, prior to lysis, giving more confidence of cellular relevance, and eliminating the possibility of post lysis association. However, the use of reactive cross-linkers also potentially brings in possibilities of off-target cross-linking, can perturb cellular homeostasis, can mask epitopes, and may not be compatible with other transformations/experimental protocols. The reaction products of cross-linking experiments are also complex aggregates that require extensive verification and (typically) excellent antibodies that have been rigorously validated. However, oftentimes protein complexes/aggregates can be resolved using SDS-PAGE, allowing for identification of hetero/homo-dimers and/or higher-order aggregates to be assigned with reasonable accuracy (Aye et al., 2012).

Even though post-lysis associations are minimized by cross linking, there is little information offered concerning where in the cell this association occurs. This can be addressed by imaging experiments. Fluorescence colocalization of FP, or otherwise tagged proteins, or immunofluorescence has been used to visualize associations in live cells (Pedley and Benkovic, 2017), as has FRET (Kenworthy, 2001) and similar methods (Coffey et al., 2016). The use of proximity ligation (Fredriksson et al., 2002; Bellucci et al., 2014), which is read out via immunofluorescence on fixed cells, is also increasing. This method uses DNA-tagged antibodies that when in "close" proximity (40 nm) can template a rolling PCR reaction, allowing for puncta to be observed in specific cellular compartments where an association occurs. This method is signal amplifying, and hence very sensitive. However, since the distance covered (40 nm) by this method is much larger than most proteins, resolution is likely insufficient to "prove" a "direct" interaction.

There are numerous genetic methods to probe PPIs. The most commonly investigated method is the yeast-2-hybrid (Y2H) assay (Vidal and Fields, 2014). This method uses a split transcription factor one terminus of which is fused to a bait protein, and the other terminus of which is typically fused to a series of test proteins. Pairwise combinations of the bait and each test construct are expressed in yeast. When the bait and a test protein interact, the split transcription factor is able to form a viable protein, and typically drives transcription of a gene required for survival, such that only cells expressing proteins that interact with the test protein survive. Aside from the requirement to use ectopic protein and the fact that the native proteins are not used, criticism has been levied at this method because yeast is not a similar environment to human cells in terms of complexity, organelle structure and the posttranslational modifications it is capable of. Interactions must also happen in the nucleus. Furthermore, many Y2H methods are based off a 2 micron-plasmid system (Chan et al., 2013) that gives high expression of each protein, which "may" provide false positives. However, false positives are clearly not as detrimental as false negative, which are also abundant due to incomplete coverage of screening libraries, incomplete expression and poor folding. The use of autosomally replicating sequence-containing plasmids can also alleviate the issue of high protein expression/high copy number (Newlon and Theis, 1993).

Y2H has been extended to mammalian cells, where more complex modifications are possible, but many of the same issues remained, and the library generations are arguably more complex. Non-allelic non-complementation is a screening method that looks for unexpected non-complementation (i.e., where a cross of two strains with mutations to different genes do not give viable offspring) and can be carried out in numerous organisms (Firmenich et al., 1995; Rancourt et al., 1995; Yook et al., 2001). The likely explanation for such an effect is that proteins reside in the same pathway, and commonly these proteins form a complex that is so depleted in the double heterozygote complementation is not possible. Although this is clearly an indirect assay, it has proven very informative and variations of this assay have been used to uncover interesting aspects of cancer biology (Davoli et al., 2013). Aside from these in-cell-relevant experiments, phage display has also been used for HT-protein protein interaction screening (Gibney et al., 2018). This method is of course sensitive and accurate. However, it lacks the ability to be employed in cells (Kokoszka and Kay, 2015).

Chemotype Specific Sensing and Signaling: REX Technologies

REX technologies developed by our laboratory were ultimately aimed at studying the signaling function of reactive electrophilic species (RES) in living systems with individual-protein specificity and in precise space and time (**Figure 4**) (Fang et al., 2013; Lin et al., 2015; Parvez et al., 2015, 2016; Long et al., 2017a,b, 2018a; Hall-Beauvais et al., 2018; Surya et al., 2018; Zhao et al., 2018). The method uses custom-designed bi-functional small-molecule probes [such as Ht-PreHNE for controlled release of a native electrophile 4-hydroxynonenal (HNE)]. One terminus of the probe binds HaloTag irreversibly by virtue of a pendant alkylchloride function. The other end of the bi-functional probe delivers a payload of a specific reactive electrophilic species, e.g., HNE, upon light illumination ($t_{1/2}$ of release for various enals/enone-derived electrophiles, < 1 min) (Lin et al., 2015). Upon RES liberation, sensor proteins responsive to a given RES have to rapidly intercept the RES prior to diffusion and/or degradation/metabolism (Liu et al., 2019). Thus, the concept underlying REX technologies is unusual in that it harnesses intrinsic "reactivity/affinity-matching" between the released ligand and (a) POI(s) (Long and Aye, 2016, 2017; Long et al., 2016, 2017c; Parvez et al., 2018; Poganik et al., 2018; Liu et al., 2019). HaloTag-targetable photocaged probes such as Ht-PreHNE (1–20 μM)

are tolerated by cells for > 2 h, and worms/developing fish for several days (Parvez et al., 2016; Long et al., 2017a,b, 2018a; Hall-Beauvais et al., 2018; Surya et al., 2018; Zhao et al., 2018). Ht-PreHNE does not affect DNA damage response, ubiquitination, and several other essential processes in cells and fish (Parvez et al., 2016; Long et al., 2017a,b; Zhao et al., 2018).

We discuss below two different REX technologies, as well as potential or yet-unnoticed shortcomings of the method.

T-REX: Target-Specific Reactive Small-Molecule Sensing and Signaling

T-REX (**Figure 4A**) uses a HaloTag-POI fusion to give the specific POI first refusal for the RES (e.g., HNE) photouncaged from Halo (Fang et al., 2013; Lin et al., 2015; Parvez et al., 2015, 2016; Long et al., 2017a,b, 2018a; Hall-Beauvais et al., 2018; Surya et al., 2018; Zhao et al., 2018). In this way, a specific POI, providing it is HNE-sensitive, can be HNEylated in the backdrop of a largely unperturbed cell. T-REX gives relatively high RES-occupancy of a specific POI, but incurs very little RES-modification/stress of the total proteome (Parvez et al., 2016; Long et al., 2017a,b; Zhao et al., 2018). Thus, T-REX is also a highly spatially-restricted method and has proven to be compatible with numerous other chemical biology/genetic techniques. Finally, because individual POIs are modified, functional downstream responses elicited as a consequence of specific POI—RES interaction can be read out. Interestingly, proteins that are appreciably modified by HNE under T-REX tend to undergo phenotypically-dominant effects as a consequence of substoichiometric-HNEylation (Lin et al., 2015; Parvez et al., 2015, 2016; Long and Aye, 2017; Long et al., 2017b; Zhao et al., 2018). Thus, T-REX has established that some proteins are wired to react rapidly with HNE and to modulate signaling at fractional occupancy. We have dubbed such proteins privileged first responders (PFRs) (Long and Aye, 2017; Parvez et al., 2018; Poganik et al., 2018; Zhao et al., 2018; Liu et al., 2019). Using T-REX, HNEylation, at individual protein-specific levels, has been shown to impact numerous critical signaling subsystems and pathway intersections, including ubiquitination (Zhao et al., 2018) and phosphorylation (Long et al., 2017b).

The POI-specific nature of T-REX renders the method not particularly high-throughput. G-REX (vide infra) (Zhao et al., 2018) can assume this role if it is needed. Critically, because T-REX uses ectopic expression, RES-labeling and downstream signaling require the HaloTag protein to be fused to POI; and expressing the POI and HaloTag separately and replicating T-REX in this "split" control system ablates both the POI RES-modification and signal propagation downstream (Lin et al., 2015; Parvez et al., 2015, 2016; Long et al., 2017b). Similar controls were recently introduced and shown to be effective for APEX2 (Ariotti et al., 2015, 2018). We have also identified point mutants that are enzymatically or functionally active but do not sense the RES delivered under T-REX conditions (Long et al., 2017b; Surya et al., 2018; Zhao et al., 2018). Notably, these mutants are also refractory to downstream signaling changes induced upon T-REX (Long et al., 2017b; Surya et al., 2018; Zhao et al., 2018).

T-REX has found application to several model organisms, such as *C. elegans* and larval zebrafish (Long et al., 2017b, 2018a; Hall-Beauvais et al., 2018; Zhao et al., 2018). G-REX has as yet not been so applied. T-REX was used in fish embryos to study the effects of HNEylation of two different sensor proteins, Ube2V2 (Poganik et al., 2018; Zhao et al., 2018) and Akt3 (Long and Aye, 2017; Long et al., 2017b). It was noted that in these systems, expression of the transgenes was similar to that of the endogenous proteins (Long et al., 2017b; Zhao et al., 2018), rendering the systems more "natural" than that in cultured cells where the level of Halo-POI-overexpression was significant. Satisfyingly in both cases, delivery and downstream signaling was observed in zebrafish similarly to cell culture. However, because of the implicit requirement of UV-light that is poorly tissue-penetratable, whole organism studies with T-REX on, for instance, mice or adult fish, are not yet possible. This current limitation would not restrict use in certain organs like the brain or blood, however. Two-photon-based photocages would render REX technologies more broadly compatible and would also lower the overall impact of the method on UV-sensitive molecules/processes, such as DNA-synthesis/repair and RNA regulation.

G-REX: Genome-Wide Assay for Protein Reactivity With Specific Electrophiles

G-REX (**Figure 4B**) was established to address limitations underlying with the existing RES-sensor profiling strategies, which rely upon high doses of reactive covalent chemicals for long periods of time. Such flooding strategies tend to incur significant off-target effects due to mass action. These approaches, although they likely achieve high occupancy and modification of multiple potential targets, also affect physiology through, for instance, perturbing cellular redox environment, and inducing stress and apoptosis. RES-permeability, intracellular distribution, metabolism, and specific subcellular redox environments, etc., altogether render the consequences of cell treatment by a reactive molecule such as HNE highly context dependent.

G-REX is designed to release a small, defined pulse of (alkyne-functionalized) RES [e.g., ∼5 μM of HNE over 2–5 min in HEK293T cells with ubiquitous Halo expression (Zhao et al., 2018)]. Under these controlled conditions, PFRs to HNE are identified. HNEylated proteins are biotinylated by Click coupling with azido-biotin, precipitation, resolubilization, and streptavidin enrichment followed by mass spectrometry. Using this approach, several PFRs to HNE, including Ube2V2 and Ube2V1, were identified as well as numerous known HNE sensors. Importantly, any enriched hits from G-REX can be validated for HNE-sensing and HNEylation-specific signaling function using T-REX. By contrast, G-REX is not intended to study downstream signaling.

Using G-REX—T-REX coupled strategy, Ube2V2 and Ube2V1 were validated to be HNE-sensitive and modification impact respective signal propagation downstream (Zhao et al., 2018). Several biochemical methods further document these findings. Thus G-REX is an unusual strategy in that it is a global method that aims to achieve only low-occupancy on-target proteins (Liu et al., 2019). Its spatial resolution is currently unknown, although HaloTag itself has been successfully localized

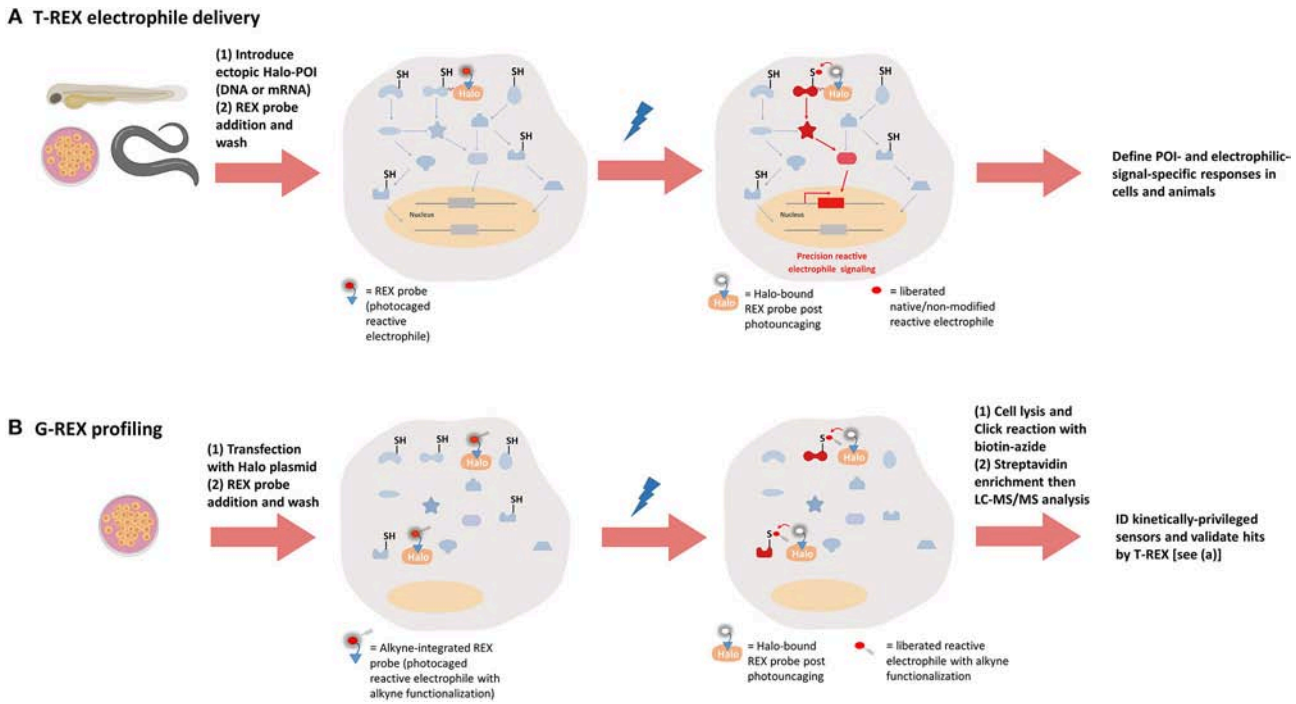

FIGURE 4 | REX technologies to interrogate precision electrophile signaling (T-REX) and mine kinetically-privileged sensors (KPSs) to specific reactive electrophilic species (RES) (G-REX). **(A)** T-REX electrophile delivery. A functional Halo-POI fusion protein is expressed either transiently or stably in live cells, worms, or larval fish. Treatment of these living models with a bio-inert REX probe [photocaged-RES (with or without alkyne functionalization)] (1–25 μM, 1–2.5 h, depending on the system) results in stoichiometric covalent binding of the probe to Halo. After several rounds of exchange with fresh growth media/buffer containing no probe (to washout the unbound REX probe), light exposure (1–3 min, 365 nm, 0.3–5 mW/cm^2, depending on the system) liberates a specific RES of choice (with or without alkyne-modification) within the microenvironment of Halo-POI, thereby giving the POI the first refusal to the RES. Labeling occurs provided the POI is a KPS of this RES. Provided the resulting substoichiometric RES-modification of the POI is sufficient to elicit either gain-of-function or dominant-loss-of-function signaling responses, T-REX presents a unique means to directly link target-engagement to function. [We define such sensors that can elicit dominant responses at low-occupancy as privileged first responders (PFRs)]. When the alkyne-modified version of the probe is used, the magnitude of measured responses can be quantitatively correlated with the POI-target-occupancy (by fluorescence-gel-based analysis following Click coupling of the alkyne-functionalized-RES-modified-POI with an azido-fluorophore). **(B)** *G-REX profiling.* G-REX enables genome-wide direct ID of KPSs under controlled and RES-limited conditions. Cells ectopically expressing HaloTag-protein are treated with the same REX probe used in T-REX (but the alkyne-modified version) under conditions similar to those deployed in T-REX. Without fusing Halo to any proteins, G-REX approach that allows for user-defined time-, dose-, and locale-controlled release of a specific RES is set to directly capture (localized) native sensors (i.e., KPSs) most responsive to the liberated RES, at low-occupancy covalent RES-modifications. Cell lysis and click coupling with biotin-azide followed by streptavidin enrichment engender RES-bound KPS(s) to be ID'ed by digest LC-MS/MS. The resultant top hits can be functionally validated using T-REX **(A)**.

to specific subcellular compartments. It remains unknown how diffusive/reactive HNE is, which may intrinsically limit this method's utility to organelle-specific release.

G-REX has several method-specific limitations. First, G-REX only releases a brief and low concentration pulse of RES. Thus, G-REX is a "target-poor" strategy and could potentially miss some privileged sensors. Such issues can be circumvented by repeating experiments numerous (3 or more) times and further integrating quantitative proteomics such as SILAC (Ong et al., 2002) or TMT-labeling (Thompson et al., 2003). However, MS analysis is costly and time consuming and these constraints should be considered when planning/choosing G-REX. To enable target ID, an alkyne-functionalized variant of native RES is used in G-REX. For lipid-derived electrophiles (LDEs), alkyne tagging is minimally (if at all) invasive, although alkynylated versions of many drugs have been successfully deployed for successful target ID (Wright and Sieber, 2016; Parker et al., 2017). Radioisotope tagging or antibody affinity methods present alternatives to alkyne. However, antibodies are much lower sensitivity than alkyne-based Click coupling/enrichment, and radioisotope incorporation may still prove difficult to apply to highly reactive electrophiles, where there is significant background radioactivity, especially given the low occupancy of RES-modification that underlies G-REX. To users' benefit, biotin/streptavidin-based enrichment permits the non-alkynylated electrophile to be used as an "ideal" control for comparison.

VALIDATIONS AND CURRENT LIMITATIONS

REX-probes currently rely on UV-illumination to liberate RES, admittedly for a short period of time and at low-power light sources that the data show does not affect the cell/animal in any appreciable way (Parvez et al., 2016; Long et al., 2017a,b; Zhao et al., 2018). Second, REX-platforms require ectopic expression

of HaloTagged-POI (in T-REX) or HaloTag alone (in G-REX) to enable localization and concentration of probe (e.g., Ht-PreHNE) [and liberated RES (e.g., HNE)]. The effects of HaloTag protein on cellular functions are not clearly known, although HaloTag has been applied to numerous systems with little negative effects reported (England et al., 2015).

Notably, identical modification/signaling outcomes are achieved irrespective of N- vs. C-terminal HaloTagging on the POI in T-REX (Lin et al., 2015; Parvez et al., 2016). This outcome indicates that the origin of HNE-liberation is not particularly relevant to sensing. Thus, it can be inferred that T-REX is mimicking genuinely what happens post entry of the liberated RES into the solvent cage of POI fused to Halo. However, we are still unsure whether solvent cage entry is rate-limiting for POI-modification, and if reorganization may cause unanticipated issues that affect efficacy of for instance, POI RES-sensing, or conformational properties of ligand and POI. These concerns have been partially addressed by assaying *in vitro* relative rates of HNEylation of POIs identified to be highly RES-reactive by T-REX in cells/animals (Long et al., 2017b; Surya et al., 2018; Zhao et al., 2018). All sensors assayed were found to be uniquely HNE-sensitive. T-REX assays on POIs identified through G-REX agree with these conclusions (vide infra).

Third, photocaged probes, such as Ht-PreHNE, may be subject to inherent biases (intrinsic concern for any small-molecule probe). Beyond deploying various REX-technical controls and hypomorphic sensing-defective functional mutants (Long et al., 2017b; Zhao et al., 2018), the *in vitro* and other RES bolus dosing experiments in cells discussed above help assuage this worry (Surya et al., 2018). Improved photocaging strategies are presently being undertaken to further limit the possibility of artifacts.

NON-TETHERED APPROACHES

All the above methods share the unifying theme that a "minor" perturbation to typical signaling pathways occurs. Critically, T-REX and G-REX use an ectopic protein anchor to ensure such a system is maintained as much as possible, i.e., the Halo protein serves in part to allow washout of excess probe, ensuring any probe-specific perturbations of the system (due to the lipid fragment of the probe, for instance) can be removed. Similar techniques using non-localized/tethered probes have been applied to mechanistic analysis and target ID, using dual photocaging (Höglinger et al., 2017). However, in these methods, the photocaged cannot be completely washed away, due to having no probe-anchoring device, such as Halo. Organelle specificity has been instead achieved by chemical means, such as fusing triphenylphosphine to direct the probe to the mitochondria (Wagner et al., 2018), and many pioneering contributions have been made in this arena. The probe concentrations and those of the released lipids are difficult to normalize under these systems, and are likely not readily tunable or comparable between different cells. When using an ectopic protein, as the ectopic protein expression can be calculated, and the amount of precursor on the protein can also be assessed, these values are much more readily normalized. To some extent, the adverse effects of the excess probe and the uncaged species can be circumvented by irradiating specific sections of a cell. However, this approach is restricted to single or a few cell-based analyses.

OUTLOOK

Our aim in this review is 2-fold: to stimulate discussion on the fundamentals of chemical biology methods; and to highlight methods development at the boundary of chemistry and biology with the focus on emerging chemistry-driven perturbation methods that shed light on the biological locale/interactome and signaling consequences. It is at this intersection of biochemical/enzymological and organic chemistry disciplines where we feel chemical biology is most useful and where as a field we need to go. Improvement and further expansion should be built on our better understanding and appreciation of where the field currently is in terms of limitations that it faces and successes it has had, on our conscious and responsible use of methods and understanding of systems to apply them, and on having a firm idea of where the field is going. We strongly believe that chemical biology has the ability to deeply probe complex biological questions but our progress is hampered by reliance on unrealistic models and analogy to former biochemical studies. Using the most relevant model systems will be an enabling step forward in successfully tackling the important problems unsolvable by traditional genetics and biochemistry.

AUTHOR CONTRIBUTIONS

MJCL and XL contributed equally to this work. XL contributed to the creation of all figures and tables as well as manuscript editing and formatting. MJCL drafted the manuscript. YA oversaw the manuscript outline, overall direction and planning. All authors contributed to reference collection, selection and final proof.

ACKNOWLEDGMENTS

Novartis Foundation for Medical-Biological Research (Switzerland); National Centre of Competence in Research (NCCR): Chemical Biology (Swiss National Science Foundation), NIH innovator award (1DP2GM114850), and Swiss Federal Institute of Technology Lausanne (EPFL) are acknowledged for research support. G-REX technology had been filed for patent application by Cornell University (USA). BioRender is used for all figures.

The lipid composition of the cellular membrane plays an important role in a number of biological processes including the binding of membrane-active peptides. Characterization of membrane binding remains challenging, due to the technical limitations associated with the use of standard biophysical techniques and available membrane models. Here, we investigate the lipid binding properties of two membrane-active peptides, VSTx1, a well characterized ion-channel inhibitor, identified from spider venom, that preferentially binds to anionic lipid mixtures, and AA139 an antimicrobial β-hairpin peptide with uncharacterised lipid binding properties, currently in pre-clinical development. The lipid binding properties of these peptides are elucidated using nanodiscs formed by both linear and circularized (sortase-mediated) forms of a membrane scaffold protein (MSP1D1ΔH5). We find that nanodiscs formed by circularized MSPs—in contrast to those formed by linear MSPs—are sufficiently stable under sample conditions typically used for biophysical measurements (including lipid composition, a range of buffers, temperatures and concentrations). Using these circularized nanodiscs, we are able to extract detailed thermodynamic data using isothermal titration calorimetry (ITC) as well as atomic resolution mapping of the lipid binding interfaces of our isotope labeled peptides using solution-state, heteronuclear, nuclear magnetic resonance (NMR) spectroscopy. This represents a novel and general approach for elucidating the thermodynamics and molecular interface of membrane-active peptides toward flat lipid bilayers of variable composition. Our approach is validated by first determining the thermodynamic parameters and binding interface of VSTx1 toward the lipid bilayer, which shows good agreement with previous studies using lipid micelles and liposomes. The method is then applied to AA139, where the membrane binding properties are unknown. This characterization, involved solving the high-resolution structure of AA139 in solution using NMR spectroscopy and the development of a suitable expression system for isotope labeling. AA139 was found to bind exclusively to anionic membranes with moderate affinity (K_d∼low μM), and was found to have a lipid binding interface involving the termini of the β-hairpin structure.

The preference of AA139 for anionic lipids supports a role for membrane binding in the mode-of-action of this peptide, which is also consistent with its higher inhibitory activity against bacterial cells compared to mammalian cells. The described approach is a powerful method for investigation of the membrane binding properties of this important class of molecules.

Keywords: arenicin, VSTx1, nanodiscs, POPC, POPG, cNW9, membrane-active peptide

INTRODUCTION

The composition of the lipid bilayer can have a significant impact on a number of biological processes including the trafficking of soluble proteins, the structure, dynamics and function of integral membrane proteins and the action of membrane-active peptides (Escriba et al., 2008). The latter have emerged as an important class of molecules in the search for novel antimicrobials and ion-channel inhibitors (Zhang et al., 2018). A major limitation in the characterization of membrane-active peptides is the lack of detailed thermodynamic, kinetic and structural information regarding their lipid interactions. Such information can usually be facilitated by biophysical studies in solution (Lee, 2018). Structural characterization of peptides is traditionally conducted using nuclear magnetic resonance (NMR) spectroscopy (Klint et al., 2013), while membrane-binding assays are most commonly conducted using a combinations of chromatography and fluorescence methods (Deuis et al., 2016) or surface plasmon resonance analysis (Hodnik and Anderluh, 2013). Thus, structural details of the binding of membrane-active peptides to lipid bilayers is often only available at very low resolution, hampering efforts to elucidate their mode-of-action. High-resolution structural data is often difficult to obtain by X-ray diffraction methods due to difficulties in crystallization of peptide-lipid complexes. Solid-state NMR is often the only method to study these systems at atomic resolution, although the analysis of such data is often challenging and time-consuming (Mani et al., 2006). Solution-state NMR experiments can with relative ease provide high-resolution information about binding interfaces, although such studies have been limited to use of detergent and/or lipid micelles or bicelles as membrane mimetics (Warschawski et al., 2011; Lau et al., 2016). These models do not accurately reflect the geometry of the cell membrane, in particular they have a significantly higher curvature, which can cause peptides to adopt non-native conformations, or to aggregate (Catoire et al., 2014).

Lipid bilayer nanodiscs (ND) have been developed to solubilize and reconstitute membrane proteins in lipid bilayers, and their use is rapidly expanding (Bayburt et al., 2002; Shaw et al., 2004). NDs are self-assembled soluble particles (from ∼10 to 50 nm in diameter), where each particle consists of two membrane scaffold proteins (MSPs), derived from human apo-lipoprotein I that is wrapped around a flat phospholipid bilayer. NDs are increasingly being used in biophysical studies, typically for structural studies of membrane proteins and binding interaction studies of lipophilic ligands or ligands that interact with membrane proteins (Hagn et al., 2013; Shenkarev et al., 2014). Recently, a variant of NDs has been described where the *N*- and *C*-termini are ligated via a peptide bond using sortase enzymes (Nasr et al., 2017; Yusuf et al., 2018)–circularized nanodiscs referred to as cNDs hereafter.

A significant advantage of (c)NDs is in their modularity. Different compositions of synthetic phospholipids can be encapsulated, and these soluble discs can then be studied under a range of solution conditions (pH, temperature, salt etc.). It is often possible to incorporate specific lipid compositions and obtain homogeneous NDs (Lee et al., 2015; Yeh et al., 2016). In particular, we are here interested in studying the binding of membrane-active peptides that have shown activity against anionic lipid bilayers mimicking those of Gram-negative bacteria. We employ heteronuclear NMR experiments using isotope labeled peptides to map the lipid binding interface of these peptides at atomic resolution. In these experiments, the nanodisc is unlabelled and therefore remains undetected. To ensure that these discs remain stable under the conditions of typical NMR experiments we have conducted a detailed study of the solution characteristics and stability of linear and circularized NDs containing mixtures of POPC and POPG.

The stability of the NDs were evaluated by size-exclusion chromatography (SEC), electron microscopy (EM) and mass spectrometry (MS), under different storage conditions with variable buffer (pH), temperature and concentration. While non-circularized NDs containing anionic lipids were shown to be poorly stable, excellent stability was found when using the cNDs. The latter was then used for solution-state biophysical studies to investigate the lipid binding interactions of two peptides that are known to exert their function in anionic lipid bilayer environments.

To determine the binding of these membrane-active peptides to model membranes of Gram-negative bacteria in NDs, we first studied the well characterized spider toxin, VSTx1, isolated from the venom of *Grammostola spatulata*. In previous studies using centrifugation coupled with chromatography, the peptide has been shown to partition into liposomes containing mixtures of POPC and POPG, but these studies did not find partitioning of the peptide into liposomes containing only zwitterionic POPC

Abbreviations: Nanodisc, ND; circular MSP1D1ΔH5, cNW9; linear MSP1D1ΔH5, dH5; antimicrobial peptides, AMPs; membrane scaffold protein, MSP; protein databank, PDB; dodecylphosphocholine, DPC; 1,2-dimyristoyl-sn-glycero-3-phosphocholine, dodecyl-β-D-maltoside (DDM), decyl-β-D-maltoside (DM), DMPC; 1,2-Dimyristoyl-sn-glycero-3-phosphorylglycerol, DMPG; palmitoyloleoyl-phosphatidylcholine, POPC; palmitoyloleoyl-phosphatidylglycerol, POPG; size exclusion chromatography, SEC; electron microscope, EM; mass spectrometry, MS; chemical shift perturbation, CSP; polymerase chain reaction, PCR.

lipids (Jung et al., 2005; Ozawa et al., 2015; Lau et al., 2016). The peptide was, however, found to bind to zwitterionic DHPC (and DM) micelles in NMR studies (Lee and Mackinnon, 2004; Wang et al., 2018).

Here, we first measured the thermodynamics of the binding of the peptide against cNDs using isothermal titrations calorimetry (ITC) experiments. We then mapped the lipid binding interface of the peptide using chemical shift mapping experiments by analysis of, 2D ^{1}H-^{15}N-HSQC, solution-state NMR experiments. Our results show very weak binding of the peptide to POPC bilayers in cNDs–much weaker than that observed when using DHPC micelles. In contrast, the peptide binds very strongly to anionic cNDs, consistent with the previous liposome experiments, suggesting that the binding of the peptide to micelles is different than to bilayers.

Next, the described approach was applied to an antimicrobial peptide, AA139, currently undergoing preclinical trials for the treatment of Gram-negative bacterial infections. AA139 is an analog of arenicin-3, a peptide antibiotic that was originally identified as part of a group of broad-spectrum antimicrobial peptides isolated from the lugworm *Arenicola marina* by *Novozymes* (Novozymes A/S Copenhagen). The mode-of-action of this peptide remains unknown; however, the related arenicin-2 peptide was shown to form pores in planar lipid bilayers, suggesting a cytotoxic mode-of-action (Shenkarev et al., 2011). A bacterial expression system was developed for recombinant expression and labeling of the peptide. To map the binding interface of the peptide, the structure of the peptide was also solved in solution by standard NMR methods, revealing a twisted β-hairpin fold, common in this family of peptides. The biophysical data (EM/NMR/ITC) show that AA139 does bind to anionic cNDs but does not form pores, suggesting a different mode-of-action to arenicin-2 (Shenkarev et al., 2011).

The presented approach provides a platform for measurement of both thermodynamic and structural data for membrane-active peptides using a planar bilayer system, using standard NMR experiments. The flexibility and stability of the cNDs as a model system promises to improve our understanding of this important class of molecules.

MATERIALS AND METHODS

Materials

The construct for the evolved pentamutant of Sortase A in a pET29 vector was a gift from Prof. David R. Liu's laboratory (Harvard University). Expression and purification of the pentamutant Sortase A from *Escherichia coli* BL21(DE3) cells was performed as previously described (Chen et al., 2011). The construct for MSP1D1ΔH5 (dH5 hereafter) in a pET28a vector was a gift from Prof. Gerhard Wagner at the Harvard Medical School. Using NEB Q5 Site-Directed Mutagenesis Kit (New England BioLabs, NEB), a DNA sequence encoding LPGTGAAALEHHHHHH was appended into the end of the encoding sequence for MSP1D1ΔH5 construct to create the NW9 construct. Synthetic lipids, palmitoyloleoyl-phosphatidylcholine (POPC) and palmitoyloleoyl-phosphatidylglycerol (POPG), in powder form were purchased from Avanti Polar Lipids (Alabaster, AL). These were resuspended in chloroform and dried by nitrogen flow and vacuum overnight to a thin layer in glass tubes. Lipid stocks were sealed and left at −80°C for long-term storage.

Peptide Expression and Purification

Isotopically single labeled ^{15}N-VSTx1 was expressed and purified as previously described (Lau et al., 2016). A synthetic AA139 gene was introduced into both a pOPINE vector (Berrow et al., 2007) and a pLIC vector (Klint et al., 2013), containing a SUMO and MBP fusion tag, respectively. Initial expression tests show that soluble AA139 was only overexpressed when using the pOPINE expression vector with a SUMO tag. Subsequently we also screened the expression of VSTx1 in a similar N-terminal SUMO-tagged fusion expression vector (unpublished), which also produced high soluble protein yields (∼0.5 mg per liter of culture). Recombinant ^{15}N-AA139 was expressed as a His_6-tagged SUMO fusion protein in *E. coli* (SHuffle T7 strain cells–NEB cat. C3029J) using standard biochemical methods. Details of the expression and purification methods are provided in the **Supplementary Information**.

NMR Structure of AA139

1D ^{1}H NMR experiments were recorded at different pHs and at pH 3.3 all non-exchangeable backbone amide protons could be observed. The spectra at pH 3.3 and 6.5 were superimposable indicating that the structure is unaffected by the change in pH. Subsequently, 2.5 mM synthetic AA139 (provided by Adenium) was analyzed in 20 mM phosphate buffer at pH 3.3 containing 5% D_2O. All NMR experiments were performed on a Bruker Avance III spectrometer equipped with a cryogenically cooled triple resonance probe operating at a nominal ^{1}H frequency of 700 or 900 MHz. The excitation sculpting sequence was used to suppress the solvent (H_2O) resonance. Two-dimensional TOCSY [t_m (MLEV17 spin-lock mixing pulses) = 80 ms], NOESY [t_m (mixing time) = 300 ms], ^{15}N-HSQC and ^{13}C-HSQC were recorded at 25°C. Chemical shifts were directly (for ^{1}H) or indirectly (for ^{13}C, ^{15}N) referenced relative to the 2, 2-dimethylsilapentane-5-sulfonic acid (DSS) signal at 0 ppm. The assignment of proton resonances was carried out using TOCSY and NOESY data using the CCPNMR software (Skinner et al., 2015). Torsion angles constraints were obtained using the TALOS+ software (Shen et al., 2009), and structure calculations were performed using CYANA 3.0 (Guntert, 2004).

Hydrogen-Deuterium Exchange Studies

All NMR spectra for the hydrogen-deuterium exchange studies were recorded on the spectrometer described above at 25°C. Spectra were referenced to DSS at 0 ppm. Lyophilized peptide was initially solubilized in 20 mM phosphate buffer at pH 3.3. The peptide was then lyophilized and subsequently dissolved in 100% D_2O followed by immediate transfer to the spectrometer for measurement. 1D ^{1}H and 2D TOCSY spectra were recorded at specific time points over a 24 h period. Hydrogen-deuterium exchange rates were measured by integrating each exchangeable amide resonance separately.

Amide Temperature Coefficient Studies

The temperature dependence of amide proton resonances was derived from 1D ^{1}H to 2D TOCSY spectra recorded on a Bruker ARX 500 MHz spectrometer. Spectra were measured between 15° and 35°C, in 5°C increments, and referenced to DSS at 0 ppm. Assignment of the spectra was performed using the CCPNMR software (Skinner et al., 2015).

NW9 Circularization

NW9 protein expression and purification followed standard procedures and is described in detail in the **Supplementary Information**, yielding 20 ± 5 mg of NW9 per liter of LB media. NW9 after TEV protease cleavage was buffer exchanged into the reaction buffer (20 mM Tris·HCl pH 7.5 and 150 mM NaCl) and then supplemented with 1 mM dodecyl-β-D-maltoside (DDM), 1 mM 2-mercaptoethanol and 10 mM $CaCl_2$. 1:2 molar equivalents of evolved 5'-1' pentamutant Sortase A and NW9 were mixed and diluted to a total protein concentration of 15 μM. The reaction was left stirring for > 3 h at room temperature, for complete cyclisation of NW9 to cNW9. Subsequently, SM-2 Biobeads (Bio-rad) at 1 g/100 ml of reaction mixture were added to remove the detergent DDM from the reaction mixture. After incubation of 1 h of detergent absorption, the reaction mixture was filtered on a 0.45 μm polyethersulfone (PES) membrane and loaded into two 5 mL HisTrap Fast Flow Ni(II) columns (GE Healthcare) pre-equilibrated with reaction buffer to remove histidine tagged products including Sortase A, TEV protease and cleaved histidine tags. The flow-through containing cNW9 was collected and buffer exchanged to buffer A_{ex} (20 mM Tris·HCl pH 7.5, 1 mM DDM). The sample was purified and fractionated by anion-exchange chromatography using a HiScreen Q HP Column (GE Healthcare) using liquid chromatography (AKTAPurifier, GE Healthcare). After sample loading a linear gradient from 0 to 80% buffer B_{ex} (20 mM Tris·HCl pH 7.5, 500 mM NaCl, 1 mM DDM) was applied for 40 column-volumes.

ND Production

To assemble NDs, dH5 or cNW9 and lipids were co-dissolved at [lipid]:[MSP] ratio of 50:1 in reconstitution buffer (20 mM Tris·HCl pH 7.4, 100 mM NaCl, 0.5 mM EDTA and 100 mM cholate) and mixed for 1 h at 4°C. A molar ratio of 1:50 (MSP:lipids) was calculated using the equation: $N_L \times S = (0.423 \times M\text{-}9.75)^2$, where N_L is the number of lipids per ND, M is the number of amino acids in the scaffold protein and S is the mean surface area per lipid used to form the lipid-nanodisc, measured in Å^2 (Ritchie et al., 2009)–POPC and POPG have been estimated to have a similar mean surface area of around 70 Å^2 (Janosi and Gorfe, 2010). Nevertheless, to confirm these calculations for the anionic lipid mixtures a range of MSP:lipid ratios (1:10, 1:30, 1:40, 1:50, and 1:80) were screened to monitor aggregation behavior. SEC chromatography of the assembled discs, showed high monodispersity in the 1:30–1:50 range, while 1:10 and 1:80 ratios produced chromatograms with evidence of high levels of inhomogeneity. Finally, the homogeneity of the lipid mixtures within the discs, was monitored by anion exchange chromatography and the elution profile was found to consist of a single peak, confirming efficient mixing of the lipids within the nanodiscs.

0.6 g of Bio-Beads SM-2 (Bio-rad) was added per mL of reaction volume, to absorb the detergent (cholate), and thus initiating ND assembly. The mixture was gently stirred for 4 h at 4°C for complete detergent removal. The solution was filtered through a 0.45 μm PES membrane to remove the Bio-Beads and then concentrated using centrifugal filtration (Amicon Centricon with a 10 kDa MW cut-off). The sample was buffer exchanged using a PD-10 column (GE Healthcare) into three different buffers: (i) 20 mM Tris·HCl pH 7.5, 50 mM NaCl, 1 mM EDTA; (ii) 20 mM $NaPO_4$ pH 6.5, 50 mM NaCl, 1 mM EDTA; (iii) 20 mM Bis·Tris pH 6.5, 50 mM NaCl, 1 mM EDTA. After buffer exchange of NDs into one of three buffers, samples were concentrated by centrifugal filtration to ∼5 mg/mL (unless otherwise stated) and stored at 4 °C.

Electron Microscopy (EM)

Lipid NDs were diluted to a final concentration of 200 nM in 20 mM Tris–HCl, pH 7.5, 50 mM NaCl and adsorbed to glow-discharged and carbon-coated EM grids. Samples were prepared by conventional negative staining with 1 % (w/v) uranyl acetate. EM images were collected with a Tecnai 12 electron microscope operated at an acceleration voltage of 120 kV.

Liquid Chromatography–Mass Spectrometry (LC-MS)

LC-MS analysis was conducted on lipid nanodiscs using Agilent Technologies 1200 Series Instrument with a G1316A variable wavelength detector set at λ = 210 nm, 1200 Series ELSD, 6110 quadrupole ESI-MS, using an Agilent Zorbax Eclipse XDB-Phenyl column (3 × 100 mm, 3.5 μm particle size, flow rate 1 mL/min, the mobile phases 0.05% formic acid in water and 0.05% formic acid in acetonitrile).

Isothermal Titration Calorimetry (ITC)

The affinities of AA139 and VSTx1 for cNDs (both POPC and POPC:POPG mixtures) were determined using a Microcal iTC200 instrument (Malvern, UK). Experiments were performed in 20 mM Bis·Tris (pH 6.5), 50 mM NaCl and 1 mM EDTA. The peptides (at 350 μM) were titrated into 25 μM cNDs in 15× 2.8 μl (AA139) and 19× 2.2 μl (VSTx1) injections at 25 °C. Considering the symmetry of the cNDs the stoichiometry (n) was fixed at an even integer value (2, 4, 6 etc.). The concentration of the peptide was fixed and the effective concentration of the nanodisc allowed to vary together with the remaining variables. The effective nanodisc concentration was then fixed to the above determined value and all other parameters (including n) allowed to vary in order to determine the dissociation constants (K_d) and enthalpy of binding (ΔH). During the fitting procedure the ITC response was integrated and normalized to a single-site binding model. The apparent binding free energy (ΔG) and entropy (ΔS) were calculated from the relationships $\Delta G = RT\ln(K_d)$ and $\Delta G = \Delta H\text{-}T\Delta S$. All experiments were performed at least in triplicate to ensure reproducibility of the data.

NMR Titration

Solution NMR titration experiments between ^{15}N-VSTx1 and ^{15}N-AA139 and unlabelled cNDs [cNW9 (POPC/POPG (4:1))] were performed on a Bruker Avance III spectrometer equipped with a cryogenically cooled triple resonance probe operating at a nominal ^{1}H frequency of 700 MHz. ^{15}N-HSQC spectra were recorded at 25 °C. The concentration of ^{15}N-VSTx1 or ^{15}N-AA139 were kept constant at 20 and 40 μM respectively, while the concentration of cNDs [cNW9 (POPC/POPG (4:1))] was increased from 0 to 20 μM, with a total of up to six concentrations. A second titration of ^{15}N-VSTx1 against cNDs [cNW9 (POPC)] was conducted under identical conditions to those noted above for this peptide. Each 2D experiment was acquired for ∼ 45 min (16 scans and 75 complex points for AA139, and 32 scans and 37 complex points for VSTx1). All titrations were performed in 20 mM Bis·Tris buffer (pH 6.5), 50 mM NaCl and 1 mM EDTA.

NMR titration experiments between unlabelled VSTx1 or AA139 and ^{15}N-cNDs [^{15}N-cNW9 (POPC/POPG(4:1))] were performed on a Bruker Neo spectrometer equipped with a cryogenically cooled, triple resonance probe, operating at a nominal ^{1}H frequency of 900 MHz, at 50°C. Three experiments were performed, the concentration of cNDs [^{15}N-cNW9 (POPC/POPG (4:1))] was kept constant at 100 μM, while the concentration of VSTx1 or AA139 was increased from 0 to 50 then 100 μM. Each experiment was acquired over 4 h (128 scans and 50 increments).

NMR Data Analysis

All spectra were processed using Topspin (Bruker Biospin) and the Rowland NMR toolkit (University of Connecticut). CCPNMR was used for spectral analysis. The change in peak intensity between titration points is the product of several dynamic processes that occur due to the binding event (for further details see **Supplemental Discussion**). The intensity of the signal is thus attenuated according to the weighted average of the free and bound states of the peptide:

$$I_{obs} = f_F I_F + f_B I_B \tag{1}$$

The change in signal intensity due to this process I_{obs} can be related to the fraction of the peptide bound to the cND:

$$\Delta I_{obs} = f_B \Delta I_{\max} \tag{2}$$

f_B (fraction of the concentration of ligand bound to cNDs over the total ligand concentration- $\frac{[L_B]}{[L_T]}$) can then be fitted to a quadratic equation to obtain estimates of the dissociation constant, K_d, and the number of equivalent binding sites on the cND, n, available for peptide binding (Granot, 1983; Williamson, 2013):

$$f_B = \frac{(n \times [cND_T] + [L_T] + K_d) - \sqrt{\left((n \times [cND_T] + [L_T] + K_d)^2 - 4\,[L_T] \times (n \times [cND_T]\right)}}{2\,[L_T]} \tag{3}$$

where $[L_T]$ is the total ligand concentration (^{15}N labeled peptide), $[cND_T]$ is the total concentration of cND at each titration point, $I_{\max}$ is the normalized maximum intensity change and I_{obs} is the normalized change in signal intensity for a given spin pair and correlates with the mole fraction of peptide bound to the cND. It is assumed that (i) the signal observed is due to free ligand in addition to any residual signal from the bound ligand, due to fast local motion; (ii) at the highest concentration of nanodisc the binding is saturated (i.e., any signal remaining at highest cND conc. belongs to residues having fast local motion). Given the preceding conditions, normalization of the maximum-intensity-change ensures that the change in intensity observed is bounded between the free and saturated state (accounting for fast local motion). This allows us to fit data from all of the HSQC signals simultaneously. However, prior to this global fitting, each residue was fitted individually, those residues that yielded poor fits to the equation (i.e., produced very large fitting errors or negative K_d values) were excluded on the basis that additional processes were dominating the observed signal intensity change (other than chemical exchange due to binding). At this step residues with insufficient valid titration points (i.e., low initial intensity or very rapid decay, yielding fewer than three titration points above the noise level) and those from overlapping residues were removed. For all of the remaining residues a nearly constant value of n was found. The value of n was found to be close to an even integer, which agreed with the symmetry of the nanodisc, and the value of n was subsequently fixed to this nearest even integer value. Once this value was fixed a global fit of all of the data to equations 2/3 was performed. The fitting was performed using a Levenberg-Marquardt iterative non-linear least squares method (in Gnuplot v.3.5).

RESULTS

cNW9 Production

MSP circularization following standard Sortase A reaction conditions (Tris·HCl, NaCl and $CaCl_2$ conditions) (Nasr et al., 2017), led to a low yield of monomeric, cyclised, cNW9 (∼3 mg/l of LB, corresponding to 15% of total NW9 produced). We observed that a large proportion of the reaction products were multimeric by-products (Mei and Atkinson, 2015; Henrich et al., 2017). To improve the yield of monomeric cNW9, we conducted a screen of reaction conditions including (i) temperature, (ii) total protein concentrations and (iii) different detergents/supplements added. Under optimized conditions, the reactions at 4 °C, room temperature and at 37°C were mostly complete in >24, ∼3, and <1 h, respectively. Lowering the total protein concentrations from 30 to 5 μM led to detectable improvements in the fraction of monomeric products. A screening of detergents showed that non-ionic detergents such DM or DDM significantly improved the yield of monomeric cNW9 formed (from ∼3 to ∼6 mg/l of LB; or equivalently from 15 to 30% yield), while ionic detergents such as cholate had minimal effects on the final yield (see **Figure S1A**). Similar improvements in yields (doubling of the yield in presence of detergents) has been independently observed elsewhere using

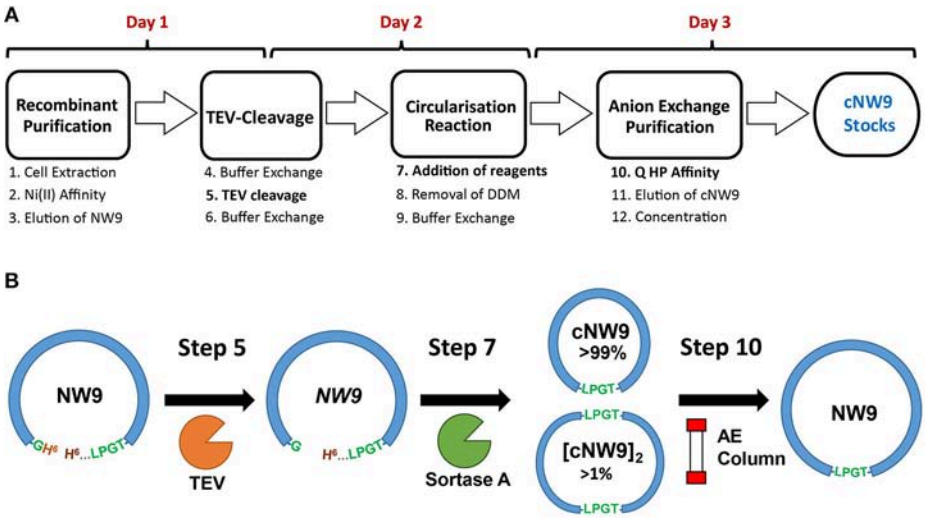

FIGURE 1 | Production and circularization of cNW9. **(A)** Cell extraction of recombinant, noncircular cNW9 (NW9) followed by affinity purification (Ni Sepharose resin) and TEV cleavage (day 1 and overnight). TEV-cleaved NW9 circularization to a circular monomeric product (cNW9) and multimeric by-products ($[cNW9]_n$) mediated by sortase A and assisted with lipid-detergents (day 2). Purification of cNW9 by anion exchange chromatography (Q HP resin) and concentration of protein stocks (day 3). **(B)** Reaction scheme for circularizing NW9 to cNW9 is illustrated with the key components/variants as designated in **(A)** (NW9, TEV, sortase A, anion-exchange column) and annotated with the key reaction steps in **(A)**.

the non-ionic detergent Triton X-100 (Yusuf et al., 2018). In both cases the presence of detergents leads to near-complete removal of multimeric by-products. Following circularization, reverse nickel affinity and anion exchange chromatography, cNW9 is obtained at >99% purity (**Figure 1** and **Figure S1B**). The assembly of the lipid cNDs routinely resulted in a yield of > 80% of pure lipid nanodiscs, regardless of the lipid composition.

Nanodisc Stability Study

Three buffer conditions were chosen for the study of lipid-nanodiscs (ND) following the literature (Shenkarev et al., 2014; Susac et al., 2014) and NMR titration requirements:

(i) 20 mM Tris·HCl pH 7.5, 50 mM NaCl, 1 mM EDTA, a standard buffer-salt condition;
(ii) 20 mM $NaPO_4$ pH 6.5, 50 mM NaCl, 1 mM EDTA, a common NMR condition at a relatively low pH; and
(iii) 20 mM Bis-Tris pH 6.5, 50 mM NaCl, 1 mM EDTA, where the low pH is retained while the favorable conductivity of the Tris based buffer is also retained.

Size-exclusion chromatography (SEC) was performed on ND samples at 5 mg/mL concentration, using a Superdex S200 5/150 *Increase* gel filtration column, pre-equilibrated in 20 mM Tris·HCl pH 7.5, 150 mM NaCl. Samples run over SEC were monitored and assessed for stability (all SEC traces can be found in **Figures S2**–**S5**).

To start, samples were stored at 4°C and monitored by SEC over intervals from day 1 to 30. The SEC profiles for circular cNW9 NDs were always sharper, indicating greater homogeneity of the sample. With the lipid composition consisting solely of POPC lipids, virtually no change in sample profiles was observed for cNW9 or dH5 NDs up to 30 days in the standard buffer condition (i).

cNDs were stable up to 30 days in all buffers tested. However, dH5 NDs in the lower pH conditions of (ii) and (iii) resulted in SEC profiles having an asymmetric peak, with a shoulder at shorter elution times (indicating either unassembled MSP or aggregates) after only 3 days of storage. It should be noted that unassembled MSP elutes earlier than the assembled NDs, indicating a larger effective molecular radius. Under these conditions the phosphate buffer condition (ii) seemed to be slightly worse for stability than the Bis-Tris buffer condition (iii).

The introduction of 20% POPG into the NDs did not affect the stability of cNW9 ND samples at 4°C. However, significant changes in the profile were observed in all buffer conditions for dH5 NDs at 4°C, with the observed effect getting worse from Tris (i) to Bis-Tris (iii) to phosphate (ii) buffer conditions. In the Bis-Tris buffer condition (iii), significant changes in the profile were observed for dH5 NDs at storage temperatures of 25° and 37°C. However, for cNW9 NDs, no changes were observed at either of these temperatures. **Table 1** summarizes our observations, where the sample is deemed unstable if a clear change in the SEC profile can be seen, in particular noting the presence of shoulders or peaks at elution times earlier than that of the main ND peak.

A detailed study was conducted for both constructs of NDs containing POPC/POPG (4:1) in 20 mM Bis-Tris pH 6.5, 50 mM NaCl, 1 mM EDTA using an analytical Supderdex S200 10/300 *Increase* column. Note that this column provides a higher resolution than the smaller S200 5/150 column used in our screening experiments described above (i.e., traces in **Figures S2**–**S5**). At assembly time (day 0), both constructs were analyzed by SEC, using the 10/300 column pre-equilibrated in 20 mM Tris-HCl pH 7.5, 150 mM NaCl (**Figures 2A,B**). The NDs were

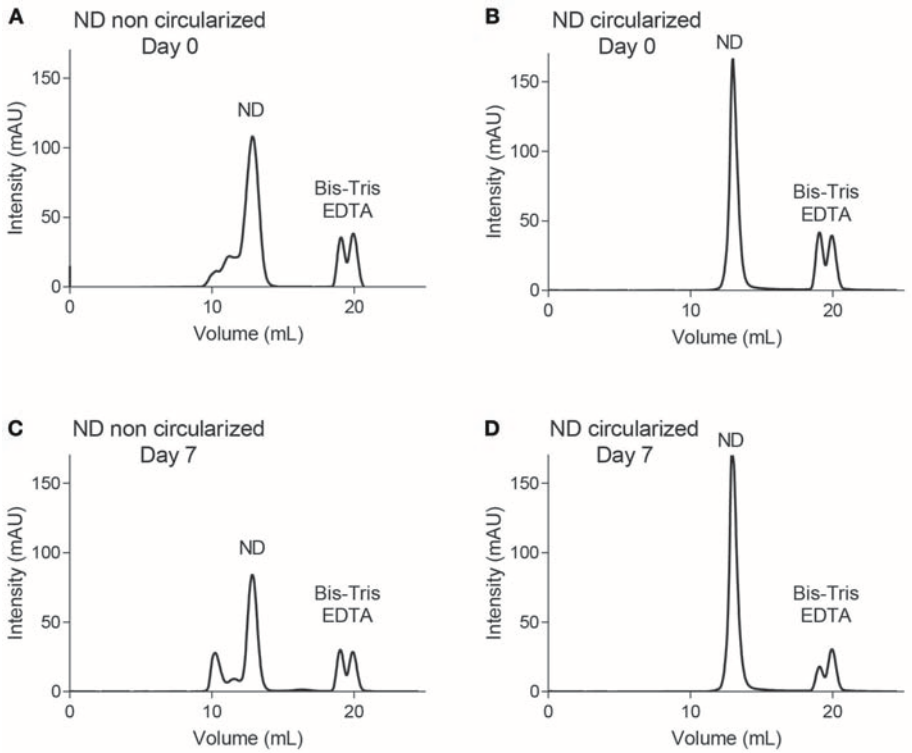

FIGURE 2 | Size exclusion chromatography using an S200 Increase 10/300 column. Traces of NDs containing POPC/POPG (4:1) lipids using membrane scaffold proteins dH5 **(A,C)** and cNW9 **(B,D)** at day 0 **(A,B)** and day 7 **(C,D)** after storage at room temperature.

TABLE 1 | Summary of nanodisc stability under different storage conditions.

Buffer	Temperature (°C)	Days stable/ total days			
		NDs with POPC		NDs with POPC:POPG (4:1)	
		dH5	cNW9	dH5	cNW9
i. 20 mM Tris pH 7.5 *50 mM NaCl and 1 mM EDTA*	4	30/30	30/30	1/30	30/30
ii. 20 mM PO_4 pH6.5 *50 mM NaCl and 1 mM EDTA*	4	3/30	30/30	1/30	30/30
iii. 20 mM Bis-Tris pH6.5 *50 mM NaCl and 1 mM EDTA*	4	3/30	30/30	1/30	30/30
	25	–	–	1/2	2/2
	37	–	–	0/2	2/2
	−20	–	–	2/2	2/2

Circular and linear (cNW9 and dH5) nanodiscs containing either zwitterionic (POPC) or anionic [POPC:POPG (4:1)] lipid mixtures were stored at different temperatures in different buffers (all including 50 mM NaCl and 1 mM EDTA). The stability of the discs was monitored by size-exclusion chromatography using an S200 Increase 5/150 column (GE Healthcare), at daily intervals.

left at room temperature for seven days and reanalyzed via SEC (**Figures 2C,D**). Each fraction was subjected to LC-MS (**Figures S6**–**S7**). Negative stain EM was also performed for selected fractions of NDs [dH5 (POPC/POPG (4:1))], confirming the presence of NDs of increased diameter after 7 days of storage (**Figure S8**). The dH5 ND samples aggregated over time, while no degradation was observed for cNW9 NDs.

Recombinant Peptide Production and Solution Structure Determination

VSTx1 was produced using an MBP-fusion construct as previously described, where the structure of this peptide is also reported (Lau et al., 2016)–yielding ∼1 mg of peptide per liter of bacterial culture. VSTx1 was also produced using a SUMO-fusion construct. The smaller fusion partner further simplified the purification step by HPLC, where MBP would often be present as a significant and difficult to remove contaminant. The SUMO fusion of VSTx1 yielded ∼0.5 mg of pure peptide per liter of culture.

AA139 was expressed in *E. coli* SHuffle cells transformed with a pOPINE-His_6-SUMO-AA139 plasmid vector. The transformed cells were cultivated in minimal medium containing ^{15}N-NH_4Cl. The His_6-SUMO-AA139 fusion protein was obtained in the soluble fraction after cell lysis. Following Ni^{2+} affinity chromatography and cleavage with SUMO protease, AA139 was purified via reversed-phase HPLC. The final yield was approximately 1 mg of ^{15}N-AA139 per liter of culture. The purity and mass were analyzed by LC-MS. The mass of the peptide is 2548.1 g/mol. The experimentally measured m/z values of ^{15}N-AA139 (647.9 [+4], 518.6 [+5] and 432.3 [+6]), match the calculated values (647.8, 518.4 and 432.2). The purity of both peptides was >99% (as measured by HPLC).

TABLE 2 | Thermodynamic parameters for VSTx1 and AA139 binding to cNDs.

Peptide	K_d	ΔH	−TΔS	ΔG	*n*
	μM	*kcal/mol*	*kcal/mol*	*kcal/mol*	
VSTx1	2.02 ± 0.81	−1.92 ± 0.73	−5.88 ± 0.94	−7.80 ± 0.22	2.00 ± 0.20
AA139	1.16 ± 0.28	−6.29 ± 0.61	−1.83 ± 0.75	−8.12 ± 0.16	4.09 ± 0.09

The average and standard deviation of three replicates are presented. Fitted values of the dissociation constant (K_d), enthalpy (ΔH) of binding and stoichiometry (n), as well as the calculated binding free energy (ΔG) and entropy (-TΔS) are reported.

Chemical shifts of the protons of AA139 were measured from 2D ^{1}H–^{1}H TOCSY and NOESY NMR spectra. ^{13}C and ^{15}N shifts were obtained from 2D HSQC spectra (**Table S1** – BMRB ID: 30260). Secondary Hα shifts (**Figure S9**) show that AA139 is composed of two β-strands and a turn forming a β-hairpin structure (Wishart et al., 1995), further supported by hydrogen bonds (see **Tables S2**, **S3**), The chemical shifts were used to predict backbone dihedral angles (TALOS), and were subsequently used in structure calculations. The peptide structure is further stabilized by two disulfide bridges Cys^{3}-Cys^{20} and Cys^{7}-Cys^{16}, these were defined by three upper and three lower distance restraints between the heteroatoms, and included in the structure calculations. The above restraints were supplemented with NOE based distance restraints and the NMR solution structure of AA139 (PDB 5V11), was calculated by torsion angle dynamics (CYANA–see also **Figure S10** and **Table S4**). The two β-strands cover residues Cys^{3}-Arg^{10} and Arg^{13}-Cys^{20}. The β-strands are intervened by a type I' β-turn (Asn^{11}/Gly^{12}) forming slightly twisted anti-parallel β-strands in the β-hairpin structure. The distortion created by the right-handed twist of the two-stranded β-sheet results in an amphipathic structure, commonly observed in membrane interacting peptides.

Peptide-Lipid Interactions by ITC and NMR

cNDs containing a zwitterionic (POPC) or an anionic lipid mixture [POPC:POPG (4:1)] in the above described Tris-Bis buffer (20 mM BisTris (pH 6.5), 50 mM NaCl and 1 mM EDTA–used in all subsequent experiments) were used to study the interactions between the cNDs and the membrane-active peptides (VSTx1 or AA139) by isothermal titration calorimetry (ITC) and NMR. Neither peptide showed binding to zwitterionic cNDs by ITC.

Initial NMR experiments were conducted to find concentration ranges where clear intensity changes could be observed (data not shown). Based on these concentrations, a titration was conducted where the concentrations of uniformly isotopically labeled ^{15}N-VSTx1 or ^{15}N-AA139 was fixed at 20 and 40 μM, respectively, and NMR spectra were acquired in the presence of increasing concentrations of cNDs.

ITC Results

The ITC binding isotherms using anionic cNDs produced results consistent with weak binding in the μM range (**Figure S11**). During the fitting, first the stoichiometry for the binding of VSTx1 to cNDs was determined to be 2 peptides per disc [i.e., other even integer values used produced larger errors, see also Materials and Methods section Isothermal Titration Calorimetry (ITC)]. Using this information, the effective concentration of cNDs in the ITC experiment was determined (4.54 μM). This is roughly 1/5 of the concentration determined by measurement of absorbance at 280 nm from the MSPs, and consistent with the POPG ratio within the discs. The experiment was repeated with different starting concentrations of peptides and nanodiscs, in all cases yielding the same fitted parameters (data not shown). The effective cND concentration determined by the fitting procedure was used for all subsequent modeling, where, instead the stoichiometry was allowed to vary. This yielded a stoichiometry of 4 AA139 peptides to each cND. The ITC data are shown in **Figure S11** and the fitting of these data to the binding isotherm summarized in **Table 2** (see also **Table S5**).

^{15}N HSQC Titrations of VSTx1

^{15}N-VSTx1 at a concentration of 20 μM was titrated in a series against anionic cNDs [POPC:POPG (4:1)] with increasing concentration: 0, 5, 10, and 20 μM (20 mM BisTris (pH 6.5), 50 mM NaCl and 1 mM EDTA). Each of the four samples was then used to acquire a 2D ^{1}H-^{15}N-HSQC experiment. A concentration dependent broadening of the signals was observed (see **Figure 3**). There were also minor chemical shift changes in a concentration dependent manner for signals that experienced significant line-broadening. The fitting was performed as described (see Materials and methods), where the backbone amide of Leu31 was excluded due to a very sharp signal loss leading to insufficient points for fitting (only 2 points above the noise–taken as 3 times the noise level). Glu2, Lys5, Ser13, and Ser24 were completely undetectable under conditions tested. Resonances of Cys10 and Asn12 were removed due to overlap.

The initial fit of individual residues to Equations (2) and (3) showed that residues Cys3, Asn14, Asp15, Cys16, and Phe35 as well as the sidechain resonance of Asn14 did not produce reliable fits to the model. The remaining residues fit the binding isotherm having, $n = 2.3 \pm 0.7$ (equivalent binding sites). The resonances of Gly4, Met7, Trp8, Ser23, Arg25, Trp26 and the sidechain of Trp28 all decayed rapidly with increased cND concentration, and these only had three valid titration points (missing a signal above noise level at the highest concentration of nanodisc). The value of, *n*, was subsequently fixed to 2 (even integer) for a global fit of all remaining resonances containing four valid data points after normalization, i.e., Phe6, Lys9, Lys11, Cys17, Lys18, Asp19, Leu20, V21, Cys22, Lys27, Trp28, Cys29, Val30, Ala32, Ser33, and sidechain NH resonances of Trp8, Asn12 and Trp26. This yielded

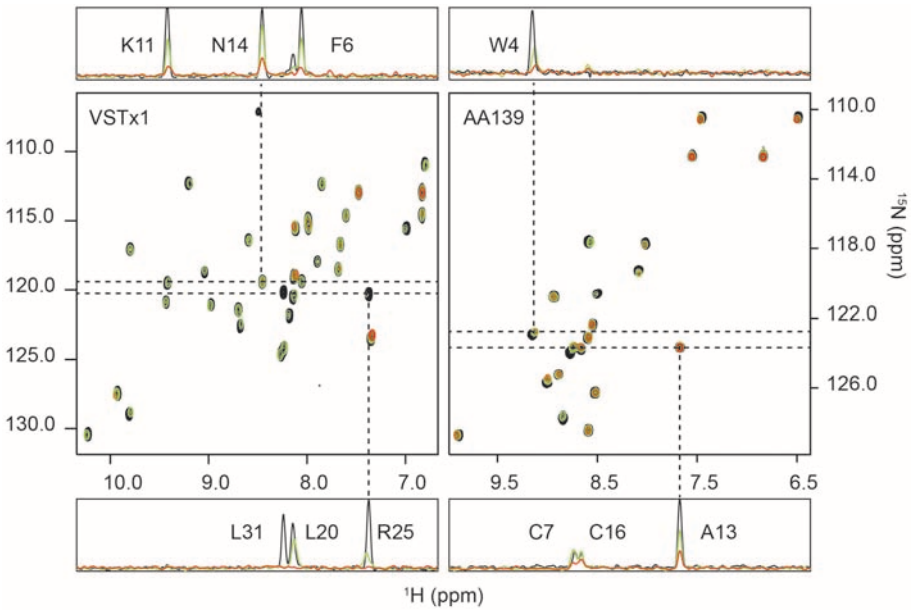

FIGURE 3 | ^{1}H-^{15}N HSQC titrations of membrane-active peptides against nanodiscs containing bacterial model membranes. (Left) The titration of ion-channel inhibitor VSTx1 (20 μM) against increasing concentration of nanodiscs [POPC:POPG (4:1)]. The three superimposed spectra correspond to a [peptide]:[nanodisc] ratio of 1:0 (black), 1:0.25 (green) and 1:1 (red). (Right) The titration of antimicrobial peptide AA139 (40 μM) against increasing concentration of nanodiscs [POPC:POPG (4:1)]. The three superimposed spectra correspond to a [peptide]:[nanodisc] ratio of 1:0 (black), 1:0.25 (green) and 1:0.375 (red). In both cases 1D traces are shown at ^{15}N frequencies corresponding to peaks that show a small change in intensity that does not fit to the binding isotherm (N14 for VSTx1 and Ala13 for AA139), and a signal (Arg25 for VSTx1 and Trp4 for AA139) having a strong intensity change that fits the binding isotherm. The latter also display an observable chemical shift and linewidth change consistent with intermediate exchange due to binding. Assignments are provided in 1D traces.

an equilibrium dissociation constant, K_d, of 1.11 ± 0.13 μM– using a constant value of 2 equivalent binding sites (**Figure S12**).

Further to the above titration, a second series of experiments were conducted with cNDs containing zwitterionic lipids. It had previously been observed that VSTx1: 1) binds to zwitterionic micelles, and 2) binds to the MSP of NDs (Shenkarev et al., 2014; Lau et al., 2016). The titrations were conducted under identical conditions as those described above for the anionic lipid NDs. This approach allows us to isolate the effect of the anionic lipids from any binding to zwitterionic lipids and MSP as well as potentially providing insights into the binding of the peptide to neutral lipids. The results show a significantly weaker binding than that observed for the anionic lipids (note that this binding was undetectable using ITC). The average change in peak height between the control experiments and the lowest concentration of added nanodisc (5 μM) is 38% (standard deviation of 15%) for the anionic lipid mixture and only 5% (standard deviation of 10%) for the zwitterionic mixture (in both cases removing L31 as an outlier). Only a few peaks displayed significant intensity changes (>10%) in the zwitterionic lipid mixture at this concentration of cNDs (backbone amides of Gly4, Phe6, Lys9, Lys11, Arg25, Trp26, Leu31, Ala32 as well as the sidechain amides of Trp8 and Trp26). Interestingly, the pattern of peak intensity changes remains similar in both cases, indicating that the binding mode is conserved. We also note that the majority of these amino acids could be fitted to the binding isotherm in the previous titration.

^{15}N HSQC Titrations of AA139

^{15}N-AA139 (40 μM) was titrated in the presence of cNDs [POPC:POPG (4:1)] at 0, 5, 7.5, 10, 12.5, 15 and 20 μM. For each sample a 2D ^{1}H-^{15}N HSQC spectrum was acquired. The increasing concentration of the ND added did not result in any significant chemical shift changes, however, significant broadening of the signals was observed in a concentration dependent manner (see **Figure 3**). The change in intensity was modeled using a quadratic equation to obtain estimates of the stoichiometry and dissociation constant of the interaction (Equations 2, 3). As noted in the methods section, several residues were removed for either yielding too few data points (backbone amides of Phe2, Asn11 and Gly12) or due to overlap (Val6 and Cys7). The initial fitting led to the exclusion of residues that did not fit to the model (Cys3, Ala8, Arg9, Arg10, Ala13, Arg14, Cys16, and Cys20). The line-broadening in these residues cannot be modeled by equations (2) and (3), either due to an insufficient change in intensity across the concentration range tested or the presence of other exchange processes. The remaining seven residues all fit the model well and produced values of equivalent binding sites, n, of 3.9 with a standard deviation of 0.3. This value was then fixed to 4, and after normalization of the observed maximum height change, a global fit of the data for all residues was performed, yielding an equilibrium dissociation constant, K_d, of 0.41 ± 0.13 μM (**Figure S12**).

Further, a qualitative analysis of the likely binding interface of the peptide was performed by comparing the intensity of the signals at the first two titration points (in the absence of cNDs and in the presence of 5 μM of cND). Residues that are most strongly affected at this low concentration of ND, are most likely to be at the binding interface. These residues include the hydrophobic and acidic residues at the termini of the β-hairpin loop (see also **Figure 4**).

Peptide-MSP Interactions by NMR

As noted above it had previously been suggested that there is an interaction between the anionic MSP and cationic peptides such as VSTx1 and AA139 (Shenkarev et al., 2014). A titration series of unlabeled peptides at 0, 50 and 100 μM against cNDs [^{15}N-cNW9: (POPC)] at 100 μM was conducted in the Tris-Bis buffer (iii) described above. The titration was followed by 2D ^{1}H-^{15}N TROSY experiments acquired at 50 °C for 4 h. The spectra featured well dispersed peaks for ^{15}N-cNDs at this temperature (at 25 °C the signals were unresolvable). In both cases, there were no peptide-concentration dependent chemical shift or intensity changes, suggesting that there is little or no interaction between the MSP and the peptides (**Figure S13**). The sample stability was monitored before and after each experiment by SEC and 1D ^{1}H NMR (not shown), and the NDs were found to be intact in all cases (see also **Figure S14**).

DISCUSSION

Production and Stability of Anionic NDs

The procedure described here for production of cNDs, departs from the original protocol described (Nasr et al., 2017). Here, a sortase inhibitor was not required and lipid-detergents (1 mM DDM) were used in the cyclisation reaction, which not only allows for higher protein concentrations in the circularization reaction but also leads to improved yields of the monomeric product, likely due to disruption of the formation of dimeric MSPs in solution. Our results are consistent with the independently developed protocol by Yusuf et al. where introduction of Triton X-100 (1 mM) was shown to significantly reduce multimeric by-products when trying to cyclise small MSP constructs through the same sortase-mediated reaction (Yusuf et al., 2018). The convergence of these methods on the optimal concentration of detergents during cyclisation is an encouraging sign of arrival at a general approach to generating high yields of cNDs.

In this work, we investigated the stability of NDs containing anionic lipid mixtures commonly used to model the bacterial membrane [POPC:POPG (4:1)], and compare this to NDs containing zwitterionic lipids (POPC). The stability of the NDs is evaluated based on EM images and SEC profiles, where in the latter aggregation or disassembly results in asymmetric elution profiles with increased absorbance at early elution times. For the linear NDs there is a general trend that the lower pH buffers result in higher heterogeneity of the NDs (**Figures S2–S3**). The level of heterogeneity increases over time and after ∼ 3 days we find that in the lower pH buffers (Bis-tris and phosphate at pH 6.5) the shoulders of the ND elution peaks increase in intensity sufficiently to be observed as distinct peaks. These trends are exacerbated in the presence of anionic lipid mixtures (in linear NDs), where at low pH there is clear evidence of aggregation/disassembly even at day 0 (**Figure S3**), in all buffers tested (result of all observations summarized in **Table 1** based on data in **Figures S2–S5**). We note that the observed heterogeneity would render most biophysical measurements unfeasible.

Fortunately, the introduction of head-to-tail cyclisation of the MSP resulted in excellent (c)ND stability regardless of the lipid composition or sample conditions–i.e., no changes were observed to the SEC elution profiles or EM images. Our conclusion based on these results is that small linear NDs are unsuitable for studies of anionic lipid bilayers. We further note that, although it is known that the presence of anionic lipids does not alter the membrane thickness or its fluidity, it has a very significant effect on the stability of lipid nanodiscs in solution. This conclusion may shed some light into previous work on the use of anionic NDs for studies of membrane-active peptides, where it was found that VSTx1 binds very effectively to anionic NDs, and based on analysis of NMR titration data a stoichiometry of ∼35 peptides to each ND was found (Shenkarev et al., 2014). This value appears physically unlikely considering that the peptide diameter can be estimated to be ∼20 Å (measured from the pdb structure 2N1N across the orange region in **Figure 4A**) and the ND used in the reported study has an available lipid diameter of ∼ 58 or 35 Å when excluding one or two shells of MSP bound lipids, respectively (Hagn et al., 2018). Based on our findings (although using a smaller ND) the apparently high stoichiometry may have been a consequence of aggregation due to instability of the linear NDs used. Indeed, despite the inherent experimental limitations at the observed binding affinities, our NMR and ITC data are both consistent with two independent binding sites for VSTx1 on cNW9 (available lipid diameter of cNW9 estimated to be 43 or 26 Å when excluding one or two shells of MSP bound lipids, respectively; Hagn et al., 2018), which provides a physically more realistic binding mode.

Although protein interactions with NDs have been studied previously by ITC (Agamasu et al., 2017), to our knowledge, ITC has not previously been utilized to quantify interactions between membrane-active peptides and NDs, and our results demonstrate that it may prove to be a valuable tool in future studies of such peptides. Finally, we also acquired dynamic light scattering (DLS) data for our samples to determine if this could be used to distinguish assembled and unassembled NDs. However, for these small NDs, the size difference between the MSP and the ND was too small to generate a reliable difference in scattering (data not shown).

Expression and Binding of Membrane-Active Peptides to Bacterial Model Membranes

Isotope labeling of both membrane-active peptides was achieved through recombinant protein expression in bacteria. In the case of AA139, a SUMO-fusion tag produced high soluble

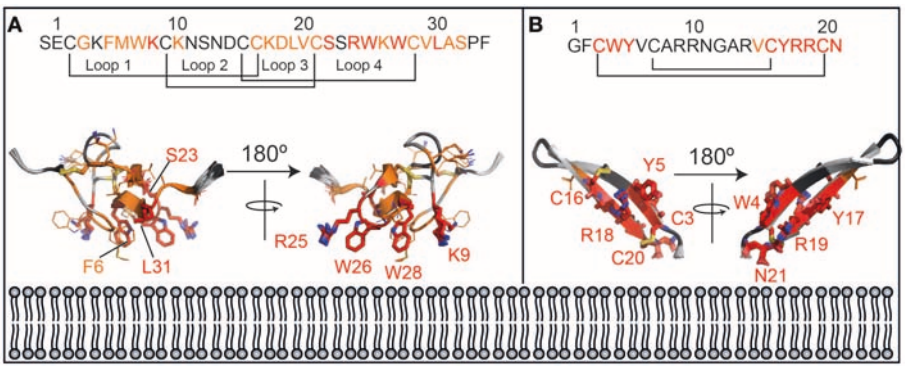

FIGURE 4 | Lipid interaction of membrane-active peptides. Cartoon representation of the peptides [**A** = VSTx1 (PDBID: 2N1N), **B** = AA139 (PDID: 5V11)] are oriented to show the likely binding orientation with respect to the lipid bilayer (bottom) based on the NMR titration data (180° rotation also shown). Disulfide bonds are shown as sticks. The peptide sequences and numbering are shown above the peptides. The residues in red (sidechains as sticks and labeled) are those that show the strongest perturbation upon addition of nanodiscs, those in orange show an intensity change consistent with the binding isotherm (sidechains as sticks) and residues in dark gray show smaller perturbation that do not fit the binding isotherm. Residues that were not included in the analysis (missing/overlapped) are shown in light gray. Structures in panels **(A)** and **(B)** are not to the same scale.

yields (∼1 mg per liter of culture) when expressed in SHuffle cells, in contrast to the MBP fusion expressed in the BL21 strain, where no soluble protein was found. It is worth noting the inherent challenge in finding a suitable bacterial expression system for an antimicrobial peptide. In this case it appears that the SUMO-fusion may have reduced the toxicity of the peptide. Although the bacterial expression of VSTx1 had previously been described, we also found that VSTx1 could be produced in relatively high yields using this strategy (SUMO-fusion in SHuffle cells–yielding 0.5 mg per liter of culture).

Transferring the results of the analysis of the NMR data (see discussion in **Supplementary Information**), onto the structure of the two peptides, allows us to gain some insights in the likely binding pose of the two molecules (**Figure 4**). In particular, those residues that show large intensity changes and fit the binding isotherm [fall into category (c or d) in **Supplemental Discussion**] are most likely to be in the binding interface and are shown in red with their sidechains displayed as sticks. These residues also show the highest intensity changes at the lowest concentration of NDs added.

Those that fit the binding isotherm but show smaller changes in their intensity [category (a) in **Supplemental Discussion**] are likely to experience membrane binding to some extent, and these are shown in orange with sidechains as lines. Those that show relatively small intensity changes, and do not fit the binding isotherm [category (b) in **Supplemental Discussion**] are least likely to be close to the binding interface and are shown in dark gray without sidechains indicated. Residues that were not included in the analysis are shown in light gray. This data is consistent with the interpretation that the red residues are inserting into the membrane while the orange residues are at the lipid/water interface.

The lipid binding data for VSTx1 are consistent with previous findings, and show, perhaps unsurprisingly, that the positively charged peptide binds more strongly to lipids containing negative head-groups. What is surprising, however, is that the same amino acids show the strongest perturbations in both titrations (against anionic and zwitterionic bilayers). This would suggest that the binding is driven by the hydrophobic patch of the peptide (loops 1 and 4) and that the affinity is enhanced by the basic residues in these loops in the presence of acidic moieties at the bilayer surface. This is particularly interesting as this peptide has been found to interact with acidic residues on its ion-channel receptor, in what appears to be a conserved mode-of-action in the inhibitory function of gating-modifier toxins (Lau et al., 2016; Zhang et al., 2018). It is also worth noting that the peptide had previously been found to bind zwitterionic micelles with moderate affinity by NMR spectroscopy (Ozawa et al., 2015; Lau et al., 2016). In contrast, we find that the peptide binds very weakly to zwitterionic lipids in cNDs and that this binding is undetectable by ITC. These results are more consistent with the centrifugation assays performed using liposomes (where no partitioning into zwitterionic liposomes is observed). Taken together, this suggests that the peptide has a stronger affinity for micelles than for bilayers–it remains to be seen if this is a general finding for membrane-active peptides or a property of VSTx1. Interestingly, however, the micelle binding interface identified by NMR (Ozawa et al., 2015; Lau et al., 2016) is the same as the cND interface identified here. Thus, although in this case, we find that the peptide has a stronger affinity for micelles than lipid bilayers, it appears that the binding mode is conserved.

The structure of AA139 reveals a twisted β-hairpin structure similar to other members of this family of antimicrobial peptides (Edwards et al., 2016). In contrast to the related arenicin-2 peptide, however, we do not observe any evidence of the peptide disrupting lipid membranes (from EM data–**Figure S14**). The NMR data suggest that the termini of the peptide are the likely interface with the lipid bilayer. This segment of the protein

contains a hydrophobic N-terminus and a basic C-terminus, which are both likely to contribute to its interaction with the anionic lipid bilayer. An interesting observation is that the negatively charged C-terminus is likely to form unfavorable interaction with both the head-groups and the tails of the lipids, and that amidation of this residue may enhance its affinity toward bacterial membranes. The binding pose also suggests that the long axis of the peptide is likely to be closer to being perpendicular to the plane of the bilayer, than in the plane. This may provide some support for the higher stoichiometry (of peptide to disc) derived for this peptide from the NMR data when compared to VSTx1.

The ITC experiments revealed that both peptides had binding affinities in the low μM range. Interestingly, although the binding free energy (ΔG) is similar in both cases (∼-8 kcal/mol), the relative contribution of entropic and enthalpic terms is different. The binding of VSTx1 appears to be largely driven by an entropic component (∼-6 kcal/mol) rather than an enthalpic component (∼-2 kcal/mol). The larger entropic term is consistent with increased disorder either in the peptide or the lipid bilayer upon binding. Although it is difficult to deduce the relative contributions of each of these components, we do see a very significant broadening of residue L31 of VSTx1 even in the presence of small concentrations of cNDs. This is consistent with a conformational change upon binding, and is likely to account for some of the observed gain in entropy. The change in conformation of a leucine residue is likely to occur in a highly apolar environment and the data would suggest that this face of the molecule partitions into the lipid bilayer.

In contrast to VSTx1, the ITC results for AA139 reveal a reversal of the relative thermodynamic terms, with a greater enthalpic term (∼-6 kcal/mol). AA139 has a net charge of +5 which is due to the presence of five arginine residues accounting for almost a quarter of the total amino acid composition. This would suggest that the binding of the peptide is driven by charge-charge interactions at the lipid interface, involving some of these residues. As noted above the masking of the C-terminal charge through amidation would increase the net charge to +6 which may further strengthen the enthalpic contribution to the binding energy.

In general, there is good qualitative agreement between the ITC and the NMR data. The binding constants derived from the NMR data were as expected exaggerated when compared to the ITC data, thus, although not quantitative provide a reasonable estimate of the binding. The stoichiometry was consistent when comparing data from the two methods. We note that in both cases the relatively weak binding observed, required careful analysis of the data, where a priori knowledge regarding the symmetry of the disc was used to improve the fitting of the data. Thus, although there is good agreement in the values derived, we note that these data are near the limits of binding interactions that can be detected by the two methods and some uncertainties are likely associated with the inherent sensitivity of these techniques in this binding regime.

CONCLUSION

We present a method to obtain high yields of cNDs in 3 days and assess their suitability for biophysical studies in solution. We performed size-exclusion chromatography (SEC) of linear and cyclised NDs of different compositions under varying conditions. The cNDs consistently displayed significantly improved stability over their noncircular counterparts. The study revealed that linear NDs can be unstable under common experimental conditions, particularly in phosphate buffers at a low pH and when containing anionic lipids. In contrast, cNDs were stable at all solution conditions and lipid compositions tested. In addition, the sharper peaks observed in the SEC profiles indicate greater homogeneity. Finally, we describe a method for high-yield (∼mg per liter of culture) recombinant production of two membrane-active peptides, notably including an antimicrobial peptide–AA139.

These materials are then used to evaluate the use of biophysical methods to study the membrane binding properties of membrane-active peptides against cNDs containing anionic lipid mixtures, that approximate the charge distribution of bacterial membranes. We use ITC to measure the binding thermodynamics, and heteronuclear 2D NMR to characterized the binding of ^{15}N-labeled peptides against cNDs. We first study the well characterized VSTx1 peptide to validate the proposed approach, and find good agreement with previous reports while revealing new information regarding the thermodynamics of the binding event. We then apply our method to gain insights into the activity of AA139, an antimicrobial peptide with an unknown mode-of-action. ITC and NMR data show that AA139 binds to the cNDs with low μM affinity, which is driven by a significant enthalpic contribution (−6 kcal/mol) and a stoichiometry of 4 peptides per disc. We further solved the structure of AA139 by NMR, which revealed a twisted β-hairpin fold, and allowed us to determine the likely lipid-binding interface of the peptide, which included the tails of the antiparallel β-sheets. These results establish the use of cNDs in combination with ITC and solution-state NMR as a novel and general method for investigating the membrane binding properties of membrane-active peptides.

AUTHOR CONTRIBUTIONS

AZ, IE, and MM conceived the study. AZ, IE, BM, GS, MH, and XJ performed the experiments. AZ, IE, BM, MH, BC, and MM analyzed the data. IE, AZ, and MM wrote the paper with input from all authors. All authors contributed to different components of the study design.

ACKNOWLEDGMENTS

This project was supported by the Australian Research Council (ARC grants: DP140101098, FTl10100925) and the National Health and Medical Research Council (NHMRC grants: APP1102267, APP1080405, APP1106590 and APP1136021). IE and AZ are supported by an International Postgraduate

Award and an Australian Postgraduate Award Ph.D. scholarship, respectively. We thank Adenium Biotech for allowing this work using AA139 and Dr. Frank Sainsbury for his technical assistance. We are also grateful to Dr. Mahmoud L. Nasr and Prof. Gerhard Wagner for MSP1D1ΔH5 expression plasmid and Prof. David R. Liu for sortase A pentamutant expression plasmid. Finally, we thank Dr. Zhenling Cui and Prof. Kirill Alexandrov for the advice and reagents regarding SUMO-tag cleavage by SUMO protease.

SUPPLEMENTARY MATERIAL

The Supplementary Material for this article can be found online at: https://www.frontiersin.org/articles/10.3389/fchem.2019.00238/full#supplementary-material

The supporting information include further details on the NMR analysis, ITC data, size exclusion chromatography profiles, thin layer chromatography images, EM negative staining images and LC-MS traces.

Electrochemistry

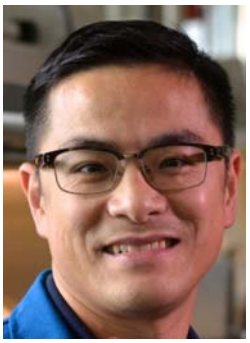
Ruoxue Yan

Dr Ruoxue Yan is an Assistant Professor at the Department of Chemical and Environmental Engineering. She obtained her PhD degree in Chemistry from UC Berkeley in 2010 with a designated emphasis on nanoscience and nanotechnology, a MSc degree in 2005 and a BSc degree in 2002)in Chemistry from Tsinghua University. Her research is focused on the synthesis, processing, and fabrication of high performance nanomaterials for advanced electronics, photonics, and biological applications. Her lab is currently engaged in research concerning optical biosensing, flexible electronics, surface and tip enhanced Raman spectroscopy, and the development of advanced nanoscale chemical imaging tools.

Syed Mubeen

Syed Mubeen attended the Central Electrochemical Research Institute to complete his undergraduate education in Chemical and Electrochemical Engineering. After his doctoral studies at the University of California, Riverside and postdoctoral research at the University of California, Santa Barbara, he moved to the Midwest in 2014 to assume a position of Assistant Professor at the University of Iowa in the Chemical and Biochemical Engineering Department. His group are interested in several problems related to energy and water research, including solar fuels and chemicals, electrochemical energy conversion, desalination and water purification, and engineering novel materials (including plasmonic nanostructures), and systems for energy applications. Mubeen has co-authored over 30 publications and has one issued and four pending US patents on gas sensors, photoelectrocatalysis, and batteries. He is also Lead Scientist at HyperSolar, Inc, a public company developing solar technologies for water purification.

Juchen Guo



Juchen Guo is an Associate Professor at University of California Riverside. He earned his Bachelor's degree in chemical engineering from Zhejiang University in 1999 and his PhD in chemical engineering from the University of Maryland in 2007 under the supervision of Prof. Timothy A. Barbari. From 2007 to 2011, he performed his postdoctoral studies at the University of Maryland under the direction of Profs. F. Joseph Schork and Chunsheng Wang. He also performed postdoctoral studies at Cornell University from 2011 to 2012 under the direction of Prof. Lynden A. Archer prior to joining the Department of Chemical and Environmental Engineering at UC Riverside in 2012. He was the recipient of the 2014 Hellman Fellowship and the 2018 NSF CAREER Award. His research interests include interfacial phenomena and material properties in electrochemical energy storage systems.

Su Ha

Su Ha is a Professor in the Gene and Linda Voiland School of Chemical Engineering and Bioengineering at Washington State University. His research has been cited over 4,500 times and he has an h-index of 29. In 2014, he was named as Highly Cited Researcher by Thomson Reuters. His research focuses on generating hydrogen gas from bio-fuels and abundant natural gases, developing fuel cells that directly convert the chemical energy of small organic molecules (e.g., formic acid) or logistic fuels (e.g., gasoline) to electrical power, working with natural enzymes to produce electrical power from sugars, and developing electric field assisted fuel reforming systems.

Jungbae Kim

Jungbae Kim is a Professor in the Department of Chemical and Biological Engineering at Korea University. He completed his Bachelor's and Master's in Chemical Engineering at Seoul National University, before completing his PhD and a post-doctoral position in Biochemical Engineering at the University of Iowa. Prior to his position at Korea University, Junbae Kim held positions at Rensselaer Polytechnic Institute and the Pacific Northwest National Laboratory. His research expertise includes but is not limited to nanobiocatalysis, single enzyme nanoparticles, enzyme coatings, nanoscale enzyme reactors, biosensors, and biofuel cells.

Jennifer L. Schaefer

Jennifer L. Schaefer is an Assistant Professor in the Department of Chemical and Biomolecular Engineering at the University of Notre Dame. Dr Schaefer obtained MEng and BChE degrees in chemical engineering and a BSc in chemistry from Widener University in 2008. She obtained a PhD in chemical engineering at Cornell University in January 2014. She then held a NRC Postdoctoral Research Associateship in the Materials Science and Engineering Division at the National Institute of Standards and Technology, until moving to the University of Notre Dame in July 2015. Her research group studies ion transport, interfacial phenomena, and applied polymer materials in electrochemical and electroactive devices.

Ekaterina V. Skorb

Ekaterina V. Skorb obtained her PhD, summa cum laude, in physical chemistry in 2008. Subsequently, she was the Alexander von Humboldt Fellow at the Max Planck Institute of Colloids and Interfaces (MPIKG, Germany) with Prof. Möhwald. Since 2013 she has been group leader at the Biomaterials Department (MPIKG, Germany). She was a Visiting Scholar at Harvard in Prof. Whitesides group (2016-2017). Since 2017 she is a Professor at the ITMO University leading the Infochemistry group. Her current scientific interests are broad and include the synthetic cell, smart dynamic materials, and systems for personal diagnostics, study, and the modeling of nonlinear chemical processes.

Abhishek Lahiri

Abhishek Lahiri is a senior scientist at the Institute of Electrochemistry, Clausthal University of Technology, Germany. He obtained his PhD degree from the Institute of Materials Research, University of Leeds, UK in 2008. He worked as a postdoctoral researcher at the University of Alabama, USA and Tohoku University, Japan from 2008 to 2011. His research interest includes electrochemical synthesis of functional materials for batteries and catalysis, interfacial electrochemistry in ionic liquids, and understanding the battery interface in ionic liquid electrolytes.

Monolayer transition metal dichalcogenide (TMDs) are promising candidates for two-dimensional (2D) ultrathin, flexible, low-power, and transparent electronics and optoelectronics. However, the performance of TMD-based devices is still limited by the relatively low carrier mobility and the large contact resistance between the semiconducting 2D channel material and the contact metal electrodes. Phase-engineering in monolayer TMDs showed great promise in enabling the fabrication of high-quality hetero-phase structures with controlled carrier mobilities and heterojunction materials with reduced contact resistance. However, to date, general methods to induce phase-change in monolayer TMDs either employ highly-hostile organometallic compounds, or have limited compatibility with large-scale, cost-effective device fabrication. In this paper, we report a new photochemical method to induce semiconductor to metallic phase transition in monolayer MoS_2 in a benign chemical environment, through a bench-top, cost-effective solution phase process that is compatible with large-scale device fabrication. It was demonstrated that photoelectrons produced by the band-gap absorption of monolayer MoS2 have enough chemical potential to activate the phase transition in the presence of an electron-donating solvent. This novel photochemical phase-transition mechanism advances our fundamental understanding of the phase transformation in 2D transition metal dichalcogenides (TMDs), and will open new revenues in the fabrication of atomically-thick metal-semiconductor heterostructures for improved carrier mobility and reduced contact resistance in TMD-based electronic and optoelectronic devices.

INTRODUCTION

Layered transition metal dichalcogenides (TMDs) have attracted major research interests in recent years because of their special two-dimensional layer structures and potential as high-performance functional nano-materials. The presence of a finite band gap, photo-responsivity, and outstanding electronic and optical properties make them promising candidates for optoelectronics and nanoelectronics.

Field effect transistors (FET) based on monolayer TMDs, in particular, MoS_2 and WSe_2, have been widely studied due to their excellent properties including high on/off ratios (exceeding 10^8), immunity to short channel effects, and abrupt subthreshold switching (Yoon et al., 2011; Song et al., 2013; Kappera et al., 2014a; Pradhan et al., 2014; Liu et al., 2015). To further improve the device performance, research efforts have been focused on enhancing the carrier mobilities, investigating the contact mechanisms, and limitations in carrier transport (Radisavljevic et al., 2011; Kim et al., 2012; Das et al., 2013; Gong et al., 2013; Radisavljevic and Kis, 2013; Sangwan et al., 2013; Li et al., 2017; Lv et al., 2018). Currently, the reported carrier mobilities have a wide range of variations from 1 to 400 $cm^2V^{-1}s^{-1}$, depending on the fabrication method, contact resistance, and it was recently found out that they also depend on the phase of the TMD layer (Kappera et al., 2014a,b; Guo et al., 2015; Ma et al., 2015). TMDs have several different phases, including the most common 2H phase (semiconducting) and 1T phase (metallic) (van der Zande et al., 2013; Voiry et al., 2013; Zhou et al., 2013; Kappera et al., 2014a; Acerce et al., 2015; Tang and Jiang, 2015). These two phases have different electronic band structures and other properties such as carrier mobility and optical absorption efficiency in the visible range (Guo et al., 2015; Xiong et al., 2015). Theoretical studies have put the electron and hole mobilities in 1T-MoS_2 at 6.4×10^4 cm^2 V^{-1} s^{-1} and 5.7×10^4 cm^2 V^{-1} s^{-1}, respectively, which are about two orders of magnitude higher than in 1H-MoS_2 (1.2×10^2 cm^2 V^{-1} s^{-1} for electrons and 3.8×10^2 cm^2 V^{-1} s^{-1} for holes) (Kan et al., 2014). This large enhancement was attributed to the reduction of the electron (hole) effective mass from 0.49 m_e (0.60 m_h) to 0.12 m_e (0.05 m_h) when the 2H-MoS_2 is converted to 1T-MoS_2 (Kan et al., 2014). It has also been shown that the 1T-phase MoS_2 can significantly decrease the contact resistance of monolayer-MoS_2-based transistors to ∼200–300 Ω-μm at the room temperature from ∼1,000 Ω-μm in devices using pure 2H-MoS_2 (Kappera et al., 2014a), an impressive level that is getting close to the best contact resistance between graphene and palladium reported by IBM ($110 \pm 20\,\Omega\,\mu m$ at 6 K) (Xia et al., 2011). Phase-engineering in monolayer TMDs has offered an extra handle in performance optimization of TMDs-based nano-electronics and optoelectronic by enabling the preparation of novel structures, such as high-quality mix-phase material with controllable carrier mobility and patternable heterojunction materials (Duan et al., 2014; Duesberg, 2014; Gong et al., 2014; Huang et al., 2014; Mahjouri-Samani et al., 2015; Zeng et al., 2015; Zheng et al., 2015).

Traditionally, 2H to 1T phase transition is realized through alkali metal (Li^+, Na^+, or K^+) intercalation using highly reductive organometallic compounds, such as n- or t-butylithium, and has been studied for about three decades in bulk MoS_2 (Py and Haering, 1983; Zheng et al., 2014; Mahjouri-Samani et al., 2015; Tan and Zhang, 2015). In a typical synthesis, MoS_2 is intercalated with lithium to form the reduced Li_xMoS_n phase with expanded lattice, which can be exfoliated into monolayer films by ultrasound-assisted hydration process. The reduced Li_xMoS_n phase has the same octahedral symmetry as 1T-MoS_2, and the subsequent deintercalation preserves the octahedral structure, yielding a metastable 1T metallic phase. Recently, this method has been extended to the preparation of mono- or few layer TMDs (Eda et al., 2011; Zeng et al., 2011; Cheng et al., 2014; Dong et al., 2014; Eng et al., 2014; Knirsch et al., 2015). The major drawback of this technique is the long lithiation time (e.g., a range of 2 h to 3 days soaking at 100°C), and the poor film quality due to the damage due to the violent reaction between lithium and water. The use of expensive and hostile organometallic compounds requires an oxygen- and water-free processing environment and is highly explosive, which leads to cost and safety concerns as the phase-engineering process is scaled up. Thus, there is a lot of interest in developing a method to induce phase change in monolayer MoS_2 that is safer, more time efficient and lower cost. Several alternative methods have been proposed to induce the 2H to 1T phase transition in monolayer MoS_2, including strain, electron beam, plasma bombardment, and plasmonic hot electron induction (Enyashin et al., 2011; Kang et al., 2014; Lin et al., 2014; Katagiri et al., 2016; Zhu et al., 2017). However, in general, a clean, low cost and scalable phase engineering technique is still not available.

In this paper, we report a new photochemical route to induce 2H to 1T phase transition in MoS_2 monolayers in a benign chemical environment. We find that photoelectrons produced by the band-gap absorption of monolayer MoS_2 have enough chemical potential to activate the phase transition in the presence of a hole scavenger. This novel photochemical phase-transition mechanism was systematically investigated by *in-situ* 2D photoluminescence (PL) mapping, *in-situ* Raman, atomic force microscopy (AFM), and X-ray photoelectron spectroscopy (XPS) and control experiments demonstrating the dependence of the phase-change process on the redox environment.

RESULTS AND DISCUSSION

Figure 1 shows the mechanistic illustration of the photochemical phase-transition mechanism. As shown in **Figure 1A**, the 2H-MoS_2 has the D_{3h} symmetry, and its crystal field splits the five Mo 4d orbitals into three groups (**Figure 1B,** left): an *a* orbital ($4d_{z^2}$), which is the most stable of all, followed by two degenerate *e'* orbitals ($4d_{xz}$ and $4d_{yz}$) and two degenerate *e"* ($4d_{x^2-y^2}$ and $4d_{yz}$) orbitals. The Mo ion is in the +4 oxidation state and has two 4d electrons, both residing in the lowest lying $4d_{z^2}$ and leaving the higher energy 4d orbitals empty. The complete occupation of the $4d_{z^2}$, which correspond to the valance band in its electronic band structure, renders 2H semiconducting. On the contrary, 1T-MoS_2 has a centrosymmetric O_h symmetry (**Figure 1A**, right), which splits the Mo 4d orbitals into 2 groups (**Figure 1B**, right): the lower energy t_{2g} orbitals ($4d_{xy}$, $4d_{xz}$, and $4d_{yz}$) and the higher energy e^*_g orbitals ($4d_{z^2}$ and $4d_{x^2-y^2}$). At the ground state, the two Mo 4d-electrons has to fill in 2 of the 3 degenerate t_{2g} orbitals instead. The incomplete occupation of the 1T t_{2g} orbitals indicates partially occupied valence band, making 1T phase metallic (Chhowalla et al., 2015). The S 3p states do not influence the electronic structure of the materials, as they are located approximately 3 eV away from the Fermi level. Since the $4d_{z^2}$ orbital in 2H-MoS_2 is slightly more stable than the t_{2g}

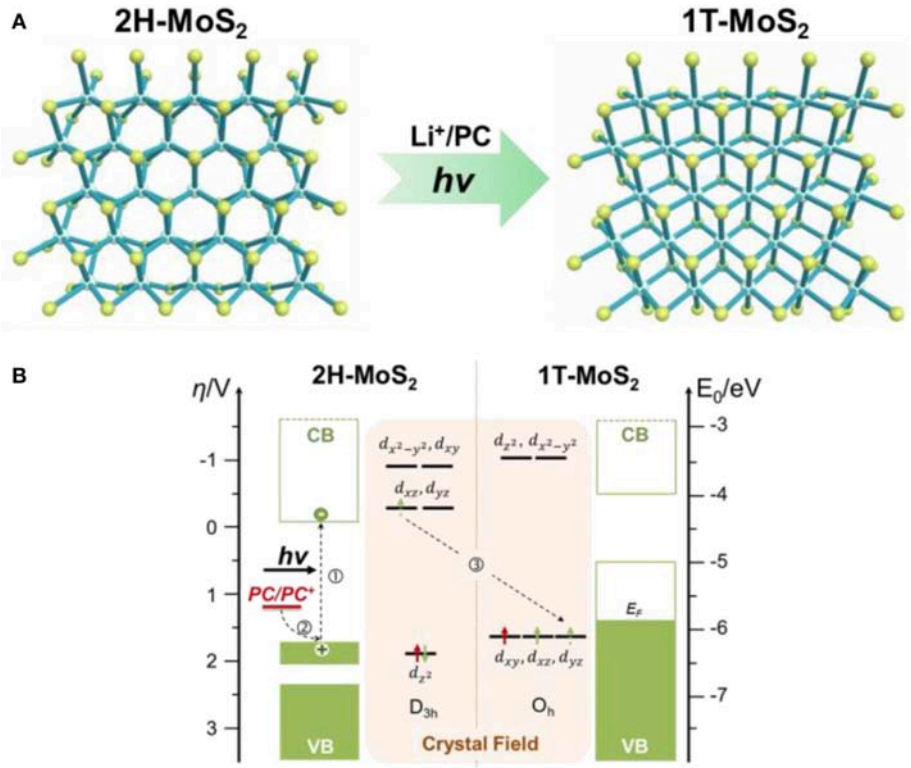

FIGURE 1 | Mechanistic illustration of the photochemical 2H to 1T phase transition in monolayer MoS_2. **(A)** Atomic structures of 2H- and 1T-MoS2. **(B)** Energy diagram of 2H- and 1T-MoS_2 and the corresponding crystal fields of Mo 4d orbitals. The proposed route of photochemical phase transition is marked by dotted arrows. Step 1, photo absorption to generate photo electrons in the conduction band (CB) and photo holes in the valence band (VB) of 2H-MoS_2 (left). Step 2, electron donation from the hole scavenger, propylene carbonate (PC), whose redox potential falls above the valence band of the 2H-MoS_2. The photo-assisted electron injection to the conduction band of 2H-MoS_2 destabilizes the 2H phase. Step 3, phase transition from the destabilized 2H phase to the thermodynamically more stable 1T phase (for d^3 configuration). The green arrows on the 4d orbitals represent the original 4d electrons on the Mo atom, while the red arrows represent the extra electron donated by the hole scavenger molecule.

orbitals in 1T-MoS_2, the total energy of Mo 4d-electrons are also lower, rendering 2H phase thermodynamically favored.

When the 2H-MoS_2 accept an extra electron, that electron is forced into the high energy *e*' orbitals, which is much higher than $4d_{z^2}$ due to the large crystal field stabilization energy in D_{3h} symmetry, destabilizing 2H phase. On the contrary, the triply degenerate t_{2g} orbitals in 1T phase would be able to accommodate all three Mo 4d electrons and reach the stable half-filled configuration. Since t_{2g} in 1T-MoS_2 is much lower in energy than *e*' orbitals in 2H-MoS_2, the total energy of the d^3 configuration is considerably lower in 1T phase, thus allowing phase conversion to occur (Enyashin and Seifert, 2012; Cheng et al., 2014; Kan et al., 2014). This forms the foundation of electron-injection-induced MoS_2 phase transition. Instead of using the hostile reductant like butylithium in the chemical intercalation method, or direct physical electron injections using high-energy electron beams or plasmonic hot-electrons, in the photochemical route, low energy visible light was used to provide the extra electron by generating photoelectrons in 2H-MoS_2.

As shown in **Figure 1B**, visible light with a photon energy beyond the bandgap of monolayer 2H-MoS_2 (∼1.8eV) excites a valence band ($4d_{z^2}$) electron into the conduction band, which corresponds to the degenerate *e*' orbitals ($4d_{xz}$ and $4d_{yz}$). The photo-generated hole left behind in the $4d_{z^2}$ state is filled by an electron transferred from a hole scavenging molecule, whose oxidation potential is higher than $4d_{z^2}$, or the top of the valence band. Effectively, this is a photo-reduction process, in which the electron injected into MoS_2 is supplied by the hole scavenger and the activation energy is provided by a visible photon. In our demonstration, the hole scavenger used is propylene carbonate (PC), the oxidation potential of which is 1.2V vs. NHE (Kanamura et al., 1995), which converts to −5.6 eV vs. vacuum. This is slightly above the valence band of monolayer 2H-MoS_2, which is roughly around −6.5 eV below vacuum (Schlaf et al., 1999; Choi et al., 2013; Furchi et al., 2014). The reduced MoS2 goes through phase-transition to the more-stable 1T structure, which was then stabilized by Li^+ ions, which balance the negative charges on reduced 1T-MoS_2. The Li^+ ion here is not from harsh organolithium, but is from a mild lithium salt ($LiPF_6$) dissolved in PC.

Figure 2 shows the *in situ* 2D photoluminescence mapping that follows the photochemical phase transition of 2H-MoS_2 monolayer flakes grown with chemical vapor deposition (CVD) on a SiO_2 substrate. The substrate was encapsulated in a liquid

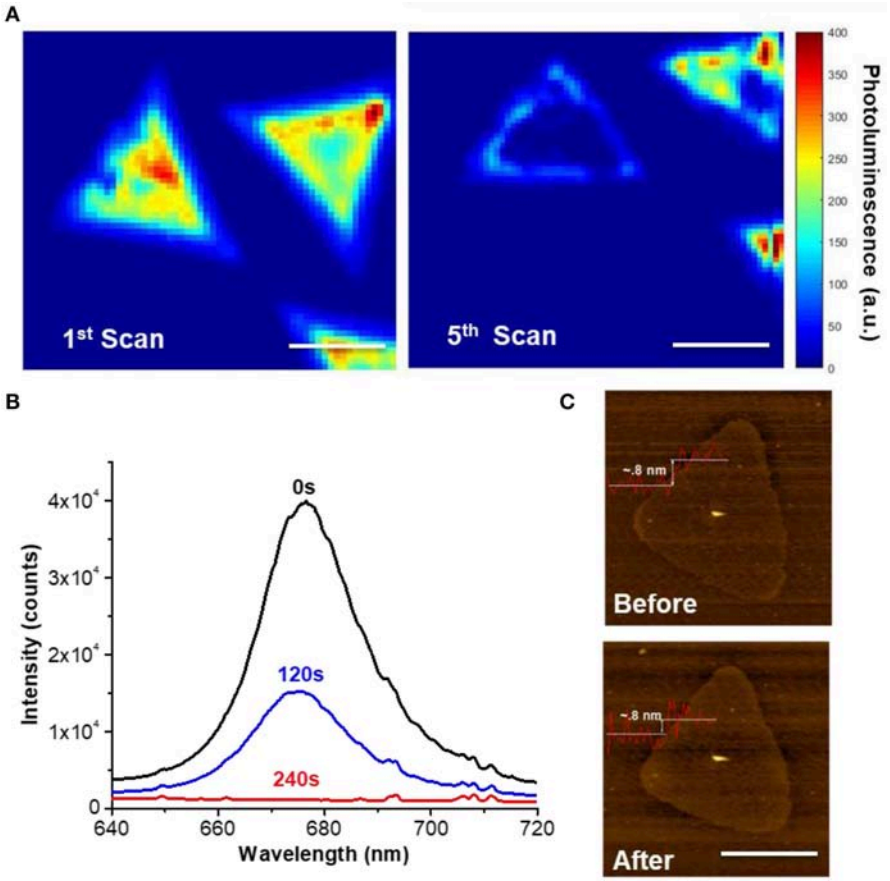

FIGURE 2 | Optical and morphological characterization of the photochemical phase change of monolayer CVD MoS_2. **(A)** *in-situ* 2D photoluminescence (PL) imaging following the photochemical phase change of a single MoS_2 monolayer flake (left). The left image shows the initial scanning and the right image shows the 5th consecutive scan after 2 h of imaging with a laser power of 0.76 mW/μm^2 at 532 nm and 1 s/pixel. The right image was slightly drifted/rotated with respect to the right image during alignment and slight distortion was also observed due to piezo hysteresis. Scale bar: 10 μm. **(B)** Time dependent PL spectra of a MoS_2 flake during illumination showing clear PL quenching (5 s accumulation time). **(C)** AFM image of the same MoS_2 monolayer flake before and after the photochemical phase change showing no sign of photodamage to the structure integrity. Scale bar: 10 μm.

chamber with 1M PC solution of $LiPF_6$ and sealed to prevent evaporation. The MoS_2 monolayer flakes were then scanned with a tightly-focused 532 nm laser. With a photon energy higher than the band gap of monolayer MoS_2, the laser served dual purposes: providing activation energy for the photo-reduction and exciting MoS_2 photoluminescence, the quenching of which serves an *in-situ* indicator of the formation of the 1T metallic phase (Eda et al., 2011). The laser power was maintained at 0.76 mW/μm^2 (1.2 μm spot size) to prevent photodamage and an accumulation time of 1 s per pixel was used for all 2D scanning. **Figures 2A,B** show the result of the 1st and 5th laser scan of the same MoS_2 flake (on the left), which shows a clear PL quenching which suggests the increase of the metallic 1T-phase component. The entire 5 scans were compiled in **Figure S1**, which shows the gradual PL quenching of the left domain with time evolution. It is worth mentioning that scan 3 and 4 was stopped early so the total illumination times of the two MoS_2 flakes on the right are shorter than the domain on the left. The different degrees of PL quenching among the MoS_2 flakes clearly demonstrates the correlation between the PL intensity and the duration of light exposure. **Figure 2B** shows the PL spectra of another MoS_2 flake, collected at different times during continued illumination, also showing a clear time-dependence in PL quenching on light exposure. **Figure S2** further shows that the PL intensity decays exponentially with the illumination time. AFM images taken before and after laser exposure (0.76 mW/μm^2, 240 s) in $LiPF_5$/PC solution (**Figure 2C**) indicate that the sample was not damaged by laser ablation. This is consistent with previous reports that the thermal effect is insignificant at such low power densities and laser thinning requires at least 20 mW/μm^2 in laser power (Najmaei et al., 2012; Hu et al., 2017).

We have observed considerable variations in different CVD MoS_2 samples. The CVD grown MoS_2 flakes are highly prone to chalcogen deficiency because of the high volatility of chalcogenides, and therefore contain an abundance of chalcogen vacancies inherently creates structural defects that affect carrier diffusion and activate non-radiative recombination channels (Zhou et al., 2013; Hong et al., 2015). Depending on the

growth parameter, such as the amount and distance of solid precursors, growth temperature and duration, the film quality can vary significantly from batch to batch and even at different positions on the same substrate (Zafar et al., 2017). These variations affect the optical behavior of the sample as well as any photo-induced processes, however, there have been increasing research attentions directed on the defect-controlled growth of high-quality MoS_2 films (Chen et al., 2015; Tao et al., 2017). The continued improvement in MoS_2 synthesis will provide more precision in the optimization of the photochemical phase transition method.

In-situ confocal Raman spectroscopy was carried out to examine the structure evolution of the MoS_2 flakes. The Raman spectra (**Figure 3**) show characteristic peaks at 382 and 402 cm^{-1}, which can be assigned to the E^1_{2g} and A_{1g} phonon modes, respectively (Sun et al., 2014). Chemically exfoliated 1T-MoS_2 using butyllithium solution shows distinct Raman signature of superlattices at 150 cm^{-1} (J_1), 226 cm^{-1} (J_2), and 333 cm^{-1} (J_3)(Yang et al., 1991). The appearance of these superlattice peaks has been used as the indication of the 1T phase (Kang et al., 2014; Kappera et al., 2014b; Zhu et al., 2017), however, it is also worth noting that their relative intensities, and even whether or not they appear together in mixed phase monolayer MoS_2 samples are not in agreement across the literature. For example, 1T-MoS_{-2} flakes produced with 40 s Ar plasma treatment has 40% 1T phase, but J_1 and J_2 intensities are both quite similar to the pristine sample before treatment, leaving J_3 is the most prominent peak (Zhu et al., 2017). In a separate case, 48 hours of n-butyl lithium treatment yields 70% of 1T phase and its Raman spectra shows a very prominent J_2 peak, a very weak J_3, and no J_1(Kappera et al., 2014b). In our case, the lowest frequency J_1 peak is too weak to be discerned from the residue laser background which takes off quickly below 175 cm^{-1}. The J_2 peak is very close to LA mode of MoS_2 at 227 cm^{-1}, which also makes it difficult to stand out. However, with the increasing illumination time, a new J_3 peak was clearly observed after 20 min under a laser illumination power of 0.14 mW/μm^2, clearly indicative of a 1T phase formation. We have also observed a new peak at ~370 cm^{-1}, which was also seen in chemically exfoliated 1T-MoS_2 together with the superlattice peaks, however, its structural origin was not clear (Yang et al., 1991). The broadening and intensity attenuation of E^1_{2g} peak was not obvious, indicating a partial phase-change under this illumination condition, without the significant loss of the D_{3h} symmetry (Yang et al., 1991). We want to point out here that the degree of phase change is limited in the *in-situ* confocal Raman measurement because of a limited illumination power attainable at the sample surface and the stage drifting of the confocal Raman. However, the presence of characteristic 1T-MoS_2 Raman peaks at the low frequency region supports the PL measurement result.

X-ray photoelectron spectroscopy (XPS) provides additional evidence of the formation of 1T phase through the photochemical phase transition process. **Figure 4** shows the select-area XPS spectra of the as-synthesized CVD monolayer MoS_2 flake (top) and a CVD MoS_2 sample phase-modified with the photochemical method. The MoS_2 flake was illuminated with a 532 nm laser

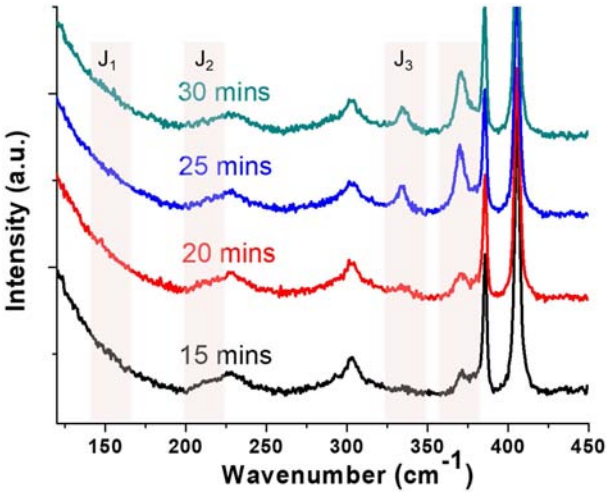

FIGURE 3 | *In-situ* Raman spectra following the time evolution of a monolayer MoS_2 flake during photochemical phase change. Two new peaks (330 and 370 cm^{-1}) indicative of the 1T phase appeared with increasing illumination time (532 nm, 0.14 mW/μm^2). The 19.8 cm^{-1} distance between the E^1_{2g} and A_{1g} peaks indicates that the sample is a MoS_2 monolayer.

(~0.2 mW/μm^2, 1.2 μm spot size) for 30 min in the presence of 1M $LiPF_4$/PC solution. The XPS measurement was performed with an AXIS Supra (Kratos Instruments) using a 500 mm Rowland circle monochromated Al Ka x-ray source and an aperture of 20 μm diameter for select area measurement. All spectra were calibrated by the C 1 s peak at 284.5 eV (see **Figure S3**). The peaks around 230 and 233 eV, corresponding to the Mo^{4+} $3d_{5/2}$ and Mo^{4+} $3d_{3/2}$ components in 2H-MoS_2, shifted slightly but distinctly to lower energies after the photochemical process, important evidence of the presence of the 1T phase (Eda et al., 2011; Cai et al., 2015). For the as-made 2H-MoS_2, the XPS intensity goes back to the baseline between peaks (234 eV and 231 eV), whereas the phase-modified sample shows clear peak broadening on the low energy side and the intensity no longer goes back to the baseline at these locations, also indicating the presence of additional peaks. The deconvolution of Mo and S XPS peaks reveals 1T peaks at lower energy along with the original 2H peaks, and the relative content of 1T phase is estimated to be ~15% for this particular MoS_2 flake. Considering the laser spot size of 1.2 μm and the XPS aperture of 20 μm, the illuminated region accounts for only a tiny fraction (0.3%) of the XPS probed area. The measured spectrum represents the averaged results over the entire probed area, which indicates that the photochemical phase-modification can go far beyond the illuminated region, possibly due to exciton/charge carrier diffusion and laser scattering in the liquid chamber.

In order to further validate the proposed mechanism, the effect of different experimental parameters, such as the presence of Li^+ ion, the illumination wavelength, the redox potentials of hole scavengers, were studied. **Figure 5** summarized the

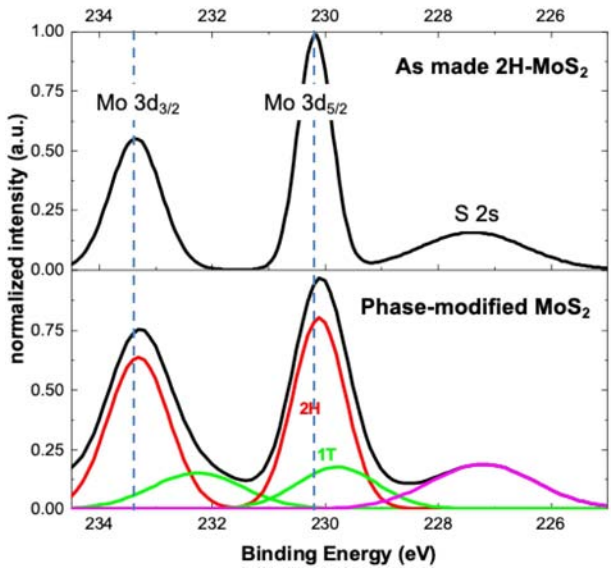

FIGURE 4 | XPS spectra of as-synthesized and phase-modified monolayer MoS_2. The phase-modified MoS_2 sample (bottom black curve) shows a distinct shift and peak broadening in the Mo $3d_{3/2}$ and $3d_{5/2}$ binding energies, indicating the presence of 1T phases.

photoluminescence (PL) spectra measured on single CVD-MoS_2 monolayer flakes before and after 1 h of laser illumination under different conditions. The powers of the illumination laser and the excitation laser used for PL measurement, as well as the accumulation time of the PL spectra, was kept the constant for all control experiments. **Figure 5A** shows the expected PL quenching on a single MoS_2 flake induced by 532 nm laser illumination in 1M $LiPF_6$-PC solution, indicative of the semiconductor to metal phase transition. As illustrated in **Figure 5E**, the 532 nm laser has a photo-energy of 2.33 eV, large enough to bridge the 1.8 eV bandgap of monolayer MoS_2 and excite photoelectrons that destabilize the 2H phase. The photogenerated holes left behind in the valence band were filled by electrons transferred from the PC, whose redox potential sits above the top of the MoS_2 valence band. On the contrary, if the photon energy of the illumination laser is lower than the MoS_2 bandgap or the redox potential of the hole scavenger sits below the top of the MoS_2 valence band, no significant PL quenching was observed, as shown in **Figures 5B,C.** The 785 nm laser has a photon energy of 1.58 eV, not enough excite photoelectrons into the conduction band of monolayer 2H-MoS_2. The acetonitrile (AN) solvent, which is more stable against oxidation than PC, has an oxidation potential of >2.6 V vs. NHE (Portis et al., 1972), which converts to −7.0 eV vs. vacuum, lower than the valence band top of the monolayer 2H-MoS_2 (−6.5 eV below vacuum), and unable to function as an efficiency electron donator (e.g., hole scavenger). We have also observed that the Li^+ also plays a critical role in the photochemical phase transition mechanism. As shown in **Figure 5D**, PL quenching was not observed with pure PC and no Li^+ to stabilize the photoreduced MoS_2. The role of Li^+ is similar to that of the chemical exfoliation method, where the chemically reduced MoS_2 (by butylithium) is intercalated with Li^+ ions to form a stable Li_xMoS_n phase that has the same O_h symmetry as 1T-MoS_2. After deintercalation, the octahedral structure is preserved to yield the 1T-MoS_2 phase. The absorption of Li^+ on photoreduced monolayer MoS_2 stabilizes the negative charges and facilitates the D_{3h} (2H) to O_h (1T) structural transition. The results of these control experiments support the proposed photochemical phase transition mechanism illustrated in **Figure 1**.

CONCLUSION

In summary, we have demonstrated a new photochemical route to induce 2H to 1T phase transition in MoS_2 monolayers in a benign chemical environment. Photoelectrons generated by the band-gap absorption of monolayer MoS_2 provide the chemical potential necessary to activate the phase transition in the presence of a proper electron-donating solvent and stabilizing metal ion. Clear evidence of phase transition was seen with a combination of characterization methods including *in-situ* 2D PL mapping, *in-situ* Raman, AFM, and XPS. This benchtop solution-based photochemical phase engineering method does not rely on glove box or any expensive clean-room technique, and is compatible with photolithography for phase-patterning on wafer-scale CVD sample. It demonstrates great promises as a clean, low cost and scalable alternative of the monolayer TMD phase engineering, and further advances the optimization and commercialization of TMD-based electronic components.

EXPERIMENTAL

Preparation of Monolayer MoS_2 Sample

Monolayer MoS_2 was synthesized on a thermal oxide (300 nm SiO_2/Si) substrate at a growth temperature of 650°C in a custom CVD system using sulfur (99.98%, Sigma Aldrich) and MoO_3 (99.99%, Sigma Aldrich) powder as solid precursors and Argon as carrier gas (20 sccm). After growth, the silica substrate was placed in a custom microscope liquid cell filled with 5 microliters of $LiPF_6$: PC solution (1.0M, battery grade, Sigma Aldrich) and sealed to prevent liquid evaporation.

Photoluminescence Measurement

The PL was measured with an inverted microscope with a HORIBA iHR550 spectrophotometer and a Synapse EM CCD. A green laser (GEM 532, $\lambda = 532$ nm, Laser Quantum) was used to excite the MoS_2 PL and to induce photochemical phase change. The power density of the laser is tuned by optical density filters and the reported values in the paper was measured at the sample plane. *In-situ* 2D mapping was conducted at 1 s/pixel using a custom LabView program. The PL spectra were measured with a 20 μm slit and 5 s accumulation time.

AFM Measurement

The topological images of the MoS_2 monolayer flake before and after illumination were collected with a commercial AFM (SmartSPM, AIST-NT). The before image was measured on as-synthesized sample. After the illumination in $LiPF_6$/PC solution, the sample was removed from the liquid cell

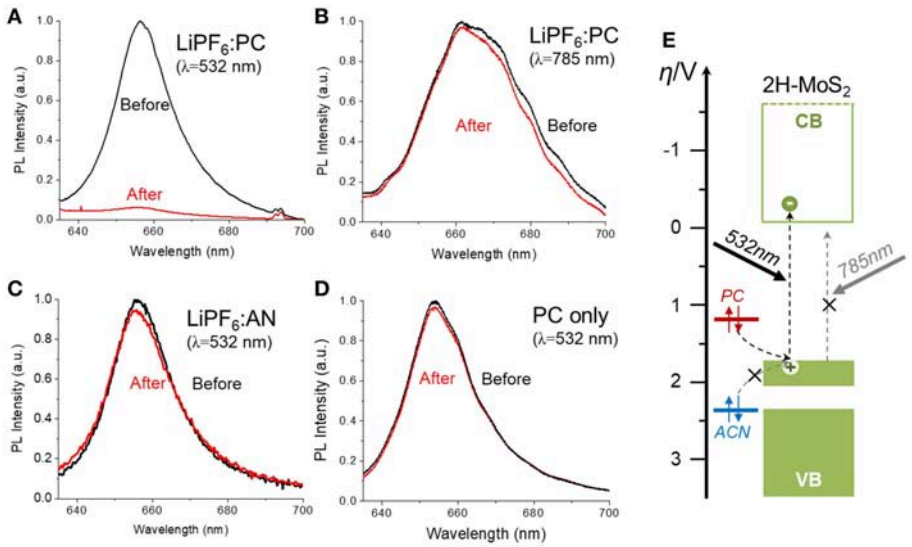

FIGURE 5 | Measured MoS_2 Photoluminescence (PL) spectra before and after 1 h of laser illumination under different conditions: **(A)** 1M PC solution of $LiPF_6$ with 532 nm illumination, **(B)** 1M PC solution of $LiPF_6$ with 785 nm illumination. The 785 nm laser correspond to 1.58 eV in photon energy, **(C)** 1M acetonitrile (AN) solution of $LiPF_6$ with 532 nm illumination, **(D)** Pure PC (no Li^+ ion) with 532 nm illumination. The power density of the illumination lasers in different control experiments were kept constant. Each PL spectrum was measured under 532 nm excitation for the same accumulation time (5 s), **(E)** The energy diagram illustrating the alignment of the 2H-MoS_2 bands with redox potentials of the hole scavengers (PC and AN).

and washed with pure propylene carbonate solvent and ethanol several times to remove excess $LiPF_6$ on the surface. The sample was then dried and characterized by AFM immediately.

In-situ Raman Measurements

The Raman spectra were measured with a commercial confocal Raman system (LabRAM, Horiba). A green Raman laser (532 nm, 0.14 mW/μm^2 measured at the sample surface) was used to excite the Raman spectra and induce the photochemical phase transition. Each Raman spectra was taken with 10 s exposure time and three accumulations.

Preparation of 1M $LiPF_6$ in Acetonitrile

Pure $LiPF_6$ powder (99.9%, Sigma Aldrich) was mixed in acetonitrile under an inert atmosphere for two days at high spin speed.

XPS Analysis

XPS analysis was done using a Kratos Instruments AXIS Supra with a 500 mm Rowland circle monochromated Al Ka X-ray 1486.6 eV source at the University of California, Irvine Materials Research Institute.

DATA AVAILABILITY

All datasets generated for this study are included the manuscript and/or the **Supplementary Files**.

AUTHOR CONTRIBUTIONS

RY and ML conceived the idea and designed the experiment. PB carried out the experiment and analyzed data. PB and RY wrote the manuscript with input from all authors.

FUNDING

Funding for this research was provided by the National Science Foundation under Award DMR-1649795. Work by PB was partially supported by the GAANN Fellowship.

SUPPLEMENTARY MATERIAL

The Supplementary Material for this article can be found online at: https://www.frontiersin.org/articles/10.3389/fchem.2019.00442/full#supplementary-material

Minimizing Pt loading is essential for designing cost-effective water electrolyzers and fuel cell systems. Recently, three-dimensional macroporous open-pore electroactive supports have been widely regarded as promising architectures to lower loading amounts of Pt because of its large surface area, easy electrolyte access to Pt sites, and superior gas diffusion properties to accelerate diffusion of H_2 bubbles from the Pt surface. However, studies to date have mainly focused on Pt loading on Ni-based 3D open pore supports which are prone to corrosion in highly acidic and alkaline conditions. Here, we investigate electrodeposition of Pt nanoparticles in low-loading amounts on commercially available, inexpensive, 3D carbon foam (CF) support and benchmark their activity and stability for electrolytic hydrogen production. We first elucidate the effect of deposition potential on the Pt nanoparticle size, density and subsequently its coverage on 3D CF. Analysis of the Pt deposit using scanning electron microscopy images reveal that for a given deposition charge density, the particle density increases (with cubic power) and particle size decreases (linearly) with deposition overpotential. A deposition potential of −0.4 V vs. standard calomel electrode (SCE) provided the highest Pt nanoparticle coverage on 3D CF surface. Different loading amounts of Pt (0.0075–0.1 mg_{Pt}/cm^2) was then deposited on CF at −0.4 V vs. SCE and subsequently studied for its hydrogen evolution reaction (HER) activity in acidic 1M H_2SO_4 electrolyte. The Pt/CF catalyst with loading amounts as low as 0.06 mg_{Pt}/cm^2 (10-fold lower than state-of-the-art commercial electrodes) demonstrated a mass activity of 2.6 ampere per milligram Pt at 200 mV overpotential, nearly 6-fold greater than the commercial Pt/C catalyst tested under similar conditions. The 3D architectured electrode also demonstrated excellent stability, showing <7% loss in activity after 60 h of constant current water electrolysis at 100 mA/cm^2.

Keywords: hydrogen evolution reaction, electrocatalyst, platinum nanoparticle, carbon foam, 3D support

INTRODUCTION

Water electrolysis offers the potential to produce clean H_2 sustainably from renewable electricity and water (Esposito et al., 2012; Chen et al., 2016; Jia et al., 2016). To design high-efficiency electrolyzers, highly active stable electrocatalysts are needed that can operate without corrosion in either strong acids or strong bases (Chen et al., 2018; Fu et al., 2018). To date, only electrocatalysts made of expensive platinum group metals (PGMs), specifically Pt, Ir, and Rh can deliver these needs (Angelo, 2007; Li et al., 2015; Zhang et al., 2015; Cheng et al., 2016; Tymoczko et al., 2016). Current practices to minimize mass loading of precious metals rely on constructing catalysts in the form of nanoparticles on low-cost 2D carbon supports (e.g., carbon cloth or carbon paper), with state-of-the-art commercial catalysts having a PGM mass loading of ∼0.1–1 mg_{PGM}/cm^2 (Friedrich et al., 2004; Tymoczko et al., 2016; Park et al., 2018). However, for wide-spread practical applications, the target PGM loading level should be <0.125 mg_{PGM}/cm^2 (Benjamin et al., 2017). It is to be noted that considerable amount of revolutionary work has been dedicated to the development of earth-abundant catalysts for water electrolysis for some years (Cabán-Acevedo et al., 2015; Callejas et al., 2016; Liu et al., 2016; Tang et al., 2017). However, their activity and stability at present state are not sufficiently advanced to be performance-competitive (Faber et al., 2014).

Use of macroporous open-pore 3D catalyst supports (e.g., foam architecture; **Figure 1**) has been recommended to improve catalyst utilization efficiency and lower the PGM metal loadings (Li et al., 2015; Pierozynski and Mikolajczyk, 2016). These foams have pore sizes ranging from 0.2 to 5 mm and can serve as both current collectors and as supports to load catalysts (Xing et al., 2011; Huang et al., 2017). Compared to traditional 2D supports, 3D open-pore foam architecture provides large surface area, enhanced electrolyte penetration, and gas diffusion, excellent structural integrity, and fast 3D electron transfer pathways (Friedrich et al., 2004; Aldalbahi et al., 2018). Additionally, the continuous, open-pore architecture of the 3D foams, is expected to provide excellent mass and ion-transport to and from the catalyst site, significantly improving the bubble convection when operated at high water electrolysis current densities. Recently, several approaches have been demonstrated to load PGMs on 3D open-pore metallic foams. For example, van Drunen et al. (2014) deposited platinum nanoparticles electrolessly on Ni foam and evaluated its performance for different electrocatalytic reactions. Li et al. (2015) demonstrated successful deposition of complete-monolayer of Pt on a 3D nickel foam substrate using Au or Ag buffer layer for hydrogen evolution reaction.

While many possible 3D foams are amenable to loading electrocatalyst, for large-scale cost-effective production of catalyst/support assemblies, the support should be made of low-cost materials and should be highly resistant to chemical and electrochemical corrosion. In this regard, carbon foam supports are of particular interest due to their low-cost and excellent chemical stability. In fact, 3D carbon foams (CF) have been used successfully as current collectors for microbatteries (Johns et al., 2011), metal ion removal (Friedrich et al., 2004), supercapacitors (Fischer et al., 1997), and enzymatic fuel cells (Kizling et al., 2017). However, to the best of our knowledge, no report exists on optimizing PGM loading on 3D carbon foams and benchmarking its electrocatalytic activity for important reactions such as hydrogen evolution reaction (HER).

In the present work, we synthesize uniformly dispersed Pt nanoparticles on inexpensive 3D open-pore carbon foam support using electrodeposition and optimize its catalytic activity for HER reaction. We elucidate the dependence of Pt nanoparticle diameter, density, and mass loading on electrodeposition potential and deposition charge density. The Pt/CF catalyst with loading as low as 0.06 mg/cm^2 (∼10-fold lower than state-of-the-art commercial electrodes) yield the highest mass and surface area specific activity that is six and 67 times the activity of commercial Pt/C catalyst tested under similar conditions. Moreover, the Pt/CF catalyst also demonstrate highly stable HER activity in acidic conditions after a continuous long-term chronopotentiometry run at high current density (@100 mA/cm^2).

MATERIALS AND METHODS

Materials

Reticulated vitreous carbon (RVC) foam substrates with 100 pores per inch (PPI) and a specific surface area of 2×10^3 square feet per cubic foot, and 1.96×10^{-2} ohms sq^{-1} electrical surface resistance were purchased from McMaster-Carr (Duocell RVC Foam, ERG Aerospace). Commercial Pt/C cloth (0.5 mg/cm^2, 67 m^2/g_{Pt}, 20 wt%, E-TEK; Muthuswamy et al., 2013) and bare carbon cloth were purchased from Fuel Cell Store. All chemicals were purchased from Fisher Scientific (sodium chloride (NaCl, 99%), potassium hydroxide (KOH, 86.3%), sulfuric acid (H_2SO_4, 96.3%), hydrochloric acid (HCl, 36.5%), nitric acid (HNO_3, 69%), potassium tetrachloroplatinate (K_2PtCl_4, 99.9%), and copper sulfate pentahydrate ($CuSO_4 \bullet 5H_2O$, 98%). The standard solutions for Pt and Rh detection using ICP-MS (1,000 ppm platinum and 1,000 ppm rhenium) were purchased from Inorganic Ventures. All solutions for deposition and catalyst testing were prepared using ultrapure water (18 $M\Omega$/cm).

Pt Nanoparticle Deposition on Carbon Foam Surface

A room temperature three-electrode electrochemical set-up was used for Pt electrodeposition with carbon foam as the working electrode, Pt wire as the counter electrode and a Saturated Calomel Electrode (SCE) as the reference electrode. The plating solution was made of 0.5 M sodium chloride and 3 mM potassium tetrachloroplatinate (K_2PtCl_4) with pH adjusted to 4 using dilute HCl. All depositions were carried out on a new carbon foam substrate with dimensions cut to $2 \times 1 \times 0.3$ cm. The Pt nanoparticles were deposition following a potentiostatic double pulse deposition technique (**Figure S1**). In this technique, each pulse consisted of a constant potential deposition period (till 15 mC of charge was passed) and a constant potential surface activation period (5 s). The target deposition potentials were chosen from linear sweep voltammetry curves (**Figure S2**). The target deposition charge density was obtained by controlling the

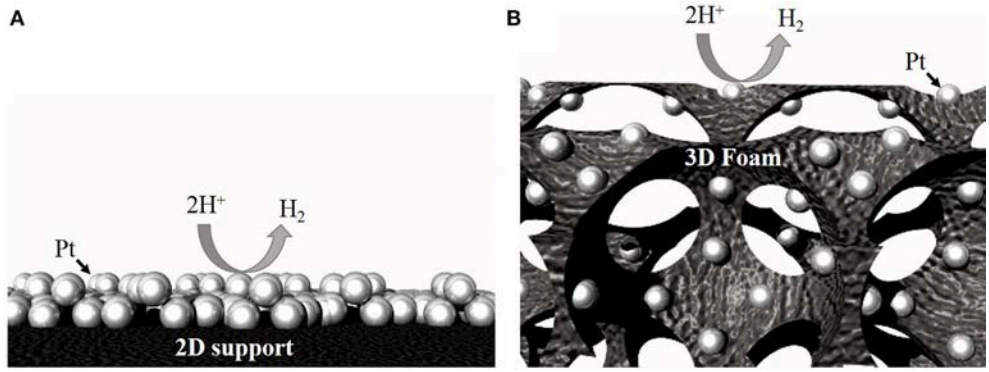

FIGURE 1 | Schematic showing higher accessibility for the same number of particles on a 3D support **(B)** compared to a 2D support **(A)**.

total number of pulses. Four different deposition potentials [-0.2,−0.3,−0.4, and−0.5 V vs. SCE (V_{SCE})] and four different deposition charge densities (50, 100, 150, and 300 mC/cm^2) were investigated for this study. A potential of 0 V_{SCE} was chosen as the surface activation potential for all depositions to remove any adsorbed chloride and hydrogen atoms from the deposited Pt surface.

Characterization

Scanning Electron Microscopy (SEM) was done by using a field emission SEM (Hitachi S-4800), and the particles size and density were determined by using Image-J software. For each sample, three separate areas were analyzed with Image-J to give an average for the particles diameter and density. A low-magnification SEM image of carbon foam loaded with Pt nanoparticles is shown in **Figure S3**.

Mass loading of Pt was determined using inductively coupled plasma mass spectrometry (ICP-MS). One square centimeter area of the carbon foam with deposited Pt particles was digested in 1 mL of aqua regia. The aqua regia was prepared from concentrated hydrochloric acid and concentrated nitric acid that was combined in a molar ratio of 3:1 HCl:HNO_3. This was diluted by a factor of 10,000 to bring the concentration to the ppb range. Samples were analyzed on a Thermo X-series II ICP-MS instrument. All samples were doped with a known amount of Re to correct for instrumental drift. Multiple Pt isotopes were measured to verify that polyatomic interferences were not an issue with these samples. Calibration curves were made for each isotope (^{194}Pt, ^{195}Pt, ^{196}Pt) (**Figure S4**). All resulted in consistent concentrations, and the final values were calculated from a weighted average using the natural abundances of the three major platinum isotopes.

Electrochemical active surface area (ECSA) of Pt nanoparticles on carbon foam was calculated using copper underpotential deposition method (Cu-UPD) technique. The Pt loaded carbon foam served as the working electrode, Pt wire served as the counter electrode and Ag/AgCl as the reference electrode. The Cu-UPD experiments were carried out in 0.001 M $CuSO_4$in 0.5 M H_2SO_4 solution. The electrodes were cycled between the potential limits of 0.15–0.8 vs. $V_{Ag/AgCl}$ at a scan rate of 20 mV/s until the charges associated with Cu stripping remained constant for each cycle (**Figure S5**). By comparing this value to the charge of the formed Cu monolayer on polycrystalline Pt (410 μC/cm^2), and by knowing the total mass loading of Pt, the ECSA can be calculated using the following equation:

$$ECSA_{Pt}\left(\frac{cm^2}{mg_{Pt}}\right) = \left[\frac{Q_{Cu-UPD\ (\mu C)}}{410\frac{\mu C}{cm^2}\ X\ mg_{Pt}}\right]$$

Hydrogen Evolution Reaction Experiments

Platinum nanoparticle-loaded carbon foam samples were tested for hydrogen evolution reaction (HER) in acid (1 M H_2SO_4) and alkaline (1 M KOH) electrolyte. A three-electrode electrochemical set-up was used for all HER studies. The carbon foam with Pt loading was used as the working electrode, pure platinum wire as the counter electrode, Ag/AgCl as a reference electrode for the acidic electrolyte, and Hg/HgO as the reference electrode for the alkaline electrolyte. Cyclic voltammetry (CV) runs were done at a scan rate of 100 mV/s. For all representative CV curves shown in this study, the electrodes were cycled for at least 30+ times (totaling 50–70 C/cm^2) which allowed for a stable and repeatable curve. The overpotential values were calculated from the final cycle of the CV graphs. All CV runs were compensated for iR losses. For stability tests, a constant cathodic current density of 100 mA/cm^2 was applied and the potential was monitored as a function of time (chronopotentiometry technique). Similar strategy of cycling the electrodes as explained above was practiced prior to all stability tests.

RESULTS AND DISCUSSION

Effect of Deposition Potential on Pt Nanoparticle Size and Density

Figures 2A–D shows representative top-down scanning electron microscopy (SEM) images of Pt nanoparticles deposited on carbon foam for different deposition potential pulses. Four different deposition potentials,−0.2,−0.3,−0.4, and−0.5 V vs. Standard Calomel Electrode (V_{SCE}) (from linear sweep voltammetry; **Figure S2**) were chosen for this study. As shown

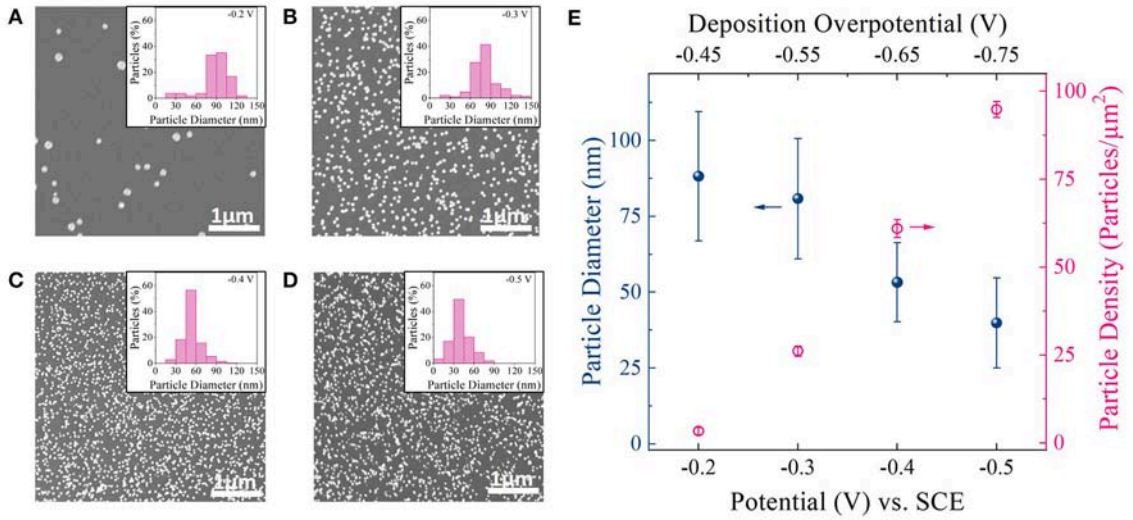

FIGURE 2 | (A–D) SEM images of Pt particles on carbon foam supports deposited at -0.2 V_{SCE}, -0.3 V_{SCE}, -0.4 V_{SCE}, and -0.5 V_{SCE}. Inset: Histogram showing particle size distribution for each deposition potential. **(E)** Average diameter and density of Pt nanoparticles deposited at different deposition potential pulses. Top x-axis: Deposition overpotential (η) value for Pt deposition.

in **Figure S2**, these deposition potentials are well negative to the equilibrium potential for Pt deposition ($+0.25$ V_{SCE}) (Liu et al., 2012). Deposition potentials more negative than -0.5 V_{SCE} resulted in hydrogen evolution ($E^0_{H+/H2,pH=4} = -0.48$ V_{SCE}) during Pt deposition and consequently was not chosen. All depositions were carried for an equivalent deposition charge density of 150 mC/cm^2. Corresponding i-t deposition transients for each deposition potential is shown in **Figure S6**.

The SEM images (**Figures 2A–D**) revealed well dispersed Pt nanoparticles on the carbon surface for all deposition potentials. **Figure 2E** shows a plot of particle diameter and density as a function of deposition potential as measured from ImageJ software. Corresponding histogram plots are shown in the inset of SEM images. From the SEM images, histogram plots, and **Figure 2E** one could observe a clear decrease in particle size and increase in particle density as the deposition overpotential increased. This suggests that at low electrodeposition overpotential (-0.2 V_{SCE}), the nucleation rate is slower than the rate of the nucleus growth on the carbon foam surface (Hussain et al., 2017). That is, it is more favorable for Pt to deposit on the existing nuclei and grow before the next nucleus is formed on carbon surface (heterogeneous reduction), resulting in larger and fewer number of Pt nanoparticles (**Figure 2A**). With the increase in deposition overpotentials (-0.3, -0.4, and -0.5 V_{SCE}), the rate of nucleation increases resulting in densely distributed smaller Pt nanoparticles (**Figures 2B–D**). In fact both particle diameter and particle density follows classical heterogeneous nucleation and growth mechanism (Pei et al., 2017), with particle diameter decreasing linearly with deposition overpotential and particle density increasing to the cube power with increasing deposition overpotential (**Figure S7**).

Since for electrocatalysis application, high surface coverage of smaller Pt nanoparticles on a given support surface directly translates to high geometric activity, we chose to work with higher deposition overpotentials for further catalyst optimization studies. Particularly -0.4 V_{SCE} was chosen as our optimal deposition potential, since it provided the highest Pt surface area to support surface area among the deposition potentials chosen for this study (**Figure S8**).

Effect of Deposition Charge on Pt Mass Loading

To address the challenging cost targets associated with Pt, it is very important to significantly reduce Pt mass loading without compromising its geometric and specific activity. Mass loading of Pt on CF was controlled by simply tuning the deposition time (mass deposited is directly proportional to the charge passed). Four different charge densities were chosen to electrodeposit Pt on CF surface (50, 100, 150, and 300 mC/cm^2; denoted hereafter as Pt/CF_{50}, Pt/CF_{100}, Pt/CF_{150}, and Pt/CF_{300}). These deposition charge densities were selected such that the Pt mass loading for the highest deposition charge (Pt/CF_{300}) was lower than the recommended target Pt loading level of <0.125 mg_{Pt}/cm^2 for electrocatalytic applications. As discussed above, a deposition potential pulse of -0.4 V_{SCE} was selected for all these studies.

Table 1 column 2 summarizes Pt mass loading (mg_{Pt}/cm^2) results measured using inductively coupled plasma mass spectrometry (ICP-MS; see Materials and Methods section) for different deposition charge densities. As expected, the Pt mass loading increased with increasing deposition charge density, varying from 0.0075 mg_{Pt}/cm^2 for Pt/CF_{50} to 0.1015 mg_{Pt}/cm^2 for Pt/CF_{300} sample.

Figures 3B–E shows SEM images of Pt deposition progression as a function of deposition charge density. **Figure 3A** is a plot of particle density and diameter as a function of mass loading. For Pt/CF_{50}, the particle density on average was 66 particles/μm^2 (**Figure 3A** red trace), and the particles remained sparsely distributed on the carbon foam surface. Doubling

the deposition charge density increased the particle density by ~27% to 84 particles/μm^2 while effectively keeping the average particle diameter constant (43 nm; **Figure 3A** black blue trace). This observed increase in particle density with deposition charge signifies that the Pt deposition on 3D foam follows a progressive nucleation and growth process. That is, as deposition time increases, more and more Pt nuclei are formed at the carbon surface, increasing the surface area of Pt per unit volume of the catalyst support. This is consistent with the trend observed for measured surface area (cm^2_{Pt}) of the catalyst which shows an increase with increasing deposition charge density (**Table 1** Column 4). For an instantaneous nucleation and growth mechanism, the particle density should remain relatively constant as the deposition charge increases (Grujicic and Pesic, 2002).

The histogram plots for the particle diameter (**Figures 3F–I**) further elucidates the Pt deposition mechanism with increasing deposition charge. A log-normal distribution was observed for each loading level. A log-normal distribution is expected when nucleation dominates growth, which increases the number of small particles with time with simultaneous growth of larger particles deposited initially. The above observation is very similar to what was observed by Teran et al. (2010) who calculated the grain size distribution for a random nucleation and growth process. However, with further increase in mass loading (Pt/CF_{300}) the particle density starts to decrease (**Figure 3A**, red trace), possibly due to coalescence of the neighboring particles as evidenced by the increase in average particle diameter from 43 to 70 nm (**Figure 3A**, blue trace). The coalescence of the particles observed for Pt/CF_{300} is also evident from the histogram plot **Figure 3H**, where the peak of the distribution shifts to the right with a larger spread.

TABLE 1 | Tabulated data of each platinum loading level using a 1 cm^2 geometric area of Pt/CF.

Sample	Mass Pt (mg_{Pt}/cm^2)	Electrochemical active surface area		Pt surface area (cm^2_{Pt})
		(m^2_{Pt}/g_{Pt})	(cm^2_{Pt}/mg_{Pt})	
Pt/CF_{50}	0.0075	11.066	110.66	0.83
Pt/CF_{100}	0.0325	5.877	58.77	1.91
Pt/CF_{150}	0.059	6.322	63.22	3.73
Pt/CF_{300}	0.1015	6.732	67.32	6.80

HER Activity

The effect of Pt mass loading on HER activity in acidic and alkaline conditions was evaluated using a standard three-electrode electrochemical cell. **Figure 4A** shows geometric HER current densities (mA/cm^2_{geo}) obtained in 1 M H_2SO_4 for Pt/CF samples by sweeping voltages from 0.1 V vs. reversible

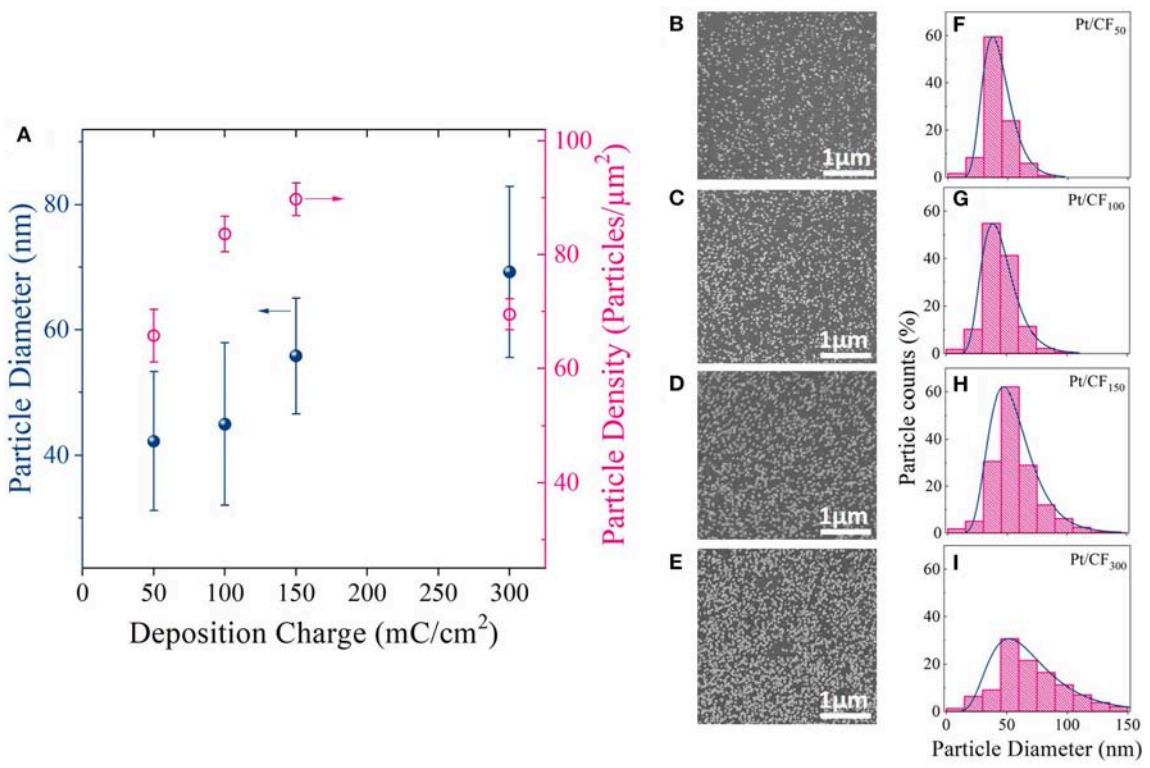

FIGURE 3 | (A) Average Pt particle diameter and density for different deposition charge densities (50, 100, 150, and 300 mC/cm^2). The deposition potential was kept constant at −0.4 V_{SCE}. **(B–E)** SEM images and **(F–I)** corresponding histogram plots showing the particle diameter distribution for each charge density.

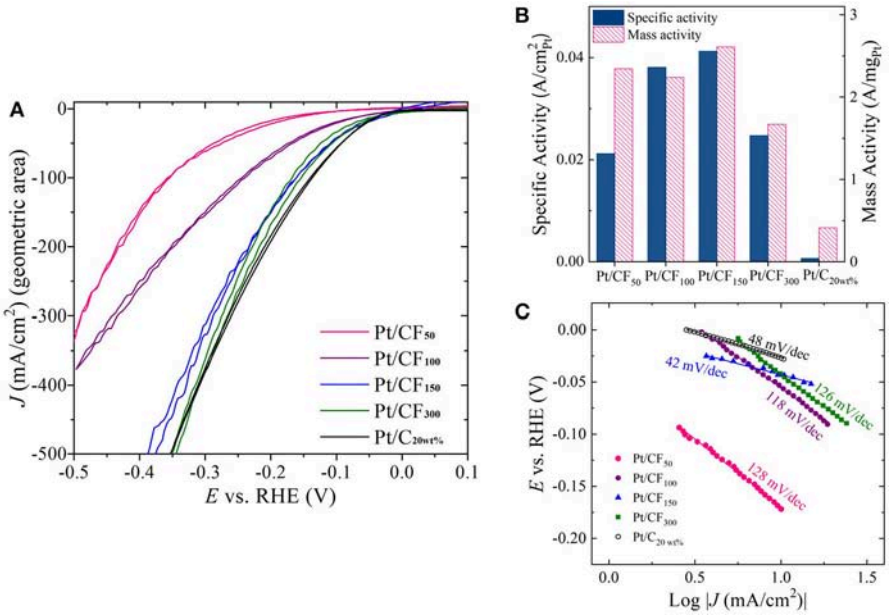

FIGURE 4 | (A) Cyclic voltammetry (CV) sweeps showing HER activity in 1 M H_2SO_4 for four Pt loading levels (50, 100, 150, and 300 mC/cm^2) as well as commercial Pt-loaded carbon cloth. **(B)** Plot of specific activity and mass activity of each catalyst at $\eta = 200$ mV. **(C)** Tafel slope plots constructed for each Pt loading level.

hydrogen electrode (V_{RHE}) to −0.5 V_{RHE} at a rate of 100 mV/s (see the Materials and Methods section for more details). All Pt/CF electrodeposited samples were directly used as working electrodes for the HER tests. Commercial Pt/carbon cloth with 20 wt. % Pt and mass loading of 0.5 mg_{Pt}/cm^2 (denoted hereafter as $Pt/C_{20wt\%}$) was also selected as a reference point and studied under the same conditions. For all measurements, the HER currents were measured as a function of ohmic-corrected potential. As shown in **Figure 4A**, the Pt/CF catalysts demonstrated increasing HER currents with increase in Pt mass loading. Particularly, Pt/CF_{150} and Pt/CF_{300} catalyst showed excellent HER activity, as evidenced by the very small overpotential (η) of 370 and 340 mV needed to deliver a high current density of 500 mA/cm^2. **Figure S10** provides cyclic voltammograms from the 10th CV cycle for each Pt loading with its corresponding Tafel slope analysis. These values are comparable to state-of-the-art commercial 2D $Pt/C_{20wt\%}$ sample (**Figure 4A**, black trace). It should be noted that the Pt/CF_{150} and Pt/CF_{300} samples had Pt mass loading 10- and 5-fold lower than the commercial $Pt/C_{20wt\%}$electrode and HER results were obtained under quiescent electrode/electrolyte conditions (no vigorous stirring and/or electrolyte flow).

Although geometric current density serves as a practical metric to compare catalyst performance, for optimal catalyst design it is important to compare mass activity (A/mg_{Pt}) and specific activity (A/cm^2_{Pt}) as a function of Pt loading. **Figure 4B**, red bars show mass activity measured at $\eta = 200$ mV for different deposition charge densities. The mass activity of Pt/CF samples remained more or less independent to initial deposition charge density, with the highest mass activity of 2.61 A/mg_{Pt} obtained for Pt/CF_{150}, which is 6.3 times higher than that of the state-of-the-art commercial $Pt/C_{20wt\%}$ (0.41 A/mg_{Pt}). The mass activity decreased with further Pt mass loading (Pt/CF_{300}; 1.67 A/mg_{Pt}), possibly due to the reduction in Pt mass utilization due to coalescence of smaller particles as discussed above (**Figures 3E,I**). However, we note that the lowest mass activity obtained for Pt/CF_{300} (1.67 A/mg_{Pt}) is still four times higher than that of the commercial catalyst.

The specific activity (A/cm^2_{Pt}) for each catalyst was determined from its mass activity (A/mg_{Pt}) and electrochemical active surface area (ECSA; cm^2_{Pt}/mg_{Pt}). The measured ECSA for different mass loading (in cm^2_{Pt}/mg_{Pt} and $m^2_{Pt}/g_{Pt)}$ is summarized in **Table 1** Column 3. Cu-underpotential (Cu-UPD) deposition was used to determine the ECSA assuming a specific charge of 420 $\mu C/cm^2_{Pt}$ per monolayer Cu deposited on the Pt surface (see Materials and Methods Section). No Cu-UPD was observed on bare carbon foam substrate. The specific activity of the catalyst increased with Pt loading with Pt/CF_{150} catalyst showing nearly 67 times greater specific activity compared to commercial $Pt/C_{20wt\%}$ catalyst (**Figure 4B**, blue bars). The specific activity decreased with further increase in deposition charge density (Pt/CF_{300}) likely due to decreased Pt mass utilization caused by nanostructure/morphology changes as discussed above. The Tafel analysis (**Figure 4C**) gave Tafel slope values of 128, 118, 42, and 126 mV/dec for Pt/CF_{50}, Pt/CF_{100}, Pt/CF_{150}, and Pt/CF_{300} when plotted for current density ranges 3–30 mA/cm^2. The Tafel slope for Pt/CF_{150} was lower than commercial $Pt/C_{20wt\%}$ (48 mV/dec), which is consistent with this catalyst having the highest mass and specific activity. When tested in alkali media (1M KOH), the Pt/CF catalysts exhibited similar trends to that observed in acidic electrolyte (**Figures S9, S11**). The Pt/CF_{150} catalyst exhibited the best catalytic performance with a specific activity of 0.126 A/cm^2_{Pt} (@$\eta = 400$ mV) with a reasonably small Tafel slope (105 mV/dec) for alkaline conditions. XRD Data

for different Pt loading levels is provided in **Figures S12, S13** provides current density-volage profile for Pt/CF_{150} sample with Graphite as the counter electrode.

To better understand the role of 3D carbon foam substrates on observed HER enhancement, electrochemical tests were carried out on 2D carbon cloth with Pt mass loading similar to the best performing Pt/CF electrode (Pt/CF_{150}). The Pt was loaded on the 2D carbon cloth following the exact electrodeposition protocols. The amount of Pt deposited was controlled by tuning the deposition charge and HER tests were carried out using the same electrochemical set-up with similar reactor volume and electrode positioning. As shown in **Figure 5A**, for the same mass loading, the Pt/C and Pt/CF electrode (represented as Pt/C_{150} and Pt/CF_{150}) have similar overpotential values up to current densities of 75 mA/cm^2 (see **Figure S14** for Tafel slope analysis). However, with increasing current densities, the Pt/CF_{150} behaved superior compared to its 2D counterpart. For example, to achieve 400 mA/cm^2, the Pt/CF_{150} required a modest overpotential of 350 mV compared to 500 mV for Pt/C_{150} electrode. No significant HER currents were observed on bare carbon cloth (C_{Bare}). The observed superior performance for Pt/CF_{150} at higher current densities further corroborates that 3D CF substrate provides better bubble convection and access to catalyst sites compared to 2D carbon cloth. We also normalized the performance of both Pt/C_{150} and Pt/CF_{150} electrode by their corresponding actual catalyst loadings and found that the difference in mass activity between Pt/CF_{150} and Pt/C_{150} increases with increasing HER overpotential (**Figure 5B**). At an overpotential of 400 mV ($-0.4V_{RHE}$), the mass activity of Pt/CF was 8.75 A/mg_{Pt}, almost 70% higher than that of Pt/C electrode.

Long-Term Stability

To evaluate the long-term stability of the Pt/CF catalysts, accelerated degradation studies were performed for the best performing Pt/CF_{150} catalyst in acidic conditions. The stability was assessed by monitoring the increase in overpotential in 1 M H_2SO_4 for an applied current density of 100 mA/cm^2. No *iR* compensation was carried out for the stability runs. **Figure 6** shows that after 60 hours of continuous operation the overpotential increased by less than 16 mV (7%) in acid. It is to be noted that the current density used here for stability measurement is 10-fold higher than that of the most reported literature values for low PGM loaded materials (Li et al., 2015). The catalysts after stability testing were characterized by SEM images, which showed no obvious change to the structural morphology (particle diameter and density), indicating that the Pt nanoparticles are extremely stable and bound strongly to the carbon foam support even under high current density operation.

In conclusion, we demonstrated a simple solution-processed electrodeposition technique to load low amounts of Pt nanoparticles on low-cost, high surface area 3D carbon foam support for HER reaction. We established the dependence of particle diameter and density as a function of deposition potential and charge density and investigated the HER activity

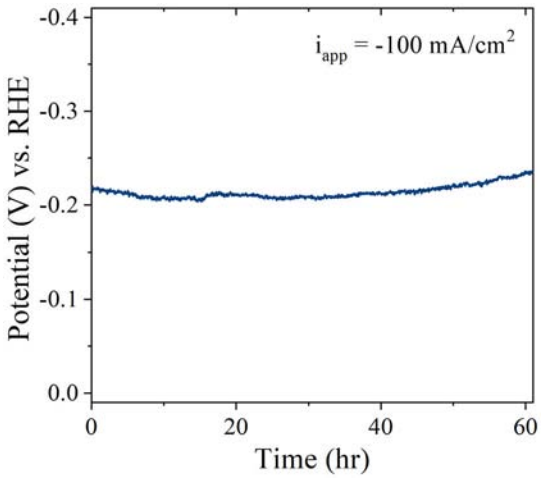

FIGURE 6 | Stability of Pt/CF_{150} operating at−100 mA/cm^2 in 1 M H_2SO4.

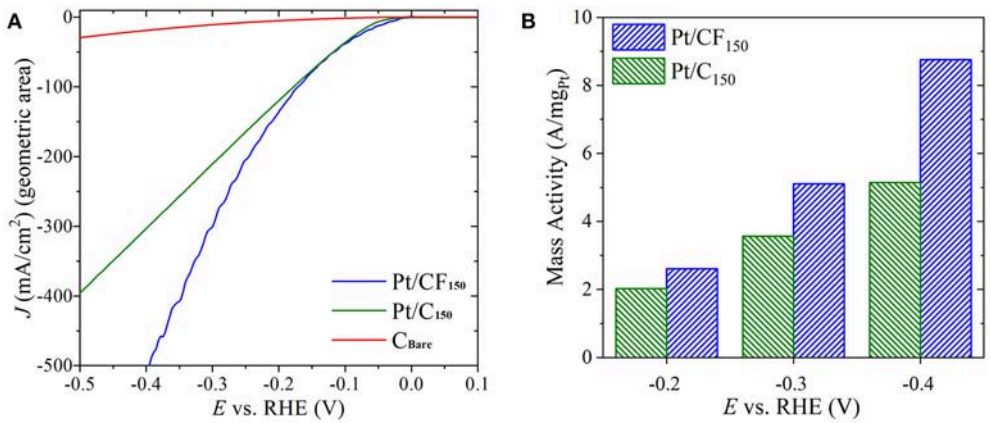

FIGURE 5 | (A) Forward scan from cyclic voltammetry (CV) sweeps showing HER activity in 1 M H_2SO_4 for Pt loaded on 3D carbon foam with 150 mC/cm^2 loading (Pt/CF_{150}), Pt loaded on carbon cloth with 150 mC/cm^2 loading (Pt/C_{150}), and bare carbon cloth (C_{Bare}). The potential is iR-compensated. **(B)** Mass activity of Pt/CF_{150} and Pt/C_{150} at three overpotentials.

of the Pt-loaded carbon foams. All synthesized Pt/CF catalysts exhibited excellent mass activities that are superior to the state-of-the-art commercial Pt/C catalyst. For the best performing Pt/CF catalyst, the mass and specific activity were 6.3 and 67 times higher than commercial Pt/C catalysts. Also, the best performing catalyst showed excellent stability with minimal degradation when operated at high current densities. We attribute this significant improvement in catalytic activity observed for Pt/CF samples to the following reasons. (i) The electrodeposition technique allows binder-free deposition of Pt directly on the electroactive site of the support facilitating efficient charge transport across support/catalyst interface. (ii) Enhanced mass transport: the 3D open-pore foam architecture provides enhanced electrolyte penetration and improved diffusion of H^+ ions and H_2 to and from the Pt nanoparticle surface. (iii) Increased surface area of the 3D carbon foam providing easy access to the catalytic sites.

AUTHOR CONTRIBUTIONS

AG and JK designed and carried out all the synthesis, characterization, and data analysis. BH performed Tafel analysis. AR, WC, and JL assisted AG and JK with material synthesis and microscopy characterization. DP performed ICPMS measurements. SM supervised the work, designed experiments with AG and JK. All authors were involved in manuscript writing.

ACKNOWLEDGMENTS

This work was partially supported by Desalination and Water Purification Research and Development Program, Bureau of Reclamation under Agreement No. R16AC00126. JK and WC are grateful for the support by The University of Iowa through Sponsored Research Agreement with HyperSolar Inc., under grant number 18786500. SM and AR also acknowledge the support of the University of Iowa startup funds.

We demonstrate a new technique to produce lithium sulfide-carbon composite (Li_2S-C) cathodes for lithium-sulfur batteries *via* aerosol spray pyrolysis (ASP) followed by sulfurization. Specifically, lithium carbonate-carbon (Li_2CO_3-C) composite nanoparticles are first synthesized via ASP from aqueous solutions of sucrose and lithium salts including nitrate ($LiNO_3$), acetate (CH_3COOLi), and Li_2CO_3, respectively. The obtained Li_2CO_3-C composites are subsequently converted to Li_2S-C through sulfurization by reaction to H_2S. Electrochemical characterizations show excellent overall capacity and cycle stability of the Li_2S-C composites with relatively high areal loading of Li_2S and low electrolyte/Li_2S ratio. The Li_2S-C nanocomposites also demonstrate clear structure-property relationships.

INTRODUCTION

Lithium-sulfur (Li-S) batteries are regarded as one of the most promising electrochemical energy storage technologies due to their low cost, environmental benignity, and outstanding theoretical capacity (Wang et al., 2013; Son et al., 2015). However, despite tremendous research and development efforts, there are still a number of challenges hindering their commercialization. Among these key challenges are the polysulfides shuttle effect and high electrolyte/sulfur ratio, which are significantly magnified by the instability of the Li metal anode (Chen J. et al., 2017; Chen S. et al., 2017; Pan et al., 2018; Wu et al., 2018). Therefore, high capacity non-Li anodes, particularly those comprised of silicon-based materials, have been proposed as replacements for Li metal in Li-S batteries (Yang et al., 2010). The use of silicon anode materials would require a pre-lithiated sulfur cathode, i.e., lithium sulfide (Li_2S). In recent years, various methods to synthesize Li_2S-carbon composite materials have been reported, including high-energy mixing Li_2S with carbon (Cai et al., 2012; Jha et al., 2015), chemical lithiation of S-C composites (Hwa et al., 2015), Li_2S-C composites synthesis *via* dissolving and precipitating Li_2S in ethanol (Wu et al., 2014a,b,c, 2015, 2016), embedding Li_2S in carbon matrix *via* Li-nitrogen interaction (Guo et al., 2013), reaction between Li metal and carbon disulfide (Tan et al., 2017), converting LiOH to Li_2S *via* sulfurization with H_2S (Dressel et al., 2016), and thermal reduction of Li_2SO_4 by carbon (Yang et al., 2013; Kohl et al., 2015; Li et al., 2015; Yu et al., 2017; Zhang et al., 2017; Ye et al., 2018). In addition, the mechanism studies on Li_2S activation and capacity degradation were also reported (Vizintin et al., 2017; Piwko et al., 2018). In this work, we report a new scalable method for synthesizing Li_2S-C composites via aerosol spray pyrolysis (ASP) followed by sulfurization.

MATERIALS AND METHODS

Materials Synthesis

Three lithium salts including lithium nitrate ($LiNO_3$), lithium acetate (CH_3COOLi) and lithium carbonate (Li_2CO_3) were used as the precursors for Li_2S with sucrose as the precursor for carbon. Each Li salt was dissolved in deionized water with sucrose at different concentrations as listed in **Table S1**. The obtained solutions were used in the ASP process.

The ASP system in this study is illustrated in **Figure S1**. The commercial aerosol generator (TSI, Model 3076) consisting of a nebulizer and a solution reservoir is attached to a diffusion dryer followed by a tubular furnace and a filter collector. The diffusion dryer was composed by two concentric tubes: The outer tube is made of 3-inch inner diameter PVC tubing and the inner tube is made of 0.5-inch diameter steel mesh with the annular space filled with porous silica gel. The aerosol of the precursor solution was generated by the nebulizer and carried through the diffusion dryer by argon gas to desiccate the water content. The resultant dry particles were continuously carried into the tube furnace heated at 850°C to produce the Li_2CO_3-C nanoparticles, which are collected with a stainless-steel filter down stream outside the tube furnace.

The synthesized Li_2CO_3-C composite is placed in an alumina boat in a tubular furnace, followed by purging with argon for an hour. The furnace was then heated to 725°C and maintained at this temperature for 5 h under a flow of 5 vol.% H_2S and 95 vol.% argon. After 5 h the flow gas was switched to pure argon and the furnace was cooled naturally to room temperature. The product was collected in an argon-filled glovebox due to the sensitivity of Li_2S to moisture.

Materials Characterization

The nitrogen adsorption-desorption isotherms of the produced composite materials were obtained with a surface area and porosity analyzer (Micromeritics ASAP2020). For a particular analysis, approximately 200 mg sample was first degassed at 150°C for 3 h, then the nitrogen adsorption-desorption isotherms were measured from 0 to 1 relative pressure. The surface area was obtained with the Brunauer-Emmett-Teller (BET) method. The crystalline species in the composites were characterized by powder X-Ray diffraction (XRD, PANalytical) with a CuKα source and a scan rate of $0.11^\circ\ s^{-1}$. Kapton tape was used to seal the Li_2S-C composites to protect Li_2S from reacting with the moisture in ambient environment during measurement. The morphology and microstructure of the composites were characterized by scanning electron microscopy (SEM) and transmission electron microscopy (TEM, Tecnai T12). Carbon content in the Li_2CO_3-C composites was measured with thermogravimetric analysis (TGA, TA Instruments). The TGA samples were held at 120°C for 30 min to remove the moisture absorbed from environment, followed by heating to 600°C at a rate of $10°C\ min^{-1}$ with an isothermal step in dry air. The carbon contents in Li_2CO_3-C_{NitS}, Li_2CO_3-C_{AceS} and Li_2CO_3-C_{CarS} (**Figure S2**) are very consistent at 20.7, 22.8, and 21.2 wt.%, respectively. Assuming complete conversion from Li_2CO_3 to Li_2S without carbon loss, the Li_2S content in Li_2S-C_{NitS}, Li_2S-C_{AceS} and Li_2S-C_{CarS} can be estimated as 70.4, 67.8, and 69.8 wt.%, respectively. The accurate Li_2S content in the Li_2S-C composites is determined as follows: 100 mg Li_2S-C was thoroughly washed 4 times using 15 mL ethanol each time in the glovebox to remove Li_2S. The obtained carbon was weighed after dried at 120°C for 8 h in the glovebox. The Li_2S content is 71.3 wt.% in Li_2S-C_{NitS}, 69.1 wt.% in Li_2S-C_{AceS}, and 71.6 wt.% in Li_2S-C_{CarS}, which all agree very well with the estimated values.

Electrode Preparation and Cell Testing

The electrode is composed of 80 wt.% of Li_2S-C composite, 10 wt.% of carbon black additive, and 10 wt.% of polystyrene as the binder. Polystyrene was selected as the binder to avoid the use of polar solvents (both protic and aprotic), most of which dissolve Li_2S to some extent. Instead, mesitylene (Sigma-Aldrich) was used as the solvent for polystyrene in the electrode slurry. The electrodes were coated on carbon-coated aluminum current collector (MTI Corporation) in the argon-filled glovebox, with the average loading of Li_2S-C composite at $2\ mg\ cm^{-2}$. The electrodes were dried overnight in argon glovebox at room temperature, followed by drying at 120°C for 4 h. The dried electrodes are assembled into 2032-type coin cells with lithium foil anode (99.9%, Alfa Aesar) and Celgard® 2,500 separator. The electrolyte used in this study is 1M lithium bis(trifluoromethanesulfonyl)imide (LiTFSI) solution in a mixture of 1,3-dioxolane (DOL), dimethoxyethane (DME) and 1-butyl-1-methylpyrrolidinium bis(trifluoromethanesulfonyl)imide (Pyr14TFSI) (1:3:1 by vol.) with 1.5 wt.% of $LiNO_3$. The electrolyte to Li_2S ratio (μL/mg) was kept at 10 in all coin cells testing. To activate the Li_2S-C electrode, the first anodic scan in the cyclic voltammetry (CV) was to 3.9 V vs. Li^+/Li, and the anodic limit in the following scans was 2.6 V vs. Li^+/Li. Similarly, the first charge was run at a rate of $50\ mA\ g^{-1}$ (with respect to Li_2S) to a charge cutoff of 3.5 V. Subsequent cycles are run at $117\ mA\ g^{-1}$ between 2.6 V and 1.8 V vs. Li^+/Li.

RESULTS AND DISCUSSION

During ASP synthesis, three aqueous solutions containing sucrose (as carbon precursor) and either lithium nitrate ($LiNO_3$), lithium acetate (CH_3COOLi), or lithium carbonate (Li_2CO_3), denoted as NitS, AceS, and CarS, respectively, were atomized into aerosols with a pressure-enabled atomizer. The aerosols were subsequently carried by argon gas through a diffusion dryer and a tubular furnace for pyrolysis within an inert environment. The powder X-ray diffraction (XRD) patterns in **Figure 1A** clearly indicate that the obtained composites from all three lithium salts are Li_2CO_3-C composite with comparable carbon content (20.7 wt.% in Li_2CO_3-C_{NitS}, 22.8 wt.% in Li_2CO_3-C_{AceS} and 21.2 wt.% in Li_2CO_3-C_{CarS} *via* thermalgravimetric analysis, **Figure S2**). It is worth noting that sucrose solution without the lithium salts (i.e., precursors of Li_2CO_3) completely decomposes during the same ASP without any carbon formation. This observation reveals that Li_2CO_3 serves as the nucleation sites for carbonization of sucrose in ASP (Skrabalak and Suslick, 2006). However, the formation mechanisms of Li_2CO_3 from these three Li salts are clearly

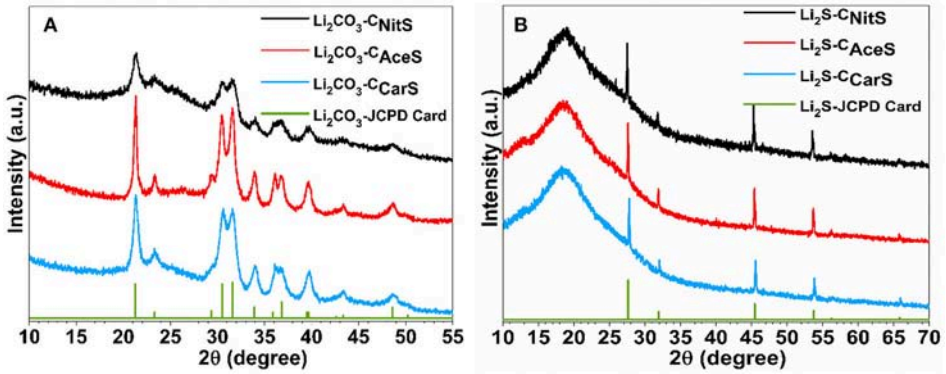

FIGURE 1 | XRD patterns of **(A)** the Li_2CO_3-C composites obtained from ASP and **(B)** the Li_2S-C composites after sulfurization.

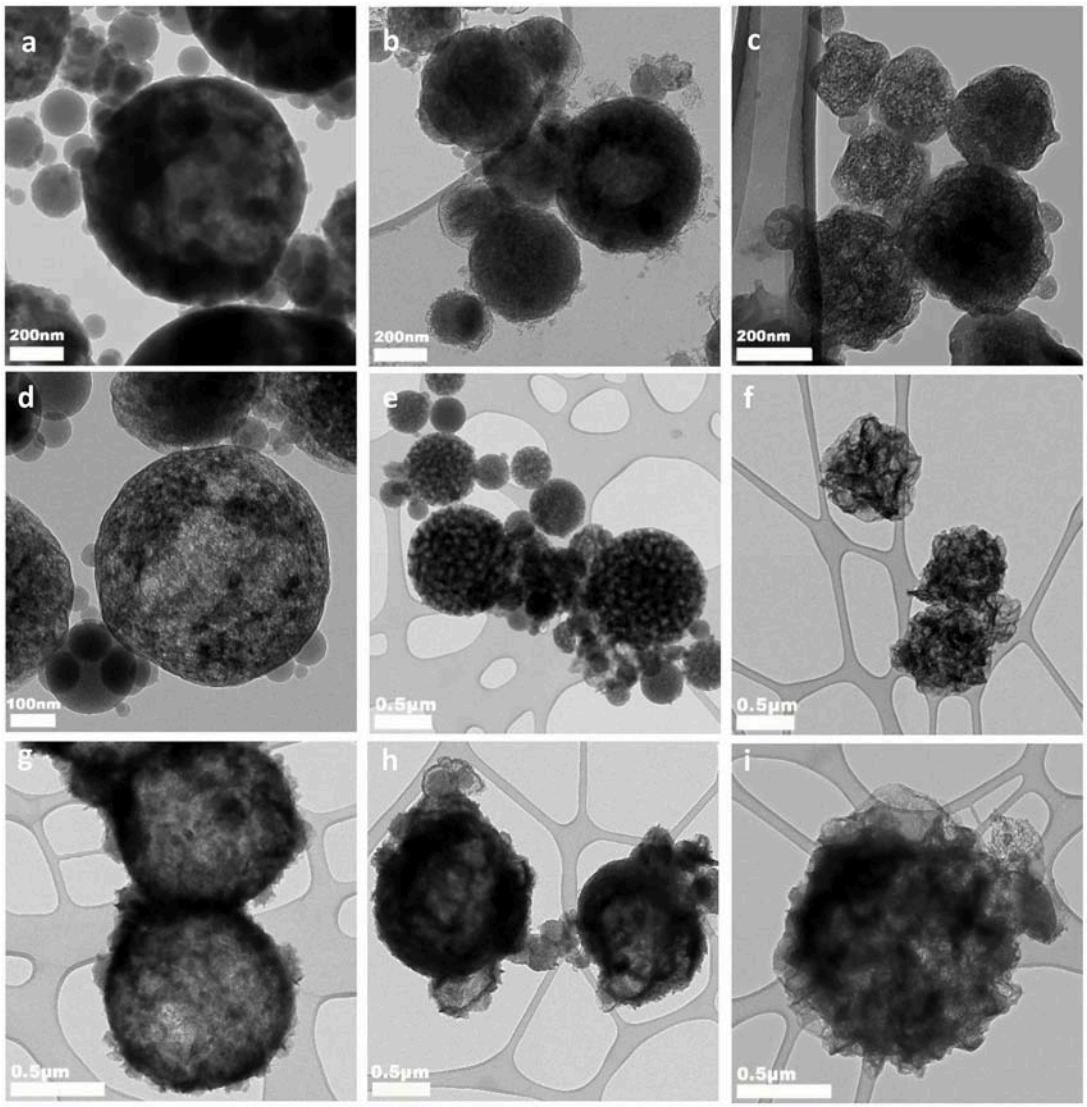

FIGURE 2 | TEM images of **(a)** Li_2CO_3-C_{NitS}, **(b)** Li_2CO_3-C_{AceS}, **(c)** Li_2CO_3-C_{CarS}; TEM images of the carbon matrix of **(d)** Li_2CO_3-C_{NitS}, **(e)** Li_2CO_3-C_{AceS}, **(f)** Li_2CO_3-C_{CarS} after Li_2CO_3 removed; and TEM images of **(g)** Li_2S-C_{NitS}, **(h)** Li_2S-C_{AceS}, **(i)** Li_2S-C_{CarS}.

different. For $LiNO_3$, its thermal decomposition is known to proceed according to **Reaction 1**: (Stern and Weise, 1969)

$$\mathbf{2LiNO_3 \rightarrow Li_2O + 2NO_x + (2.5 - x)O_2} \quad (1)$$

Based on the XRD evidence of Li_2CO_3 with the absence of crystalline Li_2O, it can be speculated that carbon dioxide (CO_2) released from pyrolysis of sucrose further reacts with Li_2O to generate Li_2CO_3 according to **Reaction 2**:

$$\mathbf{Li_2O + CO_2 \rightarrow Li_2CO_3} \quad (2)$$

CH_3COOLi undergoes thermal decomposition to generate Li_2CO_3 and acetone according to **Reaction 3**: (Roe and Finlay, 1952)

$$\mathbf{2CH_3COOLi \rightarrow Li_2CO_3 + C_3H_6O} \quad (3)$$

For the CarS precursor, Li_2CO_3 undergoes precipitation during ASP without decomposition, thus becoming directly embedded into the carbon matrix formed by the carbonization of sucrose.

Although the obtained Li_2CO_3-C composites have consistent composition and carbon content, they have distinctively different microstructures as displayed by the transmission electron microscopy (TEM) images in **Figure 2** (scanning electron microscopy images in **Figure S3**). The Li_2CO_3-C_{NitS} nanoparticles in **Figure 2A** have a hollow-shell structure with irregular-shaped interior voids due to the release of NO_x and O_2 gases during pyrolysis. The high solubility of $LiNO_3$ in water also contributes to the formation of this hollow structure. When water evaporates during ASP, $LiNO_3$ precipitates at the outer surface of the aerosol droplets following the surface precipitation mechanism (Messing et al., 1993). The microstructure of the Li_2CO_3-C_{NitS} nanoparticles is further revealed by the TEM image in **Figure 2D**, after the removal of Li_2CO_3 using diluted hydrochloric acid (HCl). The carbon matrix of Li_2CO_3-C_{NitS} has a highly porous structure after Li_2CO_3 removal, indicating that Li_2CO_3 occupies the majority of the volume in the Li_2CO_3-C_{NitS} nanoparticles. The specific surface area of Li_2CO_3-C_{NitS} before and after Li_2CO_3 removal obtained from the nitrogen adsorption-desorption isotherms (**Figure 3** and **Table S2**) is consistent with this observation: the specific surface area of Li_2CO_3-C_{NitS} is significantly increased from 26.8 to 608.2 $m^2\ g^{-1}$ after Li_2CO_3 removal.

On the other hand, Li_2CO_3-C_{AceS} nanoparticles show a denser spherical structure in **Figure 2B**. It is worth noting that the AceS precursor solution has a significantly lower sucrose/lithium salt molar ratio at 1:15 compared to 1:1.5 in NitS and 1:1.18 in CarS. Given the 22.8 wt.% carbon content in Li_2CO_3-C_{AceS}, it is believed the generated acetone during the pyrolysis of CH_3COOLi must function as the major source for carbon formation. The TEM image of the carbon matrix after Li_2CO_3 removal in **Figure 2E** reveals the distribution of Li_2CO_3 in the Li_2CO_3-C_{AceS} nanoparticles is not as uniform as in Li_2CO_3-C_{NitS}. The carbon matrix has a golf ball-like structure with relatively large pores, previously occupied by Li_2CO_3, distributed within. The specific surface area of Li_2CO_3-C_{AceS} is 76.3 $m^2\ g^{-1}$, which increases to 184.9 $m^2\ g^{-1}$ after Li_2CO_3 removal. This modest increase of surface area also indicates the relatively larger size of Li_2CO_3 compared to that of Li_2CO_3-C_{NitS}.

As shown in **Figure 2C**, the Li_2CO_3-C_{CarS} nanoparticles clearly have a different structure resembling crumpled spheres, which is due to the much lower solubility of Li_2CO_3 in water than those of $LiNO_3$ and CH_3COOLi. The concentration of Li_2CO_3 in the CarS precursor solution is 0.1 M, which is close to saturation (Zou et al., 2013). Therefore, Li_2CO_3 undergoes fast and uniform precipitation from the aerosol droplets' evaporation in ASP according to the volume precipitation mechanism (Messing et al., 1993). In addition, the ASP of CarS precursor also releases fewer gaseous species without decomposition of Li_2CO_3. Both factors contribute to better confinement and more uniform distribution of Li_2CO_3. After Li_2CO_3 removal, the carbon matrix retains its original structure with apparently higher porosity as shown in **Figure 2F**. The specific surface area of Li_2CO_3-C_{CarS} nanoparticles is 43.7 $m^2\ g^{-1}$, which increases to 443.6 $m^2\ g^{-1}$ after Li_2CO_3 removal.

The Li_2CO_3-C nanoparticles obtained *via* ASP were subsequently reacted with mixed hydrogen sulfide and argon gas (H_2S/Ar at 5/95 vol.%) at 725°C to yield the Li_2S-C composites

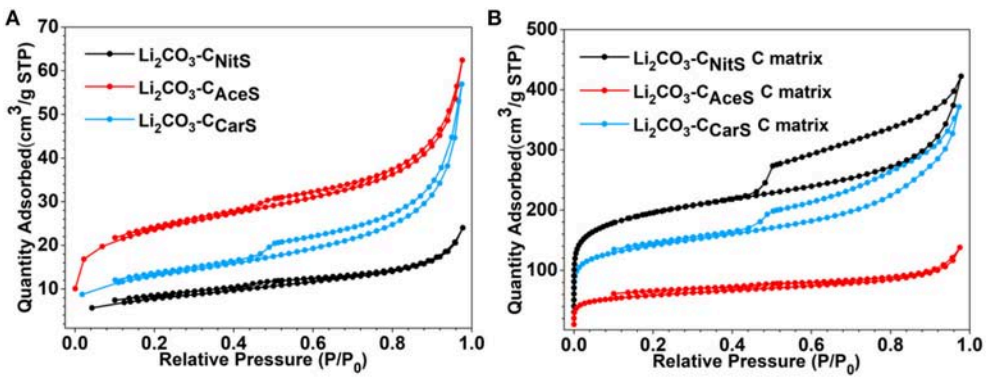

FIGURE 3 | N_2 adsorption-desorption isotherms of **(A)** Li_2CO_3-C nanoparticles and **(B)** the carbon matrix after Li_2CO_3 removal.

according to **Reaction 4**, confirmed by the XRD patterns shown in **Figure 1B**.

$$Li_2CO_3 + H_2S \rightarrow Li_2S + H_2O + CO_2 \quad (4)$$

The TEM images of the Li_2S-C composites in **Figures 2G–I** (scanning electron microscopy images in **Figure S4**) demonstrate that these nanoparticles sustain their original structures after the conversion to Li_2S from Li_2CO_3.

Figure 4 shows the first three CV cycles of the Li_2S-C vs. Li counter/reference electrode in two-electrode cells. The cathodic peak in the first delithiation scan of Li_2S-C_{NitS} is centered at 3.5 V with a small shoulder at 3.4 V. The Li_2S-C_{AceS} composite demonstrates a broader delithiation peak at the same potential.

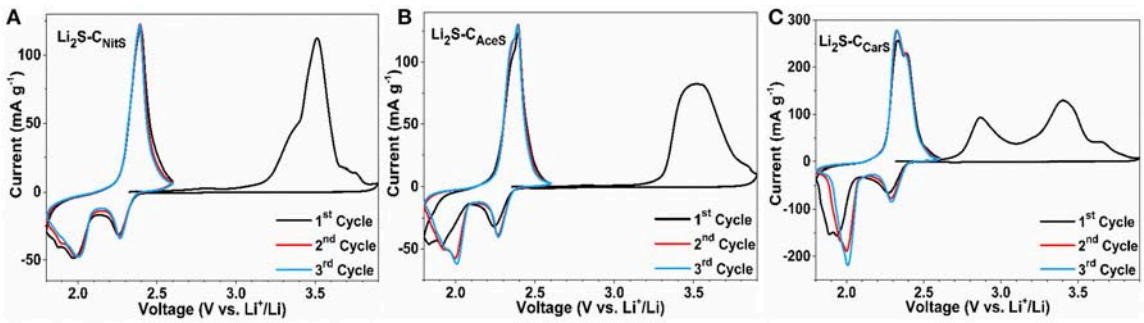

FIGURE 4 | CV scans of **(A)** Li_2S-C_{NitS}, **(B)** Li_2S-C_{AceS}, **(C)** Li_2S-C_{CarS} using 0.2 mV s^{-1} scan rate.

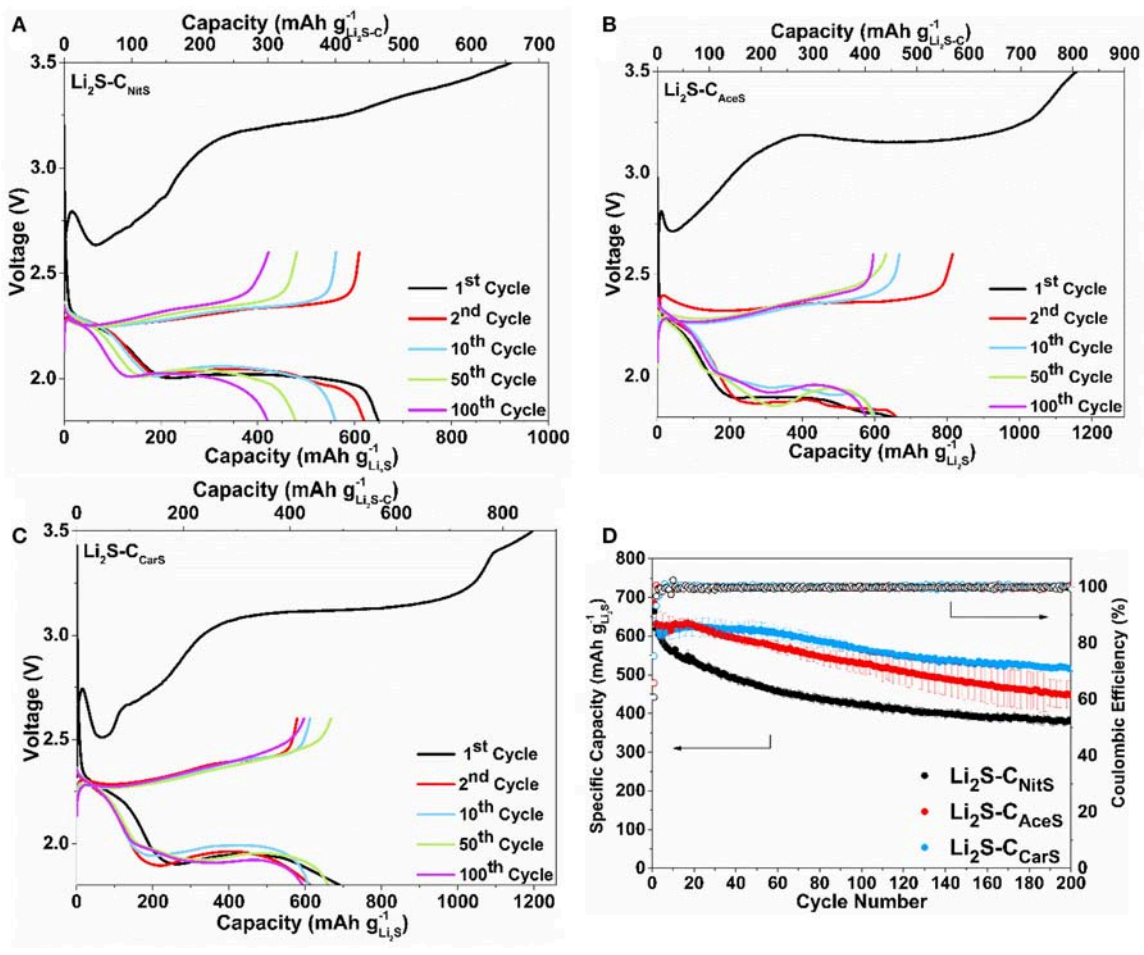

FIGURE 5 | Representative charge-discharge curves of **(A)** Li_2S-C_{NitS}, **(B)** Li_2S-C_{AceS}, **(C)** Li_2S-C_{CarS} at the 1st, 2nd, 10th, 50th, and 100th cycle, and **(D)** the cycle stability of these composites at 117 mA g^{-1}.

In contrast, Li_2S-C_{CarS} shows two distinct cathodic peaks at 2.75 and 3.4 V vs. Li^+/Li. The lower cathodic peak of the Li_2S-C_{CarS} composite at 2.75 V indicates a lower energy barrier for the delithiation reaction (Zhou et al., 2017). The Li_2S-C_{CarS} composite also demonstrates the highest peak current in the consecutive lithiation-delithiation scans. The superior performance of Li_2S-C_{CarS} may be reflective of the intimate contact of Li_2S and the carbon matrix. **Figure 5** displays the representative charge-discharge curves and the cycle stability of the Li_2S-C composites. The electrolyte/Li_2S ratio is 10:1 (μL/mg), and all Li_2S-C composites are first charged to 3.5 V (activation) vs. Li^+/Li with a current density of 50 mA g^{-1}. The charge-discharge curves demonstrate similar cycling behavior of these three Li_2S-C composites. However, Li_2S-C_{AceS} shows the highest charge-discharge hysteresis, which is consistent with the lowest surface area of its carbon matrix. On the other hand, although Li_2S-C_{NitS} shows the lowest voltage hysteresis due to the highest surface area of its carbon matrix, its capacity rapidly fades. As a composite with the balanced microstructure, Li_2S-C_{CarS} demonstrates the best overall performance: After 200 cycles, Li_2S-C_{CarS} can retain a capacity of 540 mAh g^{-1}, superior to 385 mAh g^{-1} of Li_2S-C_{NitS} and 460 mAh g^{-1} of Li_2S-C_{AceS}, indicating the effectiveness of the Li_2S-C_{CarS} composite architecture in sequestrating polysulfides. The overall performance demonstrated by Li_2S-$C_{CarS,}$ in terms of areal loading, E/Li_2S ratio, overall capacity, and cycle stability, is on par with the best performance reported to date (**Table S3**).

In summary, we examined a new synthetic route for the production of Li_2S-C composite materials for Li-S batteries. The combination of aerosol spray pyrolysis and sulfurization has been shown to be a robust method for the conversion of various lithium salts including nitrate, acetate, and carbonate to Li_2S-C nanocomposites using sucrose as the carbon precursor. Furthermore, the cycling performance of the Li_2S-C composite has been found to be closely correlated to its precursor-derived microstructure. The combination of Li_2CO_3 and sucrose results in the Li_2S-C composite with the best electrochemical performance, which has a non-hollow composite structure with Li_2S uniformly embedded in the carbon matrix. The detailed mechanism of aerosol spray pyrolysis and the optimization of the composite's structure and electrochemical performance will be further investigated in our future studies.

AUTHOR CONTRIBUTIONS

NH completed most of the experiments. JS, JZ, and CF helped with the experiments and data analysis. JG designed the experiments. All authors co-wrote the manuscript.

Biofuel cell (BFC) electrodes are typically manufactured by combining enzymes that act as catalysts with conductive carbon nanomaterials in a form of enzyme-nanocomposite. However, a little attention has been paid to effects of the carbon nanomaterials' structural properties on the electrochemical performances of the enzyme-nanocomposites. This work aims at studying the effects of surface and bulk properties of carbon nanomaterials with different degrees of graphitization on the electrochemical performances of glucose oxidase (GOx)-nanocomposites produced by immobilizing GOx within a network of carbon nanopaticles. Two types of carbon nanomaterials were used: graphitized mesoporous carbon (GMC) and purified mesoporous carbon (PMC). Graphitization index, surface functional groups, hydrophobic properties, and rate of aggregation were measured for as-received and acid-treated GMC and PMC samples by using Raman spectrometry, *X-ray photoelectron spectroscopy (*XPS), contact angle measurement, and dynamic light scattering (DLS), respectively. In addition to these physical property characterizations, the enzyme loading and electrochemical performances of the GOx-nanocomposites were studied via elemental analysis and cyclic voltammetry tests, respectively. We also fabricated BFCs using our GOx-nanocomposite materials as the enzyme anodes, and tested their performances by obtaining current-voltage (IV) plots. Our findings suggest that the electrochemical performance of GOx-nanocomposite material is determined by the combined effects of graphitization index, electrical conductivity and surface chemistry of carbon nanomaterials.

Keywords: graphitized mesoporous carbon, graphitization index, hydrophobic properties, biofuel cells, glucose oxidase, enzymatic nanocomposites

INTRODUCTION

Self-powered implantable devices such as deep brain neurostimulators, pacemakers, and biosensors for environmental monitoring have enormous potential in medical, agricultural or even military applications (Falk et al., 2012; Katz, 2013). Biofuel cells (BFCs) can be an alternative portable power solution to batteries for powering these devices, due to their capability to continuously convert the chemical energy from organic fuels, such as glucose in fruits or human blood, into electricity

(Katz, 2013; MacVittie et al., 2015). Enzymatic BFCs use (1) enzymes to catalyze both oxidation of organic fuels and reduction of oxidizing agents, and (2) conductive materials (such as carbon nanomaterials) to transmit the electrons between the enzymes' active sites and the electrodes. Thus, the physical properties of both materials—enzymes and nanomaterials—play a key role in the BFC's electrochemical performances. However, to the best of our knowledge, little attention has been paid to the effects of the carbon nanoparticle's surface and bulk properties on the overall electrochemical performance of the enzyme electrodes.

Graphitized mesoporous carbons (GMC) and purified mesoporous carbons (PMC) are two types of mesoporous carbon materials with similar chemical composition and morphological properties, but different surface and structural properties. This contrast on the properties of GMC and PMC makes them the ideal carbon nanomaterials for investigating the effects of carbon nanomaterials' properties on the electrochemical performances of BFCs.

Graphitized and non-graphitized carbons are structurally different (Franklin, 1951). The graphitization process of the carbon is a method to produce well-organized graphite (Mattia et al., 2006). Non-graphitized carbons exhibit a cross-linked structure where graphitic structures are randomly oriented in a rigid mass. Conversely, graphitized carbons present a compact structure where the graphite layers have a nearly parallel orientation. Graphite layers play a major role in both the surface and bulk properties of these materials. The hydrophobicity and electrical conductivity of the carbon materials, for example, are directly related to the level of graphitization of the carbon materials (Pantea et al., 2003). Hydrophobicity also affects the nanoparticle aggregation process (Nel et al., 2009). It is known that the surface of graphitized materials presents smaller amounts of oxygen functionalities compared to that of non-graphitized materials, which strongly repels water molecules (due to their hydrophobic nature) and decreases electrostatic repulsion among the nanoparticles. Consequently, these nanomaterials can form a compact carbon network with low dispersion in an aqueous medium. These unique properties of nanomaterials have been used to physically entrap large enzyme aggregates within the carbon networks and to form protein-nanocomposite materials (Garcia-Perez et al., 2016). This observation suggests that the performance of this hybrid protein-nanoparticle composite structure highly depends on the graphitization index of the carbon nanomaterial used as the enzyme support. Literature shows that the GMC sample can be used to entrap enzymes to build bioelectrodes (Garcia-Perez et al., 2016; Walcarius, 2017), although no information has been reported in the literature on employing the PMC sample for electrochemical applications.

This work aims to study the effects of the bulk and the surface properties of different carbon nanomaterials on the electrochemical performances of glucose oxidase (GOx)-nanocomposite bioanode materials under the BFC operation mode. For the present study, a homemade Proton Exchange Membrane (PEM) fuel cell was used to test the enzymatic BFC performances. Four different bioanodes were manufactured using GOx as catalysts and (a) GMC, (b) PMC, (c) acid treated GMC, and (d) acid treated PMC as carbon supports.

MATERIALS AND METHODS

Materials

Graphitized mesoporous carbons (GMC) (specific surface area of 70 m^2/g and average pore diameter of 13.7 nm, purity >99.95%) and purified mesoporous carbons (PMC) (specific surface area of 200 m^2/g and average pore diameter of 6.4 nm, purity >99.95%) were purchased from Sigma Aldrich. Glucose oxidase (GOx) Type VII from *Aspergillus niger,* glutaraldehyde (8% in water), ammonium sulfate (molecular biology grade), Nafion® (5 wt% in a mixture of water and lower aliphatic alcohols), D-glucose, o-Dianisidine dihydrochloride, and Peroxidase Type II from *Horseradish* were also obtained from Sigma Aldrich. Nanopure water (>18 MΩ-cm) was used to prepare sodium phosphate buffer (hereafter referred to as PB) and Tris-buffer solutions. The glucose solutions used during the electrochemical tests were prepared 1 day in advance to allow mutarotation of α-glucose to β-glucose.

Methods

GOx-Nanocomposites Preparation

The GOx-nanocomposites were prepared using cross-linked GOx aggregates as the catalyst and the GMC or the PMC as the carbon supports. The carbon materials were first acid treated using 25 ml of a mixture of nitric acid and sulfuric acid in a volume ratio of 1:3. The acids were mixed in a 50 ml bottle and allowed to cool down to room temperature. Then, 0.25 g of the carbon nanoparticles were added into the acid mixture, as they were stirred with a magnetic bar. The suspension was then shaken for 24 h. Following the acid treatment, the samples were washed with nanopure water and vacuum filtered. The GOx-nanocomposites were prepared by adding 5 ml of ammonium sulfate solution (0.5 mg/ml) to 2.5 ml of GOx solution (1 mg of GOx/ml) to precipitate the enzymes. Then, 0.13 vol% of glutaraldehyde was added to the solution in order to obtain the cross-linked GOx aggregates. Next, 5 ml of nanocarbon solutions (1 mg/ml) was added and stirred for 30 min using a shaker (Max Q 2,000) to form the GOx-nanocomposites. These nanocarbon solutions included the GMC, PMC, acid treated GMC (herein referred to as GMCac), and acid treated PMC (herein referred to as PMCac) dispersed into the buffer solution. The nanocomposites were washed 6 times: 2 times with Tris-buffer solution (pH 7.2) to cap the underreacted glutaraldehyde and 4 times with sodium phosphate buffer (PB, 100 mM, pH 7.0) to remove the free GOx. Each washing process consisted of adding 10 ml of buffer to each suspension and then vortexing, shaking, and centrifuging. The supernatant was then removed. Finally, the PB solution was added to the GOx-nanocomposites to reach a final volume of 5 ml. The nanocomposite suspension in PB was stored at 4°C. The prepared samples will be referred to as: the GOx-GMC for cross-linked GOx aggregates-GMC; the GOx-GMCac for cross-linked GOx aggregates-GMC acid treated; the GOx-PMC for cross-linked

GOx aggregates-PM; and the GOx-PMCa for cross-linked GOx aggregates-PMCac.

Elemental analysis and surface characterization

The ratio of enzyme to carbon material (mg of enzyme/mg of mesoporous carbon) present in each nanocomposite was estimated by determining the elemental composition (C, H, N) of the GOx-nanocomposites, GOx and carbon nanomaterials. The tests were conducted by Intertek Pharmaceutical Services (Intertek.com). For the elemental analysis, the GOx-nanocomposites samples were washed with PB only, skipping the Tris-buffer washing step for the elemental analysis tests to guarantee the enzymes are the only major source of nitrogen (Kim et al., 2011). Before sending the GOx-nanocomposite samples to Intertek Pharmaceutical Services, the samples were freeze-dried to remove water from the system. Both the GOx enzyme and nanomaterial samples were sent to the company for the elemental analysis without any special treatments. The residual water contents of the carbon nanomaterial samples were determined (prior to the elemental analysis) through thermogravimetric analysis (TGA) (García et al., 2013). Based on our TGA analysis, the water contents for the nanomaterial samples were negligible (i.e., there was no water content for both the GMC and GMCac samples, while the PMC and PMCac samples contained 2.4 and 5.9 weight% of water content, respectively).

The elemental composition of the GOx-nanocomposites, GOx, and the carbon nanomaterials was measured and reported in terms of weight%. The GMC, GMCac, and PMC contained no nitrogen. Unlike the GMC, GMCac, and PMC, the elemental analysis of the PMCac showed a trace of nitrogen element. However, its amount was insignificant and we can ignore its contribution for estimating the GOx amount presented in the GOx-PMCac nanocomposite sample. Since every GOx contains a fixed number of nitrogen element and GOx is the only major source of nitrogen element, we can easily approximate the total amount of GOx presented in each GOx-nanocomposite sample using the nitrogen weight% information obtained from the elemental analysis. Based on the carbon weight% information, we can also estimate the total amount of carbon nanomaterials presented in each GOx-nanocomposite sample. Based on this total amount information of both GOx and carbon nanomaterials, we can determine the ratio of enzyme to carbon nanomaterial (weight% of enzyme/weight% of carbon nanomaterial) for each GOx-nanocomposite sample.

The aggregation process of the carbon nanoparticles was studied by conducting dynamic light scattering (DLS) measurements. The size of the carbon nanoparticles aggregates was determined every 1 min. In addition, the interaction between the carbon nanomaterials and water was visualized by creating a thin film of each carbon nanomaterial and placing 20 μl of nanopure water on the top of it.

The graphitization index of the samples was determined via Raman Spectrometry. The Raman tests were carried out using a Jobin–Yvon Horiba LabRAM-HR spectrometer at 532 nm excitation wavelength. Prior to the tests, the samples were diluted 10 times in KBr. Each sample was scanned at least 6 times. All Raman measurements were conducted at room temperature. In addition, the functional groups on the surfaces of the samples were studied by means of X-ray photoelectron spectroscopy (XPS). The XPS spectra were recorded on a Kratos AXIS-165 XPS spectrometer using a monochromatized AlKα X-ray anode (1,486.6 eV) in an ultra-high vacuum system. The spectrometer was calibrated against both the Au $4f_{7/2}$ peak at 84.0 eV and the Ag $3d_{5/2}$ peak at 368.3 eV. Survey scans were recorded at 80 eV pass energy with a step size of 1 eV. C 1s core level spectra were recorded at 40 eV pass energy with a step size of 0.1 eV. CasaXPS software was used to analyze the XPS spectra of C 1s for all samples. The full width at half maximum (FWHM) were set to 0.8 eV for C-C bond, 1.2 eV for C-OH bond, 1.5 eV for C=O, O-C=O and carbonate bonds, and 2 eV for the $\pi \rightarrow \pi^*$ transition. Finally, all the spectra curves were smoothed using the Sawitzki-Golay algorithm with a kernel of five points.

Carbon nanoparticle's morphological characterization

Microscopy techniques were performed to visualize the structure of the carbon nanoparticles and the GOx-nanocomposites. A Zeiss 510 Confocal Microscope was used to conduct confocal analysis. In addition to confocal analysis, transmission electron microscopy (TEM) was carried out to visualize the distribution of

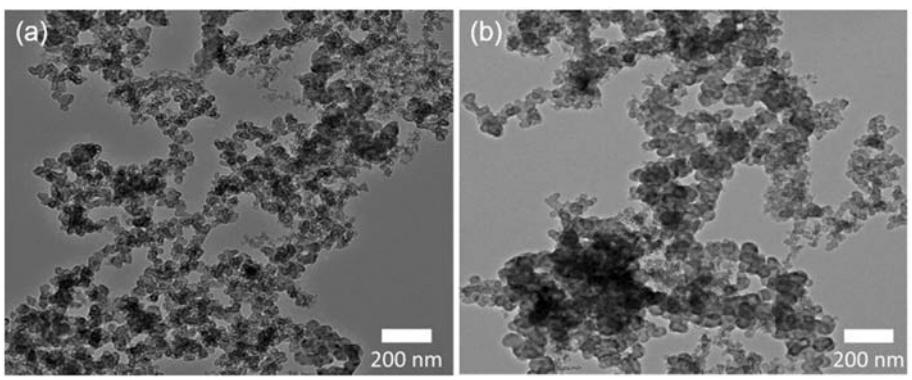

FIGURE 1 | TEM images of as-received carbon nanomaterials: **(a)** GMC and **(b)** PMC.

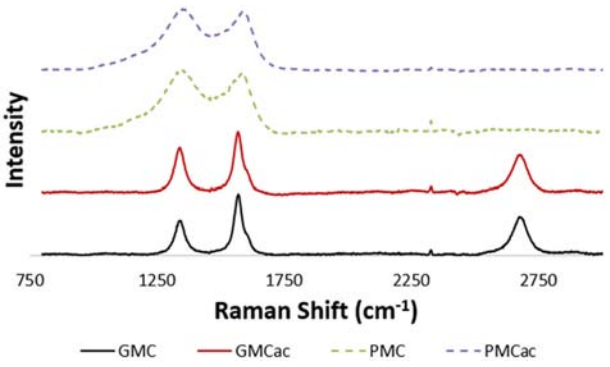

FIGURE 2 | Raman spectra of GMC, GMCac, PMC, and PMCac.

the enzymes within the carbon nanoparticle network at a smaller scale. The TEM tests were conducted using a FEI TEM T20 microscopy at least in 5 different spots. The preparation of the samples was conducted using a similar step reported in a previous work (Garcia-Perez et al., 2016).

Electrochemical properties

Cyclic voltammetry (CV) was conducted using a conventional three electrode setup. Pt mesh and Ag/AgCl (KCl saturated) electrode were used as a counter electrode and a reference electrode, respectively. In addition, the working electrodes were prepared by placing 10 μl of the GOx-nanocomposites suspension (∼1.5 mg of GOx-nanocomposite/ml of suspension) on a glassy carbon electrode using Nafion® binder (0.5% of the total volume). All of the CV tests were carried out using N_2-saturated PB (100 mM, pH of 7.0) at room temperature, while the working electrode was rotated at 500 rpm. The N_2-saturated PB solutions were prepared by bubbling high purity N_2 into the solutions for 30 min before the test, followed by blanketing the solutions with N_2 during the tests.

The enzyme anodes were prepared by physically absorbing the GOx-nanocomposites onto carbon paper disk with a geometric area of 0.332 cm^2. A concentrated solution of GOx-nanocomposites was prepared by centrifuging an aliquot of 0.6 ml of GOx-nanocomposite from the main stoke for 5 min, removing 410 μl of supernatant, and adding 10 μl of 5% Nafion® solution into the remaining pellet. After that, the carbon disks were added one by one to the suspension and shaken for 10 min. The electrodes were then removed and dried for 1 h under hood conditions. Finally, the electrodes were washed three times with 100 mM PB buffer (pH 7.0) and stored at 4°C before use.

The electrochemical properties of the GMC, GMCac, PMC, and PMCac samples were studied by using CV tests. The electrodes were prepared by placing 40 μl of a nanoparticle suspension (1 mg of carbon nanoparticle/ml of ethanol) on the glassy carbon electrode and let it dry at room temperature. The ferrocyanide/ferricyanide couple is a benchmark used in our electrochemical measurements to determine the electron transfer characteristics of each electrode. The CV plots were obtained in the presence of 1 mM of potassium ferricyanide in PB (100 mM, pH 7.0) at scan rate of 10 mV s^{-1}. The current density (μA/cm^2) was determined by dividing the current obtained in the CV test with the total surface area of carbon nanomaterial (see Materials).

A homemade PEM fuel cell was used to evaluate the electrochemical performance of the GOx-nanocomposites under the enzymatic biofuel cell (BFC) operating mode as presented in previous papers (Fischback et al., 2006; Garcia-Perez et al., 2016).

TABLE 1 | A summary of Raman spectra for the GMC, GMCac, PMC and PMCac samples.

Samples	FWHM (G band)	FWHM (D band)	I_G/I_D	$1/(I_G/I_D)$
GMC	39.05	45.95	1.87	0.54
GMCac	44.73	47.91	1.45	0.69
PMC	111.24	206.22	–	–
PMCac	112.73	212.74	–	–

RESULTS AND DISCUSSION

Morphology, Graphitization Index, Surface Chemistry, and Wettability of GMC and PMC

Figure 1 presents the TEM images of as-received GMC and as-received PMC. Both carbon nanomaterials present similar polygonal conformations and dimensions in the nanoscale range, but they offer different specific surface areas (200 m^2/g for PMC and 70 m^2/g for GMC) according to their vendor information. **Figure 2** presents the Raman spectra of the four carbon nanomaterials used in this work (GMC, PMC, GMCac, and PMCac). The GMC sample presents large G and D peaks at around 1,582 cm^{-1} and 1,350 cm^{-1}, respectively. The GMC sample also shows a strong D′ peak at around 2,700 cm^{-1}. These sharp G peak and strong G′ peak shown in the Raman spectrum of the GMC sample indicate that the GMC is consisted of a multilayer of graphene and, consequently, it presents a very organized bulk structure. Furthermore, the *full width half maximum* (FWHM) of the G and D peaks for the GMC and PMC samples show different values: around 39–45 cm^{-1} (G-D peak) for the GMC and 111–206 cm^{-1} (G-D peak) for the PMC (see **Table 1**). The higher FWHM values for the PMC's G and D peaks as well as the disappearance of its G′ peak at around 2,700 cm^{-1} indicate a lack of three-dimensional order of PMC materials, which is probably due to its turbostratic conformation (Ferrari, 2007). In summary, the GMC sample presents a highly graphitized structure, while the PMC sample mainly consists of turbostratic carbon structures with a low degree of bulk organization.

The graphitization index was calculated as an intensity ratio between the G peak and the D peak (*IG/ID*) of Raman spectra, and their inverse values (*ID/IG*) were used to quantify the defects in the carbon structure (**Table 1**). The high graphitization index of the as-received GMC (1.87) and GMCac (1.45) confirms that these materials present a well-organized bulk structure. However, the graphitization index of GMCac is lower than that of the

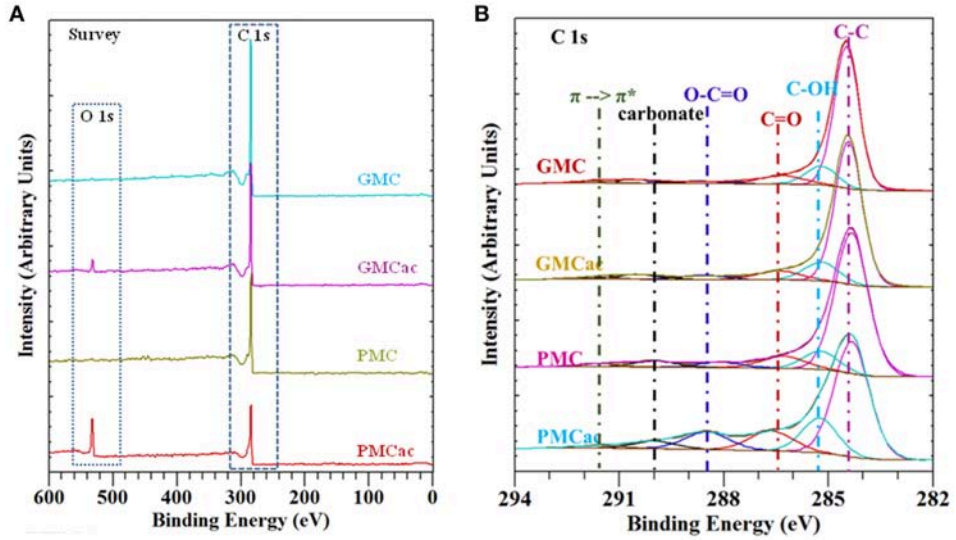

FIGURE 3 | (A) XPS survey spectra and **(B)** curve fitted XPS C 1s peaks for GMC, GMCac, PMC, and PMCac.

as-received GMC (a reduction of ∼22%), suggesting that the acid treatment creates defects on the GMC. For amorphous materials, this G peak can be attributed to the presence of benzene rings that are condensed into the amorphous structure (Schwan et al., 1996). Therefore, the intensity of this G peak (I_G) and *IG/ID* peak ratios cannot be used to quantify the graphitization index of PMC materials. Thus, both the *IG/ID* and *ID/IG* peak ratios of both the PMC and PMCac samples are not included in **Table 1**.

The functional groups present on the surface of the GMC, GMCac, PMC, and PMCac nanomaterials were determined by XPS measurements. The XPS spectra are presented in **Figure 3**. As shown in **Figure 3A**, a main peak at around 284 eV for C 1s in the XPS survey scan was detected for all four samples. New peaks around 532 eV are observed in the XPS survey scans for both the GMCac and the PMCac samples. Such new peaks were identified as O 1s, which indicate that the surface of GMC and PMC nanomaterials are functionalized after the acid treatment. The effect of the acid treatment can be analyzed from the ratio between the amount of O and C elements obtained from the XPS spectra. The O/C ratios for the as-received GMC and as-received PMC samples were 0.004 and 0.001, respectively. These results indicate that both as-received nanomaterials present a low percentage of oxygen functionalities on their surfaces. After the treatment with H_2SO_4/HNO_3, the O/C ratio increased to 0.045 and 0.218 for the GMCac and PMCac samples, respectively. This increase in the O/C atomic ratio indicates that the acid treatment has effectively introduced oxygen functional groups on the surface of both materials. The higher increase in the oxygen functionalities content of the PMC sample after the acid treatment (PMCac; 17.90%) than that of the GMC sample (GMCac; 4.39%) indicates that the PMC sample is more easily oxidized than the GMC sample, probably due to its larger number of surface defects.

TABLE 2 | Atomic percentages of the oxygen functional groups on the surface of the carbon nanoparticles obtained by XPS.

Sample	Atomic %					
	C-OH	C=O	O-C=O	Carbonate	C	O
GMC	12.21	8.12	2.40	3.40	99.60	0.40
GMCac	12.31	7.58	3.33	3.75	95.61	4.39
PMC	9.97	8.27	3.84	4.44	99.90	0.10
PMCac	16.74	11.99	10.62	4.47	82.10	17.90

The XPS C 1s high resolution spectra for the GMC, GMCac, PMC, and PMCac nanomaterials are shown in **Figure 3B**. Six main peaks were derived from curve fitting. The peaks obtained at 284.4 eV, 285.4 eV, 286.7 eV, 288.5 eV, and 290.1 eV are attributed to C-C, C-OH (phenol or alcohol), C=O (carbonyl or quinone groups), O-C=O (carboxyl, lactone, or ester groups), and carbonate groups, respectively (Chiang and Lee, 2009). The percentages of carbon and oxygen functionalities obtained from the deconvolution of the XPS spectra in the C 1s region is presented in **Table 2**. It is known that the oxidation reaction of carbon nanostructures occurs in two steps. The first step consists of the oxidant attack on the graphene structure by electrophilic reactions to generate active sites. The actives sites are sites on the nanoparticle surface where chemical functionalities are introduced, for instance C–OH groups (Santangelo et al., 2012). In fact, the C-OH groups are the oxygen functional groups that are present in higher percentage on the surface of all the carbon samples. The increase of the atomic % of C-OH groups observed for the PMC sample after the acid treatment (from 9.97 atomic% in the PMC to 16.74 atomic% in the PMCac) indicates that a significant amount of active sites were created on its surfaces during the oxidation process (Chiang and Lee, 2009).

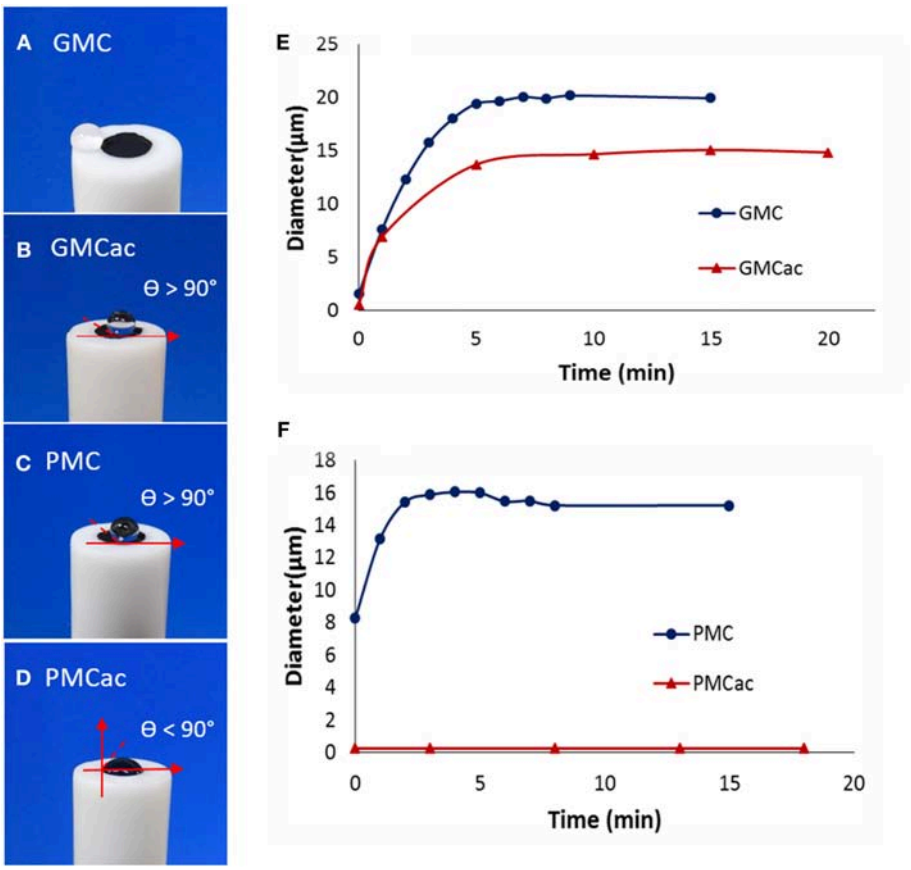

FIGURE 4 | Images of a drop of water (20 μm) placed on films of **(A)** GMC, **(B)** GMCac, **(C)** PMC, and **(D)** PMCac. Dynamic light scattering measurements for the aggregation of **(E)** GMC/GMCac and **(F)** PMC/PMCac as a function of time.

Meanwhile, only a small increase in the number of C-OH groups was observed after the acid treatment for the GMC sample. Thus, the generated surface defects on the GMC sample by the acid treatment is lower than that of the PMC sample, probably due to its higher graphitization index compared to that of the PMC sample. The second oxidation step consists of a process where the active sites generated in the first step are further oxidized and the aromatic rings are opened (Santangelo et al., 2012). During this process, some of the C-OH groups generated in the first oxidation step are consumed to produce O-C=O. In fact, the surface concentration of O-C=O functional group increases in both samples after the acid treatment, but in different proportions. The atomic percentage of O-C=O increases by 176.6% in the case of the PMC sample but only by 37.5% in the case of the GMC sample, which is in agreement with the fact that carbon nanomaterials with the lower graphitization index are easier to oxidize (Bi et al., 2008).

Figure 4A shows that GMC presents a super-hydrophobic surface, where a drop of water jumps away from the carbon nanomaterial due to their lack of affinity. The acid treatment of this material increases its affinity for water, but the surface is still hydrophobic since a drop of water deposited on its surface has a contact angle higher than 90° (shown as $\theta > 90°$ in **Figure 4B**). **Figure 4C** shows that the as-received PMC is also a hydrophobic material. However, it has lower hydrophobicity than the as-received GMC (**Figure 4A**). This is in an agreement with the fact that the hydrophobicity of carbon materials decreases as the degree of graphitization decreases (Mattia et al., 2006). In contrast, the PMCac nanomaterial is hydrophilic, which shows a contact angle of <90° (**Figure 4D**). A high affinity of the PMCac nanomaterial for water is related to the large percentage of oxygen functionalities on its surface after the acid treatment.

The DLS measurements presented in **Figure 4E** indicate that the GMC and GMCac nanomaterials aggregate very quickly and form the aggregates with a diameter around 21 μm and 14 μm, respectively. The high aggregation rate for the GMC nanomaterial probably results from a combination of its high hydrophobic forces and low electrostatic repulsion among the individual GMC nanoparticles. The presence of oxygen functionalities on the surface of the GMCac nanomaterial would lead to a decrease of the hydrophobic forces and an increase of the electrostatic repulsions, producing a decrease in its aggregation rate. Meanwhile, the DLS measurements of the PMCac nanomaterial (**Figure 4F**) indicate its low tendency to form the carbon aggregates, which is probably due to "hydrophilic repulsions" between the

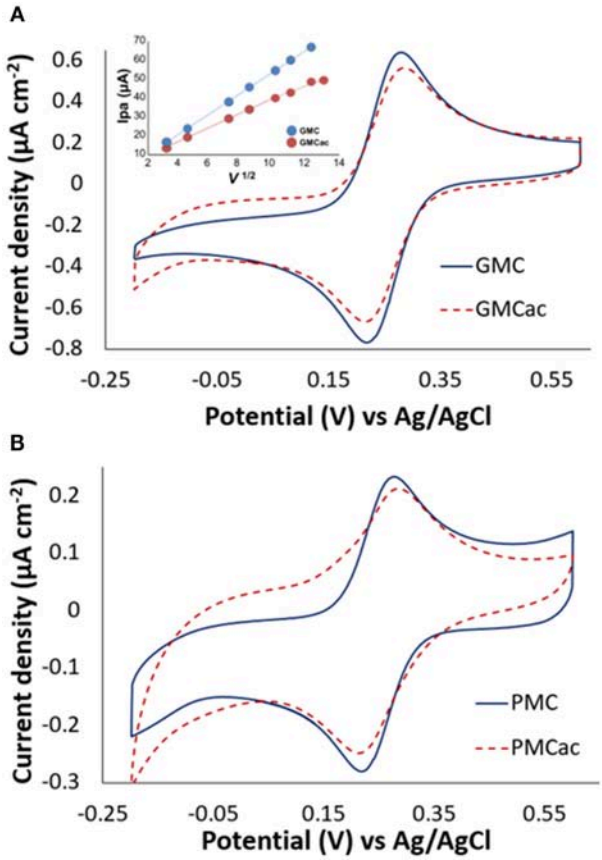

FIGURE 5 | Cyclic voltammograms of **(A)** GMC/GMCac and **(B)** PMC/PMCac obtained in 1 mM of $K_3[Fe(CN)_6]$ at 10 mV s^{-1}. The inset in A shows the plot of i_{pa} *vs.* $v^{1/2}$ *for GMC and GMCac*.

individual PMCac nanoparticles. It has been reported that water molecules can adhere to hydrophilic particles (solvation phenomena) with enough energy to create a layer on its surface that prevents the nanoparticles from aggregating with each other (Nel et al., 2009).

Electrochemical Characterization of GMC and PMC

Figure 5 presents the CV plots for the GMC, GMCac, PMC, and PMCac nanomaterials obtained in the presence of 1 mM of potassium ferricyanide in PB (100 mM, pH 7.0) at the scan rate of 10 mV s^{-1}. The CVs of the GMC and PMC show well-defined redox peaks at $E_{pc} = +0.22$ V (cathodic peak) and $E_{pa} = +0.27$ V (anodic peak). The separation between the peaks ($\Delta E_p = E_{pa} - E_{pc}$) in both cases is around 50 mV and the calculated formal potential was $E^\circ = +0.25$ V vs. Ag/AgCl. This value is close to the formal potential calculated for the $[Fe(CN)_6]^{3-/4-}$ redox reaction for a glassy carbon electrode ($E^\circ = +0.24$ V vs. Ag/AgCl), indicating the high electron transfer rate.

The effect of the acid treatment on the electrical conductivity of the carbon nanomaterials is also presented in **Figure 5**. The GMCac nanomaterial presents a 16.80% higher value of ΔE_p than that of the GMC nanomaterial (**Figure 5A**), while the PMCac nanomaterial presents a 27.20 % higher value of ΔE_p than that of the PMC nanomaterial at 10 mV s^{-1} (**Figure 5B**). This result suggests that the electron transfer capabilities of both the GMC and PMC samples have been negatively affected by the acid treatment, which may be due to the damage of their graphitic structures produced by its chemical oxidation in the H_2SO_4/HNO_3 solution. The CV tests were also conducted at different scan rates. Based on these CV data, a plot of i_{pa} vs. $v^{1/2}$ for the GMC and GMCac nanomaterials is constructed as shown in **Figure 5A**. The GMC sample presents a linear behavior with a slope of 5.53 μA $mV^{-1/2}$ $s^{1/2}$ for the entire scan range. Therefore, the GMC sample is able to efficiently transfer electrons (i.e., reversible electron transfer) with the high electron transfer rates. Meanwhile, the GMCac sample presents a linear behavior with a slope of 3.86 μA $mV^{-1/2}$ $s^{1/2}$, but only till 100 mV s^{-1}, indicating that the redox reaction deviates from the behavior proposed by the Randles-Sevcik equation at the high scan rates. This suggests that the GMCac sample experiences an irreversible electron transfer at high scan rates, confirming that the GMCac sample is less electrically conductive than the GMC sample.

The peak-to-peak potentials (ΔE_p) for the GMC and PMC samples at 100 mV-s are a) GMC: $\Delta E_p = 59.62mV$ and b) PMC: $\Delta E_p = 63.20\ mV$. Since higher values of ΔE_p are associated with lower electron transfer rates, these results indicate that the electron transfer rate of the PMC sample is smaller than that of the GMC sample. This difference is more important when the scan rate is increased (GMC: $\Delta E_p = 64.9\ mV$; PMC: $\Delta E_p = 75.25\ mV$ at 200 mV-s). The presence of an ordered graphitic layer for the GMC sample is responsible for its enhanced electrical conductivity due to the localization of the π electrons (Portet et al., 2007; Lu et al., 2009). In summary, in terms of the electrical conductivity, the GMC nanomaterial is the best selection for making the high performance GOx-nanocomposite anode material.

Morphology and Enzyme Loading of the GOx-Nanocomposites

Confocal microscopy was used to visualize the GOx-nanocomposites at higher magnifications (**Figure 6**). The locations of GOx aggregates in the confocal images were identified as bright spots due to the fluorescent property of the enzymes, while the carbon nanomaterials appear as black spots. **Figures 6a–c** show that the GOx-nanocomposites produced with the GMC, GMCac, and PMC samples present large enzyme aggregates. Thus, the physically entrapped enzyme aggregates are in a close contact with a large network of carbon nanomaterials. However, the GOx-PMCac nanocomposites are highly dispersed within the PB solution as shown in **Figure 6d**. This is in an agreement with the low aggregation tendency of PMCac observed in the DLS measurements. TEM tests were conducted in order to obtain a more detailed visualization of the small GOx-PMCac nanocomposites. The TEM image presented in **Figure 6e** shows the presence of GOx-aggregates within the PMCac network. This image suggests that the PMCac

nanomaterial is able to entrap the smaller enzyme aggregates along with a much less compact carbon network structure compared to that of the GMC, GMCac, and PMC nanomaterials.

Our elemental analyses results showed that the nanocomposites contain 0.54 ± 0.05, 0.47 ± 0.01, 0.55 ± 0.11, and 0.45 ± 0.07 mg enzyme/mg of mesoporous carbon for the GOx-GMCac, GOx-GMC, GOx-PMCac, and GOx-PMC samples, respectively. These enzyme loading results suggest that the carbon nanomaterials are able to entrap similar amounts of enzymes per amount of carbon nanomaterials. Thus, any differences observed in their electrochemical performances cannot be attributed to differences in the enzyme loading but to the differences of carbon nanoparticles' physical properties.

Electrochemical Behavior of GOx-Nanocomposites

The electrochemical performances of the GOx-nanocomposites were studied using CV tests. **Figure 7** shows the CV plots obtained for the GOx-GMC, GOx-GMCac, GOx-PMC, and GOx-PMCac samples at 100 mV s^{-1} under the N_2-saturated PB condition. **Figure 7A** presents the CV plots for the GOx-GMC sample, while the GOx aggregates and the GMC nanomaterial are shown as control. The CV plot for the GMC nanomaterial is featureless, indicating that the carbon nanoparticle by itself is not able to produce any electrochemical responses under the N_2-saturated PB condition. The CV plot corresponding to the GOx aggregates shows a small redox peak. Meanwhile, the CV test for the GOx-GMC (**Figure 7A**) shows two well-defined redox peaks: an anodic peak at −0.437 V and a cathodic peak located at −0.419 V. The fact that an improved electrochemical activity is observed for the GOx-GMC sample when compared with the GOx aggregates and the GMC nanomaterial, suggest that the compact carbon network of the GOx-GMC sample provides the enhanced electron transfer process.

The formal potential (E_o') calculated as $E_0^{'} = \frac{E_{pa} + E_{pc}}{2}$ was −0.429 V vs. Ag/AgCl, which is close to the formal potential of FAD/$FADH_2$ (Guiseppi-Elie and Baughman, 2002; Liu et al., 2007; Vogt et al., 2014; Wilson, 2016). The origin of this peak is still not clear (Luong et al., 2016; Milton and Minteer, 2017). It is currently accepted that the direct electron transfer is very difficult to occur for GOx-based enzyme electrodes because the active site of GOx is buried inside its protein structure and the surface of GOx is covered by non-conductive glycosylation layer (Wilson, 2016). This peak has been ascribed to adsorbed free FAD (flavin adenine dinucleotide) on the carbon nanomaterials or the presence of impurities in the commercial GOx (Vogt et al., 2014; Wilson, 2016). Some authors also suggested that small traces of O_2 in the solution can also promote pseudo-direct electron transfer (pseudo-DET) (Milton and Minteer, 2017). Determining the electron transfer mechanism between the active site of GOx and the electrode surface requires further study and is beyond the scope of this paper. The CV curves obtained for the GOx-GMCac and GOx-PMC nanocomposites also exhibit two redox peaks at around −0.429 V vs. Ag/AgCl (**Figures 7B,C**). Conversely, the GOx-PMCac sample shows a featureless CV plot indicating its low electrochemical activity.

According to **Figure 7**, the redox peaks of the GOx-GMC sample show higher current peak intensities than that of the GOx-GMCac and GOx-PMC samples (Ipa = 6.63 μA for the GOx-GMC vs. Ipa = 4.23 μA for the GOx-GMCac and 3.13 μA for the GOx-PMC). This may result from the enhanced electrical conductivity of the GMC sample, which arises from its high graphitization index and low concentration of oxygen functionalities on its surface (Datsyuk et al., 2008). The peak-to-peak potentials (ΔE_p) were 19.8, 27.06, and 39.72 mV for the GOx-GMC, GOx-GMCac, and GOx-PMC samples, respectively. It is known that this parameter is directly related to the electron transfer rate constant (k_s) (i.e., the decreased separation between the redox peaks indicates the faster electron transfer rate during the charge transfer reaction).

The electron transfer rate constant (k_s) for each sample was also determined by using the Laviron method for ΔE_p is $<200/n$ mV (n is the number of electrons transferred during the reaction) and the transfer coefficient value varies between 0.3 and 0.7 (Laviron, 1979). The k_s for the GOx-GMC, GOx-GMCac, and GOx-PMC nanocomposites were 6.63, 4.57, and 2.74 s^{-1}, respectively. Therefore, the GOx-GMC nanocomposite displayed the highest electron transfer rate, confirming that the as-received GMC is the best electron transfer promoting carbon nanomaterial. The value of k_s cannot be estimated for the GOx-PMCac sample since it does not show any distinctive redox peak. This result indicates that the PMCac sample doesn't facilitate the efficient electron transfer process in the system due to its low conductivity and lack of continuous carbon network.

The mechanism governing the electron transfer process in the GOx-based enzyme electrodes has been subjected to intense research with various interpretations (Vogt et al., 2014; Luong et al., 2016). This paper doesn't aim to determine the electron transfer mechanism in our GOx-nanocomposite materials. Instead, we intend to show the effect of employing different mesoporous carbons with various surface and bulk properties on the electrochemical performances of the GOx-nanocomposites.

Figure 8 shows the power density of the GOx-nanocomposites obtained in the BFC, using 10 mM glucose solution as the fuel. The values of maximum power density for the BFCs with the GOx-GMCac, GOx-GMC, GOx-PMC and GOx-PMCac bioanodes are 22.40, 15.80, 7.06, and 6.89 μW/cm^2, respectively. Because the enzyme loadings in all cases are similar, any differences observed in their maximum power density would be attributed to differences in carbon nanoparticles' properties.

The BFC with the GOx-GMC bioanode produces 2.2 times the power density of the BFC with the GOx-PMC bioanode (15.80 vs. 7.06 μW/cm^2). Furthermore, the BFC with the GOx-GMCac bioanode produces 3.2 times the power density of the BFC with the GOx-PMCac bioanode (22.40 vs. 6.89 μW/cm^2). As described in the earlier section, the GMC sample offers a more ordered carbon bulk structure and higher electrical conductivity than that of the PMC sample. Hence, our BFC results can be attributed to the higher electrical conductivity offered by the GMC nanomaterial than the PMC nanomaterial.

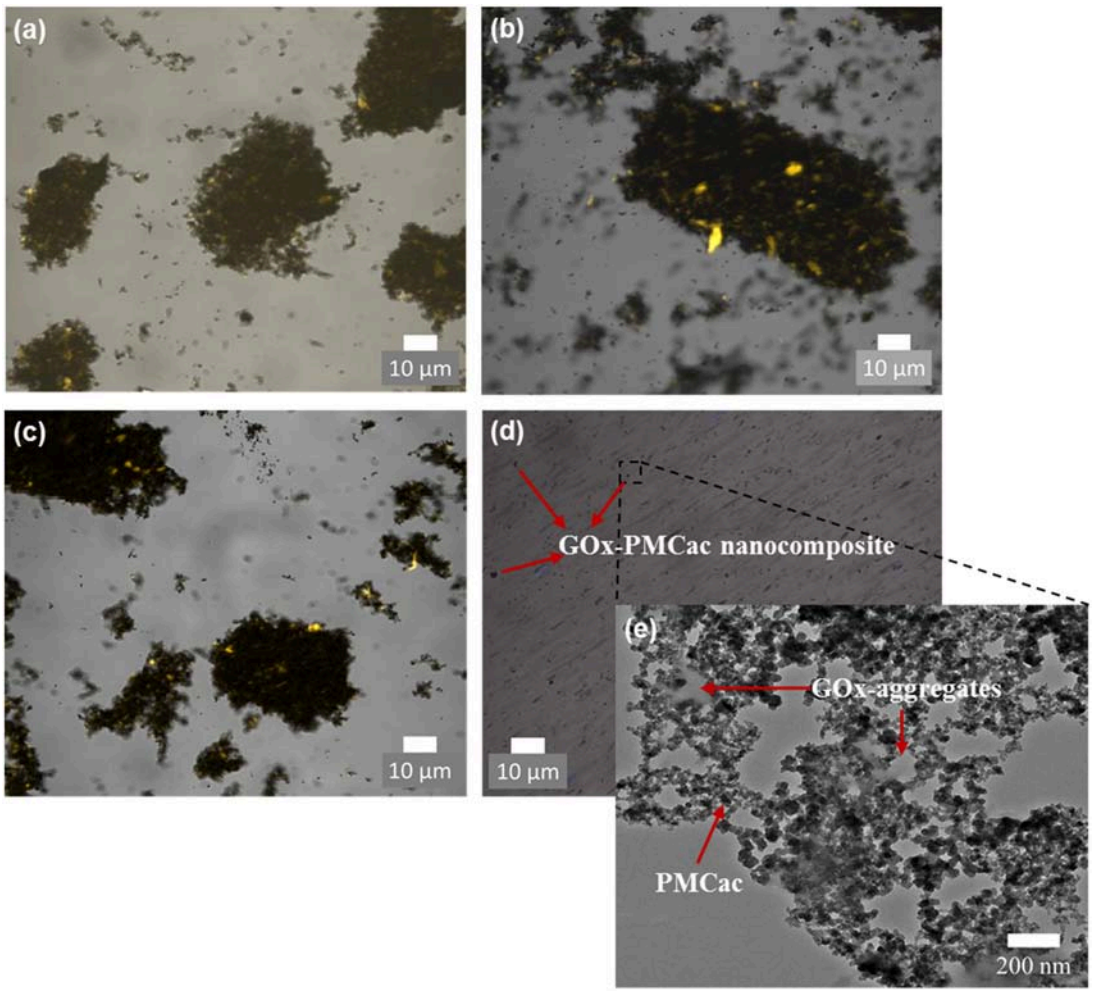

FIGURE 6 | Confocal images of **(a)** GOx-GMC, **(b)** GOx-GMCac, **(c)** GOx-PMC, and **(d)** GOx-PMCac nanocomposites; and **(e)** TEM image of the GOx-PMCac nanocomposites.

However, if the electrical conductivity of nanomaterials is the only key parameter that determines the power density of the BFC, the BFC with the GOx-GMC bioanode should provide the highest power density because the GOx-GMC offers the highest electrochemical properties and highest electron transfer rate constant (k_s) as shown in their CV tests (**Figure 5**). Nevertheless, according to **Figure 8**, the highest power density output was obtained from the BFC with the GOx-GMCac bioanode. This result suggests that the power density of the BFC does not solely depended on the electrical conductivity of the nanomaterials.

To understand this unexpected result, we need to consider the differences in the morphology of the carbon nanomaterial aggregates used. According to TEM images shown in **Figure 6**, the bright spots indicate the enzyme aggregates. It seems that the GOx-GMC sample offers a higher degree of carbon packing than that of the GOx-GMCac sample. Thus, a smaller number of bright spots (i.e., the enzyme aggregates) are exposed to the surface for the GOx-GMC sample than the GOx-GMCac sample. According to **Figure 4**, the GOx-GMC sample possesses the super hydrophobic surface property where the GOx-GMCac sample shows the decreased surface hydrophobicity due to the increased number of the surface functional group. Since the dispersion of the carbon nanomaterial in the aqueous media decreases as its surface hydrophobicity increases, the GOx-GMC sample with the higher surface hydrophobicity leads to the GOx nanocomposite material with the more compact carbon network structure than that of the GOx-GMCac sample. For the GOx-GMC sample, it seems that the carbon packing is too high where the carbon nanomaterials cover much of the enzyme aggregates at its surface and it would prevent the efficient mass transport of the fuel to the enzymes. Addition to the poor mass transport of the fuel over the surface of the GOx-GMC sample, it could also produce a very tight carbon network structure with low available internal void spaces for the efficient fuel transportation within the nanocomposite structure (Catalano et al., 2015). Consequently, the BFC with the GOx-GMCac bioanode produces the higher power density

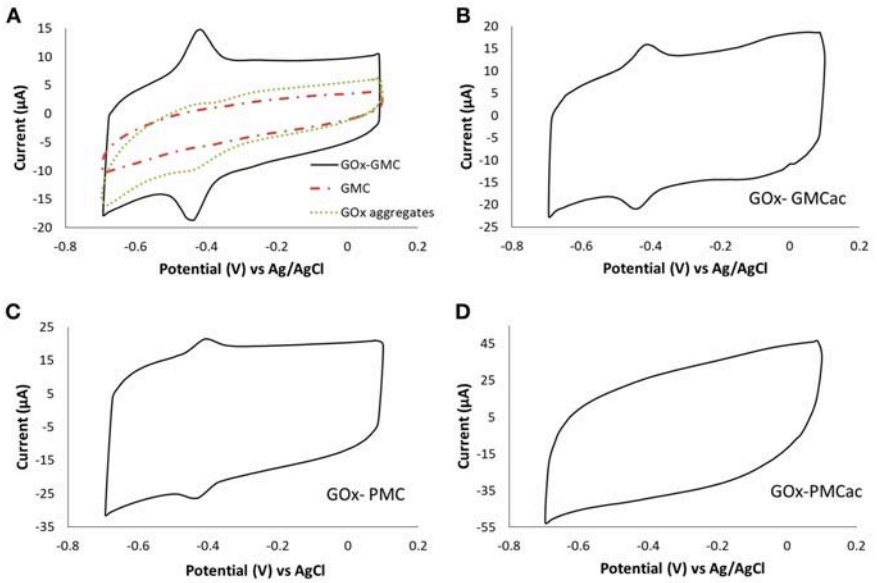

FIGURE 7 | Cyclic voltammograms of **(A)** GOx-GMC, **(B)** GOx-GMCac, **(C)** GOx-PMC, and **(D)** GOx-PMCac nanocomposites. They are obtained in a N_2 saturated PB electrolyte at a scan rate of 100 mV s^{-1}.

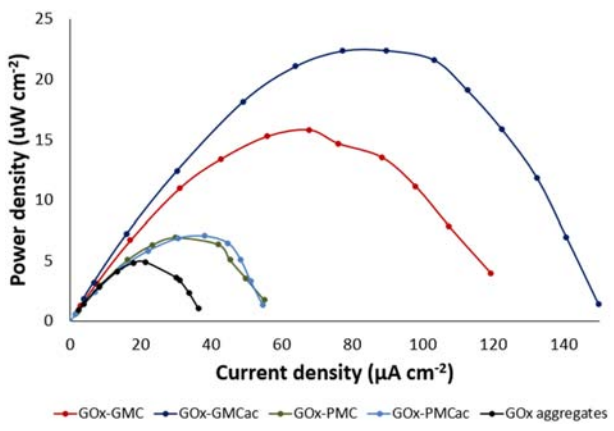

FIGURE 8 | Biofuel cell power densities, measured in 10 mM glucose solution at room temperature for GOx-GMC, GOx-GMCac, GOx-PMC, GOx-PMCac nanocomposites and GOx-aggregates anodes.

than that of the GOx-GMC bioanode where it offers both the high electrical conductivity and the efficient mass transport of the fuel.

In contrast to the GOx-GMC sample, the GOx-PMCac sample shows the most open carbon network structures with a greater number of enzyme aggregates that are exposed to the surface (**Figure 6**). Such structure would allow the high mass transport of the fuel, but it would lead to a very poor electrical conductivity because it is unable to form a continuous carbon network for the electrons to efficiently move through the system. Consequently, the BFC with the GOx-PMCac produces the one of the worst power density outputs as shown in **Figure 8**. This finding suggests that the electrochemical performance of the GOx-bioanodes is not only depended on the bulk properties (e.g., graphitization index and electrical conductivity) of the carbon nanomaterials, but it is also depended on the surface properties (e.g., concentration of surface functional group and degree of surface hydrophobicity) of the carbon nanomaterials to form the continuous carbon network structure.

CONCLUSIONS

The electrochemical performances of four GOx-nanocomposites manufactured by using four different carbon nanomaterials as the supports were studied. Our findings indicate that the physical properties of carbon nanomaterials significantly affect the electrochemical performances of the GOx-nanocomposites produced by immobilizing GOx-aggregates within a network of these carbon nanomaterials. The GOx-GMC sample offers the most efficient electron transfer rate due to its highly ordered crystalline structure and compacted carbon network structure. On the other hand, the GOx-PMCac sample offers the least efficient electron transfer rate due to its turbostratic carbon structures with a low degree of bulk organization and its inability to form the continuous carbon network (i.e., its high dispersion nature) in the aqueous media. Consequently, the BFC with the GOx-GMC bioanode produces the higher power density output than that of the GOx-PMCac bioanode. However, the highest power density of the BFC can be obtained when both the high electrical conductivity and efficient mass transport of the fuel were achieved. To this regard, the GOx-GMC sample is not the best bioanode material because its TEM image suggests that its resulted carbon network is too tight

and degree of carbon aggregate is too high for achieving the efficient mass transport of the fuel. When the GMC sample is acid treated to form the GMCac, additional surface defects were introduced decreasing both the surface hydrophobicity and the electron transport efficiency, while improving the mass transport of the fuel by reducing its tendency to form the tight carbon network. The BFC with the GOx-GMCac bioanode produced the highest maximum power density output of 22.40 $\mu W/cm^2$, which is about 42 % higher than that of the GOx-GMC bioanode. This result suggests that the positive effect of the acid treatment for the GMC material (i.e., improving the mass transport of the fuel) outweighs its negative effect (i.e., decreasing the electrical conductivity). Therefore, the GOx-nanocomposites as the effective enzyme anodes for various electrochemical applications should achieve both the high electronical conductivity and efficient mass transport of the fuel by optimizing not only its bulk property (e.g., electrical conductivity) but also optimizing its surface property (e.g., surface hydrophobicity).

The Influence of Interfacial Chemistry on Magnesium Electrodeposition in Non-nucleophilic Electrolytes Using Sulfone-Ether Mixtures

*Laura C. Merrill and Jennifer L. Schaefer**

Department of Chemical and Biomolecular Engineering, University of Notre Dame, Notre Dame, IN, United States

One of the limiting factors in the development of magnesium batteries is the reversibility of magnesium electrodeposition and dissolution at the anode. Often irreversibility is related to impurities and decomposition. Herein we report on the cycling behavior of magnesium metal anodes in different electrolytes, $Mg(HMDS)_2$ – 4 $MgCl_2$ in tetrahydrofuran (THF) and a butyl sulfone/THF mixture. The deposition morphology and anode-electrolyte interface is studied and related to Mg/Mg cell cycling performance. It is found that adding the sulfone caused the formation of a boundary layer at the electrode-electrolyte interface, which, in turn, resulted in a particle-like deposition morphology. This type of deposition has a high surface area, which alters the effective local current density and results in electronically isolated deposits. Extended cycling resulted in magnesium growth through a separator. Electrolyte decomposition is observed with and without the addition of the sulfone, however the addition of the sulfone increased the degree of decomposition.

INTRODUCTION

Demands for high performance batteries have increased with the use of portable electronic devices and electric vehicles, leading to growth in research of post lithium-ion batteries. The use of metallic anodes, as opposed to intercalation anodes, creates an opportunity to meet these high performance metrics. A metallic anode is entirely comprised of active material, thus the theoretical energy density is inherently greater than traditional lithium-ion anodes that use host matrices. Magnesium is a viable anode option as it has large theoretical volumetric and gravimetric capacities (3,800 mAh/cm^3 and 2,200 mAh/g respectively), relatively low electrodeposition potential (−2.4 V vs. SHE), and is widely abundant in the Earth's crust.

Magnesium has gained attention as a post lithium-ion anode material following the first magnesium battery prototype developed in the early 2000s (Aurbach et al., 2000). This prototype used an electrolyte composed of a Grignard reagent complexed with a Lewis acid to achieve highly reversible electrodeposition (Aurbach et al., 2000; Amir et al., 2007; Viestfrid et al., 2007). Recent progress has focused on non-Grignard chemistries through use of alternative electrolytes, such as magnesium alkoxides or magnesium bis(hexamethyldisilizide) ($Mg(HMDS)_2$) complexed with a chloride salt ($MgCl_2$ or $AlCl_3$) in tetrahydrofuran (THF) (Kim et al., 2011; Herb et al., 2015; Liao et al., 2015; Pan et al., 2015), and $Mg(TFSI)_2$, or $Mg(BH_4)_2$ in dimethoxyethane (DME) or higher order glymes (Mohtadi et al., 2012; Ha et al., 2014). Despite this progress, magnesium battery research has been hindered by low electrodeposition/dissolution efficiencies; the use of a

metallic anode requires Coulombic efficiencies >99% for practical application (Wang et al., 2018). In the presence of trace impurities and certain salts and solvents, the metal is able to form a stable passivating layer that prevents the magnesium ions from reaching the active magnesium metal surface, thus not allowing electron transfer to occur. Because of this, only certain salt and solvent combinations have resulted in reversible magnesium electrodeposition.

Recently there has been interest in magnesium deposition and how deposition kinetics can influence the resultant morphology (Viestfrid et al., 2005; Matsui, 2011; Wetzel et al., 2015; Crowe et al., 2017). Early magnesium battery research suggested that it is unfavorable for magnesium to form dendrites, unlike lithium metal; this is attributed to differences in the crystal structures of each metal (Ling et al., 2012; Jäckle and Groß, 2014; Lautar et al., 2019). Although magnesium is less likely to form dendrites compared to lithium, dendritic magnesium deposits been observed with both complex and simple salt electrolytes (Ding et al., 2018; Davidson et al., 2019). In particular, $Mg(TFSI)_2$ systems were found to short circuit cells due to the formation of an unstable solid electrolyte interphase (SEI), resultant from the partial decomposition of $Mg(TFSI)_2$ (Ding et al., 2018; Kang et al., 2019).

Previously, we reported that the addition of sulfones to an electrolyte could increase the thermal stability, however electronically isolated deposits upon continued cycling were also observed (Merrill and Schaefer, 2018). Here, we report on the crystallinity and morphology of the magnesium deposits from electrolytes with and without the sulfone as a function of current density and substrate. We also probe the interfacial impedances throughout galvanostatic cycling and relate these findings to the morphologies observed. It was found that the sulfone based electrolytes result in high surface area deposition morphologies, such a hemispheres, compared to the electrolyte containing only THF; this is attributed to the influence of a boundary layer at the electrode that forms with the addition of the sulfone.

MATERIALS AND METHODS

Materials and Electrolyte Solutions

Tetrahydrofuran (99.9%, THF), magnesium bis(hexamethyldisilazide) (97%, $Mg(HMDS)_2$), di-n-butylsulfone (99%, BS), and magnesium chloride (99.99%, $MgCl_2$) were purchased from Sigma Aldrich, and ethyl methyl sulfone (98%, EMS) was purchased from TCI. All solvents were distilled under nitrogen flow on a Schlenk line. $Mg(HMDS)_2$ was recrystallized from anhydrous n-heptane (Sigma Aldrich) in a glovebox prior to use. All solvents and solvent mixtures were dried using molecular sieves for at least 48 h before making the electrolytes. Only new or acid washed glassware was used, and all glassware was dried in a 120°C convection oven. The electrolyte formulations were $Mg(HMDS)_2$ – 4 $MgCl_2$ (nominally 1.25 M Mg) in THF, 50 THF/50 BS (v/v), and 50 THF/50 EMS (v/v). Electrolytes were prepared as described in previous work (Liao et al., 2015; Merrill and Schaefer, 2018).

Magnesium (99.95%, Solution Materials, LLC), copper (McMaster Carr), and platinum (Alfa Aesar) were used as electrode materials for this study. Platinum was cleaned with concentrated nitric acid, then washed with MilliQ water, and dried in a 120°C convection. Copper was sonicated in isopropanol and then dried. Magnesium was scraped to remove its native oxide layer, then polished with 1,200, 2,000, and 3,000 grit sand paper, washed with anhydrous THF, then scraped again to further smooth the surface. **Supplementary Figure 1** shows electron micrographs of the bulk magnesium surface before and after the final scraping step.

All electrolytes and electrochemical cells were prepared in an argon filled glovebox with <5 ppm oxygen and moisture. Coin cell measurements were completed outside of the glovebox.

Electrochemical Measurements

All electrochemical measurements were taken using a PARSTAT MC1000 from Princeton Applied Research.

Galvanostatic electrodeposition was carried out in a 2 electrode solution cell. The working electrode was either magnesium, copper, or platinum and a magnesium strip was used as the counter/reference electrode. Currents of 1 and 0.5 mA/cm^2 were applied until the total charge passed was 1 C/cm^2 for microscopy characterization or 10 C/cm^2 for X-ray diffraction (XRD) measurements.

Chronoamperometry measurements were completed using a 2 electrode solution cell. The working electrode was copper and the counter/reference electrode was magnesium. The cell was held at open circuit for 10 s followed by a potential step for 10 s. Overpotentials used include −250, −375, and −500 mV vs. Mg^0/Mg^{2+}.

Galvanostatic cycling and impedance were carried out in symmetric Mg/Mg CR2032 coin cells. The cells were assembled in an argon filled glovebox. A dried glass fiber separator was used to support the electrolyte. A current of −0.5 mA/cm^2 was applied for 1,000 s followed by +0.5 mA/cm^2 for 1,000 s. Impedance measurements were taken every five cycles, with an amplitude of 10 mV RMS and a frequency range of 10 kHz to 1 Hz.

X-ray Diffraction (XRD)

XRD measurements were obtained using a Bruker D8 Advance Davinci with a SOL-XE energy dispersive x-ray detector. Measurements were taken in the range of 20 and 70°, with a step size of 0.004°, and a step time of 2.5 s. Only copper was used as the substrate for magnesium deposition for XRD measurements. Measurements were taken on a silicon crystal zero diffraction plate from MTI Corporation.

Scanning Electron Microscopy (SEM)

SEM images were taken using an FEI Magellan 400 microscope with a voltage of 10 kV and a current of 50 pA at a working distance of 4.3 mm. Elemental analysis was completed using a Bruker energy dispersive x-ray spectrometer (EDS) at a working distance of 4.7 mm with an increased current to achieve adequate signal (>1,000 cps). Samples were washed with anhydrous THF then put under vacuum prior to characterization. A Pelco SEM pin stub vacuum desiccator was used to transfer samples from the lab to the microscope to minimize air exposure.

X-ray Photoelectron Spectroscopy (XPS)

XPS measurements were taken using a PHI VersaProbe II. Point scans were taken with a 50 W power X-ray. Prior to measurements, samples were sputtered for 2 min with 2 kV Ar^+ to clean the surface. Survey measurements were taken with a 187.85 eV pass energy over 7 scans. Each individual binding energy measurement was taken with a 23.5 eV pass energy for 12 scans. A 100 ms time step was used for all scans. Samples were washed with THF and dried under vacuum prior to analysis, then transferred to the instrument using the Pelco pin stub holder, however air exposure could not be completely avoided upon transfer into the machine's sample holder.

RESULTS AND DISCUSSION

Morphologies of Magnesium Deposits

Magnesium was deposited from each electrolyte at different current densities onto copper, platinum, and magnesium. Previous reports of magnesium deposition showed that for a Grignard based electrolyte, increasing the current density will bring it into a mass transport limited regime. Once the system is mass transport limited, the magnesium will not be able to optimize its direction of growth (Viestfrid et al., 2005; Matsui, 2011). This can then result in the magnesium crystal growing in the perpendicular direction to the substrate or growing in the same direction as the crystal facets within the substrate. Low current results in operation in the charge transport limited regime. This allows the magnesium to nucleate on the substrate and grow in a thermodynamically controlled manner, often resulting in high surface area deposits. As shown in **Supplementary Figure 2**, the formation of spherical magnesium deposits can ultimately increase the effective local current density, leading to decomposition that is evident from the charging on the deposits in the SEM images. In this work, we focus on magnesium electrodeposition at moderate (0.5 mA/cm^2) and high (1 mA/cm^2) current densities.

At 0.5 mA/cm^2, there are significant differences in the morphology of the deposits from the 50 BS/50 THF electrolyte and THF electrolyte, as depicted in **Figure 1**. This is particularly evident on the copper and platinum substrates. The deposition from the 50 BS/50 THF electrolyte consists of deposits that are spaced apart, suggesting that the magnesium was able to nucleate at different points on the substrate, but the clusters of magnesium did not merge together. Areas of charging (apparent from areas of brightness on the SEM image), caused by non-conductive materials, are present around the edges of the spherical deposits. This non-metallic material could be produced due to electrolyte decomposition or a disruption in the electric field. The THF electrolyte exhibits very flat deposition composed of small, uniform crystals; an increased magnification of the SEM image is shown in **Supplementary Figure 3**. The magnesium clusters deposited from the THF electrolyte were able to merge after the initial nucleation. For both electrolytes, the deposition is more disperse on the bulk magnesium sheet metal, and appears to grow along the ridges of the bulk material; the deposits will typically form at imperfections on the metal that generated during the removal of the passivation layer by mechanical scraping. The deposit from the THF electrolyte has a greater degree of agglomeration compared to the deposit from the 50 BS/50 THF electrolyte.

When the current density was increased to 1 mA/cm^2, the deposits became flatter and more uniform, as shown in **Figure 2**. This is likely because the increased current density does not allow for the magnesium deposits to optimize the crystal orientation, like at lower currents. However, as shown in **Supplementary Figure 4**, the morphology of the magnesium deposit varies throughout the copper substrate, likely due to the influence of different crystal facets throughout the copper. The deposits from the 50 BS/50 THF electrolyte are more uniform and flat on the platinum substrate, compared to the copper, confirming that the substrate used will alter the interfacial chemistry. Again, the deposit from the THF electrolyte resulted in smooth deposition, in particular on copper. The deposition on the magnesium substrate resulted from the agglomeration of islands, however at the higher current each cluster is smaller, which is characteristic of the increased current density.

As shown in **Figure 3**, the magnesium deposited at 0.5 mA/cm^2 on copper preferentially grows along the (1 0 1) crystal plane for both electrolytes, which is the plane with the highest surface area fraction (Lautar et al., 2019). This observation suggests that the interactions between the electrolyte and the metal are more favorable. If the electrolyte-metal interface is thermodynamically preferred, then the deposit will grow such to maximize the surface area in contact with the electrolyte. The deposit from the 50 BS/50 THF electrolyte is less crystalline, evident from both decreased peak intensity and an increased full width half maximum, compared with the signal of the deposit from the THF electrolyte. The amorphous nature may be due to the high surface area nature of the deposits or due to a greater degree of decomposition.

The corresponding XRD of the deposits grown at 1 mA/cm^2 show that different magnesium crystal orientations result from electrodeposition from each electrolyte, shown in **Figure 4**. The deposit from the THF electrolyte has increased crystallinity and a higher fraction of (0 0 2) orientation. This change in crystal orientation with current density suggests that the system with the THF electrolyte reached a transport limited regime at 1 mA/cm^2. As shown in **Supplementary Figure 5**, the (0 0 2) plane is the primary plane in the copper substrate. The deposit from the 50 BS/50 THF electrolyte continues to deposit preferentially in the (1 0 1) plane, again with a lower degree of crystallinity. Because the 50 BS/50 THF electrolyte has a lower ionic conductivity (0.8 vs. 1.5 mS/cm at 30°C), it is unlikely that the THF electrolyte would enter a mass transport limited regime at a lower current than the 50 BS/50 THF electrolyte (Merrill and Schaefer, 2018). This suggests that the interfacial chemistry between the 50 BS/50 THF electrolyte and the substrate drives the resultant morphology, and that the interfacial chemistry with the THF electrolyte is different.

It is noted that the deposits from each electrolyte look different to the naked eye. The deposits from the THF electrolyte are a silvery-white color whereas the deposits from the 50 BS/50 THF electrolyte are black (see **Supplementary Figure 6**). As shown in our previous work, there is minimal decomposition therefore

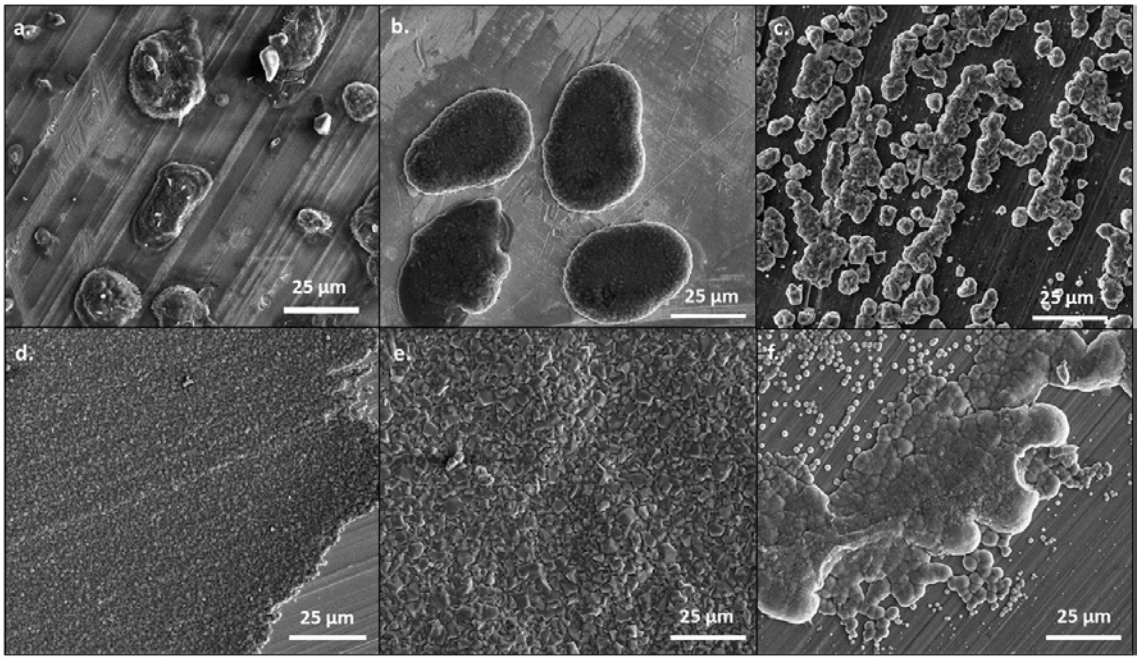

FIGURE 1 | SEM images of magnesium plated at 0.5 mA/cm^2. A total of 1 C of charge was passed for each sample. the resultant black color is likely related to the particle-like morphology (Merrill and Schaefer, 2018).

Chronoamperometry experiments were completed to further interrogate the deposition and nucleation processes for each electrolyte. The current response to a potential step is different for the two electrolytes, as shown in **Supplementary Figure 7**. The 50 BS/50 THF electrolyte begins with a large current, which immediately drops, followed by a slow increase and the beginnings of a plateau. This initial large current may be attributed to polarization of ions in the boundary layer at the electrode/electrolyte interface; this large current obscures the current due to the initial nucleation process in the 50 BS/50 THF electrolyte. In the transient for the THF electrolyte, a small local maximum is present, followed by similar behavior to the mixed solvent electrolyte. The local maximum is likely representative of the initial magnesium nucleation. Because the electron transfer reaction is hypothesized to be preceded by a chemical equilibrium step (Ta et al., 2018), it is likely that the chemical equilibrium step causes the initial decrease in current for each electrolyte. The Cottrell equation could not be fit to either electrolyte; therefore, the Scharifker and Hill models for instantaneous and progressive nucleation could not be directly applied to this system (Scharifker and Hills, 1983). Nevertheless, the local maxima in the THF electrolyte were used to plot a dimensionless graph of i^2/i_m^2 vs. t/t_m (**Supplementary Figure 8**), and suggest the formation of nucleation sites at short time scales. The complexity of the magnesium electrolytes are attributed to the changes from the ideal behavior, as previously derived to describe other systems (Scharifker and Hills, 1983); the magnesium electrolytes likely contain multiple electrochemically active complex cations with varying diffusivities. Additionally, the magnesium electrolytes facilitate boundary layer formation at the electrode/electrolyte interface when the system is at rest, as described below.

Impedance and Cycling

Symmetric magnesium coin cells were cycled 100 times at 0.5 mA/cm^2, starting with a negative current. Impedance measurements were taken every 5 cycles after the positive current. This was done to learn about the interfacial impedances throughout cycling and to determine if either passivation, or soft short circuiting, would be observed throughout extended cycling. Soft short circuiting is a phenomenon where the magnesium deposit is partially passivated and slowly grows through the separator, eventually making contact with the counter electrode, therefore short circuiting the cell. This has been observed with $Mg(TFSI)_2$ electrolytes, which are unstable in the presence of magnesium metal (Ding et al., 2018; Kang et al., 2019).

As shown in **Figure 5**, there are very large differences in resistance for each electrolyte during galvanostatic cycling. The THF electrolyte initially starts with a high overpotential of ~0.4 V vs. Mg, which then decreases throughout cycling. The 50 BS/50 THF electrolyte shows a similar decrease in overpotential during the first few cycles, however a much greater overpotential is maintained throughout cycling (about 200 vs. 75 mV). This is in part due to the greater bulk resistance caused by the lower conductivity of the 50 BS/50 THF electrolyte. Therefore, to maintain the same current, a higher overpotential is required. Over extended cycling, there is a gradual increase in overpotential for the case with the 50 BS/50 THF electrolyte; indicating an increase in resistance. The cycling behavior of a wet THF electrolyte (40–60 ppm moisture) was similar to that of an electrolyte made with dried THF. This confirms that the large over potentials present in the chronopotentiogram are unique to the sulfone electrolyte, and not related to the existence of residual water or passivation of magnesium due to residual water.

The corresponding Nyquist plots give more information about the impedances within the cells. For the THF electrolyte, there is a decrease in interfacial impedance throughout cycling until the cells appear to reach a steady state (around cycle 60), shown in **Figure 6A**. This is represented by the initial high overpotential, which then decreases and plateaus throughout cycling. The bulk impedance stays fairly constant throughout cycling. The decreasing interfacial impedance in the first 60 cycles is possibly due to a combination of two phenomena: one being the removal of trace water in the electrolyte, and the

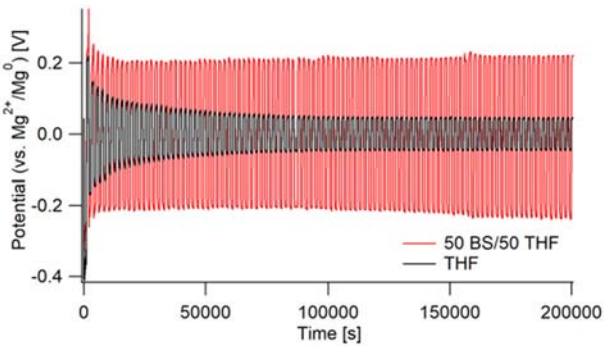

FIGURE 5 | Galvanostatic cycling of Mg/Mg cells in 50 BS/50 THF (red) and THF (black). Cells were cycled at a current of 0.5 mA/cm^2 for 1,000 s, starting with a negative current, then switching to a positive. This was repeated for 100 cycles with impedance measurements taken every 5 cycles.

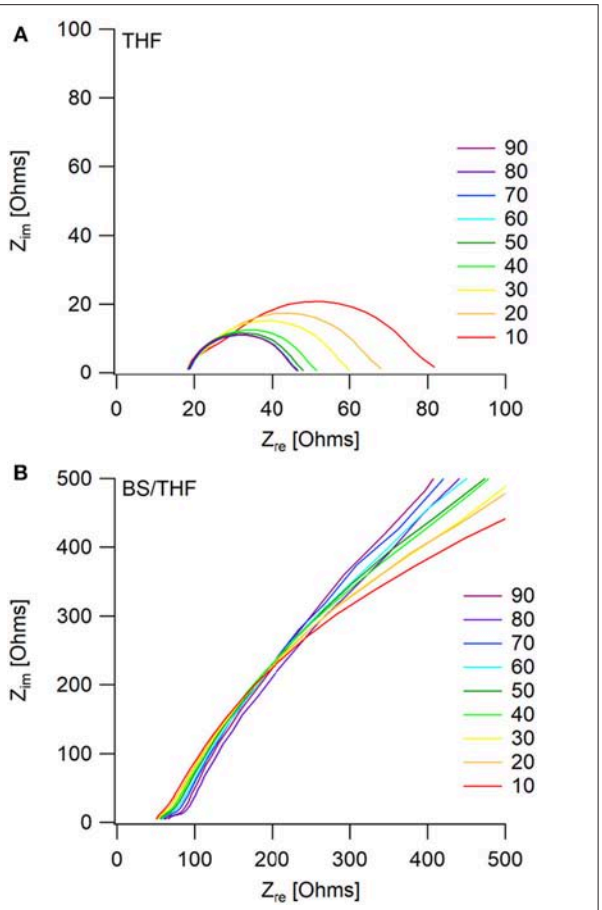

FIGURE 6 | Impedance measurements taken every 5th cycle (only multiples of 10 are shown for visual clarity) after the positive current step, during galvanostatic cycling. Mg/Mg cells were cycled in **(A)** the THF electrolyte and **(B)** the 50 BS/50 THF electrolyte.

other due to a native surface layer that forms on the electrodes as previously described by the Aurbach group (Lu et al., 1999; Doron Aurbach et al., 2003; Viestfrid et al., 2005; Attias et al., 2019). **Supplementary Figure 9** shows that the interfacial impedances for the wet THF and the dry THF electrolytes are comparable.

The similar decrease in overpotential during the first couple cycles of the 50 BS/50 THF electrolyte is likely due to the same phenomena as described with the THF electrolyte, however, a decrease in interfacial impedance is not observed, as shown in **Figure 6B**. Instead, there is a very large interfacial impedance present throughout cycling. A similar impedance is observed in the pristine cells for both electrolytes (**Supplementary Figure 10**), however after the application of a current, the interfacial impedance greatly decreases in the THF electrolyte. This impedance is caused by the formation of a boundary layer at the electrodes; because the sulfone group is polarizable and the alkane chains are able to stack, it is plausible that this boundary layer is stabilized. This boundary layer could be the cause of the high surface area deposition morphology by altering the interface. Provided the interaction between the metal and the boundary layer is more thermodynamically favorable, the deposit would grow to maximize its surface area to allow more of the metal to be in contact with the boundary layer.

The bulk resistance does increase with continued cycling, likely due to solvent loss via decomposition. As previously reported, the 50 BS/50 THF electrolyte is able to maintain Coulombic efficiencies around 90–95%, suggesting that there is a small amount of electrolyte decomposition (Merrill and Schaefer, 2018). Therefore, the gradual increase in bulk resistance and overpotential throughout cycling is related to the gradual buildup of a passivating surface layer. Over extended cycling the impedance continues to grow, suggesting that the cell will become fully passivated.

Post Mortem Analysis

SEM/EDS

Upon post-mortem analysis of the cells, the cycling of the 50 BS/50 THF electrolyte caused the separator to turn black whereas the separator used with the THF electrolyte had minimal discoloration in it (**Supplementary Figure 11**). This suggests decomposition of the 50 BS/50 THF electrolyte and/or the growth of the magnesium through the separator. The electrode used with the THF electrolyte was silvery-white whereas the electrode used with the 50 BS/50 THF electrolyte remained gray with large amounts of the glass fiber separator sticking to it, evidence that the magnesium began to grow through the separator. The SEM images in **Figures 7A**,**B** show the magnesium electrodes after a final stripping step. The electrode cycled with the 50 BS/50 THF electrolyte had areas of charging indicating partial decomposition. The electrode cycled with the THF electrolyte was more compact with the appearance of a higher degree of crystallinity. Because the resultant deposits from the 50 BS/50 THF electrolyte prefer a particle-like morphology, it is likely that the deposits are able to grow through the separator. Furthermore, as discussed earlier, this type of deposition can result in high local current densities which can lead to solvent decomposition.

Elemental analysis of the SEM-imaged surfaces are presented in **Figure 7C**. Increased proportions of elements other than

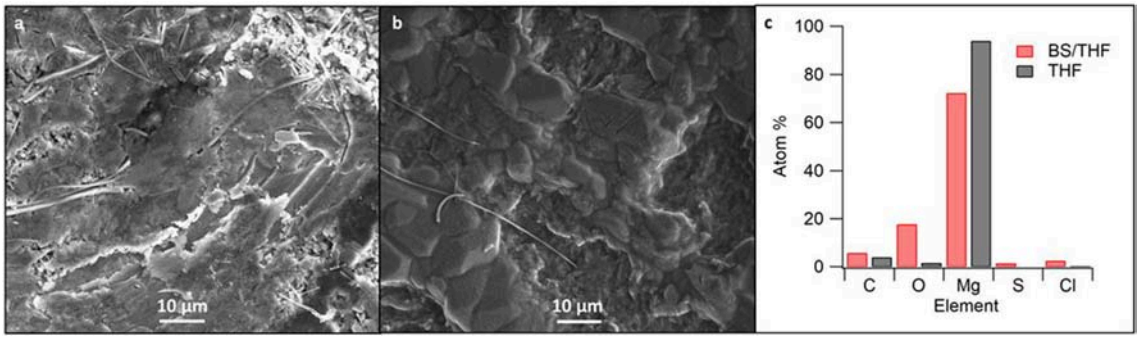

FIGURE 7 | SEM images of cycled magnesium in **(A)** the 50 BS/50 THF electrolyte and **(B)** the THF electrolyte. SEM images were taken at 1000x magnification; **(C)** shows the corresponding elemental composition as detected by EDS measurements.

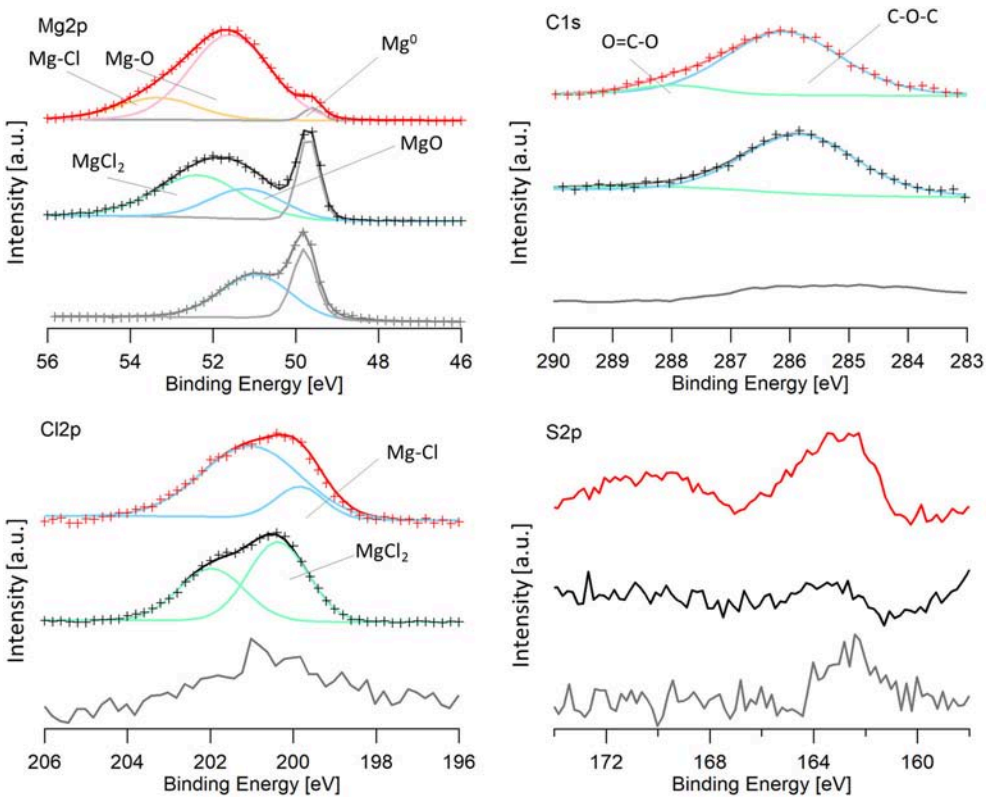

FIGURE 8 | XPS spectra of an Mg electrode cycled in the 50 BS/50 THF electrolyte (red), an Mg electrode cycled in the THF electrolyte (black), and a pristine magnesium electrode (gray). For data that is fit: the experimental data is shown by the crosses and the line with the same color is the calculated fit. Peaks are shown by blue, green, pink, orange, and gray lines and are labeled on the image. Mg-Cl and Mg-O labels on the graph refer to a magnesium-chloride species (such as RMgCl or adsorbed MgCl) and a magnesium-oxygen species (such as $Mg(OR)_2$ or $Mg(OH)_2$) and are a different from $MgCl_2$ and MgO.

magnesium are present in the deposit from the sulfone-ether electrolyte. Given that the Coulombic efficiency is <100%, the non-magnesium species are likely due to a decomposition product, such as solvent decomposition during deposition. This is further discussed with the XPS data. Alternatively, it is possible that the mixed solvent electrolyte contains a higher degree of impurities; although the butyl sulfone was distilled, its purity has not been determined.

XPS of Cycled Electrodes

Magnesium electrodes were characterized via XPS after the last dissolution step in the 100 cycles. The spectra from a pristine magnesium metal foil was included for a baseline comparison. Because oxidation was unable to be avoided upon transfer, as described in the experimental section, samples were sputtered for 2 min with Ar^+. The spectra were calibrated to the lowest energy magnesium peak, assumed to be Mg^0 (49.6 eV), because of the

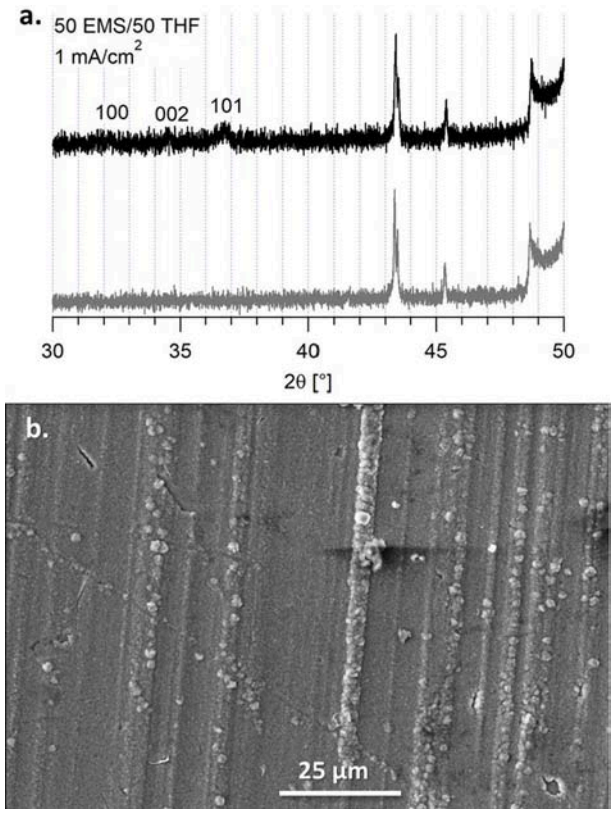

FIGURE 9 | (A) XRD of the deposit from the 50 EMS/50 THF electrolyte on a copper substrate (black) and the copper substrate (gray). **(B)** SEM image of the deposit from the 50 EMS/50 THF electrolyte on a copper substrate at a current density of 1 mA/cm^2, taken at a magnification of 1000x.

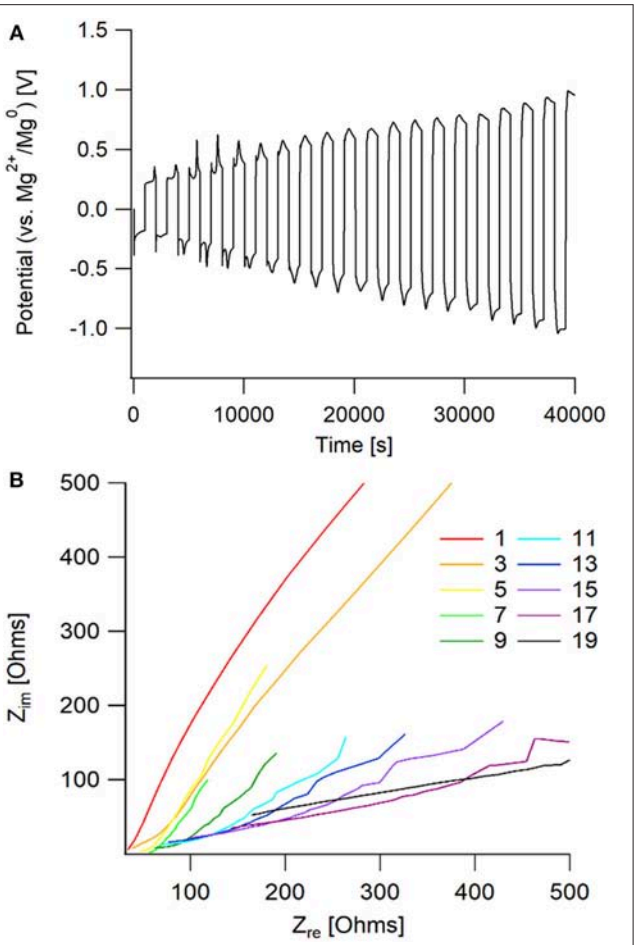

FIGURE 10 | (A) Potential vs. time graph of galvanostatic cycling of an Mg/Mg cell with the 50 EMS/50 THF electrolyte. **(B)** Nyquist plot of the impedance taken every other cycle for the galvanostatic cycling. Impedance measurements were taken after completion of the full cycle, following the positive current step.

low carbon signal. The Mg2p, Cl2p, S2p, and C1s regions are shown in **Figure 8**, for the cycled electrodes.

It is immediately evident that both cycled electrodes have a higher degree of oxidation compared to the pristine magnesium. However, the sample cycled in the 50 BS/50 THF electrolyte has a larger amount of decomposition products present, evident from the smaller metallic magnesium peak. Some oxidation may be attributed to transfer, considering the pristine magnesium metal is partly oxidized. The electrode cycled in the THF electrolyte has an oxidation peak with the same binding energy as the oxidation of the pristine electrode, shown in blue, and it is likely due to the formation of magnesium oxide. This peak is shifted to a slightly higher binding energy for the electrode cycled in the 50 BS/50 THF electrolyte. This is likely due to an Mg-O bond as well, but is attributed to a different species (ex. $Mg(OR)_2$ or $Mg(OH)_2$), resultant from decomposition.

Both of the cycled electrodes show a higher binding energy peak in the magnesium XPS spectra that is due to an Mg-Cl bond, also identified in the Cl2p region. The active species is a magnesium chloride cation and an adsorption step precedes the electron transfer, which can cause the Mg-Cl peak to be present (Doron Aurbach et al., 2003; Viestfrid et al., 2005; Attias et al., 2019). For the magnesium electrode cycled in the THF only electrolyte, the Cl2p region contains $MgCl_2$, evident from its binding energy around 200 eV (Magni and Somorjai, 1996). The residual $MgCl_2$ on the cycled electrode is due to its low solubility in THF; similar reports have been shown for $MgBr_2$ (Wetzel et al., 2015). The Cl2p peak for the electrode cycled in the mixed solvent electrolyte was shifted slightly lower (199.6 eV) (Moulder et al., 1992). This binding energy is evident of a metal-chloride (ex. RMgCl, or adsorbed MgCl), suggesting the formation of a different Mg-Cl species. This species may be resultant from the adsorption step as discussed above or a decomposition product. The Cl2p spectra for both electrodes show the presence of a secondary peak, which is due to the spin orbit splitting (Moulder et al., 1992).

The carbon spectra for magnesium electrodes cycled in each electrolyte features a major peak at 286 eV and a smaller peak at 288 eV which is characteristic of C-O-C and O-C=O, respectively. Because the XPS is carried out under high vacuum, it is unlikely that the major peak at 286 eV is due to THF solvent, but rather THF decomposition products, such as poly(ether). The O-C=O peak is also attributed to the decomposition of

THF. Although THF-based electrolytes are reported to have high reversibility, THF has been shown to decompose on magnesium electrodes upon cycling in Grignard based electrolytes (Wetzel et al., 2015).

Unique to the 50 BS/50 THF electrolyte is the presence of sulfur compounds. In the S2p region, there is a small peak at 162 eV present in the 50 BS/50 THF sample. Because the intensities of these peaks are low, the peaks could not be properly fit, and the presence of a second sulfur species could not be verified. The peak at 162 eV is representative of a metal-sulfide bond, indicating that the sulfone, or a trace sulfur-containing impurity present in the electrolyte, reacted with magnesium to form an Mg-S bond.

Other Sulfones

An alternative to butyl sulfone was studied to determine if the boundary layer effect observed in the EIS and the morphology of the magnesium deposits was due to incorporating a higher dielectric media or due to the stacking nature of the alkane chains. We previously compared the $Mg(HMDS)_2$ – 4 $MgCl_2$ electrolyte in 50 BS/50 THF to the electrolyte in sulfolane (SL)/THF (50/50, v/v), but this electrolyte was unable to support reversible magnesium deposition (Merrill and Schaefer, 2018). However, the electrolyte in a 50 EMS/50 THF mixture was able to support quasi-reversible magnesium electrodeposition. This electrolyte has a lower Coulombic efficiency, compared to the 50 BS/50 THF electrolyte, around 80% from cyclic voltammetry measurements (**Supplementary Figure 12**). Despite the flat, orderly deposition observed in the SEM image, **Figure 9**, the XRD still shows that the deposits are primarily amorphous. Because of the lower efficiency, decomposition may be causing the amorphous behavior of the magnesium deposit upon the extended potential hold. However, like with the 50 BS/50 THF electrolyte, the presence of a boundary layer can influence the deposition morphology.

This particular electrolyte was not able to maintain extended cycling in a symmetric cell, shown in **Figure 10**. The passivation layer that grew on the magnesium metal caused an increasing resistance, that lead to the system reaching the voltage threshold of $\pm$ 1.5 V vs. Mg^{2+}/Mg^0. From the Nyquist plot, it is observed that there is a large increase in bulk impedance within the first 20 cycles, indicating that there was significant solvent decomposition. However, prior to the bulk resistance increase, the same impedance behavior to the 50 BS/50 THF electrolyte is observed in the early cycles. This confirms that the sulfone group is responsible for boundary layer formation at the electrode surface.

CONCLUSIONS

It was determined that both substrate and current density have an influence on the microscopic properties of magnesium electrodeposits. More importantly, it was shown that the use of a sulfone/THF solvent mixture dramatically affects the deposition quality by changing the interfacial chemistry, leading to thermodynamically controlled deposition. It is hypothesized that the addition of sulfones to the electrolyte creates a boundary layer at the electrode-electrolyte interface due to the adsorption of the sulfone groups to the metal. It is likely that this boundary layer is what influences the formation of spherical deposits, due to the surface energies between the metal and the sulfone boundary layer.

The aforementioned particle-like deposition can be caused by the application of low current densities, prior to entering a mass transport limited regime. Increasing the current density can lessen the extent of spherical deposits, provided the interfacial chemistry, or thermodynamics, does not drive the deposition morphology—as is the case with the electrolytes containing sulfones. The high surface area deposits can change the effective current density, which results in areas of decomposition. Furthermore, upon extended cycling, non-uniform deposition into the pores of the separator is facilitated.

DATA AVAILABILITY

All datasets generated for this study are included in the manuscript and/or the **Supplementary Files**.

AUTHOR CONTRIBUTIONS

JS conceived and guided the study. LM planned and conducted the experiments and data analysis. Both authors contributed to the writing of this paper.

FUNDING

LM gratefully acknowledges the ND Center for Environmental Science and Technology and ND Energy for funding. Partial financial support was provided by the National Science Foundation through grant number CBET-1706370.

ACKNOWLEDGMENTS

We acknowledge the ND Energy Materials Characterization Facility and the Notre Dame Integrated Imaging Facility for use of their instrumentation and facilities.

Adjustment of the environmental acidity is a powerful method for fine-tuning the outcome of many chemical processes. Numerous strategies have been developed for the modification of pH in bulk as well as locally. Electrochemical and photochemical processes provide a powerful approach for on-demand generation of ion concentration gradients locally at solid-liquid interfaces. Spatially organized in individual way electrodes provide a particular pattern of proton distribution in solution. It opens perspectives to iontronics which is a bioinspired approach to signaling, information processing, and storing by spatial and temporal distribution of ions. We prove here that soft layers allow to control of ion mobility over the surface as well as processes of self-organization are closely related to change in entropy. In this work, we summarize the achievements and discuss perspectives of ion gradients in solution for information processing.

INTRODUCTION

Nobel laureate Herbert Kroemer stated that "the interface is the device" in reference to heterogeneous semiconductor structures. But this idea also inspired the development of interfacial science beyond the physics of heterostructures. Interfaces play a significant role in many physical and chemical processes. There is a wide variety of procedures for surface treatment and the modification of functional interfaces. Decher et al. (1992) described alternately exposing of charged substrates to positively and negatively charged macromolecules in order to obtain functional multilayered coatings. Layer-by-layer (LbL) assembled coatings and capsules have found various applications due to the versatility of multilayer formation technique and a variety of charged compounds which may be incorporated into it (Decher et al., 1998; Ryzhkov et al., 2019a). Polyelectrolyte multilayers are traditional components of biomaterial surface coatings (Zhukova et al., 2017), membranes for separation (Rmaile et al., 2003), as well as cargoes for drug encapsulation and delivery (Nikitina et al., 2018).

Polyelectrolyte multilayers are also considered to be an appropriate model mimicking the structure and properties of biological membranes (Zhu and Szostak, 2009). A lipid bilayer supported by a polyelectrolyte cushion provides a platform for modeling and investigating many cellular processes. Nowadays, transport processes in polyelectrolyte layers has garnered much attention. Due to their selective ionic permeability (Tanaka and Sackmann, 2005), one may perform dynamic polarization across the membrane. This process simulates neuron polarization during nerve conduction, thereby modeling information processing in living systems.

Development of a reliable model infallibly mimicking biological way of information processing is still a challenge. A lot of efforts are put to mimic biological way of computation by artificial

matter. The simplest example of information operations is switching functions following Boolean logic—logic gates. Logic gates use binary inputs and produce a single binary output. By now, several systems based on polyelectrolytes that perform information processing according to Boolean logic and using ionic signals (particularly protons) have been developed. Motornov et al. (2008) designed an enzyme-based hybrid system of pH-responsive nanoparticles assembling and disassembling following AND/OR Boolean logic. Motornov et al. (2009) also developed a pH-responsive Pickering emulsion coupled with specific enzymatic reactions performing AND and OR logic. Han et al. (2009) developed microchip polyelectrolyte diodes representing AND, OR, and NAND logic based on ion transportation through the polyelectrolyte interface. Thus, applicability of iontronic devices were demonstrated.

Reversible conformational changes of polymer brushes atop an electrode modulated by pH and influencing charge transport behavior are wifely exploited for designing biomimetic iontronic calculating devices. A more detailed mechanism is described as follows. For example, sucrose in the presence of both invertase (Input A) and glucose oxidase (Input B) results in a decrease in pH, transforming into gluconic acid (AB). The described system performs AND Boolean logic. OR logic can be designed using an ethyl butyrate-glucose mixture. Acidification of the medium (A+B) in this case can be achieved either by the oxidation of ethyl butyrate to butyric acid by esterase (Input A) or by the oxidation of glucose to gluconic acid by glucose oxidase (Input B). In brief, enzymatic inputs run a cascade of reactions leading to a pH shift to acidic values. The electrode surface with grafted shrunk poly-4-vinyl pyrrolidone (P4VP) at neutral pH is not electrochemically active because of the blocking effect of the polymer film. Output "1" of the logic operations yielded a pH drop to acidic conditions, resulting in the protonation and swelling of the P4VP polymer allowing penetration of a soluble redox probe to the conducting support. Thus, one may perform amperometry or impedance spectroscopy study for output detection. Wang et al. (2009) designed the system described above. Different groups employed a large variety of enzymes and electrode coatings for realizing a similar approach to designing biochemical logic gates. Privman et al. (2008), Katz and Minko (2015), and Poghossian et al. (2015) developed enzyme-based biocomputing systems coupled with pH-responsive membranes and electrodes. As a result, they obtained bioelectronic devices switchable by logically processed biomolecular signals. Reversible pH-responsive on-off behavior performing Boolean logic was suggested for designing novel multi switchable electrochemical biosensors based on electrodes covered by polymer network (Liu et al., 2012) or polymer brushes (Li et al., 2014) and electrodes made of inorganic-polymer composites (Wang et al., 2015).

Significant progress in DNA and molecular logic operations was made in recent years. However, various issues remain unresolved. For example, information transfer through live-machine interfaces: living matter conducts electricity mostly using ions, while machines conduct electricity mostly using electrons (Yang and Suo, 2018). It's of high importance nowadays because technologies at the interface between natural and artificial plays a central role in science. We suggest here a strategy for performing iontronic logic operations at interfaces in solutions and present it's modeling by the electrochemical and photochemical system and how they can be related to Shannon's entropy. Having an array of electrodes and applying potential bias according to some program, one may realize the spatial distribution of acidic and basic areas in water solutions close to an electrode in a unique pattern with micrometer resolution. It's key to iontronic information processing. Designating current density higher than some value as logic input "1" and pH lower than some cut-off as logic output "1," we may design different logic gates varying the geometry of input electrodes, the position of response point and cut-off values. We present here the simplest AND logic gate performed by a couple of microelectrodes and discuss assembling of individual logic gates in concatenated logic cascades and complex branching networks by multielectrode arrays.

Having an array of electrodes and applying potential, oxidation, and reduction processes may be localized at particular electrodes and hence spatially separated. Protons propagating from parental electrode serve as information transmitters. Moreover, we have demonstrated that polyelectrolyte modification of electrode surface may lead to amplification and better localization of ion fluxes and hence signal amplification and can be related to self-organization *vs*. Shannon's entropy. All this discussion is also extrapolated to polyelectrolyte modified photoelectrodes under irradiation.

ENHANCING ELECTROCHEMICALLY PRODUCED IONIC SIGNALS BY POLYELECTROLYTE ASSEMBLIES

Electrochemistry provides one with a powerful approach for the on-demand local generation of ionic signals. For example, proton fluxes may be produced by electrochemical hydroquinone oxidation (Fomina et al., 2016). Due to their proton-coupled electron transfer, low redox potential, and relative chemical stability, quinones are widely used as the electroactive species for the controlled generation/consumption of protons (Dochter et al., 2015; Garnier et al., 2015). Naturally occurring hydroquinone compounds play a significant role in electron/proton transfer of many biological processes (Jeyanthi et al., 2016). Thus, the quinone/hydroquinone transition serves as an essential electrochemical model for the development of biomimetic systems. Its changing molecular structure allows for its electrochemical properties to be tuned (Peduto et al., 2017). But characteristics of an electrode reaction are highly affected by the microstructure of the electrode surface, since the fact that electrochemical systems under investigation are heterogeneous and electrode reaction is related to electron transfer through the electrode-electrolyte interface.

Electrode surface influences diffusion of electrochemical reactants and products as well as Faradaic process. In case of hydroquinone oxidation, horizontal and vertical proton propagation is supposed to be a three-dimensional pH wave. It originates from the ion source and weakens as it moves

away. Fick's laws describe diffusion and postulate that ionic flux goes from regions of higher concentration to areas with a lower one. Furthermore, the magnitude of the driving force determining ion movement is proportional to the concentration gradient. Ion fluxes and the concentration of a particular ion close to the surface of the electrodes were investigated using Scanning Vibrating Electrode Technique (SVET) and Scanning Ion-Selective Electrode Technique (SIET), unique tools for the characterization of local ionic currents in solution and ion concentration gradient measurement, respectively (Souto et al., 2010). SVET allows the electric field in a solution to be measured for the visualization of anodic and cathodic areas on surfaces with nA precision and μm spatial resolution (**Figure 1a**). During SVET-analysis, a vibrating Pt-probe (**Figure 1b**) scans the surface, estimating its electrical potential in amplitude points of its vibration and then recalculates it in ionic currents. SIET is based on potentiometric principles. A glass capillary microelectrode with the ion-selective membrane in the tip scans the surface, measuring the concentration of a particular ion.

We have studied the effect of polyelectrolyte assembly on top of an electrode on the propagation of electrochemically generated protons. The system under investigation is a working electrode (WE) gold or platinum wire embedded in an epoxy resin so that its round section was brought into contact with a solution (**Figure 1c**). System may be also extended to several electrodes (**Figures 1d,e**). Electrochemical reaction is coupled with proton release. The pH-wave propagation is driven by a concentration gradient. Further, the surface of the noble metal electrode (WE) was subsequently modified with nanometer-thin layers of the polycation polyethyleneimine (PEI) and the polyanion poly(sodium 4-styrenesulfonate) (PSS). PEI is considered to be a proton sponge that stores electrochemically generated protons while the PSS layer serves as a cation exchange layer. The electrode was first covered by branched PEI to provide secure anchoring to the surface and to act as a positively charged terminating layer. Deposition of PSS was then carried out via electrostatic interaction with the underlying layer. Although polymer multilayer assembly leads to no change in redox processes at electrode/electrolyte interface, both the anodic and cathodic activity of the Pt electrode measured by SVET is higher for one that is polyelectrolyte coated than for a bare one (**Figures 1f,g**). It is worth noting that a terminating PEI layer resulted in more pronounced anodic/cathodic activity. However, if this polyelectrolyte membrane is thick enough, ion flux from the surface is suppressed (Ryzhkov et al., 2019b).

Since LbL polyelectrolyte assemblies contain many uncompensated charges, ions cannot freely pass through the membrane. Although it is still passive transport down their concentration gradient, ion movement pathways are more complex and cannot be explained by simple diffusion. We consider polyelectrolyte LbL assemblies as a convenient tool for controlling the transmission of the ion signal. Strong and weak polyelectrolyte assemblies, including charged biopolymers and hydrogels, can regulate charge carrier generation, the diffusion of ions at interfaces, lifetime and storage (Ryzhkov et al., 2019a). There is still no general theory precisely predicting electrode response to polyelectrolyte modification. Until now, multicomponent coatings formed by multilayers of different polyelectrolyte compositions (strong–strong, strong–weak, weak–weak) have been analyzed as nanolayers for corrosion protection. The mechanism of multilayer protective action is based on pH buffering polybasic and polyacid complexes (Andreeva et al., 2010; Skorb and Andreeva, 2015). It has also been demonstrated that polyelectrolyte layers can be used as an efficient pH-buffering protective layer for pH-sensitive soft materials (Skorb and Andreeva, 2013). It is expected that by combining polyelectrolytes of different molecular weights, strengths, and with different specific functional moieties, one can flexibly tune spatial and temporal distribution of ionic fluxes through the membrane and perform independent handling by cations and anions. That fact opens up prospects for developing futuristic biomimetic information processing using ions as signal carriers.

DISCUSSION OF SOFT MATTER ASSEMBLIES FOR CONTROLLING ION FLUXES

LbL deposition of polyelectrolyte multilayers is a universal approach to designing interfaces with unique properties. Its impact is not limited by enhancement of ion fluxes described above. Different effects may be achieved by polyelectrolytes of different nature. Recent progress in science provides an understanding of polyelectrolyte complexation principles. Despite the apparent simplicity of the assembly procedure, the processes occurring in the multilayers are incredibly complex. Polyelectrolyte layers in multilayered structures are not perfectly stratified, and polymer chains of polycations and polyanions are significantly interpenetrated (Schönhoff, 2003). Much attention is drawn to the dynamics and internal structure of polyelectrolyte multilayers and studying of internal diffusion (Fares and Schlenoff, 2017; Selin et al., 2017). Various parameters such as ionic strength (Steitz et al., 2000), charge density (Steitz et al., 2001), pH, and temperature (Karg et al., 2008) influence the internal structure of polyelectrolyte film. Several models of diffusion in ultrathin polyelectrolyte films were suggested (Klitzing and Möhwald, 1996; Farhat and Schlenoff, 2001). Three different modes of interaction of polyelectrolyte multilayers and small ionic species were observed—permeability, non-permeability, and ions accumulation. It was also found that the permeability of polyelectrolyte membranes depends mostly on film composition rather than its thickness (Hoshi et al., 2003). The outermost layer of polyelectrolyte LbL assembly carry out excess non-compensated charge and plays a crucial role in permeability properties blocking penetration of similarly charged small species (Rmaile et al., 2003). Fu et al. (2017) demonstrated that pairs of weak polyelectrolytes tend to transport small molecules or ions more, whereas multilayers assembled from strong polyelectrolytes are less permeable. Kelly et al. (2018) demonstrated that ion flux through the membrane is significantly affected by the stoichiometry of the polyelectrolyte multilayer. An excess of some component, polycation, or polyanion, changes diffusion

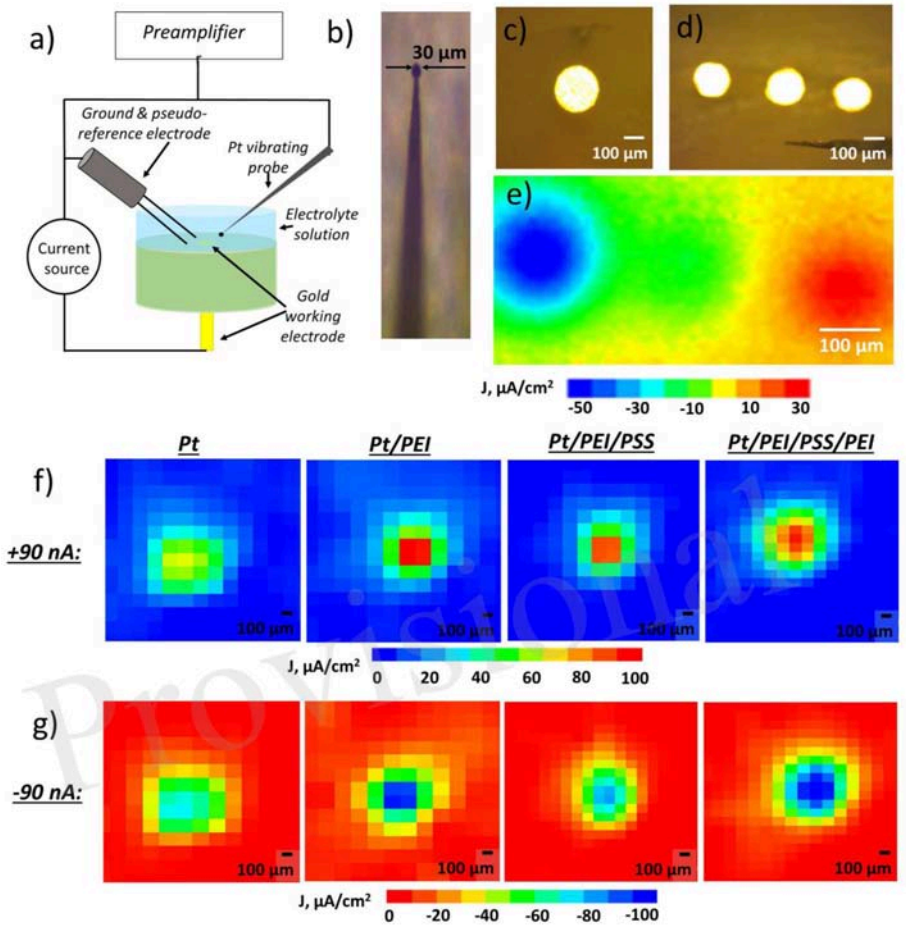

FIGURE 1 | (a) Schematic of scanning vibrating electrode technique (SVET) for determining an ionic current that can be used together with scanning ion selective electrode (SIET). **(b)** Pt-Ir vibrating probe for SVET, **(c)** top view of gold electrode embedded in epoxy resin, **(d)** top view of working electrodes (WE) embedded in epoxy resin **(e)** ion currents mapped by SVET in solution over three WEs, left electrode is negatively polarized (−90 nA), right one—positively (+90 nA), red demonstrates areas of positive ionic current in solution related to anodic activity and blue—areas of negative ionic current in solution and cathodic activity on the surface, **(f,g)** ionic current over one WE under either positively [in **(f)**] or negatively [in **(g)**] on pristine Pt or Pt covered with different polyelectrolyte multilayers—Pt/polyethylenimine (Pt/PEI), Pt/PEI/ poly(sodium 4-styrenesulfonate) (Pt/PEI/PSS), and Pt/PEI/PSS/PEI—number of layers affects drastically on the ionic current.

and permeability of ions through the polyelectrolyte multilayer. Ion transportation through polyelectrolyte multilayers can be described similarly to solid matter permeability. Thus, the action of surrounding polyelectrolyte chains affects diffusion through polyelectrolyte assemblies significantly and diffusion is thermoactivated (Spruijt et al., 2008). Internal interfaces predetermine the properties of polyelectrolyte multilayers, and one should therefore keep in mind the composition and structure of the multilayer, the internal layer chemistry, and interactions between components when designing functional polyelectrolyte multilayers (Brezhneva et al., 2019). The means of changing the permeability of polymer layers mentioned above have already found extensive use in the development of semipermeable separating membranes and electrochemical sensors with improved selectivity, sensitivity, and response time.

Thus, polyelectrolyte multilayers are a powerful instrument for the regulation of ion-fluxes. By varying membrane composition, enhanced ion transport, accumulation, and delayed release can be realized.

PH-WAVE PROPAGATION AS A BASIS FOR IONTRONICS

Precise control over electrochemically generated ion fluxes open perspectives for flexible and reliable approach for transition from machine way of information processing (via electrons) to biological one (via ions) and developing technologies at the interface between natural and artificial (wearable and implantable devices, for example).

Our interest is focused on information transfer in aqueous solutions and the prospective for communication with living matter. Here, we demonstrate a proof of concept of basic logic operations that use ions as input and/or output signals which allows unequivocal output reading. The system under

investigation is presented by an array of gold or platinum electrodes particularly embedded in an epoxy resin and immersed in the electrolyte solution. The simplest model systems containing two electrodes are shown in **Figure 2**.

By applying positive and negative potentials to the electrodes one is able to carry out a pH coupled redox process (e.g., hydroquinone oxidation). Herewith, oxidation and reduction processes may be spatially separated. As a result, the distribution of acidic and basic areas in a solution adjusted to an electrode surface may be realized particularly. Anodic and cathodic activity are localized directly at the electrodes while the resulting pH gradient is more spatially blurred. The desired localization of the proton wave may be achieved via electrode functionalization by polymer assembly. The electrodes may be designated as inputs and the acidity of the space between the electrodes as output in terms of logic gates. Simple AND logic operations (**Figure 2a**) may be performed. The main processor of any computing device is basically a bunch of interconnected logic gates, thus performing these simple logic operations is an important step toward biomimetic iontronic calculations. The open-circuit potential applied to the input electrode (**Figure 2b**) is designated as input "0" and hydroquinone oxidation potential (0.70 vs. SHE) as input "1." The acidity of the solution between the electrodes is read as an output signal. A pH lower than some threshold, for example, 5.0, is designated as output "1" with anything lower being "0." Two "0" inputs provide "0" output (**Figure 2c**). If only one of the electrodes is polarized, the resulting pH wave does not reach the output area, and pH $>$ 5.0. Therefore, the output signal is "0" (**Figure 2d**). Otherwise, if both input electrodes are polarized, generated protons propagate to the output area, making the pH there significantly acidic, $<$5.0, giving signal "1" in output area (**Figure 2e**).

In general, the model system described above may be extended to several dozen electrodes. As such, some electrodes may be assigned as inputs while others are for the reading of the electrochemical output. We started with three microelectrodes (**Figure 1d**) and, by SVET, demonstrated that the independent polarization of electrodes might be performed, while no effect of the bipolar electrode was observed in the studied potential window (**Figure 1e**).

What we plan to do next is to cover the output electrode with pH sensitive film, grafted P4VP or P2VP brushes for example (Pennakalathil et al., 2010; Ghostine and Schlenoff, 2011). This thin polymer layer in its non-protonated state is collapsed and acts as an insulator, inhibiting direct electron transfer from the electrode to the electrochemically active specimen in solution and vice versa. If only one input electrode is active, the resulting proton wave does not reach the output electrode. The polymer layer still blocks the electrode surface and no current is observed during polarization. When both inputs are "1" (applied potential of hydroquinone oxidation), then the resulting proton wave reaches the output electrode, making the surrounding media acidic enough to protonate the blocking polymer layer atop the output electrode. As a result, polymer conformation changes from collapsed to swelled, allowing penetration of hydroquinone to the electrode. Thus, an anodic current of hydroquinone oxidation may be registered at the output electrode. A Faradaic current registered at the output electrode above a certain threshold is assigned as "1" and lower as "0." Thus, switching of output electrode activity may be performed according to Boolean logic. It is worth noting that in this case some autocatalysis may be shown, and the acidification of the area close to the output electrode leads to electrochemical generation of more protons. Thus, signal amplification and signal transmission from one location to another realizing specific pathways through the electrode network may be performed.

Our future research direction will be focused on different geometries of input electrode array, varying applied potentials and passed currents, and regimes of application (constant current, pulses, etc.). Another direction is the development of novel approaches for output electrode modification for ensuring disambiguation of output response reading.

SELF-ORGANIZATION VS. SHANNON'S ENTROPY

Fundamental concept of information theory is Shannon's entropy. Entropy in this case is a measure of unpredictability of the state, or equivalently, of its average information content. We suggest here description of described above approach to designing of iontronic devices in terms of Shannon's entropy.

Idea here is a correlation of soft matter components (polyelectrolytes and lipid layers) of living cell and our biomimetic model (**Figures 3A,B**). We took photochemical system (**Figure 3C**) (Maltanava et al., 2017) shown previously as the analogy to electrochemically induced proton gradients in aqueous electrolytes and collect SIET pH maps for pristine working electrode (WE) (System I), WE covered with polyelectrolyte multilayers (System II) and WE covered with polyelectrolyte multilayers and lipid layer on top (System III).

Processes of self-organization are known to be closely related to change in entropy of the system (Haken, 2006). Typically, this occurs with spatial change in thermodynamic (as temperature, density, and pressure) as well as chemical parameters and, in particular, ion composition of the system. In our case, the changes of temperature, density, and pressure are negligible, while the local electrochemical influence affects directly the ion-distribution in the solution. Note that the spatial pH-redistribution occurs self-consistently, being accompanied by local electric potential redistribution during the free-energy minimization of the system. In result, the self-organization and the redistribution of pH-fields are directly associated with each other and, thus, the change of entropy can be illustrated using the fields of pH.

According to its definition, the Shannon's entropy is (Haken, 2006).

$$S = -\sum_i p_i \log_2 p_i \quad (1)$$

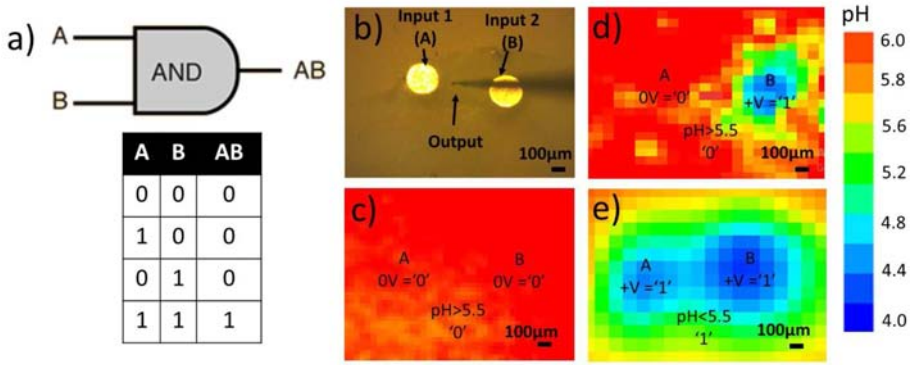

FIGURE 2 | (a) Basic AND logic gate and corresponding truth table, **(b)** system of two WEs embedded in epoxy holder, **(c–e)** 2D pH-maps via SIET of two input electrodes in hydroquinone solution during polarization of electrodes in different regimes and interpretation in terms of logic gates, positive polarization +V is determined as input "1," no polarization 0V as input "0," pH >5.0 is determined as output "0" and pH<5.0 as output "1," **(c)** no potential applied, both inputs are "0," as a result, no pH drop – output "0," **(d)** positive potential is applied to the right electrode "1," left one is not polarized "0," resulting pH drop localized on right electrode and doesn't propagate to output area "0" **(e)** positive potential applied to both electrodes "1," resulting proton wave reaches output area giving output "1".

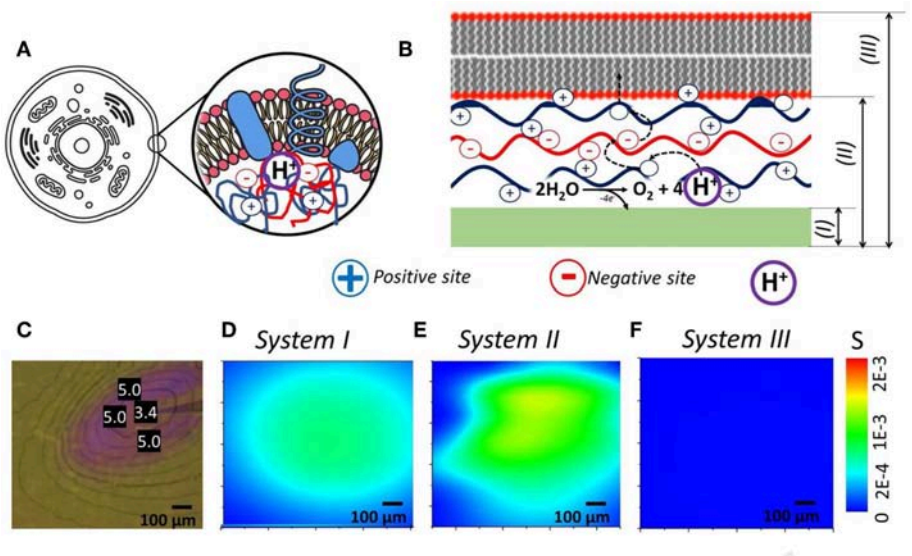

FIGURE 3 | (A,B) Idea of cell prototype system that consists of polyelectrolyte assembly or coacervates, reactions inside that are protected from environment by lipid bilayers. **(C)** System with local gradient of pH initiated by light (measured pH values are shown in units in photo). **(D–F)** Recalculated into Shannon's entropy SIET pH maps of—**(D)** pristine WE, **(E)** WE covered with polyelectrolytes, and **(F)** WE covered with polyelectrolytes and lipid bilayer—processes of self-organization are closely related to change in entropy of the system.

where $0 < p_i < 1$ is the probability to measure some observable value i. In a case of a lot of observable independent values (e.g., set of p-values at different spatial points), corresponding summation over them should be performed in the right hand side of Equation (1).

The particular physical sense of the probability p depends on the system's nature and plays an important role for interpretation of the results. For instance, p can be related to the probability of some molecular dipole orientation or electric charge in case of electric systems, an electron spin orientation or magnetic polarization in magnetic systems, a particular state of photons in optical systems, or concentration of chemicals in reacting systems (Haken, 2006). In the same manner, this approach could be naturally expanded to solutions, to consider p in sense of probability that an observed ion in the solution is an H^+ or OH^- ion (whose concentrations are related with each other). In other words, we may use the parts of H^+ and OH^- ions as the probabilities p_H and p_{OH}, to calculate corresponding contribution to the Shannon's entropy associated with the pH in a given spatial area of measurement. One should note that, generally speaking, the pH distribution provides the same information as the field of electric potential, since they are consistently related with each other in the solution.

The probability to observe H^+ cations in a solution during a measurement is simply related to the cation concentration in the system and pH of the solution as $p_H = C_H/C_0 = 10^{-pH}$, where $C_0 = 1M$ is a normalizing concentration. For OH^- anions, we have $p_{OH} = C_{OH}/C_O = 10^{pH-14}$, since $p_H\ p_{OH} = 10^{-14}$. From here, by substitution of this expression for p into Equation (1), we readily obtain the pH-related part of the Shannon's entropy as

$$\begin{aligned} S &= \log_2 10\,(pH\ 10^{-pH} + pOH\ 10^{-pOH}) \\ &= \log_2 10\,(pH\ 10^{-pH} + (14 - pH)\ 10^{\,pH-14}) \end{aligned} \quad (2)$$

Equation (2) determines the contribution to Sannon's entropy, associated with pH measured in a small volume (which we consider as a subsystem of a large system herein the pH-measurement is performed). At pH = 7, Equation (2) exhibits a local minimum. Note that Equation (2) is symmetric relatively pH = 7 and, at pH < 6.8 (pH > 7.2), the first (second) term in the parenthesizes becomes negligible.

The total entropy for given discrete spatial distribution of pH (distribution of the system states) can be calculated with summation over the *S*-values in all spatial points of the system. This situation with discrete distribution of pH field is typical for experiments we performed, since the size of a "cell" (small open volume of the solution) wherein pH is measured is determined by the electrode size.

The approach based on Equation (2) is convenient for analysis of self-organization phenomena (related to change in pH-distributions) and their interpretation in terms of entropy fields. This can be illustrated using results of our measurements of pH fields in different systems. For instance, taking spatial distribution of cations determined experimentally in cases of bare electrode, as well as for electrode covered by polyelectrolyte multilayer $(PEI/PSS)_3$ and lipid bilayer, we obtained the spatial distributions of entropy $S(x, y)$ represented in **Figures 3D–F**. Interestingly, huge difference is observed for obtained the spatial distributions of entropy that can be associated with various soft matter components for controlling ion fluxes.

CONCLUDING REMARKS AND OUTLOOK

In this perspective, we highlight information processing and signaling by spatial and temporal distribution of ions. A model electrochemical and photochemical system creating local ion-fluxes were demonstrated.

Electrodes spatially organized in a particular manner allows propagation of pH waves to be triggered and spatial distribution of H^+ according to a particular pattern to be realized. Proton diffusion from two sources is reported to model the AND logic gate. We are currently studying how the system geometry influences the pattern of proton concentration and developing a simulation that predicts pH pattern depending on the working electrode geometry and vice versa, namely suggesting electrode geometry depending on desired pH pattern.

The LbL assembly of polyelectrolyte multilayers is suggested as an instrument to control horizontal and vertical ion propagation with ability to correlate it with the spatial distributions of entropy. The experiments we have described are only a small sample of the full range of polyelectrolyte materials that can be assembled on top of electrodes and tested for ion conduction ability.

EXPERIMENTAL SECTION

Three-electrode electrochemical cells (working electrode, Pt counter electrode and Ag/AgCl reference electrode) were utilized as model electrochemical and photoelectrochemical systems. Working electrode was presented by gold or platinum wire (0.2 mm in diameter, 2–3 cm length) embedded in epoxy resin so that circular cross-section of wire exposed to outside media on flat surface of obtained holder. Anodized TiO_2 (1.5 cm^2) under low intensity light-emitted diode (365 nm) irradiation focused in spot (~0.25 cm^2) was utilized as working photoelectrode. The anodic and cathodic activity of electrode under polarization in water solution as well as photoactivity of illuminated TiO_2 was studied by SVET and generated pH gradients by SIET. To perform the SVET and SIET measurements, a system from Applicable Electronics (USA) modulated by an ASET program (Sciencewares, USA) was used. As a vibrating probe for SVET experiments, an insulated Pt-Ir microprobe (Microprobe Inc., USA) with a platinum black spherical tip 30 μm in diameter was used. The probe was made to vibrate both parallel and perpendicular to the specimen surface at a height of 150 μm. The amplitude of vibration was 30 μm, while the probe vibrated at frequencies of 136 Hz (perpendicular to surface) and 225 Hz (parallel to surface). Only the perpendicular component was used in the treatment and presentation of the data. The environmental pH measurements by SIET were carried out using glass-capillary microelectrodes filled with Hydrogen Ionophore Cocktail I (Sigma) based liquid pH-selective membrane and KCl + KH_2PO_4 internal solution. Ag/AgCl/KCl (sat) was used as the external reference electrode. The pH-selective microelectrodes were calibrated using commercially available pH buffers and demonstrated a linear Nernstian response−55 to−58 mV/pH—in a pH range from 3 to 8. The local activity of H^+ was detected 25 μm above the surface. Instrumentation allows to measure voltage with nV precision level, and measure extremely low ion concentration gradients. Step motors allow to study electrochemical activity of material with micrometer spatial resolution and high-resolution maps were obtained. Electrochemical systems were studied in 60 mM hydroquinone solution in 150 mM KNO_3, photoelectrochemical one without addition of hydroquinone.

The deposition of the polyelectrolyte multylayers onto the surface of working electrode was performed using the classical Layer-by-Layer technique. Two mg/ml each branched polyethylenimine (PEI, Mw 70 kDa, 30% water solution purchased from Alfa Aesar) and polystyrene sulfonate (PSS, Mw 500 kDa purchased from Polysciences Inc.,) were dissolved in 0.5 M aqueous NaCl to make polycation and polyanion solutions respectively. Each layer took 20 min to be deposited after which it was rinsed with excess distilled water and then steam-dried. On top of polyelectrolyte modified TiO_2 lipid bilayer was also deposited from 10 mg/ml dispersion of Lecisoy 400 vesicles for 1 h. Further electrochemical characterization

of modified electrodes and photoelectrodes were performed as described above.

SVET data presented as obtained, SIET data recalculated according to previous calibration. Mapping for each experimental condition were reproduced at least three times, one of typical maps is presented.

AUTHOR CONTRIBUTIONS

NR and ES contributed conception and design of the study. SY contributes discussion and writing of Shannon's entropy vs. H^+ concentration gradient part. NR, NM, and PN performed experimental work and treatment of the data. NR wrote the first draft of the manuscript. ES coordinated the study and helped draft the manuscript.

FUNDING

This work is supported by RSF Grant No. 17-79-20186. ES also thanks the ITMO Fellowship Professorship Program for Infrastructural Support. Contribution by SY (discussion and the entropy vs self-organization analysis) was supported by Russian Science Foundation, Grant No. 17-19-01691.

A Review on the Electroless Deposition of Functional Materials in Ionic Liquids for Batteries and Catalysis

Abhishek Lahiri, Giridhar Pulletikurthi and Frank Endres*

Institute of Electrochemistry, Clausthal University of Technology, Clausthal-Zellerfeld, Germany

Developing functional materials via electroless deposition, without the need of external energy is a fascinating concept. Electroless deposition can be subcategorized into galvanic displacement reaction, disproportionation reaction, and deposition in presence of reducing agents. Galvanic displacement reaction is a spontaneous reduction process wherein the redox potentials of the metal/metal ion in the electrolyte govern the thermodynamic feasibility of the process. In aqueous solutions, the galvanic displacement reaction takes place according to the redox potentials of the standard electrochemical series. In comparison, in the case of ionic liquids, galvanic displacement reaction can be triggered by forming metal ion complexes with the anions of the ionic liquids. Therefore, the redox potentials in ILs can be different to those of metal complexes in aqueous solutions. In this review, we highlight the progress in the electroless deposition of metals and semiconductors nanostructures, from ionic liquids and their application toward lithium/sodium batteries, and in catalysis.

INTRODUCTION

A simple route for developing various metal and semiconductor nanostructures is one of the major challenges in materials research, which has a significant impact in the fields of energy storage and conversion, catalysis, sensors, photonics and optoelectronics, and biology. Electroless deposition is an elegant and versatile technique for metal plating as well as for developing various metal nanostructures. Electroless deposition can be subdivided into three categories: (1) Galvanic Displacement reaction: **Figure 1A** shows a schematic diagram of this process. In this process, when exposing a less noble metal containing solution (S) to a more noble metal (M), a spontaneous electrochemical reaction (redox reaction) takes place wherein the more noble metal is reduced by the Electrons generated from the less noble metal, as shown in Equations (1, 2). This technique is used to develop various nanostructures which can be used for different applications in batteries and catalysis.

$$S = S^{n+} + ne^- \quad (1)$$

$$M^{n+} + ne^- = \mathrm{M} \quad (2)$$

(2) Using a reducing agent: In this process, the employed reducing agent undergoes oxidation and provides electrons to the metal ions present in the electrolyte. When exposing the substrate to a

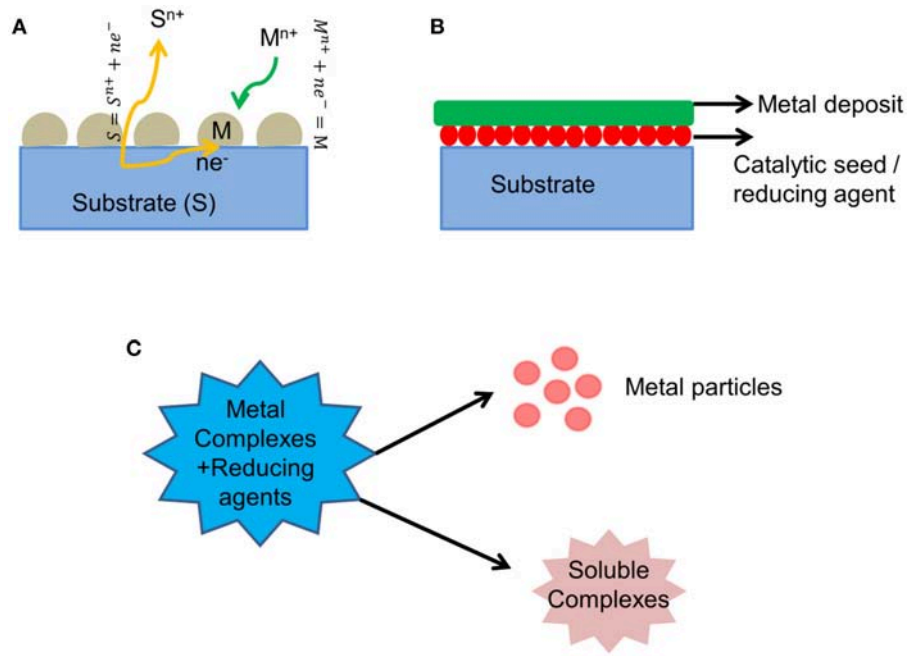

FIGURE 1 | Schematic diagram of various electroless deposition processes **(A)** Galvanic displacement reaction **(B)** Reduction using reducing agents **(C)** Disproportionation reaction.

metal ion containing electrolyte, spontaneous metal deposition occurs on the substrate as shown in the schematic diagram in **Figure 1B**. This technique is generally used for developing metal coatings over insulating or non-conductive substrates.

(3) Disproportionation reaction: In this process, the metal complex in presence of certain substances such as acids/salts or carbon monoxide, leads to the formation of metal particles, and other soluble products as shown in the schematic diagram in **Figure 1C**. This technique is usually used to generate metal nanoparticles which can be used as catalysts.

In aqueous systems, the galvanic displacement reaction occurs according to the standard electrochemical series wherein the redox reactions mainly depend on the concentration of metal ions, pH, and temperature. Furthermore, the electroless deposition is usually limited to a few monolayers without the addition of a catalyst. A change in the metal ion speciation in aqueous solutions might also result in a deviation from the standard electrochemical potentials, which has not been studied in great detail (Abbott et al., 2011, 2018), but might open up a few new opportunities for developing functional materials.

In direct comparison to aqueous solutions, ionic liquids possess advantages for favoring the galvanic displacement reaction. Ionic liquids are entirely made up of cations and anions, and can be divided into three subcategories of protic, aprotic, and deep eutectic solvents (DES) (Smith et al., 2014; Greaves and Drummond, 2015; Watanabe et al., 2017). In the last couple of years, the addition of water and molecular solvents in ionic liquids have also been explored as electrolytes for different applications and been described as the "fourth evolution in ionic liquids" (MacFarlane et al., 2018). This makes a large number of ionic liquids and its mixtures as possible electrolytes to tune the redox reactions (M/M^{n+}) and to trigger the galvanic displacement process. However, compared to aqueous electrolytes, there is no universal electrochemical series in the case of ionic liquids due to the lack of a standard reference electrode potential.

As only ions are present in ionic liquids, by changing the anions of the ionic liquids, the speciation of metals/semiconductor ions can be altered (Borisenko et al., 2018; Lahiri et al., 2018a). A change in the speciation leads to a different electrochemical behavior and has also shown to affect the morphology of the deposit (Pulletikurthi et al., 2013, 2014; Borisenko et al., 2018; Lahiri et al., 2018a). Interestingly, it was reported that changing the cations of the ionic liquids also affects the morphology of the electrodeposits (Zein El Abedin et al., 2006; Al-Salman and Endres, 2009; Ispas et al., 2010). The changes in the morphology of the electrodeposit were related to the difference in the interfacial structure of the ionic liquid at the electrode/electrolyte interface (EEI) (Endres et al., 2010). Unlike aqueous systems which form a double layer structure at the EEI, ionic liquids form a multilayered structure and the addition of metal ions affects this EEI structure (Lahiri et al., 2015a; Carstens et al., 2016), which influences the deposition kinetics. Therefore, in ionic liquids, a variation in the combination of both anions and cations can change the electrochemical behavior of metal/semiconductor deposition, which would also be the case for electroless deposition. In batteries, synthesis of various nanostructures with a high surface area and mechanical stability is important in order to develop a long-term stable battery. Electroless deposition in ionic liquids shows a promising route to

obtain such nanostructures. Furthermore, in catalysis, not only is a high surface area important, but a high number of catalytic activation sites are also necessary. Such control over morphology and tunable active sites can be achieved in ionic liquids which will be shown in the review.

Thus, based on the above brief description, it is clear that electroless deposition in ionic liquids differs from aqueous-based electrolytes. Numerous studies of electroless deposition in aqueous systems can be found in literature, yet little has been reported from ionic liquids. In this short review, we will present results on electroless deposition of metals in ionic liquids and show the application of the obtained nanostructures for batteries and catalysis. Finally, we will propose the various challenges and future prospects of electroless deposition in ionic liquids.

ELECTROLESS DEPOSITION OF NOBLE METALS

The first example of galvanic displacement reaction of silver (Ag) on Cu was shown by Abbott et al. (2007) in a DES composed of choline chloride (ChCl) and ethylene glycol (EG). Electroless deposition of Ag is an important industrial process for printed circuit boards (PCBs) to prevent degradation of the copper surface and is usually done by plating silver on copper from an $AgNO_3/HNO_3$ solution. Compared to the corrosive nature of the aqueous solution which also affects the copper in PCBs, an ionic liquid or DES does provide a safer alternative. Secondly, in aqueous solutions for the electroless deposition to prolong beyond few nanometers, a palladium catalyst is used (Shipley, 1961; Djokic, 2002). However, in the case of ionic liquids, it was shown that the galvanic displacement reaction of silver continued beyond a few nanometers without the use of any additional catalyst. In ChCl:EG eutectic ionic liquid, the galvanic displacement reaction took place according to Equation (3).

$$Ag_{IL}^{+} + Cu\,(s) = Cu_{IL}^{+} + Ag(s) \tag{3}$$

Figures 2A,B shows the AFM image of the deposit along with the height profile of Ag deposition on Cu, respectively. It is evident from **Figure 2A** that Ag electroless deposition on Cu is thick and from the height image in **Figure 2B**, the thickness was found to be ∼500 nm. This shows that electroless deposition of Ag on Cu from ionic liquids is clearly different from aqueous electrolytes where thermodynamics governs the redox potential and the reaction would stop in aqueous electrolytes once the Cu is covered with Ag. However, this was not the case for ILs as reported in Abbott et al. (2007). The authors reported from quartz crystal microbalance (QCM) investigations that during a controlled electroless deposition wherein copper was first electroplated on Au, with time, all the copper was replaced by Ag. Based on the results of scanning electron microscopy (SEM), Atomic Force Microscopy (AFM), and QCM, it was concluded that the electroless deposition of Ag on Cu might be limited by the diffusion of Cu^{+} ions. Temperature and different silver salts were also found to influence the deposition of Ag.

Different silver salts ($AgNO_3$, Ag_2SO_4, Ag(acetate), and AgCl) were investigated for silver plating. The best and most consistent result for electroless deposition of Ag on Cu was obtained from AgCl in the DES (Abbott et al., 2008). This means that the anion of the Ag salt alters the electroless deposition process which might be due to the change in speciation. However, Ag speciation studies are still lacking in DES which would have provided more information regarding the deposition quality as well as reaction kinetics. From the above studies, it appears that Cl^{-} ions can trigger the galvanic displacement reaction at the electrode/electrolyte interface. With a change in temperature from 20 to 45°C, the deposition rate was found to increase from 45 to 110 nm min^{-1} (Smith et al., 2010). Based on the results of the galvanic displacement of Ag on Cu, the authors also performed a pilot scale study for Ag plating on Cu in PCBs (Smith et al., 2010). For an industrial process, the rate of deposition must be increased to 0.2 μm min^{-1} which was achieved by increasing the Ag concentration in the liquid. **Figure 2C** shows the image of Ag coated Cu in a PCB using electroless deposition in the liquid. This clearly shows that it is possible to scale-up electrochemical processes in ILs and deep eutectic solvents with comparable/better results than the existing methods without the use of sacrificial precious metals.

Silver was also plated on Cu from a 1-butyl-3-methylimidazolium bromide (BMImBr)-AgBr electrolyte (Grishina and Ramenskaya, 2017). It was shown that the displacement reaction leads to the formation of $CuBr_2$ which dissolves in the electrolyte turning the solution to pale violet. From such a liquid, a silver coating thickness of up to 10 μm could be achieved. By studying the reaction kinetics, the authors showed that the galvanic displacement process took place in two stages. The rate constant in the first stage was found to be 5.1 × 10^{-5} s^{-1} which increased to 5.3 × 10^{-4} s^{-1} in the second stage and was related to the decrease in charge transfer resistance (Grishina and Ramenskaya, 2017). Although, compared to DES, a much thicker Ag layer could be achieved, the viscosity of BMImBr is higher than DES and therefore the removal of ionic liquids after the displacement process might be an issue. Furthermore, questions regarding the reuse of the BMImBr-AgBr electrolyte for plating silver on copper for practical applications remain unanswered.

Wang et al. studied the use of aqueous based choline chloride to study the galvanic displacement reaction of Ag on Cu with different silver salts of $AgNO_3$, AgCl, and Ag_2SO_4 (Wang et al., 2013a). It was shown that the mole ratio of ChCl and H_2O affected the deposition of Ag from $AgNO_3$. Furthermore, as observed previously by Abbott et al. with increase in temperature, the rate of deposition was shown to increase and by determining the deposition rate at various temperatures, the activation energy for Ag deposition was found to be 13 kJ mol^{-1}. However, from XRD analysis, the authors observed both Ag and Cu peaks which suggests that the thickness of Ag deposited was very low. Furthermore, the lack of adhesion tests along with limited solubility of AgCl and Ag_2SO_4 in the electrolyte questions the applicability of aqueous based electrolytes for metal plating.

The same authors also studied the electroless deposition of Pd on Ni-P coated Cu sheets using ChCl-H_2O electrolyte containing $PdCl_2$ (Wang et al., 2015a). Pd is a versatile catalyst to promote many organic reactions (Miyaura and Suzuki, 1995)

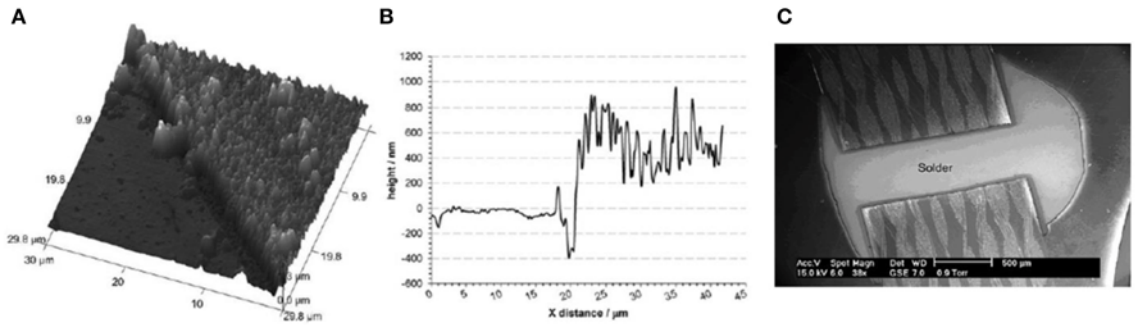

FIGURE 2 | (A) 3D AFM image of electroless deposited Ag on Cu **(B)** AFM height profile of the electroless deposited Ag on Cu shown in **Figure 1A (C)** Ag deposited on a printed circuit board. Reproduced from Abbott et al. (2007) and Abbott et al. (2008) with permission from The Royal Society of Chemistry and Elsevier.

as well as for hydrogen evolution reactions (Pentland et al., 1957) and therefore the electroless deposition becomes a simple technique to develop Pd nanostructures for catalysis applications. For electroless deposition of Pd on Ni-P coated Cu, plating parameters such as ChCl concentration, $PdCl_2$ concentration, pH, and temperature of the electrolyte were investigated. The pH of mixtures of ionic liquids and water can in principle be measured e.g., ChCl-H_2O mixtures. However, the pH of pure/neat aprotic ionic liquids cannot be defined. The galvanic displacement reaction involved the oxidation of nickel and the reduction of Pd^{2+} ions. The authors showed that as the concentration of ChCl in the electrolyte increased from 20 to 120 g L^{-1}, the deposition rate of Pd decreased from 2 to 0.6 µm h^{-1} which was attributed to the change in the coordination of Pd^{2+} ions in ChCl. Unfortunately, the speciation of Pd ions in the electrolyte was not analyzed by the authors. The microstructure of the deposit was also found to change with different immersion times. With deposition time of <5 min, spherical structures were obtained whereas with increase in time to 30 min, nanosheet like structures were observed. Increasing the electrolyte temperature from 55 to 75°C at a fixed ChCl:$PdCl_2$ ratio led to an increase in deposition rate from 1.1 to 2 µm h^{-1}. The change in pH of the electrolyte from 0.6 to 2 did not affect the deposition rate significantly. At an optimum electrolyte composition of 40 g L^{-1} ChCl, 2 g L^{-1} $PdCl_2$, and at a temperature of 60°C, Pd deposition of about 3 µm in thickness could be achieved in 90 min. Finally, the authors tested the corrosion resistance of Pd coated Ni-P/Cu in 3.5% NaCl and showed that Pd indeed improves the corrosion resistance of the material. Although, water based ionic liquids showed the possibility of galvanic displacement reaction, the applicability of the deposited Pd as catalyst was not investigated. Furthermore, the microstructure was shown to change from spherical to nanosheet like structure with deposition time. Such changes in microstructure are particularly interesting in catalytic applications. The lack of such studies makes it hard to evaluate the applicability of electroless deposition processes compared to regular electrodeposition processes.

Electroless deposition of gold was investigated from a few ionic liquids (Aldous et al., 2007; Ballantyne et al., 2015; Wang et al., 2015b). Gold deposition from chloroauric acid ($HAuCl_4$) in ChCl-H_2O was investigated on Ni-P coated Cu (Wang et al., 2015b). The authors showed that with an increase in $HAuCl_4$ concentration in the electrolyte (from 0.5 to 2 g L^{-1}), the rate of deposition increased from 5 to 22.5 nm min^{-1}. However, with higher concentration (2 g L^{-1}), the gold coating peeled off from the substrate. The change in ChCl concentration also affected the deposition rate. With decrease in ChCl concentration again the coated gold did not adhere to the surface whereas with increase in ChCl concentration, the gold deposition rate decreased. The change in the deposition rate with ChCl concentration seems to be due to a change in the coordination of $HAuCl_4$ with ChCl. However, the lack of the information regarding Au^{3+} coordination in the electrolyte makes it difficult to get a clear picture about the deposition process. The plating temperature also affected the rate of deposition. At 60°C, gold deposited at 6 nm min^{-1}, which increased to 13 nm min^{-1} at 90°C. The change in pH of the electrolyte from 0.5 to 3 did not influence the gold deposition rate. For a practical application, the authors also investigated the lifetime of the electrolyte by measuring the absorption spectra of the Au^{3+} ion as a function of time. They found that the solution was relatively stable over time and a loss in absorption of only ∼5% was observed after about 2 months. Based on this work it is clear that galvanic displacement of gold is possible from water based ionic liquids. However, the non-adhesive nature of the film rises concerns about the applicability of this electrolyte. It appears that slow rate of deposition is better for obtaining a stable gold coating. Further studies are required e.g., by preparing suitable electrode materials by surface modification to achieve good Au adhesion from the water based ionic liquid electrolyte.

A comprehensive study regarding metal-ion speciation of Au^{+} and how it influences the deposition rate and morphology was performed by Ballantyne et al. The Au^{+} speciation was studied for three different gold salts [AuCl, AuCN, and $KAu(CN)_2$] in a deep eutectic solvent composed of ChCl and 1, 2-ethanediol (Ballantyne et al., 2015). Prior to galvanic displacement reactions, the authors tested the gold electrodeposition from the three salts on Pt. The cyclic voltammetry (CV) experiments revealed that a complete

reversible process for the gold deposition and stripping occurred for AuCl whereas for both AuCN and $KAu(CN)_2$ no noticeable deposition peaks were observed.

This clearly indicated that Au speciation in the ionic liquid was different. From extended X-ray absorption fine structure (EXAFS) measurements, the authors showed that for AuCl, a coordination number of two was obtained leading to the formation of $[AuCl_2]^-$ species in the ionic liquid. However, in presence of AuCN and $KAu(CN)_2$, a mixed coordination of $[AuCl(CN)]^-$ was observed and no exchange of ligand between CN and Cl took place. Therefore, from the CV, no clear deposition and stripping peaks were obtained for the Au salts in liquids containing cyanide ions. On performing electroless deposition of Au onto nickel from the three electrolytes, the plating rate was found to be different. From AuCl, a plating rate of 1.16 nm min^{-1} was obtained whereas from AuCN and $KAu(CN)_2$ the deposition rate decreased to 0.76 and 0.37 nm min^{-1}, respectively. **Figure 3a** shows the optical image of Au plated on nickel from three different Au salts. Although, a thick gold film was obtained from AuCl (showing a dark brown color in **Figure 3a**, 1), the Au deposit did not adhere strongly to the nickel substrate, and could be easily peeled off. The best gold finish on nickel with a good adhesion property was obtained from the ionic liquid containing AuCN (**Figure 3a,** 2) whereas the deposition from $KAu(CN)_2$ did not give a good plating quality (**Figure 3a,** 3). Thus, this study clearly revealed that metal ion speciation is not only an important factor to control the deposition rate but also to develop better coating materials. Further work based on these studies can be performed to obtain different gold morphologies to be applied in catalysis.

A unique way of proton induced electroless deposition of Au was shown by Aldous et al. (2007) from the ionic liquid 1-butyl-1-methylimidazolium bis(trifluoromethylsulfonyl)amide ([BMIM]TFSA). The authors showed that gold could be deposited on glassy carbon (**Figure 3b**) without applying any potential from $H[AuCl_4]$ in [BMIM]TFSA. They argued that $[AuCl_4]^-$ gets adsorbed on specific sites of the glassy carbon electrode and the H^+ assists in the reduction of gold ions via a disproportionation reaction. It was further shown that addition of HTFSA to the electrolyte facilitated the electroless deposition process. Interestingly, the electroless deposition led to formation of triangular facet gold nanoplates as well as gold nanoparticles as shown in **Figure 3c**. However, changing the anion of IL from $TFSA^-$ to $[PF_6]^-$ or $[BF_4]^-$ did not lead to gold deposition. Although an interesting result of developing tunable gold nanoplates was demonstrated, no further studies were taken up to identify the parameters for producing only triangular shaped gold nanoplates. Gold nanoparticles and nanoplates have immense applications in biosensing (Zeng et al., 2011), plasmonic (Anderson et al., 2013), catalysis (Thompson, 2007), and so forth. Therefore, exploiting electroless deposition to directly obtain tunable plasmonic properties opens new avenues for material synthesis. Furthermore, speciation of Au might have played a key role to promote and develop different gold nanostructures which needs further investigation.

Gold deposition from $H[AuCl_4]$ in 1-butyl-1-methyl-pyrrolidinium dicyanamide ($[Py_{1,4}]DCA$) was studied on copper at different temperatures of 20–80°C (De Sá et al., 2013). The authors reported that Cu dissolves into the ionic liquid forming a copper dicyanamide complex and simultaneous deposition of gold on copper takes place. The morphology of the gold deposited on copper had a spherical structure of ∼200 nm in size and with increase in temperature, the amount of deposit was found to increase at a faster deposition rate. However, the authors neither studied the adhesive nature of gold on copper nor the speciation of Au^+ ion or the catalytic applicability of the deposit.

Electroless deposition of platinum nanoparticles was achieved from ionic liquids by a disproportionation reaction (Zhang et al., 2013). Pt was deposited onto glassy carbon from [EMIm]TFSA and $[EMIm]BF_4$ ionic liquids containing $K_2[PtCl_4]$ and HTFSA or CH_3SO_3H. It was observed that without a proton source, no reduction of Pt took place. The anion of the ionic liquid was also shown to affect the formation of Pt nanoparticles wherein it was shown that changing the anion of the ionic liquid from $TFSA^-$ to BF_4^-, a small quantity of Pt nanoparticles was obtained. This might be due to a different speciation of Pt in the employed ionic liquids which was not evaluated. Electroless deposition of Pt nanoparticles obtained from [EMIm]TFSA in presence of HTFSA is shown in **Figure 3d**, which shows Pt nanoparticles of 1.3 nm in diameter. The obtained Pt nanoparticles were used for electrocatalysis of formic acid. **Figure 3e** shows the electrocatalysis of formic acid to CO_2 on Pt nanoparticles obtained from [EMIm]TFSA containing HTFSA (solid line in **Figure 3e**) or CH_3SO_3H (dashed line in **Figure 3e**). It is evident that the oxidation current density of formic acid conversion on Pt nanoparticles deposited from HTFSA and CH_3SO_3H is different, which was related to the different facets formed in the nanoparticles. Therefore, it is possible that with proper choice of ionic liquids and reducing agents, high catalytic facet noble metal nanoparticles can be produced by electroless deposition, and exploited in catalysis.

ELECTROLESS DEPOSITION OF NON-NOBLE METALS

Tin (Sn) deposition on Cu by a galvanic displacement reaction was studied in ChCl-H_2O in the presence of thiourea (Wang et al., 2013b). From the standard electrochemical series, the Cu/Cu^+ redox potential is more positive compared to the Sn/Sn^{2+}, thus the galvanic displacement reaction should not be feasible due to a positive value for change in Gibbs energy. However, in ionic liquids, the speciation of the metal ions can be changed, and the redox potentials can favor the galvanic displacement reaction, thus making the electroless deposition of Sn on Cu feasible. Moreover, it was shown that the rate of deposition of Sn on Cu depends on temperature and concentrations of $SnCl_2$ and thiourea in ChCl-H_2O. On increasing the $SnCl_2$ concentration up to 15 g L^{-1} a deposition rate of ∼3.2 μm h^{-1} was observed. The addition of thiourea of 90 g L^{-1} marginally improved the rate of deposition to ∼3.4 μm h^{-1}. The XRD results showed that within 1 min of galvanic displacement at 40°C, prominent peaks of Sn

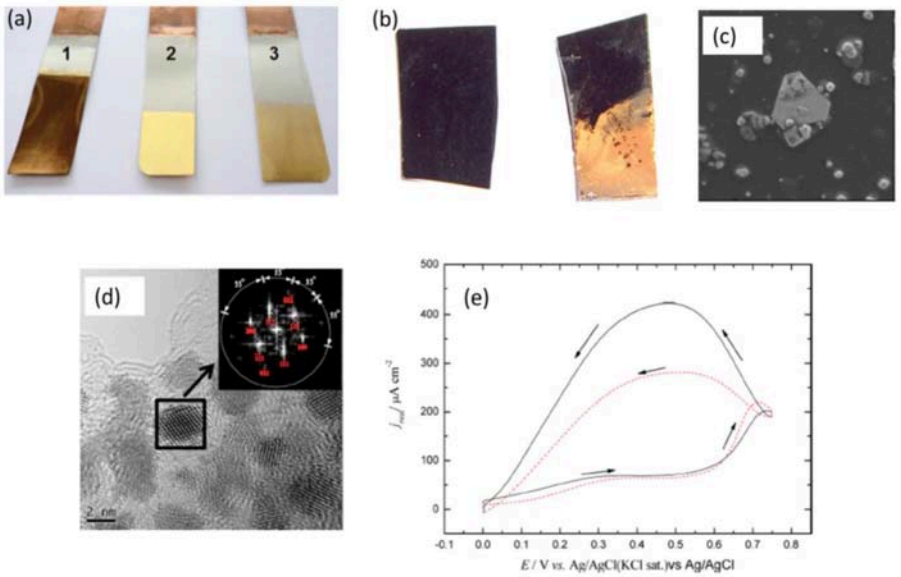

FIGURE 3 | (a) Electroless deposition of Au on nickel from (a1) AuCl (a2) AuCN (a3) $KAu(CN)_2$ in ChCl-1, 2-ethanediol **(b)** Electroless deposition of Au from $H[AuCl_4]$ in EMImTFSA in presence of HTFSA on glassy carbon **(c)** Gold nanoplates formed by electroless deposition on glassy carbon from $H[AuCl_4]$ in EMImTFSA in presence of HTFSA **(d)** Electroless deposition of Pt nanoparticles **(e)** Methanol electrooxidation on Pt nanoparticles formed by electroless deposition. Reproduced from Aldous et al. (2007), Zhang et al. (2013) and Ballantyne et al. could be distinguished. Sn is a promising anode material for both Li-ion and Na-ion batteries (Liu et al., 2016). However, no attempt was made to use these deposits for battery applications or to understand the mechanism of the galvanic displacement reaction.

Electroless plating of copper on Al and Al-5 wt%Si was shown to be feasible in ChCl-ethylene glycol (ChCl-EG) (Kang et al., 2014, 2015). Although the galvanic displacement reaction of Cu on Al is possible from aqueous solutions, the presence of an oxide layer on Al inhibits the formation of uniform Cu coatings. Furthermore, strong alkaline solutions or F-containing solutions are required to remove the oxide layer from Al to facilitate the electroless deposition process (Ai et al., 2011; Ye et al., 2012). However, in ionic liquids, no F-containing additive was needed. A few Cu(II) salts [$CuSO_4.5H_2O$, $CuCl_2.2H_2O$, and $Cu(CH_3COO)_2$] were tested for the electroless deposition on Al (Kang et al., 2014), among which $CuCl_2.2H_2O$ showed the highest solubility in ChCl-EG. Based on UV visible spectroscopy, formation of $[CuCl_4]^{2-}$ was identified and the galvanic displacement reaction was proposed as shown in Equations (4, 5).

$$Al + 3[CuCl_4]^{2-} \rightarrow Al^{3+} + 3[CuCl_2]^{-} + 6Cl^{-} \quad (4)$$

$$Al + 3[CuCl_2]^{-} \rightarrow Al^{3+} + 3Cu + 6Cl^{-} \quad (5)$$

Electrochemical noise analysis (ECN) was used to identify the number of stages for the electroless deposition process from the plots of current vs. time from which four stages were identified for the galvanic displacement reaction (Kang et al., 2014). In the first stage the sharp increase in current was attributed to nucleation-growth phenomena followed by a decrease in reaction rate in 2nd stage which led to decrease in current. In third and fourth stages, the current was low but almost constant and was related to galvanic displacement reactions. However, the displacement reaction on Al-5 wt%Si was found to be slightly different (Kang et al., 2015). From the microstructure and elemental map analyses, it was observed that initially Cu displaced only Al and did not form any coating on the silicon regions of the Al-Si alloy. With time, a uniform coating could be obtained both on Al and Al-Si alloy. However, there are a few open questions as to how did Cu(II) displace the Si in the Al-Si alloy which will need further investigation. Furthermore, with change in Si concentration in the Al-Si alloy, it would be interesting to evaluate the electroless deposition process.

To improve the corrosion resistance and mechanical properties of Al, Ni-P coating is usually used from aqueous solutions at temperatures of >80°C. Kang et al. showed that modifying the Al substrate with galvanic displacement of Cu or Zn followed by electroless deposition of Ni-P on the modified substrate led to a better and uniform coating with improved corrosion resistance (Kang et al., 2017). The authors argued that Cu/Zn acted as a catalytic material which improved the deposition of Ni-P. Unfortunately, the microstructural analysis was limited to understanding the surface phenomena without looking into the cross-sectional phenomena of Al-Cu/Zn-Ni-P. It is important to understand the cross-sectional behavior and the grain boundary formed between Al-Cu and Ni-P in order to improve the deposition characteristics. Therefore, further studies are needed to evaluate the complex displacement reaction mechanism.

Al coating on reactive metal surfaces, especially on steel is an attractive technique to prevent corrosion and to improve the conductivity. Al has been electrodeposited on various substrates from ionic liquids (Zein El Abedin et al., 2005; Zein El Abedin and Endres, 2006; Eiden et al., 2009; Giridhar et al., 2012a). $AlCl_3$ dissolution in ionic liquids is an exothermic process. Depending on the $AlCl_3$ concentration in the ionic liquid, Lewis acid or Lewis basic electrolytes can be formed. Aluminum can be electrodeposited from Lewis acids of 60:40 mol% of $AlCl_3$:[EMIm]Cl. The electrodeposits contain micrometer sized Al (**Figure 4A**).

When changing the electrolyte from $AlCl_3$:[EMIm]Cl to $AlCl_3$:1-butyl-1-methylpyrrolidinium chloride ($AlCl_3$:[$Py_{1,4}$]Cl) electrodeposition leads to nanocrystalline Al (**Figure 4B**). The change in the deposit morphology can be attributed to a change in interfacial structure at the EEI (Endres et al., 2010). Similar results have also been observed for the electrodeposition of Al from $AlCl_3$ dissolved in ILs containing bis(trifluoromethylsulfonyl)amide (Moustafa et al., 2007) and trifluoromethylsulfonate anions (Giridhar et al., 2012b) with either 1-butyl-1-methylpyrrolidinium or 1-ethyl-3-methylimidazolium cations. By mixing both [EMIm]Cl and [$Py_{1,4}$]Cl with $AlCl_3$, a range of different microstructures could be obtained. Al deposits have been made from various compositions of $AlCl_3$:1-ethyl-3-methylimidazolium chloride ($AlCl_3$:[EMIm]Cl) and $AlCl_3$: 1-butyl-1-methylpyrrolidinium chloride ($AlCl_3$:[$Py_{1,4}$]Cl). The deposits thus obtained possess nanostructures and/or microstructures depending on the amount of 60:40 mol% $AlCl_3$:[EMIm]Cl in the mixtures of 60:40 mol% $AlCl_3$:[$Py_{1,4}$]Cl and 60:40 mol% $AlCl_3$:[EMIm]Cl. This study clearly showed that the cation of the ionic liquid has a remarkable influence on the particle size of Al electrodeposited from the aforementioned ionic liquids.

Recent studies have shown the possibility of electroless coating of Al using reducing agents in ionic liquids. Koura et al. (2008) used reducing agents such as LiH, $LiAlH_4$, or diisobutyl aluminum hydride for the reduction of Al from $AlCl_3$-1-ethyl-3-methylimidazolium chloride. The plating time, temperature and concentration of the reducing agent were evaluated for electroless deposition of Al on copper. At 25 and 35°C, a maximum amount of 0.4 mg cm^{-2} of Al was obtained whereas on increasing the temperature to 45°C, the amount decreased to 0.25 mg cm^{-2}, which was attributed to the decomposition of the electrolyte. With increase in plating time and concentration of the reducing agent, the authors found that the Al particle size increased, and thicker deposits could be obtained. Among the three reducing agents, the authors found that the addition of diisobutyl aluminum hydride led to a much smoother surface. A comparison of electroless deposited Al (**Figure 4C**) and electrodeposited Al from the same electrolyte is shown in **Figure 4A**. It is evident that Al deposits in both cases show particle sizes of ∼2–3 μm on the electrode. This shows that electroless deposition in presence of a reducing agent is a simple route to obtain Al on different substrates without the need of additional energy. Furthermore, such a technique might be useful to coat Al on an insulating substrate as well.

A much more detailed study of electroless deposition of Al from $AlCl_3$/[EMIm]Cl in presence of diisobutyl aluminum hydride as reducing agent was investigated by Shitanda et al. (2009). The proposed reaction mechanism for the electroless deposition is shown in Equations (6, 7).

$$4Al_2Cl_7^- + 3e^- \rightarrow 7AlCl_4^- + Al \quad (6)$$

$$2\{(CH_3)_2 - CH - CH_2 - AlH - CH_2 - CH - (CH_3)_2\} \rightarrow 2\{(CH_3)_2 - CH - CH_2 - Al - CH_2 - CH - \left(CH_3\right)_2\}^+ + H_2 + 2e^- \quad (7)$$

The authors analyzed various parameters such as the influence of plating time, temperature, concentration of reducing agent and the concentration of metal ions on the electroless plating, and surface morphology of Al. With increase in plating time at temperatures of 35 and 55°C, the amount of Al deposit increased. However, on performing the experiments at 65°C, the amount of Al decreased due to decomposition of the electrolyte. With time, at lower temperature (35°C) it was shown that the Al crystals grew in size to 2–5 μm and on increasing the temperature to 65°C, a much smoother surface with a smaller grain size (<1 μm) was obtained. The change in $AlCl_3$ concentration in the electrolyte also affected the deposit morphology. When changing the mol% of $AlCl_3$ from 52 to 58 and 66.7, more Al could be deposited. However, a smoother film could be obtained for 58 mol% $AlCl_3$. Finally, with an increase in reducing agent concentration in the electrolyte with a fixed $AlCl_3$ concentration, more Al could be plated.

Using the same [EMIm]Cl/$AlCl_3$ electrolyte in the presence of diisobutyl aluminum hydride as reducing agent, electroless deposition of Al was also successfully obtained on nickel nanowires (Poges et al., 2018). Using SEM and neutron scattering measurements, the authors showed that a core-shell structure was obtained for electroless deposited Al on Ni nanowires. The Al coating thickness on the nickel nanowires was found to be between 300 and 600 nm. The ferromagnetic magnetization property was found to decrease from 43.3 to 31.4 emu g^{-1} from the magnetic measurement of nickel nanowires and Al coated nickel nanowires, respectively. Although, these studies showed a simple route for Al plating, further investigation on practical systems like steel might be more appropriate.

Al has also been used as a corrosion protection layer for uranium (Egert and Scott, 1987; Jiang et al., 2017). Recently, electroless deposition of Al from [EMIm]Cl/$AlCl_3$ on uranium was shown to be an effective method for coating uranium (Jiang et al., 2018). The galvanic displacement reaction of Al on U takes place according to Equation (8).

$$U + 4Al_2Cl_7^- \rightarrow Al + U^{3+} + 7AlCl_4^- \quad (8)$$

As uranium dissolves into the electrolyte, simultaneous Al deposition occurs. From UV-visible spectroscopy, the authors evaluated the dissolution rate of U during the displacement reaction. Within the first 20 min of the reaction, the U dissolution rate decreased from 0.03 to 0.02 mol min^{-1} m^{-2}. After 120 min of the reaction, an insignificant amount of U was found to

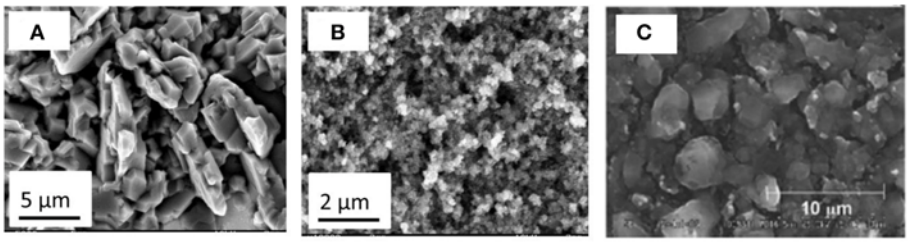

FIGURE 4 | (A) Microstructure of electrodeposited Al from [EMIm]Cl/$AlCl_3$ at −0.3 V vs. Al and **(B)** from [$Py_{1,4}$]Cl/$AlCl_3$ at −0.3 V vs. Al for 1 h **(C)** Al electroless deposited from [EMIm]Cl/$AlCl_3$ in presence of LiH as reducing agent. Reproduced from Koura et al. (2008) with permission from The Electrochemical Society.

dissolve which suggested that most of the U was covered by Al. From a cross-sectional SEM analysis, the authors showed that a 200 nm thick Al deposit was formed on U after 2 h of reaction. Although this study shows a simple route to protect U, the practical application of this process remains arguable due to cleaning procedures required after the deposition process and disposal of the U ions in the solution.

Galvanic displacement of nickel on copper was achieved using a deep eutectic solvent of ChCl and ethylene glycol mixtures (Yang et al., 2016). Nickel was shown to form $[NiCl_4]^{2-}$ ions in the electrolyte which displaced copper, forming nickel metal and $[CuCl_3]^{2-}$ ions. It was shown that the displacement reaction takes place in three stages. Initially, copper is stripped resulting in a porous structure along with progressive nucleation of nickel nanoparticles. In the second stage, more copper is dissolved leading to surface cracks along with deposition and growth of nickel. Finally, as the nickel covers the copper surface, the reaction slows down leading to the formation of a porous nickel layer. The obtained nickel was used as a catalytic material for the hydrogen evolution reaction (HER). The HER catalytic activity of nickel was shown to be better than nickel wire and required a lower overpotential of 170 mV vs. RHE for HER. A large exchange current density of 0.186 mA cm^{-2} with a relatively small Tafel slope of 98.5 mV $decade^{-1}$ could be achieved by the obtained porous nickel structures on Cu.

ELECTROLESS DEPOSITION OF ALLOYS AND COMPOSITE MATERIALS

Alloys and composite materials have been shown to be useful electrode materials for Li-ion and Na-ion batteries as they have lower volume expansion during intercalation/deintercalation processes, high theoretical capacities, and longer life time compared to carbon electrodes and to their metal counterparts (Zhang, 2011; Obrovac and Chevrier, 2014; Lahiri and Endres, 2017). Alloys and composites are in general deposited using high temperature techniques, vacuum techniques, sol-gel processes, or by electrodeposition (Zhang, 2011; Obrovac and Chevrier, 2014; Lahiri and Endres, 2017). Electroless deposition has also been used to develop alloys and composites.

A copper antimonide (Cu-Sb) alloy has been used as anode for both Li and Na-ion batteries (Lahiri and Endres, 2017). The Cu_2Sb alloy has been prepared by galvanic displacement reaction from ionic liquids (Lahiri et al., 2018b). It was observed that on exposing a copper substrate to $SbCl_3$-[EMIm]TFSA, Cu_2Sb nanoplates formed instantaneously. From mass spectroscopic analysis, it was shown that $SbCl_3$ in the electrolyte forms a $[SbCl_2(TFSA)_3]^{2-}$ complex which had a lower reduction potential compared to Cu/Cu^+ in the same electrolyte and triggered the electroless deposition to take place. The electroless deposition process was studied using *in situ* X-ray photoelectron spectroscopy (XPS), X-ray diffraction (XRD), and *in situ* atomic force microscopy (AFM). From XPS and XRD measurements, formation of CuCl was observed which suggested that a three-electron transfer process was taking place for the formation of Cu_2Sb. From *in situ* AFM, the deposition rate was estimated to be between 0.4 and 1.65 nm min^{-1}. The electroless deposited Cu_2Sb nanoplates were also tested for Li and Na ion batteries with an ionic liquid electrolyte which showed a promising battery performance. However, the question remains as to why Cu_2Sb formed a nanoplate structure by electroless deposition. Further studies using transmission electron microscopy along with selected area electron diffraction (SAED) might reveal the crystal growth mechanism.

It was interesting that Fe could also be deposited on Cu by galvanic displacement reaction from 0.15 M $FeCl_2$ dissolved in a mixture of 1-butylpyrrolidine and $AlCl_3$ (1:1.2 mol ratio) containing toluene at 60°C (Lahiri et al., 2018b). Although from aqueous standard electrochemical series, such a galvanic displacement reaction is impossible, these reactions become feasible in ionic liquids due to the difference in speciation. The electroless deposited Fe was confirmed with XRD measurements. Further studies regarding the influence of $FeCl_2$ concentration in the eutectic-based ionic liquid is required to understand the reaction mechanism of the galvanic displacement reaction process. Furthermore, such studies will be useful to improve the deposition as well as to develop different nanostructures.

Unlike Cu_2Sb, interestingly, semiconducting amorphous gallium antimonide (GaSb) was obtained by electroless deposition of Sb on Ga from ionic liquids (Lahiri et al., 2015b). Galvanic displacement of Sb on Ga was performed from two different ionic liquids with [$Py_{1,4}$]TFSA and [EMIm]TFSA. The change in the cation of the ionic liquid influenced the

morphology of GaSb deposit. The bandgap of the GaSb deposit was found to be ∼0.9 eV. From *in situ* AFM studies, the deposition rate was reported to be 2.3 nm min^{-1}. Furthermore, formation of GaSb nanowires was shown to be possible using electroless deposition. As the open circuit potential of Sb/Sb^{3+} is more positive compared to Si and Ge in the same ionic liquid, Sb modification of both electrodeposited Si and Ge was achieved (Lahiri et al., 2016, 2017). The electroless deposition of Sb on Ge from 0.1 M $SbCl_3$-$[Py_{1,4}]$TFSA led to the formation of Sb nanoparticles. **Figure 5A** shows the microstructure of the deposit wherein Ge nanoparticles of 200–300 nm are covered with Sb nanoparticles of <50 nm in size. XPS and Raman studies showed the formation of Ge_xSb_{1-x}. From Raman spectroscopy (**Figure 5B**) at room temperature, both Ge and Sb peaks are observed with a shoulder showing the formation of Ge_xSb_{1-x}. With annealing, a clear shift in the Ge peak is seen confirming the formation of Ge_xSb_{1-x}. As both Ge and Sb are possible anode materials for Na-ion batteries, Ge and Sb modified Ge were tested as battery electrodes with an ionic liquid electrolyte (Lahiri et al., 2016). **Figure 5C** compares 50 charge-discharge cycles of electrodeposited Ge and Sb modified Ge with sodium bis(fluorosulfonyl)amide (NaFSA) in $[Py_{1,4}]$FSA ionic liquid as electrolyte. It is evident that modifying the Ge with Sb led to a higher Na capacity storage even at higher current densities of 0.83 A g^{-1} compared to Ge which was cycled at a current density of 0.54 A g^{-1}. Similar to the modification of Ge with Sb, electrodeposited silicon was also modified by Ag and Sb as it was found that the open circuit potentials of both Ag/Ag^+ and Sb/Sb^{3+} are more positive to Si(IV)/Si in the ionic liquid (Lahiri et al., 2017). From quartz crystal microbalance (QCM) measurements, the rate of deposition for Sb on Si was found to be 2.7 ng sec^{-1} for the first 1,000 s which then decreases to 0.4 ng sec^{-1}. In comparison, the deposition of Ag on Si was 6.2 ng sec^{-1} which decreased to 1.8 ng sec^{-1} after 1,000 s. Although a three times increase in the deposition of Ag is expected compared to Sb deposition, it was shown that due to difference in speciation of Ag and Sb salts in an ionic liquid, the deposition rates differed. In comparison to the formation of Sb nanoparticles in the case of Ge (**Figure 5A**), a layered structure of Sb has been seen for Si (**Figure 5D**). This suggests that the nucleation-growth process of Sb on the two semiconductors is different. The electrodeposited Si and Sb modified Si was also tested as an anode for Li-ion battery.

Figure 5E shows the charge-discharge curves of the electrodeposit in 1 M LiTFSA-$[Py_{1,4}]$TFSA cycled at 0.25 C. The Sb modified Si showed a capacity of over 2,000 mAh g^{-1} for the first 10 cycles which decreased to 1,100 mAh g^{-1} at the 30th cycle. Compared to the modified Si, the electrodeposited silicon showed a lower Li storage capacity. Based on the results of Sb electroless deposition, further investigations are needed regarding long term cycling stability of the anode material. Furthermore, during battery testing, the lithiation/delithiation processes need to be evaluated in order to understand how the alloying of Sb/semiconductor changes.

CHALLENGES AND LIMITATIONS OF IONIC LIQUIDS FOR ELECTROLESS DEPOSITION

The electroless deposition process in ionic liquids has been shown to be an autocatalytic deposition process which occurs at the metal/electrolyte interface by the reduction of metallic ions/complexes in the presence or in the absence of externally added reducing agents. However, this process suffers from a few limitations such as slow ion transport/diffusion of metal ion species/complexes and slow kinetics of the deposition process at room temperature. Furthermore, issues regarding adhesion of the film, surface selectivity, control over deposit morphology, and purity of the films exist. Therefore, future efforts need to be directed toward overcoming these limitations in order to develop a successful method for material synthesis using this simple energy-free methodology.

For example, in the galvanic displacement reaction the substrate serves as a reducing agent and an electron source for the reduction of metal ion species/complexes. Here, the rate of the deposition depends on the transport of the ions to the interface and also on the rate of dissolution of the substrate. Although an increase in temperature does improve the reaction kinetics and the diffusion processes, however, adhesion of the reduced metal on the substrate might not always be sufficiently good. Therefore, an optimum condition between reaction kinetics, diffusion parameters, temperature, and adhesion of the films need to be balanced.

For better adhesion as well as to develop different nanostructures, surface selectivity plays a key role during the galvanic displacement process. A proper surface modification could lead to a good metal finish. Furthermore, it could promote development of interesting nanostructures which can then be applied in batteries and catalysis. The crystal plane of the surface will also influence the galvanic displacement reaction and deposit morphology which has not yet been studied in ionic liquids.

The grain size and growth of the deposited films for galvanic displacement reactions depend on different factors such as immersion time and temperature, rate of deposition, activation sites on the substrate and speciation in ionic liquids. Control over these factors in electroless deposition is challenging. Usually, large grains or thick films have been obtained at longer immersion times and at higher temperatures. However, by controlling the reaction kinetics and by addition of surfactants/mixture of ionic liquids, it could be possible to spatially control the grains/films which would be of interest for catalytic applications. Furthermore, it might be possible to develop various nanostructures which can then be applied as electrodes in batteries and catalysis/electrocatalysis.

One major issue with electroless deposition from ionic liquids is the cleaning process to obtain the deposited film without any contaminants. Usually, salts of the metallic substrate and trapped ionic liquid are present in the deposits which are difficult to remove. Suitable solvents are required to remove these salts/ionic liquids. It is of interest to design tuneable ionic liquids which can be used to dissolve the metal salts formed during galvanic

displacement reaction and the ionic liquid itself being soluble in simple organic solvents.

Finally, the ultimate challenge is to develop an electrochemical series for ionic liquids. This would require a universal reference electrode. At present a universal reference electrode for ionic liquids does not yet exist. Depending on the individual experiment a Pt quasi-reference electrode is an acceptable compromise.

SUMMARY AND FUTURE PERSPECTIVES

In the last decade, electroless deposition from ionic liquids has been identified as a promising route for developing various metal and semiconductor nanostructures, some of which have shown to be useful in catalysis and as electrodes for batteries. Compared to aqueous solutions, the electroless deposition of noble metals from ionic liquids does not stop after a few monolayers and leads to deposits with thicknesses between 100 nm and 10 µm. Furthermore, as the speciation of metals can be modified in ionic liquids, the electroless deposition does not always follow the standard electrochemical series. Various parameters such as the metal precursors, the employed ionic liquid, temperature, and concentration were shown to affect the deposit morphology, particle size as well as the deposition rate. The presence of an ionic liquid also affected the crystallographic planes. This was exemplified in the electroless deposition of Pt nanoparticles from different ionic liquids wherein it was shown that the formic acid oxidation current differed and depended on the low index planes of the Pt nanoparticles. Similarly, it was shown that depending on the Au precursor and the ionic liquid, triangular gold nanoplates could be formed. Therefore, ionic liquids can be used as a medium to control the crystallographic facets, which turn out to be a useful approach to improve catalytic reactions. In the case of electroless plating of noble metals (e.g., Ag) for PCBs, the adhesion of these metals is an important factor for both Au and Ag deposition. The adhesion properties of the electroless coated metals have been shown to be dependent on the metal ion speciation and the ionic liquid played a vital role to obtain a good metal finish.

Besides noble metals, the possibility of coating non-noble metals especially aluminum on steel, which is an industrially important technique for corrosion prevention makes electroless deposition a lucrative technique to be exploited. For

electrodeposition, it was shown that by changing the cation of the ionic liquid, the morphology and the grain size of the deposit could be altered which will in-turn influence the corrosion properties of the coating. Such simple modifications become a useful tool to obtain better corrosion prevention materials which are yet to be investigated by an electroless deposition route from ionic liquids.

Electroless deposition in ionic liquids was also utilized for developing intermetallics and composites which have potential applications as electrode materials for batteries. Various alloy nanostructures have been obtained by electroless deposition from ionic liquids and were shown to have good Li and Na storage properties. The ease of the process for materials synthesis makes it a beneficial technique for developing other alloy nanostructures which can be tested as electrodes for batteries.

Thus, based on the above literature, it is clear that some limitations and challenges remain in the field of electroless deposition from ionic liquids. However, it is evident that electroless deposition in ionic liquids has tremendous potential for developing functional materials both for catalysis and for batteries which are yet to be exploited. New domains comprising of mixtures of ionic liquids, addition of organic solvents and water in ionic liquids for electroless deposition of metals and semiconductors are yet to be investigated which might lead to a facile synthesis technique to obtain novel nanostructures. The possibility of developing porous materials and one-dimensional nanostructures by template-assisted techniques would also bring new perspectives to electroless deposition from ionic liquids. Finally, the challenge will be to develop ionic liquid-based electrolytes with smart functionalities that could be used to develop specific functional materials.

Green and Sustainable Chemistry

Fan Xia

Fan Xia's research is focused on bio-analytical chemistry. He obtained his PhD at the Chinese Academy of Sciences Institute of Chemistry (ICCAS) as part of Professor Lei Jiang's group. Following this he was a Postdoctoral Fellow in Professor Alan J. Heeger's group at the University of California Santa Barbara. Between 2012 and 2016 he was a Professor at Huazhong University of Science and Technology (HUST), and since 2016 he has been Dean and Professor of the Faculty of Materials Science and Chemistry at China University of Geosciences.

Reid C. Van Lehn

Reid Van Lehn is an Assistant Professor in the Department of Chemical and Biological Engineering and the Jay and Cynthia Ihlenfeld Faculty Scholar in the College of Engineering at the University of Wisconsin-Madison. He obtained a BSc and PhD in Materials Science and Engineering from the Massachusetts Institute of Technology under the supervision of Professor Alfredo Alexander-Katz. He performed his postdoctoral research with Professor Thomas Miller III at the California Institute of Technology before joining the faculty at UW-Madison in 2016. His research interests center on developing and applying molecular simulation methods to understand and engineer synthetic and biological soft materials.

Guanying Chen

Dr Guanying Chen obtained a PhD degree in optics in 2009 from Harbin Institute of Technology (HIT), China. He then became an Assistant professor in 2009, an Associate Professor in 2012, and a full Professor in 2013) at HIT. He completed his postdoc from 2009 to 2011 and became an affiliated adjunct research associate professor (since 2012) at the Institute for Lasers, Photonics and Biophotonics (ILPB), SUNY Buffalo. His interests include lanthanide luminescence, optical bioimaging, and solar cells. He has published more than 100 peer-reviewed papers and serves as an editorial board member for the SCI-indexed journals of *Scientific Reports, Nanomaterials, Crystals*, and as the guest editor for *Theranostics*.

Christopher J. Barile

Christopher Barile is an Assistant Professor in chemistry at the University of Nevada, Reno. His research combines electrochemistry, inorganic chemistry, and materials chemistry with an emphasis on energy conversion, storage, and efficiency. Chris earned a BSc with distinction and co-terminal MSc degrees in chemistry from Stanford University with James Collman. He then attended the University of Illinois at Urbana-Champaign and obtained his PhD working with Andrew Gewirth studying advanced battery technologies and reactions involving multiple proton and electron transfer steps. Prof. Barile then returned to Stanford as a postdoctoral scholar with Michael McGehee before starting his independent career in July 2017.

Fumiaki Amano

Fumiaki Amano is an Associate Professor at the University of Kitakyushu, Japan. His research is centered on photoelectrochemistry of oxide semiconductor materials. He was awarded the 9th Honda-Fujishima Prize by the Electrochemical Society of Japan in 2010, the Catalysis Society of Japan Award for Young Researchers in 2017, and the Young Scientists' Prize of the Commendation for Science and Technology by the MEXT in 2018. He obtained a PhD from Kyoto University in 2006. He worked as an Assistant Professor at Catalysis Research Center, Hokkaido University from 2006 to 2011 and as a Lecturer at the University of Kitakyushu from 2011 to 2014.

Jie He

Jie He received his BSc and MSc degrees in Polymer Materials Science and Engineering from Sichuan University in 2005 and 2007. He obtained his PhD in Chemistry from Universite de Sherbrooke (Quebec Canada) in 2010. He then worked as a postdoctoral fellow at the University of Maryland. In 2014, he joined the faculty of the University of Connecticut where he is currently an Assistant Professor of Chemistry. His research focuses on the design of polymer/inorganic hybrid materials for bioinspired catalysis and renewable energy conversion. He was a recipient of the 2018 AAUP Excellence Award and the 2012 Governor General of Canada's Academic Gold Medal.

Responsive slippery lubricant-infused surfaces (SLIS) have attracted substantial attention because of the high demand of fundamental research and practical applications, such as controllable liquid-repellency, intelligent, and easy-to-implement wettability switching. In this review, advanced development of responsive slippery surfaces is briefly summarized upon various external stimuli, including stress, electrical field, magnetic field, and temperature. In addition, remaining challenge and prospect are also discussed.

Keywords: bio-inspired, liquid-infused surfaces, slippery surface, stimuli response, wettability, interfacial adhesion

INTRODUCTION

Surface's wettability is one of the most fundamental performances in numerous biological processes and industrial technologies, which attracts researchers' interest for a long time. In the past decades, owing to new understanding of species wetting mechanism, bio-inspired materials with super-wettability are flourishing through modeled after surface morphology and chemical composition of the nature species (Liu et al., 2017; Sett et al., 2017; Li et al., 2019). For example, *Nepenthes* pitcher plants fill water in the spaces among the micro structure to form a slippery liquid film, leading insects to aquaplane into their stomach. Since Wong et al. (2011) mimicked pitcher plants' slippery surface and fabricated slippery liquid-infused porous surfaces (**Figures 1A,B**), a serial of liquid-infused surfaces, or well-known as slippery lubricant-infused surfaces (SLIS), have been developed for various applications, such as liquid repellency (Hozumi et al., 2011; Huang et al., 2017), liquid or gas transportation (Chen et al., 2016; Xiao et al., 2019), water harvesting (Zhang et al., 2017), oil-water separation (Solomon et al., 2014; Wang et al., 2017a), anti-corrosion (Lee et al., 2017; Howell et al., 2018), heat transfer (Anand et al., 2012), visual biosensors (Gao et al., 2018), and so on. The two basic components of SLIS are solid substrates to hold liquid and the liquid for infiltration, as shown in **Figure 1C**. The solid substrates may have a micro/nano structural surface to infuse lubricant (Xiao et al., 2013; Dai et al., 2015), or can be swollen in lubricant (Yao et al., 2014). The liquid hold by the solid substrates acts as stable lubricant to repel any impinging immiscible fluids, and ensures the repellent fluids to slide away without any resistance. To distinguish the liquid for infused and the fluids for repellency, we refer the infused liquid as "lubricant" in this mini review from now on. No matter the substrates' surfaces are rough or

flat, the key feature of SLIS is the thin layer of lubricant cover the substrate. This lubricant layer forms a dynamic and stable lubricant/substrate interface. If this thin lubricant is removed, the film would lose its excellent liquid repellency and droplet pin on the surface as a result. This is because the interfacial adhesion of the repelling liquid/solid surface is obviously larger than that of the repelling liquid/lubricant, as shown in **Figure 1D**. Based on this mechanism, SLIS with controllable and reversible wettability were developed through stimulus-triggered switch in substrate's chemical composition or/and morphologies, lubricant's height or/and phase, repellent liquid's chemical component and so on. Meanwhile, other properties, like optical property, will also change and endow SLIS with different functionalities. The responsive SLIS have demonstrated their ability of controllable repellent droplet's motion behavior, which provides significant insight of developing devices for fog collection (Peng et al., 2015), oil-water separation (Calcagnile et al., 2012), droplets' delivery (Hou et al., 2017), complex-flow distribution (Cao et al., 2017), biomimetic tissue (Wang Y. et al., 2018), and so on.

In addition, typical response materials have been adopted for different external stimuli. Elastic and nanoporous polymers such as polydimethylsiloxane (PDMS) and polyurethane (PU) are mainstream in mechanically responsive SLIS. Electrical responsive materials are chosen primarily based on electrowetting mechanism, generally both the substrate and the repellent liquid should be conductive. Magnetic field response strategies include magnetic particles doped substrates or introduces magnetic lubricant. Traditional thermal response is mainly realized by thermosensitive lubricant such as paraffin or mixtures of solid/liquid oil.

EXTERNAL STIMULI RESPONSIVE SLIS

Mechanically Responsive SLIS

Stretching or mechanical pressing represents a simple, straightforward and effective strategy for tuning the wettability of SLIS. Generally, replacing the rigid substrate with a continuous elastic polymer is required to enable mechanical deformation. The stress would vary the surface's morphology and lubricant layer's height, resulting in the change of surface's wettability. Yao et al. (2013) adopted a nanoporous elastic PDMS substrate to support lubricant. This film would reversibly adjust the droplet's sliding behaviors on it, as shown in **Figure 2A**. When the film was stretched, the lubricant would flow into the pores. In this case, the solid surface formed a rough interface, resulting in the droplet pinned. Without stress, the lubricant came out from the porous. The film restored its liquid repellency and made the droplet slide away. In this research, graded mechanical stimulus was proved to lead to dynamic and precise regulation of optical transparency and wettability. This film provided a new idea for fuel transport pipes or microfluidic systems. Based on Yao's research, Liu et al. (2016) constructed an elastic substrate with periodical porous structure instead of atactic porous. The film was demonstrated a variable structural-color SLIS with self-reporting surface wettability. When the film was elastically deformed by stress, lubricant thickness and structural color of surface would change simultaneously along the deformation of porous. Consequently, the accompaniment of these changes made self-reporting of surface wettability a reality. Beside optical devices, SLIS with controllable wettability also demonstrated their applications in collecting water from atmosphere or water-oil mixture (Han et al., 2016; Park et al., 2016; Fu et al., 2017). Most research was focused on strengthening condensation and shedding of water, avoiding the wind-caused loss of the water captured. Wang et al. (2017b) developed a flexible SLIS by infusing perfluoropolyether into a fluorinated-copolymer-modified PU with adjustable and elastic deformability. Through controlling the droplets' sliding behavior, the stress responsive SLIS showed some adaptability of environmental and realized high efficiency of water collection.

Although the mechanical responsive SLIS have been demonstrated reversible deformation and wettability switching, their dependence on elastic substrate severally limit their practical applications. What's more, continuous stress and deformation would trigger the potential mechanical damage. Improving the inherent durability of materials or introducing self-repairing materials should be a key point for developing mechanical responsive SLIS.

Electrical Field Responsive SLIS

Electrowetting is a method of changing interfacial wettability by adjusting the potential between the liquid and solid electrodes. Due to its fast response, wide range changes, small size and good reliability, electrowetting method has been widely used in optics, biology, and microelectronics (Mugele and Baret, 2005). Generally, to achieve electrical field responsive SLIS, both the substrate and the repellent liquid should be conductive. Heng et al. firstly put forward a serial of SLIS with anisotropic and electrically responsive sliding (Guo et al., 2016; Che et al., 2017; Wang et al., 2018a,b; Han et al., 2019). Firstly, by directional freeze drying, they synthesized oriented and conductive membrane with porous structure. Then, silicone oil was introduced into the membrane. With voltage applied, the surface's chemical components and micro/nano structure won't change. However, electrostatic attraction between the repellent conductive droplet and its image charge increased under voltage. The thickness of the lubricant reduced, and droplet's wetting status changed. As a result, the droplet was pinned on the surface (**Figure 2B**). In the other hand, without voltage, the conductive droplet slid easily due to the thick layer of lubricant. Later on, Heng's group (Che et al., 2017) filled the surface with conductive lubricant. Compared with non-conductive lubricant, an electrical double layer with higher charge density was achieved with the same voltage. Therefore, the SLIS realized droplet's reversible motion control with a smaller voltage. They (Wang et al., 2018a) further researched the lubricant's viscosity effected on the electrical field responsive SLIS. The results suggested that lubricant with low viscosity would require a smaller voltage to adjust the droplet's motion behavior. Based on tuning the properties of lubricant, Heng's a serial of research provided novel insights of SLIS' wettability adjustment. In addition, they (Wang et al., 2018b) also developed a photoelectric synergetic responsive SLIS. With voltage applied in dark, there was an electrical double layer. With illumination, the photo-generated electrons would

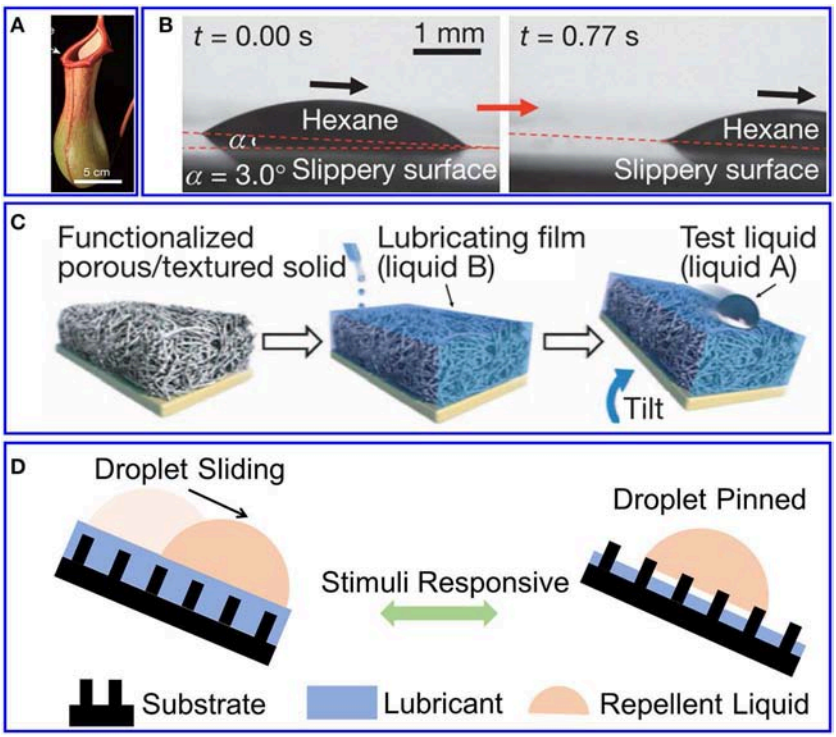

FIGURE 1 | SLIS inspired by pitch plant. **(A)** Photo of pitch plant (Chen et al., 2016). Reproduced with permission. increase the charge density, which results in a larger friction force to pin the droplet on the surface.

To achieve electrically responsive SLIS, relevant chemical environment is fatally necessary. For example, the repellent liquid should always contact with an electrode. The preconditions severely limit their applications in conductive surface, conductive repellent liquid, and even conductive lubricant. Therefore, there is still a long way for electrically responsive SLIS to come to real-life applications.

Magnetic Field Responsive SLIS

Magnetic field is one of the most employed methods of adjusting surface's wettability. Compared with other physical stimuli, the structure of surface can switch in a short time driven by magnetic force. Meantime, applied magnetic fields with different directions provide more possibilities for changing surface's different properties. The magnetic field responsive SLIS with switchable wettability have achieved fruitful development in fog collection (Peng et al., 2015), oil-water separation (Calcagnile et al., 2012), complex-flow distribution (Cao et al., 2017), droplets' delivery (Hou et al., 2017), and so on.

For example, Cao et al. (2017) constructed ferromagnetic microcilia with different tilted angles to realize unidirectional wetting behaviors. On this film, droplets slid easily in the opposite direction of the microcilia's tilted, due to the low the liquid-air interfacial adhesion. Later on, they further developed a magnetically responsive surface to control water-droplet from rolling to pinning (Hou et al., 2017). Distinct from Cao's surface, our group (Huang et al., 2017) designed a magnetically dynamic surface inspired by pitcher plant and lotus leaf, which could reversibly switch droplet between SLIS state and superhydrophobic state. In this research, PDMS was mixed with iron powder to form magnetically responsive micropillar array. The micropillar array could transform from fully upright (superhydrophobic state) to nearly flattened (SLIS state) morphology in different directions of external magnetic field, as shown in **Figure 2C**. The SLIS could alter liquid's repellency according to demand, which provided new opportunities of programmable fluid collection, smart waterproof clothing, adaptive drag control, and so on.

Instead of doping magnetic particles into the substrate, Tian et al. (2016) adopted magnetic fluids as lubricant and filled it into nano-structural substrate. The film's wettability could be adjusted by morphological transformation between rough and smooth in various magnetic fields, which provides new idea for designing microfluidic devices. Through magnetic lubricant, the tuning of interface's morphology could be more precise. Recently, Wang W. et al. (2018) designed a hierarchical magnetic responsive SLIS through infiltrating ferrofluids into surface with regular porous. The exiting capillary pressure induced multi-scale topographical responses and other novel functions. For example, when applied magnetic field, ferrofluid depleted from the microstructures.

KGaA. **(C)** Magnetic field responsive SLIS (Huang et al., 2017), Copyright 2017, WILEY-VCH Verlag GmbH & Co. KGaA. **(D)** Temperature responsive SLIS (Wang et al., 2019). Copyright 2019, ACS.

As a result, the non-magnetic colloidal particles fell down to the solid/lubricant interface and formed specific patterns. These multi-scale reconfigurable topographies can be used as biological tissues, responsive coating, and digital microfluidics.

Although various magnetic responsive SLIS have been demonstrated fast, controllable and flexible wettability switching, magnetic responsive substrates with large-scale and well-organized micro/nano structure are still rare. Combined with lithography technology may take into consideration.

Temperature Responsive SLIS

Temperature is considered as a controllable and quantitative external stimulus, which extends widely applications *in vivo*, industrial and medical fields. Generally, for typical temperature responsive SLIS, thermo-responsive solidifiable lubricants were adopted to achieve interfacial adhesion switching (Yao et al., 2014; Manabe et al., 2016; Wang B. L. et al., 2018). In Yao et al. (2014), firstly introduced *n*-paraffin to organogel and form temperature responsive SLIS. In this work, switching of droplet's wettability occurred at the paraffin's melting temperature (T_m). When the environmental temperature was higher than T_m, paraffin was in the liquid phase, acting as lubricant filled in the PDMS network. Therefore, a droplet on SLIS was in low adhesive state. However, when the temperature dropped to lower than T_m, paraffin turned into solid phase and became a part of solid substrate. The droplet on this surface was in high adhesive Wenzel state. Later on, they (Wang B. L. et al., 2018) combined anisotropic substrate and thermo-responsive SLIS to achieve more precise control of the liquid droplet motion. According to Yao's research, Manabe et al. (2016) adopted mixtures of solid/liquid paraffin as lubricant. Through adjusting the ratios of solid/liquid paraffin and ambient temperature, the film's transparency and wettability would change. Combined with optical property's change, the film displayed potential of applications in smart windows, innovative medicine, and other bio-chemical devices. Similarly, the change of lubricant condensed phase between liquid and gel also varied surface's wetting behaviors. Zhu et al. (2016) impregnated a nanostructured surface with heated mineral oil to fabricate temperature responsive SLIS. When the mineral oil cooled down to ambient temperature, the oil turned to gel. In this case, the interfacial adhesion would increase. By taking advantage of dynamic viscoelastic property of mineral oil, the droplet motion, sliding speed, and thermal variation can be well-controlled. Zheng et al. (2017) infused lubricant with lower critical solution temperature (LCST) to porous substrate. When the environmental temperature was higher than LCST (i.e., 313 K), water droplet was slippery on the surface. In contrast, when the temperature was lower than LCST (i.e., 293 K), water droplet was miscible with

the lubricant. In their research, *in situ* wetting, dewetting, penetration and optical properties could be controlled under thermo-stimuli. Recently, combined printing method, Yao's group (He et al., 2018) adopted thermochromic inks to fabricate patterned thermo-responsive SLIS with multi-functionalities, including self-reporting wettability, and sensing the temperature of contacting liquids. This kind of slippery surface would be of great importance in sensors and medical package.

Generally, traditional smart SLIS focused on the responsive components contained in solid substrate and lubricant to vary the interface's topography, modulus, and surface energy. Modification of the repellent liquid was still rare. Recently, our group (Gao et al., 2018) approved that through adjusting the hydrophobic interactions between biological droplet and lubricant, the biological droplet's motion behavior could be easily tuned. The hydrophobic interactions mainly depended on the chain length of ssDNA in repellent droplet. To the best of our knowledge, this was the first research focused on adjusting the SLIS's interfacial adhesion through the repellent liquid. Their biosensing applications for ATP, microRNA, and thrombin detection are also demonstrated. Based on this research, very recently, we (Wang et al., 2019) put forward a temperature responsive interfacial adhesion on SLIS. When environmental temperature increased, ssDNA became more flexible and more mobile. The molecular configuration transformed to reduce the hydrophobic moieties exposure. As a result, the hydrophobic interaction between lubricant and hydrophobic moieties was weakened, leading to droplet slide, as shown in **Figure 2D**. The thermo-responsive sliding behavior of the biological droplet would offer a new strategy for advanced antifouling systems.

Although various temperature-responsive SLIS have been demonstrated, most of them are still restricted to several kinds of thermo-sensitive materials. Novel materials displaying obvious difference in wettability under small change of temperature should be explored. Additionally, besides temperature-dependent substrate and lubricant, thermo-responsive repellent liquid should be considered for particular applications, such as biological droplets in micro-biochips.

CONCLUSION

In this review, we concentrate on recent development of SLIS with external stimuli responsive wettability, including stress responsive SLIS, electrical responsive SLIS, magnetically responsive SLIS, and thermo-responsive SLIS. Through introducing stimuli responsive materials or replace some parts of SLIS, repellent droplet's wetting behaviors and other properties of the film, such as structural colors and transparency, would be reversibly changed. Based on the responsive SLIS's ability of timely control of droplets, SLIS have demonstrated their potential applications in fog collection, oil-water separation, droplets' delivery, complex-flow distribution, visual biosensors, biomimetic tissue, adaptive drag control, and so on.

Although various SLIS have been demonstrated distinctive advantages and features under external stimuli challenges still remain in their practical applications. Firstly, some responsive SLIS are limited with complex, strict or high-cost preparation processes. Economical, reproducible, and effective fabrication to achieve well-organized micro/nanostructures and integrate stimuli-responsive components into SLIS is the first and foremost challenge. Secondly, reliability and durability of responsive SLIS are needed to improve. Besides substrate's long-term durability and mechanical stability, lubricant's depletion caused by cloaking effect or volatility should be paid attention (Carlson et al., 2013; Daniel et al., 2017). Appropriate selection of materials to avoid cloaking effect are advised. Choosing lubricants with higher viscosity and lower vapor pressure, or designing intelligent materials with self-healing or self-refill are also effective methods. On the other hand, since SLIS have potential applications in biomedical areas, including antibiofouling, antithrombosis, point-of-care diagnostics, surgery, and tissue integration, constructing responsive SLIS with biocompatibility materials and bioactive functions should be taken into consideration. Thirdly, smart SLIS mainly focused on introducing responsive components as solid substrate or lubricant, through stimuli responsive repellent liquid are still rare. More responsive repellent liquid should be developed. Furthermore, through design various responsive materials as different parts of SLIS at the same time, dual- or multi-stimuli responsive SLIS with multi-functionalities could be achieved. This may be a potential development direction for responsive SLIS.

Quantifying the Stability of the Hydronium Ion in Organic Solvents With Molecular Dynamics Simulations

*Alex K. Chew and Reid C. Van Lehn**

Department of Chemical and Biological Engineering, University of Wisconsin – Madison, Madison, WI, United States

The solution-phase stability of the hydronium ion catalyst significantly affects the rates of acid-catalyzed reactions, which are ubiquitously utilized to convert biomass to valuable chemicals. In this work, classical molecular dynamics simulations were performed to quantify the stability of hydronium and chloride ions by measuring their solvation free energies in water, 1,4-dioxane (DIOX), tetrahydrofuran (THF), γ-valerolactone (GVL), N-methyl-2-pyrrolidone (NMP), acetone (ACE), and dimethyl sulfoxide (DMSO). By measuring the free energy for transferring a hydronium ion from pure water to pure organic solvent, we found that the hydronium ion is destabilized in DIOX, THF, and GVL and stabilized in NMP, ACE, and DMSO relative to water. The distinction between these organic solvents can be used to predict the preference of the hydronium ion for specific regions in aqueous mixtures of organic solvents. We then incorporated the stability of the hydronium ion into a correlative model for the acid-catalyzed conversion of 1,2-propanediol to propanal. The revised model is able to predict experimental reaction rates across solvent systems with different organic solvents. These results demonstrate the ability of classical molecular dynamics simulations to screen solvent systems for improved acid-catalyzed reaction performance.

INTRODUCTION

The catalytic upgrading of biomass (e.g., wood, crops, etc.) is a promising strategy to obtain valuable chemicals from renewable resources while limiting waste products (Huber et al., 2006; Stöcker, 2008; Tock et al., 2010; Shuai and Luterbacher, 2016; Nguyen et al., 2017; Walker et al., 2019). For example, cellulose, one of the primary components of lignocellulosic biomass, can be converted through a series of dehydration and hydrolysis reactions to form 5-hydroxymethylfurfural, a platform chemical for fuels and other commodity chemicals (Chheda et al., 2007; Corma et al., 2007; Román-Leshkov et al., 2007; Pagan-Torres et al., 2012; Mellmer et al., 2015; He et al., 2017). These reactions are typically performed in aqueous solution where extensive control over reaction kinetics and selectivity is available by tuning the temperature, catalyst, and solvent composition (Huber et al., 2006; Chheda et al., 2007; Román-Leshkov et al., 2007; Mellmer et al., 2014b; Motagamwala et al., 2016; He et al., 2017; Won et al., 2017; Sener et al., 2018). Solution-phase biomass conversion reactions ubiquitously require an acidic proton catalyst (H^+), which exists

in solution as a hydronium ion (H_3O^+). In homogenous reactions, the catalyst is obtained from the addition of a Brønsted acid (He et al., 2017) and the reactions follow a specific catalysis mechanism since a protonated solvent is the catalyst. **Figure 1A** shows an example reaction for the acid-catalyzed dehydration of 1,2-propanediol to propanal, which is representative of acid-catalyzed reactions for biomass-derived model compounds (Mellmer et al., 2018; Walker et al., 2019). In these reactions, the hydronium ion catalyst (H_3O^+) protonates the reactant (R) to form a reactant/proton complex (RH^+). The reaction proceeds to a charged transition state ($[RH^+]^{TS}$) and subsequently forms the product (P) with the hydronium ion reformed (**Figure 1B**). The relative stabilities of the reactant, transition state, and catalyst in solution are thus critical for determining reaction kinetics (Shuai and Luterbacher, 2016). Understanding how these solvent effects influence reaction kinetics is necessary to guide the optimization of solvent compositions and reactor conditions and maximize the productivity of biomass conversion reactions.

Previous studies have found that mixtures of water and organic, polar aprotic cosolvents (i.e., mixed-solvent environments) can increase or decrease the rates of Brønsted acid-catalyzed reactions depending on the stability of the acid catalyst (Mellmer et al., 2014b, 2018; Shuai and Luterbacher, 2016; Sener et al., 2018). One mechanism by which the solvent composition affects catalyst stability is by shifting the acid dissociation equilibrium, which is quantified by the acid disassociation constant (K_a). For example, weak acids with small K_a values, such as formic acid or acetic acid, were found to decrease acid-catalyzed reaction rates in mixed-solvent environments compared to pure water due to the reduced availability of catalytic hydronium ions (Mellmer et al., 2014b). Conversely, strong acids with large K_a values, such as triflic acid, dissociate in a small fraction of water and were found to improve xylose conversion reaction rates by 40-fold in 90 wt% γ-valerolactone (Mellmer et al., 2014b), suggesting an alternative role for the solvent. Based on combined classical and *ab initio* molecular dynamics (MD) simulations, Mellmer et al. found that the hydronium ion catalyst in mixed-solvent systems is destabilized in the bulk solvent relative to the local solvent domain of the reactant due to unfavorable interactions between the hydronium ion and the cosolvent (Mellmer et al., 2018). As a result, the acid catalyst is thermodynamically driven to water-enriched local solvent domains formed by hydrophilic reactants when a high mass fraction of the organic phase is present, effectively lowering activation energy barriers and increasing reaction rates relative to pure water (**Figure 1B**). Together, these results indicate that the solvent composition can modulate reaction kinetics by both modulating catalyst availability and the interactions of the catalyst with the reactant.

Building upon these studies, we hypothesized that acid-catalyzed reaction rates correlate with the formation of water-enriched local solvent domains because the catalyst is assumed to be stabilized by interactions with water and thus the formation of water-enriched local solvent domains would drive the partitioning of the catalyst to the reactant (Mellmer et al., 2018; Walker et al., 2019). We derived a correlative model that used descriptors derived from classical MD simulations

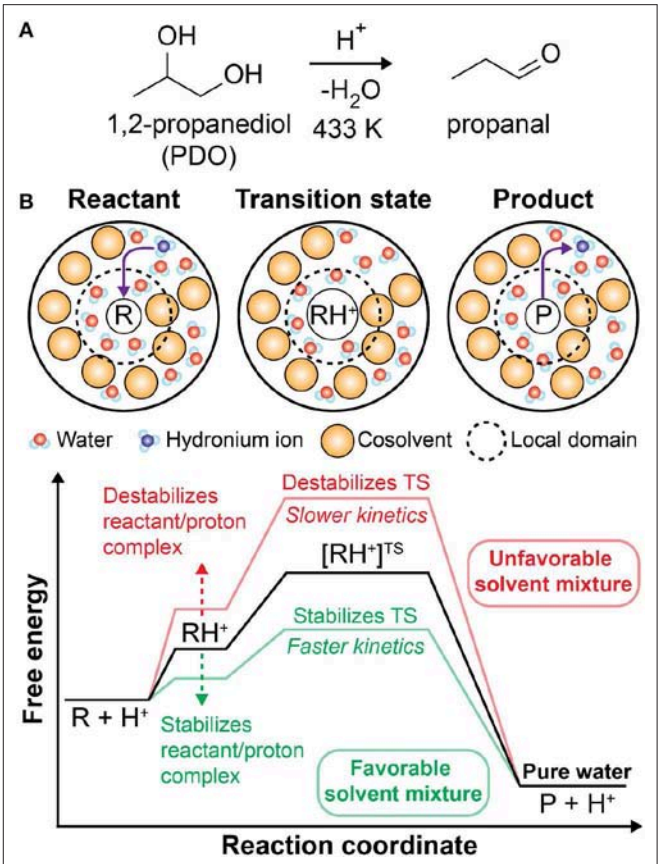

FIGURE 1 | (A) Brønsted acid-catalyzed reaction of 1,2-propanediol (PDO) to propanal. **(B)** Schematic of acid-catalyzed reactions in mixed-solvent environments. The reaction proceeds through a charged transition state (TS) formed from the protonation of the reactant by a hydronium ion catalyst. The corresponding free energy diagram schematically depicts the influence of mixed-solvent environments (red and green lines) on acid-catalyzed reactions relative to pure water (black line). This free energy landscape is representative of 1,2-propanediol dehydration based on prior computational findings (Mellmer et al., 2018). For different acid-catalyzed reactions, the relative free energies of the various states may differ (Mellmer et al., 2018), but general features should be similar.

to predict experimental reaction kinetics for seven biomass-derived model compounds in aqueous mixtures of dioxane and γ-valerolactone (Walker et al., 2019). While reaction free energies are typically determined from *ab initio* level studies (Caratzoulas and Vlachos, 2011; Mellmer et al., 2018), this hypothesis allowed us to use classical MD simulations to more rapidly screen through multiple solvent compositions and reactions. However, the assumption that the hydronium ion preferentially interacts with water is not always true. For instance, more basic organic solvents, such as dimethyl sulfoxide (DMSO), have been shown to participate in the reaction mechanism by stabilizing the proton (Mellmer et al., 2018). The addition of DMSO has also been shown to diminish acid-catalyzed conversion of *tert*-butanol (Mellmer et al., 2018), indicating that addition of organic solvents can also destabilize the reactant/proton complex, raise energy barriers, and consequently slow reaction kinetics relative to pure

water (**Figure 1B**). Therefore, understanding and quantifying the thermodynamic stability of the hydronium ion in mixed-solvent environments is essential to accurate predictions of acid-catalyzed reaction kinetics.

It is experimentally difficult to directly measure the free energy of an isolated hydronium ion in solution since electroneutrality must be maintained (Reif and Hünenberger, 2011). To obtain single-ion thermodynamics, non-classical techniques such as atomic and molecular spectroscopy combined with statistical mechanics are utilized (Hunenberger and Reif, 2011). To broaden the range of possible systems, computational tools have been developed to model the hydronium ion and isolate the role of the solvent on the acid catalyst (Varghese and Mushrif, 2019). For solution-phase reactions, we quantify the stability of the acid catalyst in terms of its solvation free energy, or the free energy for introducing the catalyst in solution. The solvation free energy accounts for interactions between the catalyst and solvent (e.g., hydrogen bonding, ion-dipole interactions, and van der Waals forces) and the solvent reorganization necessary to accommodate the catalyst. Solvation free energies are also important in determining the partitioning of ions between different phases (Duignan et al., 2017). Typically, *ab initio* level simulations are performed to accurately compute solvation free energies of the acid catalyst (Tunon et al., 1993; Tawa et al., 1998; Mejias and Lago, 2000; Pliego and Riveros, 2001; Kelly et al., 2007). However, these simulations are computationally expensive and thus challenging to perform for multiple solvent compositions. Recently, Bonthuis et al. developed a classical hydronium ion model that accurately reproduces experimental solvation free energies in pure water (Bonthuis et al., 2016). We thus hypothesize that this classical hydronium ion model can be used to compute solvation free energies of the acid catalyst and leverage the computational efficiency of MD simulations to screen stability in different solvent compositions, assuming that the hydronium ion maintains its structure in these solvents. These calculations can then be used to predict the relationship between solvent composition and reaction kinetics for acid-catalyzed reactions.

Herein, we use classical MD simulations to study the stability of a hydronium ion in six organic polar aprotic cosolvents: dioxane (DIOX), tetrahydrofuran (THF), γ-valerolactone (GVL), N-methyl pyrrolidine (NMP), acetone (ACE), and dimethyl sulfoxide (DMSO). We also study the stability of a chloride ion in the same solvents to calculate the effect of the conjugate base. We use previous literature values for the reaction rates of the acid-catalyzed conversion of 1,2-propandiol (PDO) as a model reaction to study the influence of the different cosolvents. Since our previous work found favorable agreement between MD simulation-derived descriptors with experimental reaction rates without mechanistic details of the reaction (Walker et al., 2019), we focus on studying how water-enrichment (or cosolvent-enrichment) can improve reaction performance by favorably facilitating a hydronium ion. We then quantify the stabilities of the hydronium and chloride ions in pure and mixed-solvent environments by computing the solvation free energies. We find that the free energy for transferring a hydronium ion from pure water to organic solvent can distinguish between solvents that favorably (NMP, ACE, DMSO) and unfavorably (DIOX, THF, GVL) solvate the acid catalyst. With this information, we improve our previously developed correlative model for the conversion of PDO (Walker et al., 2019) by including a cosolvent-specific descriptor that incorporates information about the stability of the hydronium ion in the solvent system.

METHODS

Classical MD simulations were performed using GROMACS 2016 (Páll et al., 2015). We used the classical hydronium and chloride ion models parameterized by Bonthuis et al. (2016), which have been found to reproduce experimental solvation free energies in pure water systems modeled using the Single Point Charge/Extended (SPC/E) water model (Berendsen et al., 1987). Bond constraints for the hydronium ion were modified to improve simulation performance by using the more efficient LINCS constraint algorithm (Hess et al., 1997) instead of the SHAKE constraint algorithm (Ryckaert et al., 1977) (**Supplementary Section 1**, Supplementary Material). PDO and all cosolvents were parameterized using the CGenFF/CHARMM36 forcefields (Vanommeslaeghe et al., 2009; Yu et al., 2012; Best et al., 2013), while water was modeled using the SPC/E model (Berendsen et al., 1987). For all simulations, Verlet lists were generated using a 1.2 nm neighbor list cutoff. Van der Waals interactions were modeled with a Lennard-Jones (LJ) potential with a 1.2 nm cutoff that was smoothly shifted to zero between 1.0 and 1.2 nm. Electrostatic interactions were calculated using the smooth Particle Mesh Ewald method with a short-range cutoff of 1.2 nm, grid spacing of 0.12 nm, and 4th order interpolation. Bonds were constrained using the LINCS algorithm. All thermostats used a 1.0 ps time constant and all barostats used a 5.0 ps time constant with an isothermal compressibility of 5.0×10^{-5} bar^{-1}.

We initialized simulation configurations using the protocol schematically depicted in **Figure 2A**. The initial simulation box containing water and cosolvent (if applicable) had dimensions of $(6\,\text{nm})^3$ in all simulations and was equilibrated in a *NPT* simulation for 5 ns at $T = 300\,\text{K}$ and $P = 1$ bar with a velocity-rescale thermostat and Berendsen barostat. A single reactant or ion molecule (designated as "M" in **Figure 2A**) was then added to the system and equilibrated with the same barostat and thermostat for 500 ps. *NPT* production simulations were performed for all systems for 200 ns with a Parrinello-Rahman barostat and Nose-Hoover thermostat; simulations of the reactant, PDO, were performed at $T = 433.15\,\text{K}$ to match the experimental reaction temperature (Mellmer et al., 2018) while simulations of the hydronium/chloride ions were performed at $T = 300\,\text{K}$. Simulation configurations were output every 10 ps and the final 190 ns of each production trajectory were used for analysis. Simulation analysis was performed using the *MDTraj* library (McGibbon et al., 2015) and analysis tools developed in-house. MD simulations were performed using a leapfrog integrator with a 2-fs time step. **Figure 2B** shows simulation snapshots of the nearby solvent environment around a hydronium ion in 90 wt% DIOX, 90 wt% DMSO, and pure water.

Each solvation free energy was computed from a series of stochastic dynamics simulations (**Figure 2A**). Simulations were

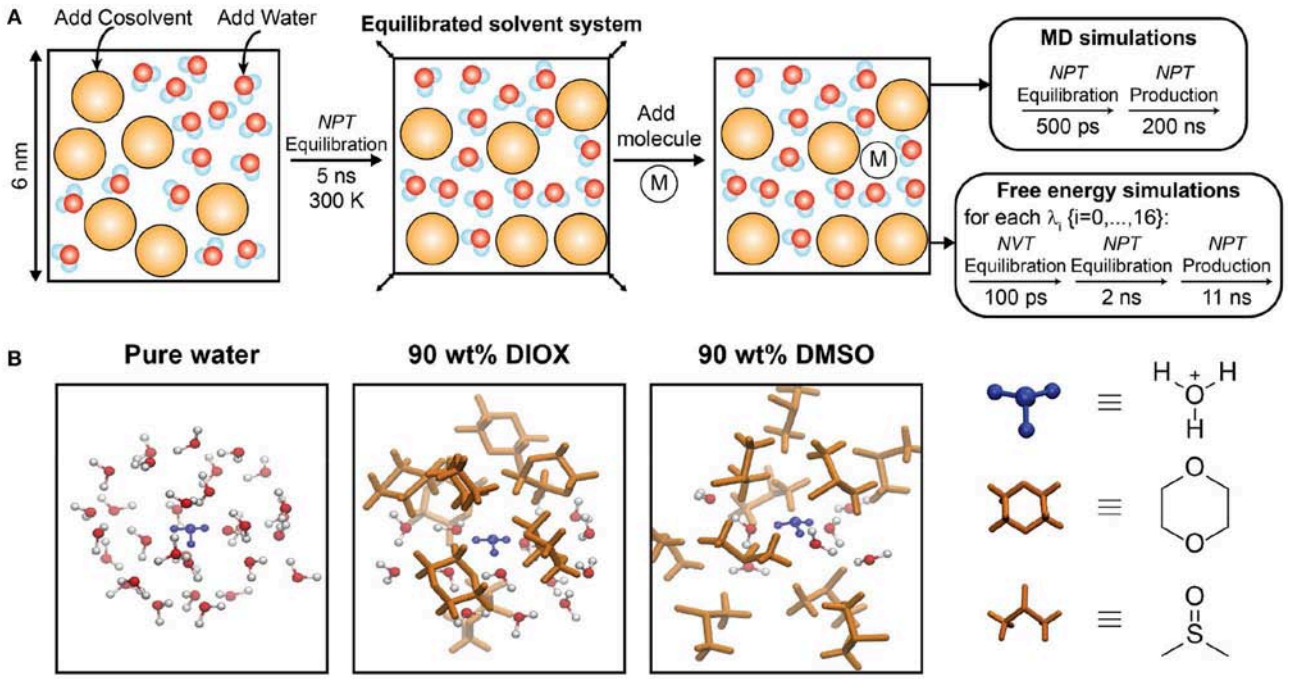

FIGURE 2 | (A) Schematic representation of simulation workflow for molecular dynamics and free energy simulations. *M* denotes either 1,2-propanediol, a hydronium ion, or a chloride ion. **(B)** Simulation snapshots of hydronium ion in pure water, 90 wt% DIOX, and 90 wt% DMSO. The hydronium ion is located at the center and only solvent molecules within a 5 Å radius is shown.

initialized using an equilibrated solvent system (as described above) with a hydronium or chloride ion added to the system. The total potential of the system was defined as a function of two parameters, λ_{LJ} and λ_{elec}, which scale the LJ and electrostatic potentials between the solute and solvent, as shown in Equation 1:

$$U\left(\lambda_{LJ},\lambda_{elec}\right) = U^{LJ}_{M,\,solv}\left(\lambda_{LJ}\right) + U^{elec}_{M,\,solv}\left(\lambda_{elec}\right) + U^{bonded}_{M} + U^{nonbonded}_{M} + U^{bonded}_{solv} + U^{nonbonded}_{solv} \quad (1)$$

$U^{LJ}_{M,\,solv}$ and $U^{elec}_{M,\,solv}$ are the LJ and electrostatic potentials between solute and solvent, U^{bonded}_{M} and $U^{nonbonded}_{M}$ are intramolecular bonded and non-bonded potentials of the solute, and U^{bonded}_{solv} and $U^{nonbonded}_{solv}$ are the bonded and non-bonded potentials between all solvent molecules (Shivakumar et al., 2010). We performed 17 independent simulations for each solvation free energy: fourteen in which $\lambda_{elec} = 0.00$ and $\lambda_{LJ} = 0.00$, 0.00922, 0.04794, 0.11505, 0.260634, 0.31608, 0.43738, 0.56262, 0.68392, 0.79366, 0.88495, 0.95206, 0.99078, or 1.00, and three in which $\lambda_{LJ} = 1.00$ and $\lambda_{elec} = 0.25$, 0.75, or 1.00. The LJ coupling parameters represent a 12-point Gaussian sequence, used previously to verify ion model parameters (Horinek et al., 2009; Bonthuis et al., 2016). All free energy simulations used a soft-core LJ potential as described in the **Supplementary Section 2.1**, Supplementary Material (Beutler et al., 1994). For each simulation, the system was energy minimized with the steepest descent algorithm and equilibrated with a 100 ps *NVT* simulation followed by a 2 ns *NPT* simulation with the Berendsen barostat. An 11 ns *NPT* production simulation was then performed with the Parrinello-Rahman barostat. All simulations were performed at $T = 300$ K and $P = 1$ bar. Energy differences computed between all pairs of windows were collected every 0.2 ps and solvation free energies were computed with the Multistate Bennett Acceptance Ratio (Shirts and Chodera, 2008) method using the python alchemical-analysis tool (Klimovich et al., 2015). The 11 ns of each *NPT* production simulation were split into two 5.5 ns trajectories and treated as two independent trials. All solvation free energy results and error bars are reported as the average and standard deviation of the two trials, respectively. We further calculated three analytical correction terms to account for: (1) finite-size effects due to system interactions with periodic images, (2) the compression free energy for transferring an ion from a 1 atm ideal gas phase to 1 mol/L ideal solution, and (3) the electrostatic energy required to pass through an interfacial potential when the ion transfers from vacuum to bulk solution. These correction terms are included to account for differences between simulation and experiments as described in **Supplementary Section 2.2**, Supplementary Material.

RESULTS

Comparison Between Experimental Reaction Rates and Preferential Exclusion Coefficient

In our previous study of solution-phase acid-catalyzed reactions (Walker et al., 2019), we hypothesized that the transition state is lower in free energy relative to the initial reactant state in

mixed-solvent environments due to two reasons: (1) the catalyst is destabilized in bulk solvent relative to a water-enriched local domain near the reactant, leading to a thermodynamic driving force for the transfer of catalytic protons to the local domain, and (2) the transition state is stabilized by water confined within this domain. We then developed a correlative model for experimental reaction rates by quantifying water enrichment in the vicinity of the reactant, supporting the hypothesis for aqueous mixtures of DIOX and GVL. This hypothesis assumes that the hydronium ion catalyst has a higher affinity for water than the cosolvent. However, this assumption may not be accurate for more basic cosolvents, such as DMSO, which can favorably stabilize the acid catalyst in bulk solution (Mellmer et al., 2018). We thus test the validity of this assumption by determining if experimental reaction rates correlate with water enrichment for a model reaction, the Brønsted acid-catalyzed conversion of 1,2-propanediol (PDO) to propanal (**Figure 1A**), in DIOX and DMSO mixed-solvent environments. These cosolvents represent extremes in polarity: the dielectric constant of DIOX is 2.20, whereas the dielectric constant of DMSO is 48.90 (Fowler et al., 1971).

We first analyze the solvent environment around PDO by calculating the radial distribution function (RDF). The RDF quantifies the solvent density, normalized by the bulk solvent density, at a distance r away from a central point. **Figure 3** shows the RDF between the center of mass of PDO and water for 90 wt% DIOX, 90 wt% DMSO, and pure water. In 90 wt% DIOX, the peak of the RDF is significantly higher than in pure water, indicating that water preferentially partitions to the local solvent domain around PDO in high concentrations of DIOX. Conversely, in 90 wt% DMSO, the first peak of the RDF is almost the same as in pure water and the RDF then drops below unity at $\sim$ 0.60 nm, indicating the local depletion of water. The diminished water content near PDO in aqueous mixtures of DMSO is due to the cosolvent's high affinity for oxygen groups, resulting in a competition between water and DMSO for the hydroxyl groups of PDO (Vishnyakov et al., 2001). These findings confirm that DMSO and DIOX significantly influence the extent to which the reactant preferentially recruits water to the local domain.

Since RDFs are difficult to compare across different cosolvent concentrations, we previously computed the preferential exclusion coefficient (Γ), a molecular descriptor that quantifies the local domain composition around the reactant (Walker et al., 2019). Γ is defined as the excess number of cosolvent molecules within the local solvent domain of the reactant relative to the bulk solvent domain, computed using Equation 2 (Kang and Smith, 2007; Shulgin and Ruckenstein, 2007; Schneider and Trout, 2009; Shukla and Trout, 2011):

$$\Gamma = -\left\langle n_C^L - n_W^L \left(\frac{n_C^B}{n_W^B} \right) \right\rangle \tag{2}$$

n_C and n_W denote the number of cosolvent and water molecules, and superscripts L and B indicate molecules within the local and bulk domains, respectively. We define the boundary between local and bulk solvent domains as the value of r at which the RDF reaches unity (**Figure 3**), which occurs at $r = 1.59$ nm for both

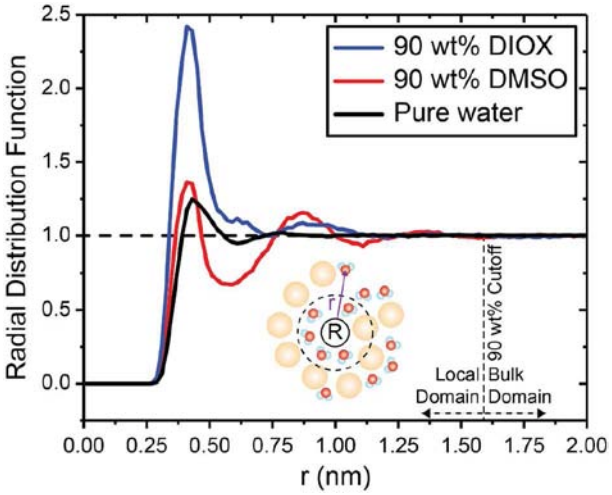

FIGURE 3 | Radial distribution function between the center of mass of PDO and water in 90 wt% DIOX, 90 wt% DMSO, and pure water. Local and bulk domain cutoffs were determined as the value of r for which the RDF reaches unity. Bin widths for the RDFs were set to 0.02 nm.

solvent systems. Positive Γ values indicate lower concentrations of cosolvent in the local solvent domain of the reactant compared to the bulk solvent domain. Therefore, positive Γ indicates the reactant has a higher affinity for water. Conversely, negative values of Γ indicate that the reactant has a higher affinity for the cosolvent.

We previously found that simulation-derived Γ correlates with experimental reaction rates quantified by the kinetic solvent parameter (σ) defined in Equation (3) (Walker et al., 2019):

$$\sigma_{org,j}^{i} = \left(\frac{k_{org,j}^{i}}{k_{H_2O}^{i}} \right) \tag{3}$$

$\sigma_{org,j}^{i}$ is the kinetic solvent parameter for the ith reaction and the subscript denotes the identity and composition (in jth mass fraction) of the organic solvent, $k_{org,j}^{i}$ is the apparent rate constant in aqueous mixtures with the organic phase, and $k_{H_2O}^{i}$ is the apparent rate constant in pure water. For simplicity, we denote $\sigma_{org,j}^{i}$ as σ. Positive σ values indicate that the reaction occurs more favorably in aqueous mixtures with organic solvents compared to pure water. Negative σ values indicate the converse. We take experimental reaction rates from Mellmer et al. (2018), which are tabulated in **Supplementary Section 3**, Supplementary Material.

Figure 4A compares values of simulation-derived Γ (filled lines) and experimentally measured σ (Mellmer et al., 2018) (dashed lines) for aqueous mixtures of DIOX and DMSO for the PDO dehydration reaction. In each separate mixed-solvent environment, Γ and σ are correlated across the solvent composition range as shown in **Figure 4B**. We report the Pearson correlation coefficient (Pearson's r) as an indicator of linear correlation: values close to 1 indicate total positive linear correlation, values close to -1 indicate total negative linear

correlation, and values close to 0 indicate no linear correlation. We find $r = 0.97$ for aqueous mixtures of DIOX, indicating strong positive linear correlation. However, we find $r = -0.97$ for aqueous mixtures of DMSO, indicating strong negative correlation and that the depletion of water around PDO in DMSO mixtures still leads to enhanced reaction kinetics. These results indicate that in either solvent system the preferential exclusion coefficient can predict reaction kinetics; however, the negative correlation between Γ and σ in DMSO suggests that increased reaction rates are not due to water enrichment. This finding suggests that the assumption that the acid catalyst preferentially partitions to water-enriched regions of the system is not valid for all cosolvents and must be revised to derive a correlative model for reaction rates that can be broadly applied to any cosolvent of interest.

Solvation Free Energy of the Hydronium Ion in Pure Solvent Systems

Previous studies have found that the hydronium ion is more stable in DMSO than water based on lower solvation free energies (Kelly et al., 2007). Since our simulations show that PDO preferentially interacts with DMSO rather than water and PDO reaction rates are increased in high concentrations of DMSO, the reactant/proton complex may be stabilized in the organic phase compared to the water phase, leading to increased reaction rates. Therefore, we hypothesize that the solvation free energy of the hydronium ion catalyst in the organic solvent can be used to classify the preference for the catalyst for either water or organic phase and develop an updated correlative model between Γ and σ for a range of cosolvents.

We calculated the solvation free energy of the hydronium ion in six organic, polar aprotic solvents (**Figure 5A**) and performed the same calculations for a chloride ion to determine the solvation free energy for a conjugate base. We selected polar aprotic solvents due to their relevance to acid-catalyzed biomass conversion processes, in which inclusion of these solvents has been found to enhance reaction performance (Mellmer et al., 2014b, 2018; Walker et al., 2019). To test the simulation approach, we first calculated solvation free energies in pure water as −465.1 kJ/mol [experimentally measured as −453.2 kJ/mol (Pliego, 2003)] for the hydronium ion and −286.4 kJ/mol [experimentally measured as −304.6 kJ/mol (Pliego and Riveros, 2000)] for the chloride ion; their sum of −751.5 kJ/mol is comparable to the estimated experimental value of −757.8 kJ/mol (Pliego and Riveros, 2000; Pliego, 2003). The experimental values reproduced from Pliego (2003) and Pliego and Riveros (2000) are modified to include the 7.9 kJ/mol correction term associated with transferring an ion from 1 atm ideal gas phase to 1 mol/L ideal solution to compare with our results (**Supplementary Section 2.2**, Supplementary Material). The relative differences between solvation free energies are more important than absolute values (Horinek et al., 2009) for inferring the behavior of the ions in different solvents; therefore, we focus on relative transfer free energies between pure water and organic solvents.

We computed the free energy of transferring the hydronium or chloride ion from water to solvent systems with organic solvents using Equation 4 (schematically illustrated in **Figure 5B**):

$$\Delta G_j^{H_2O \to k} = \Delta G_j^k - \Delta G_j^{H_2O} \tag{4}$$

k denotes the solvent system of interest and j denotes either a hydronium or chloride ion. A negative value of $\Delta G_j^{H_2O \to k}$ indicates that the ion is thermodynamically stabilized in the kth solvent system compared to pure water. **Figure 5C** shows $\Delta G_j^{H_2O \to k}$ of the hydronium and chloride ions in each pure solvent. For the hydronium ion (cyan bars), $\Delta G_{H_3O^+}^{H_2O \to k}$ is positive for DIOX, GVL, and THF, indicating that the hydronium ion is unfavorable in these solvents. These results support our prior assumption that the hydronium ion prefers water rather than the organic phase in these solvents, allowing us to correlate the formation of water-enriched local domains to reaction kinetics (Walker et al., 2019). Conversely, $\Delta G_{H_3O^+}^{H_2O \to k}$ is negative for NMP, ACE and DMSO, indicating that the hydronium ion is favorable in these solvents. Notably, these solvents are more basic than water (Fawcett, 1993) based on several solvent scales (e.g., B parameter of Koppel and Palm, 1972, or Kamlet-Taft β scale, Kamlet and Taft, 1976; Fawcett, 1993) (discussed below and in **Table 1**). The negative free energy for transferring a hydronium ion from water to DMSO agrees with prior results (Kelly et al., 2007; Mellmer et al., 2018) and supports the hypothesis that the sign of this free energy change determines the relationship between Γ and σ for DIOX and DMSO mixtures (**Figure 4**). In a similar fashion, we suspect that ACE and DMSO would exhibit similar solvent effects.

Solvation Free Energy of the Chloride Ion in Pure Solvent Systems

While the solvation free energy of the hydronium ion alone quantifies catalyst stability, the effect of the solvent on acid dissociation equilibrium depends on the solvation free energy of the hydronium ion and its conjugate base (i.e., the chloride ion). **Figure 5C** shows that $\Delta G_{Cl^-}^{H_2O \to k}$ is positive for all pure organic solvent systems (purple bars), indicating that the chloride ion thermodynamically prefers water over each of these solvents. Furthermore, the solvation free energies for the chloride ion do not vary significantly for the different organic solvents, with the exception of DIOX and THF. The difference in the solvation of the hydronium and chloride ions is likely due to differences in hydrogen bonding capabilities: the hydronium ion can donate and accept hydrogen bonds while the chloride ion can only accept hydrogen bonds. Since water is the only solvent in this study that can donate hydrogen bonds, it is expected that the chloride ion is most stable in water.

The effect of the solvent on the solvation free energies of the hydronium and chloride ions relative to their solvation free energies in water is quantified via the term $\sum \Delta G$, which we define in Equation 5 as:

$$\sum \Delta G = \sum \Delta G_{H_3O^+Cl^-}^{k \to H_2O} = \Delta G_{H_3O^+}^{H_2O \to k} + \Delta G_{Cl^-}^{H_2O \to k} \tag{5}$$

We expect that positive values of $\sum \Delta G$ would reduce acid dissociation relative to pure water due to the decreased stability of the dissociated ions in the pure organic solvent. **Figure 5C** shows

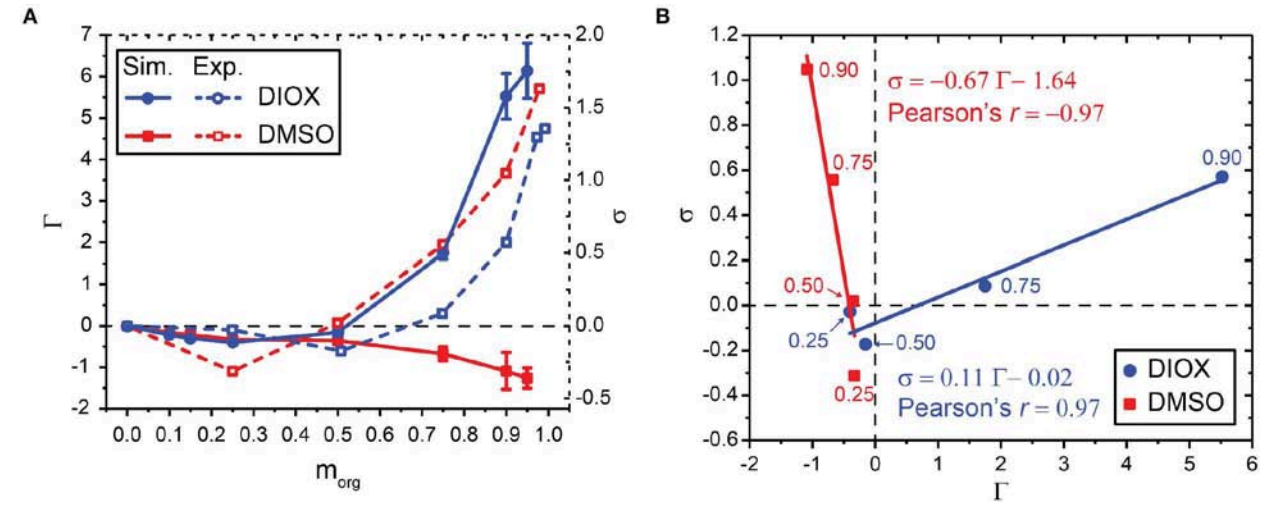

FIGURE 4 | (A) Relationship between simulated preferential exclusion coefficient (Γ) and experimentally determined kinetic solvent parameters (σ) for aqueous mixtures of DIOX and DMSO. Experimental values were taken from Mellmer et al. (2018). **(B)** Correlation between Γ and σ for aqueous mixtures of DIOX and DMSO. Data points are labeled with the wt% of the organic solvent. 25, 50, 75, and 90 wt% organic solvent was used to correlate Γ and σ as indicated for each point. The best-fit line is drawn and labeled with the corresponding equation and Pearson's *r*.

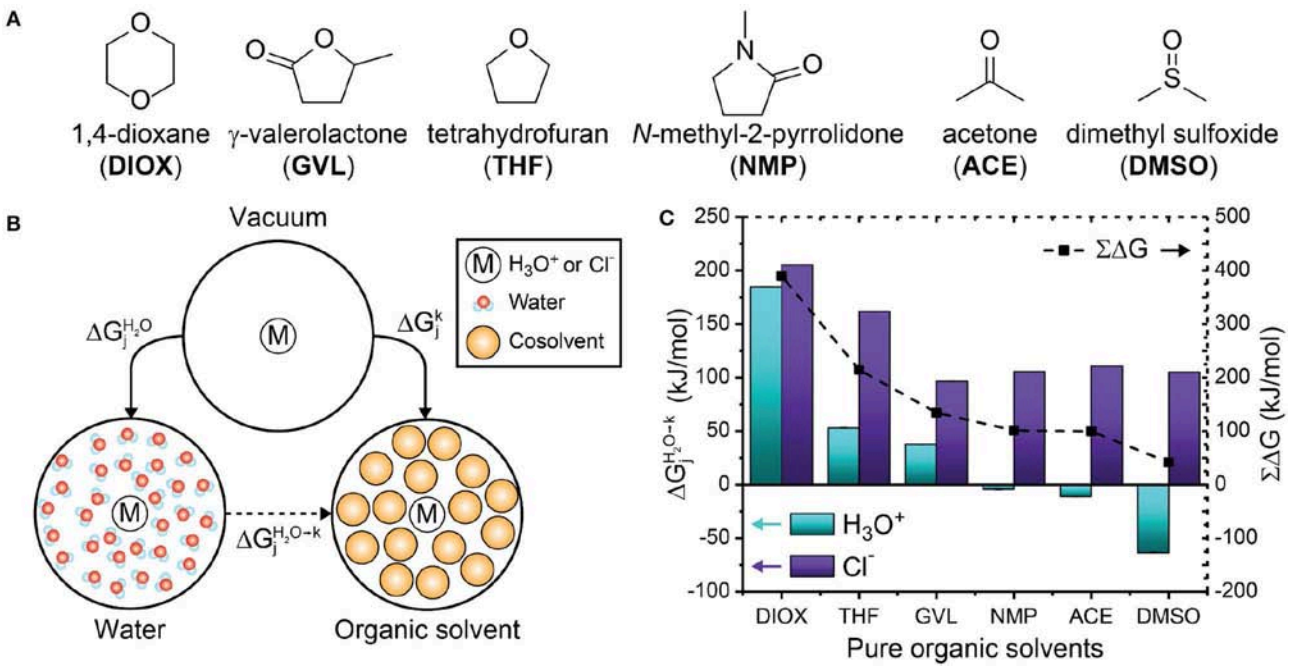

FIGURE 5 | (A) Chemical structures of the organic solvents used in this study. **(B)** Thermodynamic cycle used to compute the free energy for transferring a hydronium or chloride ion from pure water to pure organic solvent. ΔG_j^k and $\Delta G_j^{H_2O}$ are solvation free energies while $\Delta G_j^{H_2O \to k}$ is the transfer free energy computed from Equation 4. **(C)** Transfer free energies for six pure organic solvents. Cyan and purple bars indicate hydronium (H_3O^+) and chloride (Cl^-) ion transfer free energies, respectively. Dashed lines indicate the sum of the transfer energies. Error bars were computed from the standard deviation of two trials; the error is <1 kJ/mol and is not visible in the plot. The error is tabulated in **Supplementary Table 4**.

that $\sum \Delta G$ is positive for each organic solvent (black dashed lines). This result suggests that all of the polar aprotic solvents would decrease acid dissociation, leading to the reduced catalyst availability associated with weak acids based on experiments (Mellmer et al., 2014b). The sign of $\sum \Delta G$ is largely dictated by the solvation free energies of the chloride ion, indicating that the selection of the conjugate base is important for acid disassociation (Mellmer et al., 2014b), although the choice of

conjugate base would not affect the solvation free energies of the hydronium ion itself.

Relationship Between Solvation Free Energies and Solvent Parameters

Given the computational expense of free energy calculations, we next sought to relate the transfer free energy results ($\Delta G_{H_3O^+}^{k\rightarrow H_2O}$ and $\sum \Delta G$) to tabulated solvent properties to determine if these properties could accelerate solvent screening. **Table 1** compares transfer free energy values to solvent dielectric constants and Kamlet-Taft parameters (α, β, π^*). We use the dielectric constant to quantify the polarizability of the solvents and the Kamlet-Taft parameters to quantify hydrogen-bond donating ability (acidity, α), hydrogen-bond accepting ability (basicity, β), and polarity/polarizability (π^*) (Kamlet and Taft, 1976; Taft and Kamlet, 1976; Kamlet et al., 1977, 1983). Each of the Kamlet-Taft parameters are scaled from 0 to 1 based on two reference solvents. For instance, π^* uses cyclohexane and DMSO as a reference for 0 and 1, respectively (Kamlet et al., 1977; Laurence et al., 1994). We expect that the stability of a hydronium ion can be influenced by the polarity of the solvent; however, neither dielectric constant nor π^* quantitatively correlate with $\Delta G_{H_3O^+}^{k\rightarrow H_2O}$ or $\sum \Delta G$. Furthermore, basicity is expected to be an important metric of whether a hydronium ion is favored in a solvent environment, with larger β values indicating more basic solvents that would favorably solvate the acidic hydronium ion, but there is no clear correlation between β and the free energy results. We also do not find a correlation between α and the free energy results, which is expected since acidity does not directly relate to the stability of a hydronium ion in a solvent system.

These data suggest that typical solvent-specific parameters cannot easily describe the interplay of solute-solvent interactions and solvent reorganization that dictate the measured transfer free energies. We further computed the RDF between the hydronium ion and pure solvents (**Supplementary Figure 7**, Supplementary Material) to determine if solvent structure correlated with the transfer free energies, but we do not find a clear trend to explain the results found in **Figure 5C**. This data thus suggests that the free energy calculations are providing new information that can be used to predict the preference of the hydronium ion for either water or an organic solvent and quantify the effect of solvent composition on acid dissociation. It is also possible that the MD workflow is insufficiently accurate to predict these values, particularly given the classical model of the hydronium ion. However, the good agreement between the calculated solvation free energies of the hydronium and chloride ions in water with experimental data suggests that the model is reasonable. We also emphasize that DIOX, THF, and GVL have positive values of $\Delta G_{H_3O^+}^{k\rightarrow H_2O}$ and lead to increased reaction rates in mixed-solvent systems when water is enriched near the reactant, while DMSO has a negative value of $\Delta G_{H_3O^+}^{k\rightarrow H_2O}$ and leads to increased reaction rates in mixed-solvent systems when the cosolvent is enriched near the reactant. The distinct behavior of these cosolvents mirrors the difference in the sign of the calculated transfer free energies, suggesting that the transfer free energies are correctly capturing differences in the preference of the hydronium ion for bulk organic solvent.

TABLE 1 | Dielectric constants and Kamlet-Taft parameters (α, β, π^*) for pure solvents, tabulated according to decreasing transfer free energy of a hydronium ion ($\Delta G_{H_3O^+}^{k\rightarrow H_2O}$) in these solvents. $\sum \Delta G$ was computed with Equation 5.

Solvent	Dielectric constant[a]	Kamlet-taft Parameters			$\Delta G_{H_3O^+}^{k\rightarrow H_2O}$	$\sum \Delta G$

Transfer Free Energies of the Hydronium and Chloride Ion in Mixed-Solvent Systems

Figure 6A shows the free energies for transferring either a hydronium or chloride ion to aqueous mixtures of DMSO and DIOX from pure water; these solvents represent extrema of low and high affinity cosolvents for the hydronium ion. In aqueous mixtures of DMSO, **Figure 6A** shows a monotonic decrease in the hydronium ion transfer free energy (i.e., an increase in hydronium ion stability relative to pure water) as the mass fraction of the organic phase increases. Since the free energy calculations in pure organic solvents (**Figure 5C**) show that pure DMSO stabilizes the hydronium ion more than water, these results agree with the expectation that increasing concentrations of DMSO results in improved stability of the hydronium ion. **Figure 6B** shows RDFs between the hydronium ion and both water and DMSO in 90 wt% DMSO. The peak of the ion-water RDF in 90 wt% DMSO is higher than in pure water, showing a local enrichment of water around the ion; however, there is also a cosolvent peak at ∼0.38 nm, showing an enrichment in DMSO. Therefore, water and DMSO both favorable solvate the hydronium ion (visually shown in **Figure 2C**), leading to its increased stability relative to pure water. These results are consistent with experimental trends that find that increasing the concentration of DMSO monotonically increases basicity (Catalán et al., 2001). The results further suggest that there should be a driving force to partition the hydronium ion to regions of the solvent system that have the highest concentration of DMSO to reduce its free energy to the greatest extent, agreeing with the hypothesis that local enrichment of DMSO around a reactant leads to an increase in acid-catalyzed reaction rates.

In aqueous mixtures of DIOX, **Figure 6A** shows a non-monotonic trend in the hydronium ion transfer free energy as

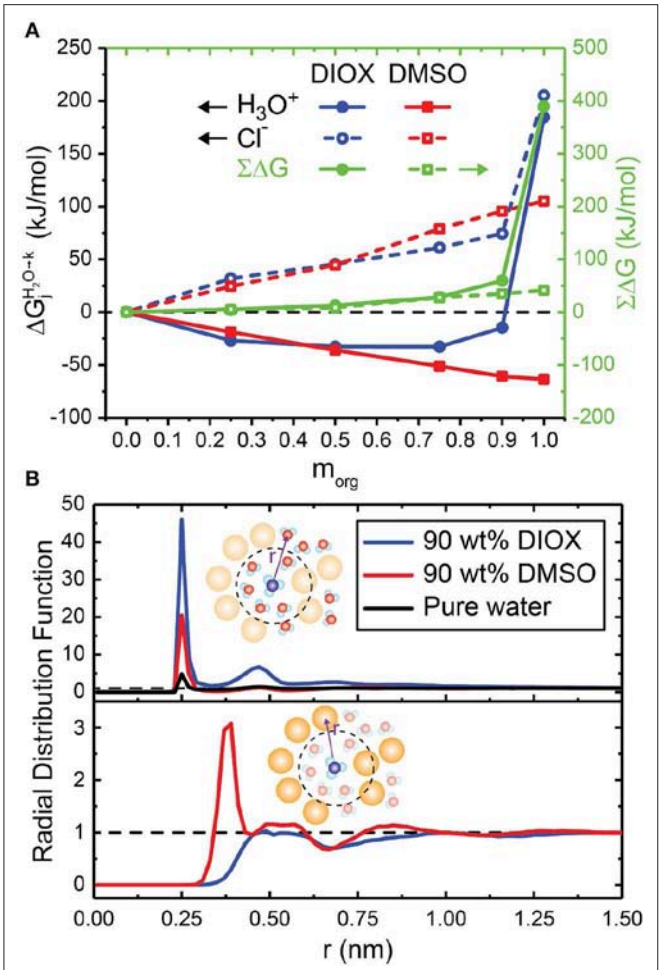

FIGURE 6 | (A) Transfer free energies for transferring hydronium (H_3O^+, filled lines) and chloride (Cl^-, dashed lines) ions from pure water to aqueous mixtures of dioxane (DIOX, blue lines) and dimethyl sulfoxide (DMSO, red lines). The sums of the transfer free energies ($\sum \Delta G$) are shown as green lines. Error bars are not shown; they range from 0 to 2.5 kJ/mol when averaging two trials and tabulated in **Supplementary Table 5**. **(B)** Radial distribution function (RDF) between the center of mass of the hydronium ion to water (top) and the organic solvent (bottom) in 90 wt% DIOX, 90 wt% DMSO, and pure water. Bin widths for the RDFs were set to 0.02 nm.

the mass fraction of the organic phase increases. The transfer free energy is negative for all mixed compositions indicating that the hydronium ion is more stable than in either pure solvent. In the RDFs presented in **Figure 6B**, the peak of the ion-water RDF in 90 wt% DIOX is almost 10-fold larger than the peak in pure water, indicating a significant enrichment of water around the hydronium ion (visually shown in **Figure 2B**). In addition, the cosolvent RDF (**Figure 6B**, bottom) shows that DIOX is depleted near the hydronium ion up to distances of about 1 nm. These results together indicate that the hydronium ion nucleates a local domain of water molecules confined within the vicinity of the ion by the surrounding cosolvent. We attribute the decreased free energy of the hydronium ion in the mixed-solvent environment to the formation of this domain, which effectively sequesters water molecules to eliminate unfavorable water-cosolvent interactions that are not present in either pure solvent. Surprisingly, this data suggests that there should not be a driving force for hydronium ions to partition from bulk mixed-solvent environments to water-enriched domains near hydrophilic reactants as previously hypothesized because the solvation free energy of the ion in pure water is higher than in the mixed-solvent environment. This finding suggests that the stabilization of the charged transition state by confined water molecules in the water-enriched local domain might be the dominant factor leading to increased reaction rates. However, these calculations omit explicit modeling of the reactant, which could affect partitioning thermodynamics.

Finally, **Figure 6A** shows that the chloride ion is not favored in any mixed-solvent composition, resulting in positive $\Delta G_j^{H_2O\to k}$ and $\sum \Delta G$ values for all DIOX and DMSO mass fractions. These data again indicate that acid dissociation is preferred in pure water rather than any mixed-solvent environment and thus weak acids are less likely to dissociate, diminishing reaction performance.

DISCUSSION

Screening Solvent Properties Using a Classical Hydronium Ion Model

Recent studies of acid-catalyzed biomass conversion reactions have illustrated that the stability of the hydronium ion catalyst in various mixed-solvent environments can dramatically affect reaction rates (Mellmer et al., 2014a,b, 2018; Shuai and Luterbacher, 2016; He et al., 2017; Walker et al., 2018, 2019; Varghese and Mushrif, 2019). Computational tools have been developed to study the hydronium ion in different solvent systems (Tawa et al., 1998; Bonthuis et al., 2016; Varghese and Mushrif, 2019), with *ab initio* molecular dynamics emerging as a powerful method to study interactions between the hydronium ion and solvent molecules due to the method's accuracy and ability to capture quantum mechanical effects (Tuckerman et al., 1994, 1995a,b, 1997; Sagnella et al., 1996; Marx et al., 1999; Morrone and Tuckerman, 2002; Izvekov and Voth, 2005; Marx, 2006). However, *ab initio* simulations are computationally expensive and difficult to expand across multiple solvent systems. Therefore, we used a classical hydronium ion model (Bonthuis et al., 2016) to compute the stability of the hydronium ion by measuring its solvation free energy in solvent systems with organic, polar aprotic solvents. Our findings suggest that the hydronium ion is unfavorable in DIOX, THF, and GVL solvents but favorable in NMP, ACE, and DMSO solvents (**Figure 5C**). These results can classify whether a solvent favorably facilitates a hydronium ion to help determine which phase the acid catalyst prefers in mixed-solvent systems. Furthermore, we could not identify a tabulated cosolvent-specific descriptor (e.g., dielectric constant, Kamlet-Taft parameters) that correlates with the hydronium ion solvation free energies, although the solvation free energies qualitatively capture features of solvent scales, such as the large distinction between DIOX and DMSO solvents. The lack of correlation suggests that the solvation free

energy calculated from a MD simulation may provide unique information on proton-solvent interactions and can act as a cosolvent-specific descriptor for the stability of the acid catalyst.

In mixed-solvent environments, the solvation structure around the hydronium ion show that water-enriched local domains are formed, analogous to water-enrichment around hydrophilic reactants (Mellmer et al., 2018; Walker et al., 2019), but the magnitude of enrichment is dependent on the choice of organic solvent. DMSO molecules compete with water for binding sites around the hydronium ion, whereas DIOX molecules are depleted around the hydronium ion. The hydronium ion solvation free energies in aqueous mixtures of DIOX suggest that small amounts of water can stabilize the hydronium ion to a greater degree than pure water or DIOX. This stabilization originates from the hydronium ion being confined by water, a solvent environment also found in water-enriched local domains formed by hydrophilic reactants. This finding suggests that stabilization of charged transition states by confined water in mixed-solvent environments may contribute to the increased reaction rates observed experimentally.

In all solvent environments studied, the sum of the transfer free energies of the hydronium and chloride ions from water was positive. This result indicates that non-aqueous environments tend to suppress acid dissociation, leading to lower catalyst availability for weak acids that translates to lower reaction rates (Mellmer et al., 2014b). However, in this work we only studied the solvation free energy of a chloride ion conjugate base, and thus investigating the effect of alternative conjugate bases on acid dissociation could yield different effects on acid dissociation. For example, triflic acid is known to readily disassociate even in high concentrations of DMSO (Mellmer et al., 2018). Future work will thus extend the framework developed here to further screen conjugate bases to determine the effect on acid dissociation, enabling the incorporation of these values into correlative models for reaction optimization.

Incorporation of Hydronium Ion Stability Into the Correlative Model of Reaction Rates

Figure 4 showed that the acid-catalyzed dehydration of PDO depends on the choice of cosolvent, with the experimentally measured kinetic solvent parameter (σ) correlating with the simulation-derived preferential exclusion parameter (Γ) in aqueous mixtures of DIOX and DMSO. This correlation is based on the physical understanding that catalytic hydronium ions preferentially partition to the water-enriched local domain around the reactant, increasing reaction performance and leading to a positive correlation between σ and Γ (**Figure 4B**). However, the correlation between σ and Γ is negative in DMSO, a solvent for which water depletion around the reactant is observed while reaction rates still increase. We hypothesized that the negative correlation may be because the hydronium ion preferentially interacts with DMSO rather than water and thus partitions to the water-depleted, DMSO-enriched local domain. This hypothesis is supported by the negative free energy for transferring a hydronium ion from water to DMSO as shown in **Figure 5B**. Thus, the correlation between Γ and σ must be adjusted to account for the stability of the hydronium ion in the local domain.

We include the sign of the hydronium ion transfer free energy between pure organic solvent to water, $\Delta G_{H_3O^+}^{H_2O\rightarrow pure\ org.}$, as a correction term in the preferential exclusion coefficient (Γ') by using Equation 6:

$$\Gamma' = \Gamma^* \text{sign}\left(\Delta G_{H_3O^+}^{H_2O\rightarrow pure\ org.}\right) \tag{6}$$

Equation 6 ensures that Γ' and σ are positively correlated for aqueous mixtures of DMSO as shown in **Figure 7A**. We interpret Γ' as quantifying the enrichment of the solvent (water or cosolvent) that preferentially stabilizes the hydronium ion, such that larger values of Γ' suggest higher catalyst availability in the local domain of the reactant. Since Γ' and σ are positively correlated for both aqueous mixtures of DIOX and DMSO, we can then write a correlative model for σ_{pred} that bridges these distinct solvents using Equation 7:

$$\sigma_{pred} = A\left(\Gamma'\right) \tag{7}$$

A is a constant. **Supplementary Figure 8** shows the correlation between σ_{pred} and σ_{exp} when combining results from both DIOX-water and DMSO-water mixtures, resulting in a best-fit slope of 0.25 (ideally this value should be unity), and a root-mean-square error (RMSE) between predicted and experimental values of 0.39. Similar to our previous work (Walker et al., 2019), we next explored the use of multiple descriptors in combination to improve this correlation. In particular, we define $\Delta G_{H_3O^+}^{k/H_2O}$ as the ratio of the solvation free energy of the hydronium ion in the kth solvent system ($\Delta G_{H_3O^+}^{k}$) to the solvation free energy of hydronium ion in pure water ($\Delta G_{H_3O^+}^{H_2O}$).

$$\Delta G_{H_3O^+}^{k/H_2O} = \frac{\Delta G_{H_3O^+}^{k}}{\Delta G_{H_3O^+}^{H_2O}} \tag{8}$$

Since acid-catalyzed reactions generally form a charged transition state after protonation of the reactant (**Figure 1B**), we interpret $\Delta G_{H_3O^+}^{k/H_2O}$ as a unitless metric that estimates transition state stability in mixed-solvent systems compared to pure water. In our prior work, the reactant-water hydrogen bonding lifetime was identified as a descriptor that quantified transition state stability (Walker et al., 2019); here, $\Delta G_{H_3O^+}^{k/H_2O}$ generalizes this prior finding to account for non-hydrogen bonding interactions. **Supplementary Figure 9** shows $\Delta G_{H_3O^+}^{k/H_2O}$ as a function of solvent composition for aqueous mixtures of DIOX and DMSO. For these cosolvents, $\Delta G_{H_3O^+}^{k/H_2O}$ is greater than unity.

We combined Γ' and $\Delta G_{H_3O^+}^{k/H_2O}$ using the multilinear regression model shown in Equation 9, where A, B, and C are coefficients. To enable comparison between the coefficients, we standardized Γ' and $\Delta G_{H_3O^+}^{k/H_2O}$ by subtracting their mean

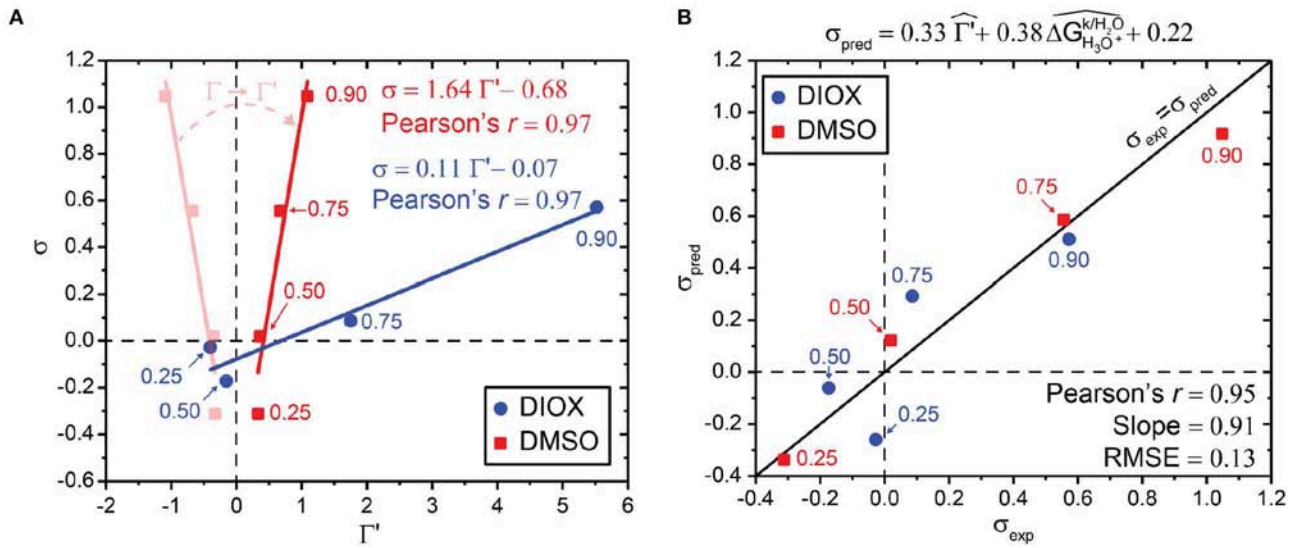

FIGURE 7 | (A) Correlation between simulated preferential exclusion coefficient with solvation free energy correction term (Γ′), as expressed in Equation 7, and experimentally determined kinetic solvent parameters (σ) for aqueous mixtures of DIOX and DMSO. Experimental values were taken from Mellmer et al. (2018). Transparent red points and lines show how Γ relates to Γ′. **(B)** Parity plot between predicted kinetic solvent parameter (σ_{pred}) and experimental kinetic solvent parameter (σ_{exp}) using results from aqueous mixtures of DIOX and DMSO. The correlative model is based on Equation 9 as shown above the plot. Data points are labeled with the wt% of the organic solvent.

and dividing by their standard deviations as described in **Supplementary Section 5.2**. All standardized variables are denoted by a hat accent.

$$\sigma_{pred} = A\left(\hat{\Gamma}'\right) + B\left(\widehat{\Delta G^{k/H_2O}_{H_3O^+}}\right) + C \tag{9}$$

Figure 7B shows the correlation between σ_{pred} and $\sigma_{\exp}$ when using Equation 9 and combining results from both DIOX-water and DMSO-water mixtures. The best-fit slope is 0.91, close to the ideal value of unity, and the RMSE between predicted and experimental values is 0.13, which is comparable to experimental error (Walker et al., 2019). Furthermore, the coefficients for $\hat{\Gamma}'$ and $\Delta G^{k/H_2O}_{H_3O^+}$ are comparable (0.33 vs. 0.38), suggesting that solvent enrichment around the reactant that favors the hydronium ion catalyst and the transition state stability are important variables for the prediction of acid-catalyzed reaction kinetics. We thus find that including information on the hydronium ion solvation free energy in an organic solvent can improve the correlation between Γ and σ when considering aqueous mixtures with different polar aprotic cosolvents. We note that additional solvent-specific descriptors (e.g., hydrogen bonding between water and the organic phase, etc.) may improve the correlation between different solvent systems and is a subject of future research.

CONCLUSIONS

We performed classical molecular dynamics simulations and solvation free energy calculations to quantify the stability of hydronium and chloride ions in six organic, polar aprotic solvents. We found that the hydronium ion is favorably solvated in pure NMP, ACE, and DMSO solvents, but unfavorably solvated in pure DIOX, THF, and GVL solvents. In mixed-solvent environments, the inclusion of water with DIOX stabilizes the hydronium ion more than their pure solvent counterparts. We attribute this increased stabilization to the formation of water-enriched local solvent domains around the hydronium ion. In aqueous mixtures of DMSO, the hydronium ion is further stabilized with increasing concentration of the organic phase. Conversely, the chloride ion is destabilized in all pure organic solvents and mixed solvent systems, inhibiting acid dissociation. By quantifying the stability of the hydronium ion in organic solvents, we obtained a new cosolvent-specific descriptor that quantifies acid catalyst stability. We incorporated this descriptor into a correlative model for 1,2-propanediol dehydration reaction rates to demonstrate that the solvation free energy results can be used to bridge reaction rate predictions across different cosolvent systems. Incorporating information about the acid catalyst stability in different solvent mixtures represents an important step toward the rational design of mixed-solvent environments for acid-catalyzed reaction schemes and has the potential to alleviate time-intensive experimentation that accompanies the optimization of biomass conversion reactions for maximum productivity.

DATA AVAILABILITY

All datasets generated for this study are included in the manuscript and/or the **Supplementary Files**.

AUTHOR CONTRIBUTIONS

AC designed, performed, and analyzed the molecular dynamics simulations. AC and RV conceived of the simulations, interpreted the results, and wrote the manuscript.

FUNDING

The authors acknowledge support from the Department of Chemical and Biological Engineering at the University of Wisconsin-Madison and the Wisconsin Alumni Research Fund. This work used the Extreme Science and Engineering Discovery Environment (XSEDE), which is supported by National Science Foundation grant number ACI-1549562. This work also used the computing resources and assistance of the UW-Madison Center for High Throughput Computing (CHTC) in the Department of Computer Sciences. The CHTC is supported by UW-Madison, the Advanced Computing Initiative, the Wisconsin Alumni Research Foundation, the Wisconsin Institutes for Discovery, and the National Science Foundation, and is an active member of the Open Science Grid, which is supported by the National Science Foundation and the U.S. Department of Energy's Office of Science.

A Strategy for Prompt Phase Transfer of Upconverting Nanoparticles Through Surface Oleate-Mediated Supramolecular Assembly of Amino-β-Cyclodextrin

*Xindong Wang and Guanying Chen**

MIIT Key Laboratory of Critical Materials Technology for New Energy Conversion and Storage, Key Laboratory of Micro-systems and Micro-structures, School of Chemistry and Chemical Engineering, Harbin Institute of Technology, Ministry of Education, Harbin, China

Lanthanide-doped upconverting nanoparticles (UCNPs) are promising for applications as wide as biosensing, bioimaging, controlled drug release, and cancer therapy. These applications require surface engineering of as-prepared nanocrystals, commonly coated with hydrophobic ligand of oleic acid, to enable an aqueous dispersion. However, literature-reported approaches often require a long time and/or multiple step treatment, along with several fold upconversion luminescence (UCL) intensity decrease. Here, we describe a strategy allowing oleate-capped UCNPs to become water-soluble and open-modified, with almost undiminished UCL, through ultrasonication of minutes. The prompt phase transfer was enabled by oleate-mediated supramolecular self-assembly of amino modified β-cyclodextrin (amino-β-CD) onto UCNPs surface. We showed that this method is valid for a wide range of UCNPs with quite different sizes (6–400 nm), various dopant types (Er, Tm, and Ho), and hierarchical structures (core, core-shell). Importantly, the amino group of amino-β-CD on the surface of treated UCNPs provide possibilities to introduce entities for biotargeting or functionalization, as exemplified here, a carboxylic-containing near infrared dye (Cy 7.5) that sensitizes UCNPs to enhance their UCL by ~4,820 fold when excited at ~808 nm. The described method has implications for all types of oleate-capped inorganic nanocrystals, facilitating their myriad bioapplications.

INTRODUCTION

Lanthanide-doped upconverting nanoparticles (UCNPs) are a new type of luminescent materials, which can produce visible or ultraviolet luminescence upon near infrared (NIR) excitation. They possess superior advantages over commonly seen luminescent materials (i.e., organic dyes, fluorescent proteins, and quantum dots), such as large anti-stoke shift, low imaging background, good colloidal stability, and deep tissue light activation (Chen et al., 2015; Wang et al., 2017). These merits empower them for uses in a comprehensive range of photonic and biophotonic applications, including solar cells, security encoding, and in particular, bio-imaging, biosensing, and light-activated cancer therapy. Most of these applications demand nanocrystal surface with critical

engineered constituents, such as functional small molecule dyes, polymers, peptides, proteins, and nucleic acids, which, however, is generally unavailable from as-prepared UCNPs surface (Liu et al., 2011b; Wang et al., 2011; Chen et al., 2014, 2016).

The pristine ligands on the as-prepared UCNPs surface constitute the basic structure for surface engineering, which have an anchoring head group to coordinate to surface exposed metallic ions and an end group that points outside when dispersed. These ligands play a significant role in controlling the process of nanocrystal growth in solution as well as nanocrystal colloidal dispensability in solvents. Until now, commonly seen UCNPs with controlled and uniform sizes, shapes, crystal phases, are often synthesized with a high boiling point ligand of oleic acid (OA) (and sometimes together with oleylamine). The head group of OA is a carboxylic group, while the end group is a long alky chain, rendering them dispersible in non-polar organic solvents such as hexane. However, the hydrophobicity of the long alky chain prevents UCNPs for uses in aqueous media as well as for introduction of groups for biotargeting and functionalization. To solve this problem, a number of approaches have been developed and reported, such as ligand exchange (Wu et al., 2009; Shao et al., 2016; Wei et al., 2016; Lee et al., 2017), silica coating (Liu et al., 2013; Li et al., 2014b; Gnanasammandhan et al., 2016), oxidation of the C=C bond in the OA ligand (Chen et al., 2008; Zhou et al., 2009; Dai et al., 2012), assembly of amphiphilic polymers (Camli et al., 2010; Danhier et al., 2012; Zou et al., 2016), and other available methods (Salinas et al., 2015; Liu et al., 2017). However, most of these literature-reported methods typically either require a long time and multiple step treatment to render UCNPs water-soluble, or the obtained aqueous nanocrystals often lack open-modified groups, such as -NH_2 and -COOH, for grafting needed functionalities (Li et al., 2014a, 2018). Moreover, these reported phase transfer processes are often in company with several fold UCL intensity decrease in UCNPs. It is still of importance to develop a simple and rapid approach to make OA-capped UCNPs hydrophilic and be open-modified for further functionalization.

Since the 1987 Nobel Prize in supramolecular chemistry, supramolecular recognition and self-assembly have been paid increased attentions in both scientific and technological developments (Yang et al., 2014; Mattia and Otto, 2015; Lehn, 2017). Cyclodextrin (CD), a water-soluble cyclic supramolecule, has a rigid well-defined ring structure and is able to firmly bind to some particular low-molecular-weight compounds, endowing these compounds new physiochemical properties (Harada, 2001; Descalzo et al., 2006). Indeed, recent results show that CD and its derivatives are able to form supramolecular complexes with OA molecules, providing possibilities for nanocrystal surface treatment to control their dispersibility properties (Wang et al., 2003; Liu et al., 2011a; Omer et al., 2011). Compared with commonly used surface treatment methods, the method of CD modification is simple and prompt (only needs ultrasonication for several minutes), leaving the pristine ligands anchored on UCNPs surface intact. As a result, this surface treatment method could avoid the formation of surface defects for energy trapping that typically leads to the decrease of UCL quantum yield.

In this work, we synthesized amino modified β-cyclodextrin (amino-β-CD) and then applied it to OA-capped UCNPs of varying type (different sizes, various types of lanthanide dopants, and core-shell structure), enabling them water-soluble and open-modified for functionalization. The interaction between the host molecule of amino-β-CD and the guest surface molecule of OA allowed a prompt, stable, and straightforward self-assembly of amino-β-CD onto the surface of UCNPs through ultrasonication of 2–4 min. Experimental results showed that the morphology, crystallographic phase, and UCL intensity of UCNPs are retained to a maximum. Importantly, the amino groups contained in the surface CD molecules allow to introduce a carboxylic-containing dye (Cy 7.5) onto the nanocrystal surface that can sensitize the nanocrystal to enhance its UCL by ∼4,820 fold when excited at ∼808 nm.

MATERIALS AND METHODS

Reagents And Apparatus

Oleic acid (OA) and 1-octadecene (ODE) were purchased from Sigma Aldrich (USA). Rare earth chloride hexahydrate ($YCl_3{\cdot}6H_2O$ 99.9%, $YbCl_3{\cdot}6H_2O$ 99.9%, $ErCl_3{\cdot}6H_2O$ 99.9%, $TmCl_3{\cdot}6H_2O$ 99.9%, and $HoCl_3{\cdot}6H_2O$ 99.9%), rare earth nitrates ($Y(NO_3)_3{\cdot}6H_2O$ 99.9%, $Yb(NO_3)_3{\cdot}5H_2O$ 99.9%, and $Er(NO_3)_3{\cdot}5H_2O$ 99.9%), sodium oleate, ammonium hydroxide, β-CD, epoxy chloropropane, neutral alumina (100–200 mesh), and sodium fluoride (NaF) were from Aladdin (Shanghai, China). Hexane, methanol, ethanol, sodium hydroxide (NaOH), and ammonium fluoride (NH_4F) were purchased from Xilong Scientific Co., Ltd (Guangdong, China). Yttrium oleate was prepared according to a method in a literature (Park et al., 2004). All the reagents were used without further purification.

The transmission electron microscope (TEM) images were acquired with a 100 CX II TEM microscope (JEM, Japan). Fourier transform infrared (FTIR) spectra were recorded on a Nicolet AVATAR360 FTIR spectrometer (Thermo Nicolet Corporation, USA). Luminescence spectra were obtained at a FLAME-T-VIS-NIR Spectrometer Assembly (Ocean Optics, USA) with an excitation from a ∼980 or 808 nm diode laser (CNI, Changchun). The integration time for the spectrometer was set to 600 ms, while the power of 980 and 808 nm laser was set to 400 and 300 mW, respectively, for all pertinent optical experiments. ^1H nuclear magnetic resonance (NMR) spectra were recorded on Bruker Avance 500 (500 MHz, USA). Luminescence lifetimes were recorded on the FLS 980 transient fluorescence spectrometer (Edinburgh Instruments, England).

Preparation of $NaYF_4$: Yb, Er UCNPs

Preparation of Small Size (6 nm) $NaYF_4$: 30%Yb, 2%Er UCNPs

Small size $NaYF_4$: 30%Yb, 2%Er UCNPs (6 nm) were synthesized according to a previous procedure with modifications (Rinkel et al., 2016). Typically, 1.59 g of rare earth oleates (Y, Yb and Er oleates with a molar ratio of 0.68: 0.3: 0.02) and 4.06 g of sodium oleate were firstly combined with 20 mL OA and 20 mL octadecene in a 100 mL three neck flask. The mixture was degassed for 1 h at 100°C under Ar atmosphere and vigorous

stirring. Then, 0.68 g of NH_4F was added to the solution, which maintained at 100°C for 30 min with Ar atmosphere protection. Subsequently, the reaction mixture containing sodium oleate, rare-earth oleates and NH_4F in a molar ratio of 8:1:11 was heated to 300°C with a heating rate of 16°C/min, and then kept at this temperature for 30 min. After cooling to room temperature, excess ethanol was added to the solution to precipitate the nanocrystals, followed by centrifugation at 10,000 rpm/min for 5 min. The collected precipitate was redispersed in a small amount of hexane, and then precipitated again with ethanol. Finally, the resultant UCNPs were collected with centrifugation and redispersed in 10 mL hexane.

Preparation of Middle Size (42 nm) $NaYF_4$: 30%Yb, 2%Er UCNPs

Middle size $NaYF_4$: 30%Yb, 2%Er particles (42 nm) were synthesized as follows: 0.2063 g $YCl_3.6H_2O$, 0.1162 g $YbCl_3.6H_2O$, and 0.0076 g $ErCl_3.6H_2O$ (Y, Yb and Er chlorides in a molar ratio of 0.68: 0.3: 0.02) were mixed with 9 mL OA and 15 mL octadecene in a 100 mL three neck flask. The slurry mixture was heated to 150°C and kept for 30 min to form a transparent solution under Ar flow protection. Then the mixture was cooled down to 50°C, followed by addition of 10 mL methanol containing 0.1482 g NH_4F and 0.1000 g NaOH, and then stirred for 30 min. Subsequently, the mixture was heated to 80°C and kept at this temperature for 30 min in order to evaporate methanol. Then the mixture was heated to 300°C with a rate of 15°C/min under Ar flow, and maintained at 300°C for 60 min. After cooling to room temperature, excess ethanol was added to the solution to precipitate the nanocrystals, followed by centrifugation at 6,000 rpm/min for 5 min. The precipitate was collected and redispersed in a small amount of hexane, and then precipitated again with ethanol. Finally, the particles were separated by centrifugation and redispersed in 10 mL hexane.

Preparation of Large Size (400 nm) $NaYF_4$: 30%Yb, 2%Er UCNPs

Firstly, 1.0846 g NaOH was mixed with 4 mL H_2O, 12 mL OA, and 6 mL ethanol, and stirred for 30 min. Then, a certain amount of rare earth nitrates (Y, Yb, and Er nitrates in a molar ratio of 0.68: 0.3: 0.02) were added into the mixture and stirred for another 10 min. Subsequently, 4 mL NaF (1.25 M) solution was added and stirred for 30 min. Finally, the solution was transferred to a stainless Teflon autoclave (50 mL), sealed, and heated at 180°C for 24 h. After cooling to room temperature, excess ethanol was added to the solution to precipitate UCNPs, followed by centrifugation at 6,000 rpm/min for 5 min. The precipitate was then redispersed in a small amount of hexane, and precipitated again with ethanol. Finally, the resultant particles were separated by centrifugation and redispersed in 10 mL hexane.

Preparation of Middle Size (42 nm) $NaYF_4$: Yb, X (X = Er, Tm, and Ho) UCNPs

The synthesis procedures are similar with the one of middle size $NaYF_4$: Yb, Er particle. A total amount of 1 mmol rare earth chloride hexahydrate (Y+Yb+X, X = Er, Tm, and Ho) were mixed with 9 mL OA and 15 mL octadecene. The slurry mixture was heated to 150°C and kept for 30 min to form a transparent solution under Ar flow. Then the mixture was cooled down to 50°C, followed by addition of 10 mL methanol containing 0.1482 g NH_4F and 0.1000 g NaOH, and stirred for 30 min. The mixture was then heated to 80°C and kept for 30 min in order to evaporate methanol. Subsequently, the solution was heated to 300°C with a rate of 15°C/min under Ar flow, and maintained at 300°C for 60 min. After naturally cooling to room temperature, excess ethanol was added to precipitate the nanocrystals followed by centrifugation at 6,000 rpm/min for 5 min. The precipitate was then redispersed in a small amount of hexane and precipitated again with ethanol. Finally, the particles were separated by centrifugation and redispersed in 10 mL hexane.

Preparation of Middle Size Core-Shell (64 nm) $NaYF_4$: Yb, Er@$NaYF_4$ UCNPs

The middle size core particles (42 nm) of $NaYF_4$: Yb, Er were synthesized using the above-mentioned procedure. The coating procedure of the inert shell layer of $NaYF_4$ was described as follows. First, 0.5 mmol of yttrium hexhydrate chloride was mixed with 9 mL OA and 15 mL octadecene in a 100 mL three necked flask. The slurry mixture was then heated to 150°C and kept at this temperature for 30 min to form a transparent solution under Ar atmosphere protection. Subsequently, the mixture was cooled down to 50°C, followed by addition of 10 mL methanol containing 0.0741 g NH_4F and 0.0500 g NaOH, and 10 mL hexane containing the 42 nm core $NaYF_4$:Yb, Er particles. After magnetic stirring at this temperature for 30 min, the mixture was heated to 80°C and kept at this temperature for 30 min to evaporate methanol. The mixture was then heated to 300°C with a rate of 15°C/min under Ar atmosphere protection, and maintained at this temperature for 60 min. After cooling to room temperature, excess ethanol was added to precipitate the nanocrystals from the mixture, followed by centrifugation at 6,000 rpm/min for 5 min. The precipitate was redispersed in a small amount of hexane and then precipitated with addition of excessive ethanol. Finally, the particles were collected by centrifugation and redispersed in 10 mL hexane.

Preparation Of Amino-β-CD

As shown in **Figure 1a**, the epoxy chloropropane was used to crosslink the amino group and the β-CD in a dilute alkali solution. The procedure to prepare amino modified β-CD is described as follows. Firstly, 8.1 g β-CD and 6.7 g KOH were added into 70 mL H_2O, which was kept stirring until β-CD was completely dissolved. The resultant mixture was then heated to 50°C, to which 3.4 g ammonium hydroxide and 10.2 g epoxy chloropropane were added in order. Subsequently, the mixture solution was heated to 60°C and maintained at this temperature for 1 h. When completing the reaction, the pH of the solution was first adjusted to 5–6, and then 150 mL ethanol was poured into the solution at room temperature. The final product was purified via neutral alumina column, using an eluent of 60% ethanol. The resultant mixture was concentrated to 30 mL by evaporating redundant ethanol, followed by adding a large amount of absolute

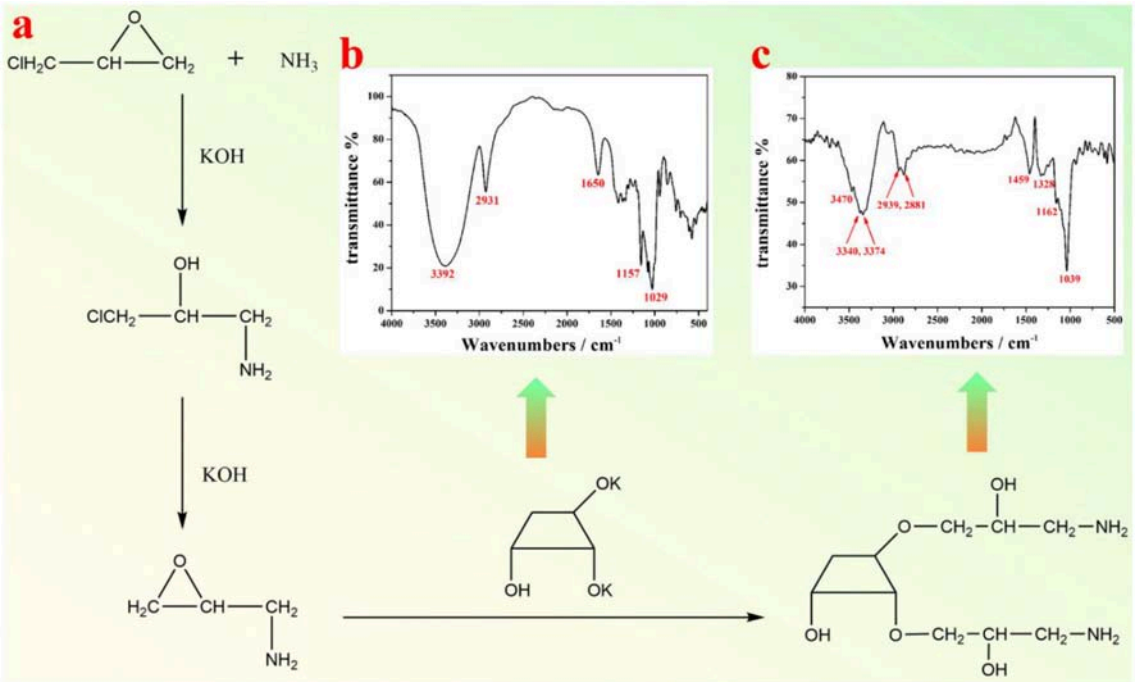

FIGURE 1 | (a) A schematic illustration of synthesis of amino-β-CD; FTIR spectra of **(b)** β-CD, and **(c)** amino-β-CD.

methanol and placed overnight. Finally, the amino-β-CD product was filtrated and dried in vacuum.

FTIR spectra of pristine β-CD (**Figure 1b**) and amino functionalized β-CD (**Figure 1c**) were both measured. As shown in **Figure 1b**, the bands at 2,931 cm^{-1} and 1,334–1,440 cm^{-1} represent the stretching and bending vibration of alkane (C-H). The bands at 3,392 and 1,650 cm^{-1} represent the stretching and bending vibration of O-H, and the bands at 1,029 and 1,157 cm^{-1} are both from the stretching vibration of C-O. After amino group modification, the vibration bands of O-H and C-H are both changed (move or split, **Figure 1c**), which are possibly due to the influence of linked amino alkane. Furthermore, the bending vibrations of O-H at 1,650 cm^{-1} and the stretching vibration of C-O at 1,157 cm^{-1} almost disappear, since the -OH group has been replaced by the amino alkane group. The appearance of the stretching vibration of the N-H group at 3,470 cm^{-1} clearly indicates the presence of amino group, and thus the successful preparation of amino-β-CD. The NMR spectrum of amino functionalized β-CD was shown in **Figure S1**. ^{1}H NMR of amino-β-CD (500 MHz, DMSO-d_6) δ 8.84 (s, 4H), 7.49 (s, 1H), 7.39 (s, 1H), 7.28 (s, 1H), 5.78–5.71 (m, 4H), 5.59 (s, 2H), 5.03 (s, 6H), 4.84 (s, 3H), 4.58 (s, 6H), 4.03 (s, 2H), 3.99–3.94 (m, 1H), 3.87 (s, 2H), 3.69 (s, 15H), 3.63 (s, 12H), 3.56 (s, 3H), 3.36 (ddt, J = 31.8, 15.0, 6.9 Hz, 14H), 3.23–3.16 (m, 21H), 3.00 (s, 1H), 2.87 (s, 2H).

Surface Modification of OA-Capped UCNPs With Amino-β-CD

Surface treatment of OA-capped UCNPs was realized through an OA-targeting supermolecular self-assembly of amino-β-CD on to the nanoparticle surface (consult **Figure 2a**). In a typical procedure, a certain amount (1 mL) of as-prepared UCNPs in hexane (concentration of 10 mg/mL) were dispersed in 10 mL water solution containing amino-β-CD (10 mg/mL) and 0.06 M hydrochloric acid. The mixture was ultrasonically treated for 2–4 min at room temperature. Note that, longer ultrasound time is needed for smaller sized particles (6 nm). Finally, the resultant mixture was centrifugally separated to collect the product, which was then washed three more times with 10 mL deionized water, and finally stored in 5 mL deionized water.

Attachment of Cy 7.5 to Amino-β-CD Modified $NaYF_4$: Yb, Er UCNPs

The attachment of near infrared Cy 7.5 dye to the surface of amino β-CD modified $NaYF_4$: Yb, Er UCNPs was realized through direct formation of a covalent amide bond between the carboxyl group of Cy 7.5 dye and the amino moiety of amino β-CD, with presence of cross-linking reagents (EDC/NHS) (consult **Figure 5A**). Specifically, 100 μL of Cy 7.5 dye water solution (2 mg/mL) was added into 1 mL water solution containing EDC (400 mM) and NHS (100 mM), which was freshly prepared before the use for activation of the carboxyl group for 2 h. Then, 2 mL of amino-β-CD modified UCNPs (10 mg/mL) water solution were added to the activated Cy 7.5 solution, and stirred for 4 h at room temperature. Finally, the resultant mixture was centrifugally separated to collect the product, followed by washing three times with 10 mL dimethyl formamide (DMF), and then stored in 5 mL DMF for measurements.

RESULTS AND DISCUSSION

Figure 2 shows the result of surface treatment of middle size $NaYF_4$:Yb, Er UCNPs (42 nm) with amino-β-CD through ultrasonication of two min. An intercalation of the long alky chain of OA molecules with the rigid ring of β-CD allows a stable attachment of amino-β-CD molecules to the nanocrystal surface (**Figure 2a**). The hydrophilicity of amino-β-CD, therefore, imparts a phase transfer of hydrophobic OA-capped UCNPs from organic phase (hexane) in the upper layer to aqueous phase at the bottom. A successful phase transfer can be indicated by an observation of strong UCL from surface-treated UCNPs in an aqueous dispersion (**Figure 2b**). To further demonstrate the successful phase transfer, we acquired FTIR spectra of UCNPs before and after amino-β-CD surface treatment (**Figure 2c**). Before surface treatment, the bands at 2,856/2,925 cm^{-1} and 1,465 cm^{-1} are from the stretching and bending vibration of alkane (C-H), while the bands at 1,150 and 1,565 cm^{-1} represent the stretching vibration of C-O and C=O groups, arising from the OA ligand molecule on the surface. After surface modification, the vibration bands of OA at both 1,150 and 1,565 cm^{-1} nearly disappear, being attributed to the host-guest intercalation of the amino-β-CD and the OA molecule. In addition, the characteristic vibration bands at 1,039, 1,328, 1,459, 2,939, and 3,374 cm^{-1} of amino-β-CD molecule (**Figure 1**), emerges after surface treatment, which indicates the successful attachment of amino-β-CD molecules onto the surface of OA-capped UCNPs.

The amino-β-CD surface treatment procedure does not produce overt effects on UCNPs size and morphology, as the $NaYF_4$:Yb, Er UCNPs, before and after treatment, are both shown to be spherical with a narrow size distribution of about 42 nm (**Figure 2b**). In addition, UCL spectra of the middle size UCNPs before (dispersed in hexane) and after (dispersed in water) amino-β-CD treatment were acquired and shown in **Figure 2d**. The UCL peaks at 525/542 and 655 nm, located in the visible spectral region, correspond to the $^2H_{11/2}/^4S_{3/2} \rightarrow {}^4I_{15/2}$, and $^4F_{9/2} \rightarrow {}^4I_{15/2}$ transitions of Er^{3+} ions, respectively, in good agreement with previously reported results (Chen et al., 2014). In addition, after phase transfer to water, the lifetime of $NaYF_4$:Yb, Er UCNPs slightly decreases from 244 to 182 μs, implying that the integrity of prestine surface was largely retained (**Figure 2d**). The UCL intensity remain almost undiminished after the phase conversion from hexane to water, showing a slight decrease of 1.5 fold. This conclusion can also be suggested from a direct comparison of UCL photographic images in both hexane and water (**Figure 2b**). To investigate the stability of amino-β-CD modified UCNPs, room temperature UCL spectra of these surface-treated UCNPs were measured at different time points (0, 6, 12, 24, 36, and 48 h) over a period of 2 days. As shown in the bottom of **Figure 2d**, the luminescence intensities of Er at 542 and 655 nm were merely slightly decreased with an increase of time, and retained about 90% of UCL intensity for up to 2 days, demonstrating the good stability of amino-β-CD surface-treated UCNPs. The amino-CD modified nanoparticles also showed good photostability using 400 mW 980 nm laser illuminated for 30 min (**Figure S2**),

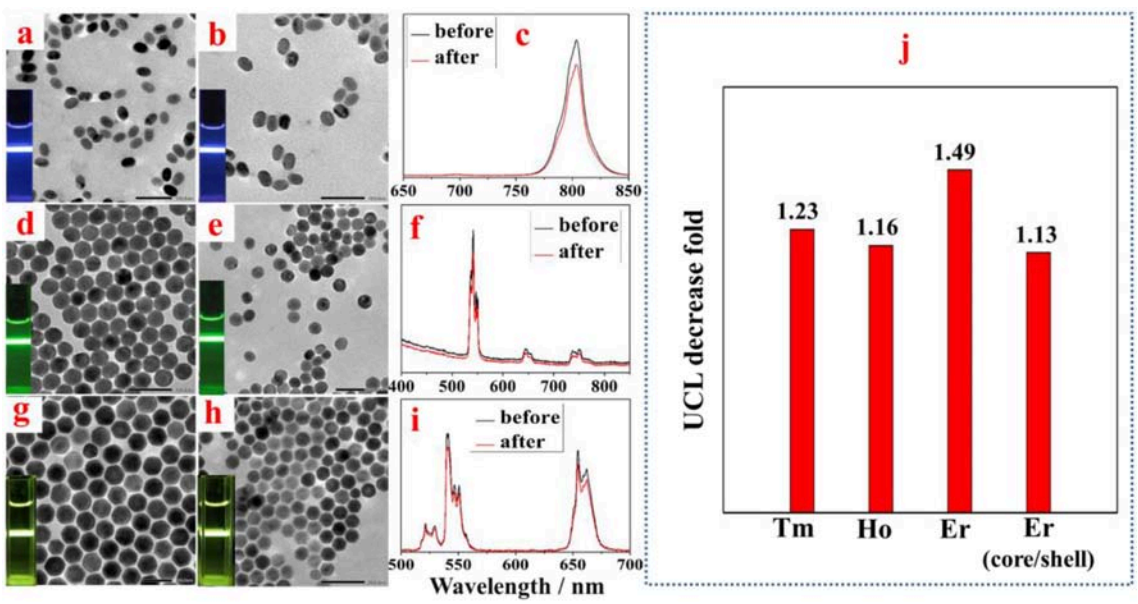

FIGURE 4 | TEM images of middle size $NaYF_4$:Yb,Tm **(a,b)**, $NaYF_4$:Yb, Ho **(d,e)**, and core-shell $NaYF_4$:Yb, Er@$NaYF_4$ UCNPs **(g,h)** before and after surface treatment. The corresponding UCL spectra from $NaYF_4$:Yb,Tm **(c)**, $NaYF_4$:Yb, Ho **(f)**, and core-shell $NaYF_4$:Yb, Er@$NaYF_4$ UCNPs **(i)**, respectively. and great chemical stability when aged in water for 12 h (**Figure S3**).

To test whether the described approach can be valid for small and large OA-capped UCNPs, we synthesized UCNPs of small size (6 nm) and large size (400 nm) and implemented the phase transfer procedure. TEM images of the $NaYF_4$:Yb, Er UCNPs of small and large size UCNPs before and after amino-β-CD modification are correspondingly shown in **Figures 3a,b,d,e**, respectively. As expected, no overt changes of morphology and size were observed. UCNPs of both small and large sizes were successfully transferred into aqueous phase, displaying intense UCL in water (small size, the inset of **Figure 3b**; large size, the inset of **Figure 3e**). The UCL intensity from UCNPs of both sizes (small size, **Figure 3c**; large size, **Figure 3f**) were almost retained. This can also be seen from a comparison of UCL photographic images before and after phase transfer (small size, the inset of **Figure 3a** vs. **Figure 3b**; large size, the inset of **Figure 3d** vs. **Figure 3e**). Note that the fold of surface treatment induced UCL decrease diminishes with an increase of the size of UCNPs, from ∼2 fold for 6 nm UCNPs to ∼1.1 fold for 400 nm UCNPs (**Figure 3g**). This observation possibly stems from the decreased surface to volume ratio with an increase of particle size. It is known that the large surface to volume ratio can produce pronounced UCL quenching effect, as a large number of rare earth ions will be exposed to surrounding quenching centers (surface defects, high energy vibrations from ligands and solvents) (Chen et al., 2014). As a result, after phase transfer, smaller size UCNPs with larger surface to volume ratio are more prone to be quenched by water molecules from solvent, thus resulting in higher UCL decrease. However, it should be noted that the observed maximum UCL decrease is merely 2 fold for small size UCNPs (6 nm). This result indicates that the intercalation of amino-β-CD to the surface of OA-capped UCNPs is able to retain the integrity of pristine particles, without creating noticeable surface defects for substantial UCL quenching that were commonly seen in literature- reported phase transfer methods.

To investigate the effect of amino-β-CD treatment on the UCL of other types of UCNPs, we prepared a set of middle size (42 nm) UCNPs with different emission bands and with a core/shell structure (core 42 nm, core-shell 64 nm). As shown in **Figure 4**, TEM images of $NaYF_4$:Yb, X (X = Tm, or Ho) UCNPs (42 nm) and $NaYF_4$:Yb, Er@$NaYF_4$ core-shell UCNPs (64 nm) before and after amino-β-CD modification present no identifiable changes on the morphologies and sizes, as expected. In addition, no spectral and relative intensities changes were observed for both $NaYF_4$:Yb, X (X = Tm, or Ho) UCNPs and $NaYF_4$:Yb, Er@$NaYF_4$ core-shell UCNPs after surface modification with amino-β-CD. The UCL intensities show a slight decrease after the conversion from hexane to water, which can be ascribed to the quenching effect induced by energetic hydroxyl (-OH) group of water molecules. However, it should be noted that the UCL quenching fold for middle size (42 nm) $NaYF_4$:Yb, Tm and $NaYF_4$:Yb, Ho are both about 1.2, a little smaller than the 1.5 fold for middle size (42 nm) $NaYF_4$:Yb, Er, presenting negligible quenching effect (**Figure 4j**). Importantly, the UCL quenching fold for the $NaYF_4$:Yb, Er@$NaYF_4$ core-shell UCNPs is just 1.1 fold, displaying almost identical UCL intensity before and after amino-β-CD treatment. This indicates that the aqueous environment produces no quenching effect for UCL from the core/shell structure UCNPs, which can possibly be due to the spatial isolation of the core from the surrounding environment.

The amino group on the surface of lanthanide-doped nanocrystals provide numerous open-modified opportunities for further functionalizations through a covalent linkage of functional molecules, such as dye, protein, and ribonucleic acid. As a proof-of-concept experiment, a type of carboxyl group functionalized near infrared dye (Cy 7.5) was linked onto the surface of $NaYF_4$:Yb, Er UCNPs through formation of an amide bond with the amino group contained in amino-β-CD on the nanocrystal surface (**Figure 5a**). It has been shown that organic dye sensitization is promising to solve the weak and narrow absorption problem of lanthanide-doped UCNPs, as the absorption of an organic dye is three orders of magnitude higher than that of a lanthanide ion. After light absorption, efficient nonradative energy transfer from organic dyes to the ytterbiurm (Yb) ions on the nanocrystal surface can empower an efficient photon upconversion through well-established Yb-X (X = Er, Ho, Tm) interactions, here X = Er (Chen et al., 2015; Wang et al., 2017). The β-CD modified $NaYF_4$:Yb, Er UCNPs without Cy 7.5 dyes served as a control sample. As shown in **Figure 5b**, under an excitation at 808 nm, the Cy 7.5 linked-$NaYF_4$:Yb, Er UCNPs exhibit intense UCL with characteristic peaks of Er at 542 and 655 nm, in marked contrast

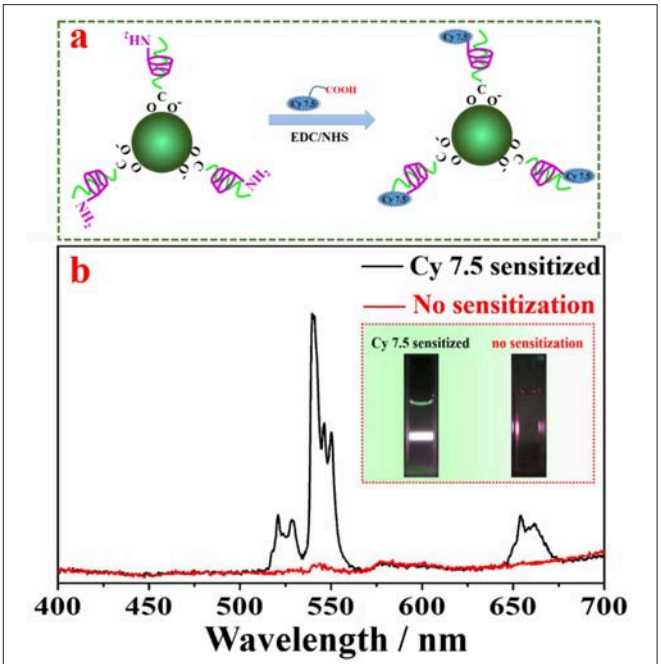

FIGURE 5 | (a) A schematic illustration of grafting Cy 7.5 dyes to the surface of UCNPs; **(b)** UCL spectra of $NaYF_4$:Yb, Er UCNPs with and without Cy 7.5 dyes on the nanocrystal surface, showing UCL enhancement of ∼4,820 fold due to the antenna effect of the grafted dye.

to none UCL from the control sample. The sensitization effect can take place through either covalently linked dyes or non-covalently linked dyes. We estimated about 80% sensitization enhancement originates from the covalent linkage of Cy 7.5 dyes (**Figure S4**). In addition, we calculated that the integrated UCL from Cy 7.5 dye-modified UCNPs in the spectral range of 400–700 nm was about ∼4,820 fold higher than that of UCL from the control sample. This significant UCL enhancement can be clearly discerned from the photographic UCL images (the inset of **Figure 5b**), which unambiguously originated from the sensitization of the $NaYF_4$:Yb, Er UCNPs by the linked Cy 7.5 dye on the UCNPs surface.

CONCLUSIONS

In summary, we have developed a simple approach for prompt conversion of hydrophobic lanthanide-doped UCNPs, commonly capped with OA ligand, to be water-soluble and open-modified for functionalization, based on OA-targeting supramolecular self-assembly of amino-β-CD. This method was shown to be valid for UCNPs with a broad spectrum of sizes (6–400 nm), a set of rare earth dopants (Yb/Er, Yb/Ho, and Yb/Tm), as well as core-shell structure through ultrasonication of 2–4 min. Importantly, UCL intensities from surface treated UCNPs were almost identical to their parent OA-capped UCNPs. Moreover, these amino-β-CD modified UCNPs were found to be stable over 48 h without overt diminishment of their UCL intensities. The amino group on the surface of resultant amino-β-CD modified UCNPs creates opportunities to graft other functionalities, as exemplified here, by a covalent linkage of the carboxylic-containing dye (Cy 7.5) to the surface, which sensitizes 42 nm $NaYF_4$:Yb/Er UCNPs, enhancing their UCL by ∼4,820 fold (when excited at 808 nm). The described approach here holds great promise for surface treatment of other kinds of OA or OA-analogs capped inorganic nanocrystals, fostering their applications in nanomedicine and theranostics.

Membrane-Modified Metal Triazole Complexes for the Electrocatalytic Reduction of Oxygen and Carbon Dioxide

*Skye N. Supakul and Christopher J. Barile**

Department of Chemistry, University of Nevada, Reno, NV, United States

In this manuscript, an electrochemical architecture is designed that controls the kinetics of proton transfer to metal triazole complexes for electrocatalytic O_2 and CO_2 reduction. Self-assembled monolayers of these catalysts are attached to a glassy carbon electrode and covered with a lipid monolayer containing proton carriers, which acts as a proton-permeable membrane. The O_2 reduction voltammograms on carbon are similar to those obtained on membrane-modified Au electrodes, which through the control of proton transfer rates, can be used to improve the selectivity of O_2 reduction. The improved voltage stability of the carbon platforms allows for the investigation of a CO_2 reduction catalyst inside a membrane. By controlling proton transfer kinetics across the lipid membrane, it is found that the relative rates of H_2, CO, and HCOOH production can be modulated. It is envisioned that the use of these membrane-modified carbon electrodes will aid in understanding catalytic reactions involving the transfer of multiple protons and electrons.

INTRODUCTION

The electrocatalysis of small molecules is important in a wide range of renewable energy devices (Duan et al., 2015; Zeng and Li, 2015; Zhang et al., 2017). Many of these conversion processes involve multiple proton and electron transfer steps (Mayer, 2004; Huynh and Meyer, 2007; Dai et al., 2015). For example, the electrocatalytic reduction of O_2 to water, which occurs in the cathode of fuel cells, requires the transfer of four protons and four electrons (Gewirth and Thorum, 2010). Similarly, the CO_2 reduction reaction, which can produce sustainable fuels, also requires multiple proton and electron transfer steps (Hori et al., 1985; Hori, 2008). These two reactions, along with most others requiring multiproton and multielectron transfer, are therefore mechanistically complex, both in terms of the reaction intermediates and in the range of products that are ultimately generated.

In both CO_2 reduction and the O_2 reduction reaction (ORR), the dynamics of proton transfer to catalytic sites are instrumental in dictating catalyst selectivity and performance (Hammes-Schiffer and Soudackov, 2008; Hammes-Schiffer, 2009). For small molecule electrocatalysts, several approaches have been used to interrogate the effect of proton transfer on catalysis. The most common methodology is to synthesize a group of ligands with pendant proton relays, which tune proton availability to a metal-centered catalytic core (Sjödin et al., 2005; Rosenthal and Nocera, 2007; Wenger, 2013). However, the incorporation of these proton relays often changes the steric

and electronic environment of the catalyst, which in turn alters its redox properties (McCrory et al., 2007; Thorseth et al., 2013). An alternative strategy is to bury electrocatalysts inside lipid membranes with embedded proton carriers (Hosseini et al., 2011). This approach allows for proton transfer dynamics to the catalyst to be controlled without changing the molecular identity of the catalyst (Barile et al., 2014). These electrode platforms consist of a thiol-based self-assembled monolayer (SAM) on Au electrodes that are covered by a lipid monolayer appended via Van der Waals interactions (Tse et al., 2015).

Previous results demonstrate that the incorporation of alkyl proton carriers inside the lipid layer of these electrodes can be used to control the kinetics of proton transfer to catalysts (Tse et al., 2016). In particular, the selectivity of a Cu triazole ORR catalyst can be improved using this platform such that adequately tuned proton transfer rates cause water to be the sole product generated. Unfortunately, the extension of membrane-modified thiol-based Au SAMs to other catalytic systems is limited by their narrow electrochemical stability. Thiol-based Au SAMs are not stable at highly negative potentials (Srisombat et al., 2011), which means they cannot be used to study reduction reactions with high overpotentials such as CO_2 reduction.

In this manuscript, membrane-modified carbon electrodes are designed that allow for proton transfer dynamics to electrocatalysts to be controlled and that exhibit greater electrochemical stability than their Au counterparts. The architecture developed here enables the interrogation of the membrane-modified ORR, and also the study of reactions such as the CO_2 reduction reaction, which occurs at high overpotentials.

MATERIALS AND METHODOLOGY

Chemicals were obtained from commercial sources and were not subjected to additional purification. 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine (DMPC) lipid was obtained from Avanti Polar Lipids, and the proton carriers dodecylboronic acid (DBA) and mono-n-dodecylphosphate (MDP) were obtained from Alfa Aesar. Triazole ligands were synthesized following a literature procedure (Li et al., 2015). For experiments under controlled temperatures, the temperature was maintained within 3 degrees of the reported value. Electrochemical analysis and attachments were conducted using a VSP-300 Biologic Potentiostat utilizing a three-electrode arrangement consisting of a leakless Ag/AgCl (3M KCl, eDaq, Inc.) reference electrode that is stable in both aqueous and ethanolic solutions, a Pt wire counter electrode, and a Au or glassy carbon working electrode. Previously reported procedures for experiments on Au electrodes were followed (Tse et al., 2016).

For experiments with carbon, a 5 mm diameter glassy carbon electrode was used as the working electrode. The working electrode was cleaned before each experiment by rinsing the electrode surface using de-ionized water, followed by manual polishing with 0.3 μm alumina particles suspended in de-ionized water on a polishing pad for approximately 6 min. After polishing, the electrode was sonicated in de-ionized water, followed by sonication in acetone, and finally sonication in isopropyl alcohol for 3 min each before being dried under a stream of air. For the electrochemical attachment of the amino-terminated triazole onto the glassy carbon electrode, cyclic voltammograms were conducted with the cleaned electrode in a 10 mL ethanolic solution containing 5 mM amino-terminated triazole and 100 mM $LiClO_4$ from a potential of 2 V to −0.01 V at a scan rate of 10 mV/s for 10 cycles. Following the attachment, the electrode was sonicated in pH 7 potassium phosphate buffer for 10 min to remove excess, unattached triazole molecules. After sonication, the amino-terminated triazole surface was immersed in a 10 mL de-ionized water solution containing 10 mM $CuSO_4$ or 10 mM $AgNO_3$ for 1 hr to form the Cu-triazole or Ag-triazole complex, respectively. For the attachment of the lipid membrane containing a proton carrier, the glassy carbon electrode modified with the Cu-triazole complex was immersed in a 1 mL $CHCl_3$ solution containing 7.4 mM DMPC and 5.6 mM proton carrier for 20 s followed by a brief submersion into 3 mL de-ionized water containing 100 mM KCl until excess $CHCl_3$ solution separated away from the electrode surface. Finally, the membrane-modified electrode was rinsed with pH 7 phosphate buffer before electrochemical analyses were performed.

To test the catalytic activity of the membrane-modified glassy carbon electrode, O_2 reduction and CO_2 reduction reactions were performed. A pH 7 phosphate buffer solution was sparged with air or CO_2 for a minimum of 20 min to ensure the solution was saturated with the specific gas. Electrocatalytic activity was evaluated using linear sweep voltammetry from 0.3 V to −0.7 V for O_2 reduction or 0.3 V to −2.0 V for CO_2 reduction at a scan rate of 10 mV/s. A blocking test to assess the integrity of the membrane-covered electrode was performed after each reduction reaction using a CV from 0.5 V to −0.5 V at a scan rate of 50 mV/s in a de-ionized water solution containing 1.5 mM $K_3Fe(CN)_6$ and 100 mM NaCl. The products of the CO_2 reduction reaction were identified using protocols modified from the literature (Tornow et al., 2012). ^{1}H NMR spectroscopy was used to quantify HCOOH production. ^{1}H NMR spectra were obtained using a Varian 400 MHz NMR Spectrometer in the Shared Instrument Laboratory (SIL) in the Department of Chemistry at the University of Nevada, Reno (UNR). CO production was quantified using a colorimetric assay based on $K_2Pd(SO_3)_2$ (Lin et al., 2018). GC-MS (Agilent 7890A) was used to identify any possible >2 e^- CO_2 reduction products such as C_2H_4 and CH_4.

RESULTS AND DISCUSSION

Ligand Design

To construct membrane-modified electrodes for electrocatalysis, two triazole molecules were first synthesized following literature protocols (Li et al., 2015). The structure of these molecules can be divided into three different sections, each with a specific function. First, the molecules contain a diaminotriazole core (**Figure 1**, blue), which upon metal binding serves as the active electrocatalytic site. This catalyst core was studied because the dinuclear Cu complex of 3,5-diamino-1,2,4-triazole has previously been demonstrated to be an efficient and stable ORR catalyst (Thorum et al., 2009). Second, the molecules contain

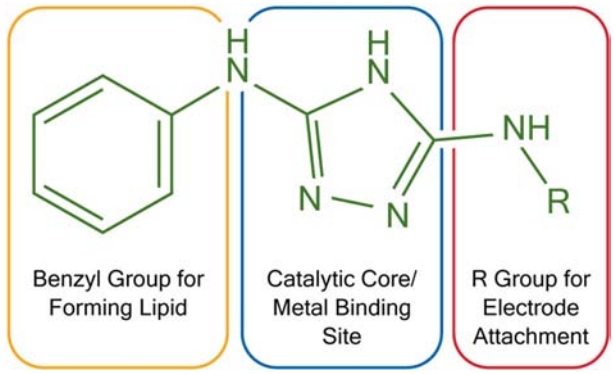

FIGURE 1 | Functional and structural features of two triazoles used in electrocatalysis. $R = -(CH_2)_6SH$ for Au electrodes and $R = -H$ for carbon electrodes.

either an alkyl thiol or a primary amine arm (**Figure 1**, red). These functional groups allow the molecules to be covalently attached to either Au or carbon electrodes, respectively. Lastly, both molecules contain a hydrophobic benzyl group (**Figure 1**, orange) so that lipid layers can be appended on top of the catalysts via Van der Waals interactions.

Electrocatalytic O_2 Reduction on Membrane-Modified Au Electrodes

After synthesizing these triazole ligands, the electrocatalytic activity of the Cu triazole complex on Au electrodes was first analyzed with and without lipid membranes. First, the Cu catalyst was attached to Au electrodes by forming a SAM of the thiol-modified triazole and subsequently immersing the SAM in a solution of $CuSO_4$ (**Figure 2**, green, $R_1 = -(CH_2)_6SH$). A linear sweep voltammogram (LSV) of the Cu catalyst in air-saturated pH 7 phosphate buffer displays an ORR onset potential of about 0 V and a diffusion-limited peak current density of about −0.062 mA/cm^2 (**Figure 3**, black line). Upon covering the catalyst with a lipid monolayer (**Figure 2**, blue, $R_1 = -(CH_2)_6SH$), the activity of the catalyst diminishes substantially due to slow proton transport through the hydrophobic lipid membrane (Barile et al., 2014; **Figure 3**, blue line). Strikingly, the incorporation of dodecylboronic acid (DBA) into the lipid layer (**Figure 2**, red, $R_1 = -(CH_2)_6SH$) revives much of the catalytic activity (**Figure 3**, red line). These observations on Au match previous results and as discussed (Tse et al., 2016), the presence of lipid-bound proton carriers accelerates proton transfer to the ORR catalyst. In particular, the proton carrier enhances the current of the ORR, but does not significantly change the ORR onset potential as compared to the lipid-only case (Hosseini et al., 2011).

The enhancement of current elicited by the proton carrier is due to a change in the ORR mechanism as demonstrated in previous work (Tse et al., 2016; Gautam et al., 2018). In the presence of lipid layer without proton carrier, the hydrophobic nature of the lipid impedes proton transfer to the catalyst, which causes the ORR to proceed primarily via a 1 e^- pathway to yield superoxide. With the incorporation of proton carrier, the proton transfer rate to the catalyst is increased, which favors the 4 e^- reduction of O_2 to water. In the absence of a lipid layer, the Cu catalyst reduces O_2 by both 2 e^- and 4 e^- pathways to produce a mixture of H_2O_2 and water. The mechanistic details for all of these electrochemical environments are illustrated in **Figure S1**.

Electrocatalytic O_2 Reduction on Membrane-Modified Glassy Carbon Electrodes

Next, the ORR catalytic activity on carbon electrodes was analyzed since carbon is more durable and inexpensive than Au, making it the electrode of choice for commercial fuel cells. Toward this end, membrane-modified glassy carbon electrodes were designed. First, the amino-terminated triazole was covalently attached to the electrode surface through the oxidation of the primary amine group using cyclic voltammetry (CV). The CVs recorded during the attachment process display anodic peaks at around 0.8–0.9 V, which indicate that the amine is oxidized at the carbon surface (**Figure 4**). These results are similar to previous studies, which use CV to electrochemically attach primary alkyl amines to carbon electrodes (Deinhammer et al., 1994).

After electrochemical attachment of the amino-terminated triazole to the carbon electrode, the Cu-triazole complex was formed by soaking the electrode in a solution of $CuSO_4$ (**Figure 2**, green, R_1 = –H). The presence of a Cu(I)/Cu(II) redox couple in a CV of the Cu-modified electrode indicates that Cu was successfully incorporated into the electrode architecture (**Figure S2**). The Cu complex catalyzes the reduction of O_2 with an onset potential of about +0.1 V and a diffusion-limited current density of about −0.04 mA/cm^2 (**Figure 5**, black line). The onset potential for this catalyst is fairly similar to what is observed for O_2 reduction by the Cu triazole complex immobilized on a Au electrode (**Figure 3**, black line). LSVs of O_2 reduction by a bare glassy carbon electrode and an electrode modified with triazole in the absence of Cu exhibit more negative onset potentials and less diffusion-limited current as compared to catalysis by the Cu triazole complex (**Figure 5**, blue and red lines, respectively). These experiments indicate that the Cu triazole complex is a more active ORR catalyst than the controls.

Having established the electrocatalytic activity of the Cu triazole complex on a carbon electrode, the surface was next modified with a lipid membrane to control proton transfer to the catalyst. The lipid membrane was formed by soaking the electrode in a solution containing DMPC using a method adapted from a previously reported procedure (Han et al., 2003; **Figure 2**, blue, R_1 = –H). The incorporation of a lipid layer on top of the Cu catalyst shifts the onset potential for the ORR significantly negative and also decreases the diffusion-limited current density (**Figure 6**, blue line). This result indicates that the ORR is inhibited by the presence of the lipid layer due to impeded proton transfer to the catalyst by the hydrophobic membrane in a manner similar to the lipid-covered catalyst on Au. The addition of DBA, a boronic acid proton carrier, to the lipid layer (**Figure 2**, red, R_1 = –H) increases the ORR diffusion-limited current density, but does not significantly alter the ORR onset potential (compare **Figure 6**, red line to blue line). The presence of a proton carrier accelerates proton transfer to the Cu catalyst, which results in the increased catalytic current density observed. The finding that the proton carrier enhances the current of the ORR, but does not significantly change the ORR onset potential as compared to the lipid-only case, suggests that the proton carrier increases the kinetics of the ORR without significantly affecting the reaction thermodynamics. Taken together, these results indicate that membrane-modified electrodes can be successfully formed on glassy carbon substrates and that the general electrochemical behavior of these systems is similar to those constructed on Au.

To assess the integrity of the lipid layer during the ORR, blocking experiments were performed using $K_3Fe(CN)_6$ in bulk solution after the ORR as described in other systems (Barile et al., 2016). A decrease in the current density observed from the Fe(II)/Fe(III) redox couple using lipid-modified electrodes as compared to membrane-free electrodes indicates that the lipid layer remains intact during the ORR process (**Figure S3**). In fact, the blocking data show that the Fe(II)/Fe(III) redox couple is less pronounced when the proton carrier is incorporated in the lipid layer (**Figure S3**, red line) as compared to lipid only

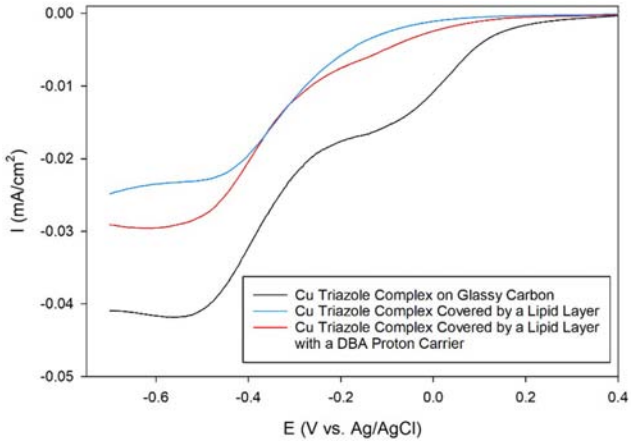

FIGURE 6 | Linear sweep voltammograms of O_2 reduction by a glassy carbon electrode modified with the Cu complex of the amino-terminated triazole (black line) covered by a lipid membrane (blue line) with DBA proton carrier (red line) in pH 7 phosphate buffer at a scan rate of 10 mV/s.

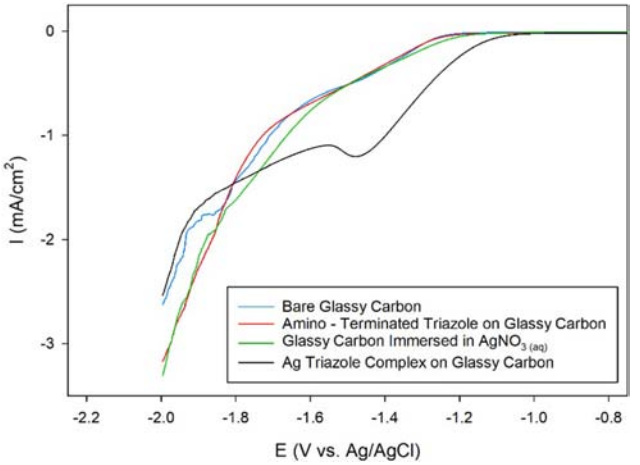

FIGURE 7 | Linear sweep voltammograms of CO_2 reduction by a glassy carbon electrode (blue line) modified with the amino-terminated triazole (red line) and the Ag complex of the amino-terminated triazole (black line) in pH 7 phosphate buffer at a scan rate of 10 mV/s. CO_2 reduction by a glassy carbon electrode immersed only in $AgNO_{3(aq)}$ and subsequently rinsed with water was also evaluated as a control experiment (green line).

case (**Figure S3**, blue line). These results demonstrate that the incorporation of the proton carrier into the lipid membrane does not adversely affect the integrity of the lipid layer and instead actually enhances lipid formation. Therefore, the increase in ORR current density elicited by the proton carrier is not caused by a disruption in the integrity of the lipid membrane. Instead, the proton carrier causes an increase in the electrocatalytic O_2 reduction current density by the Cu catalyst because it accelerates the proton transfer rate to the catalyst. The origin of this current enhancement was further confirmed by averaging results obtained across eight experimental trials (**Figure S4**). This analysis demonstrates that the proton carrier enhances the kinetics of the ORR even when taking into account the integrity of the lipid layer as determined from subsequent blocking experiments.

Electrocatalytic CO_2 Reduction on Membrane-Modified Glassy Carbon Electrodes

Electrocatalytic CO_2 reduction typically occurs at high overpotentials (Qiao et al., 2014). Hence, it is difficult to study CO_2 reduction using membrane-modified Au electrodes because Au SAMs degrade at potentials more negative than about −0.5 V (Srisombat et al., 2011). To overcome this issue, a CO_2 reduction catalyst was prepared on a membrane-modified glassy carbon electrode because carbon electrodes are more electrochemically stable. Furthermore, the majority of previous studies of CO_2 reduction catalysts on carbon electrodes utilize a binder, most commonly Nafion, to adhere the catalyst to the electrode (Tornow et al., 2012; Thorson et al., 2013; Weng et al., 2018). Inks containing carbon, Nafion, and the catalyst are usually dropcast on a glassy carbon electrode to form a porous multilayer catalyst structure that is useful for practical high current density devices, but complicates catalyst surface structure and hinders fundamental electrochemical analysis.

In contrast to a multilayer architecture, we electrochemically attach a monolayer of catalyst to glassy carbon electrodes that do not require the use of a binder. This method of surface modification allows for a more direct assessment of the activity of molecular CO_2 catalysts. Moreover, binders such as Nafion dramatically alter the proton transfer rates to embedded catalysts. The binder-free system devised here enables us to systematically analyze the effect of proton transfer on catalyst performance. In a manner similar to the previously described Cu triazole ORR catalyst, the kinetics of proton transfer to a CO_2 reduction catalyst can be tuned by covering the catalyst with a lipid monolayer.

Ag complexes containing N-based heterocycles form one class of molecular CO_2 reduction catalysts (Tornow et al., 2012). Therefore, a Ag triazole catalyst was synthesized by soaking a glassy carbon electrode modified with the amino-terminated triazole in a solution of $AgNO_3$ (**Figure 2**, green, $R_1 = -H$). A LSV of the Ag triazole complex in the presence of CO_2 displays a peak around −1.5 V and a onset potential of about −1.1 V, indicating that the complex electrocatalytically reduces CO_2 (**Figure 7**, black line). Control experiments performed using a bare glassy carbon electrode, an electrode only immersed in $AgNO_3$, or an electrode modified with only the triazole ligand do not exhibit this peak and have a more negative onset potential of about −1.25 V (**Figure 7**, blue, green, and red lines, respectively). These experiments demonstrate that the Ag triazole complex is a more effective CO_2 reduction catalyst than any of its individual components.

A further control experiment of a LSV of the Ag triazole complex conducted in a N_2 environment shows a similar onset potential of about −1.25 V and also does not exhibit a peak at −1.5 V (**Figure 8**, red line). This experiment provides two important insights into the catalytic behavior of these systems.

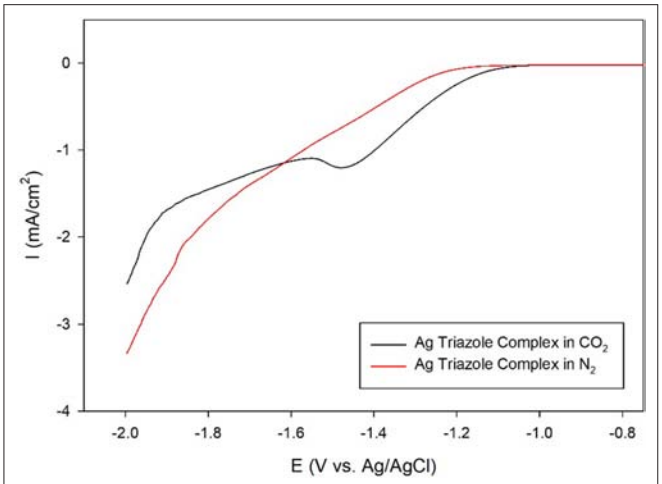

FIGURE 8 | Linear sweep voltammograms by a glassy carbon electrode modified with the Ag complex of the amino-terminated triazole in CO_2-saturated (black line) and N_2-saturated (red line) pH 7 phosphate buffer at a scan rate of 10 mV/s.

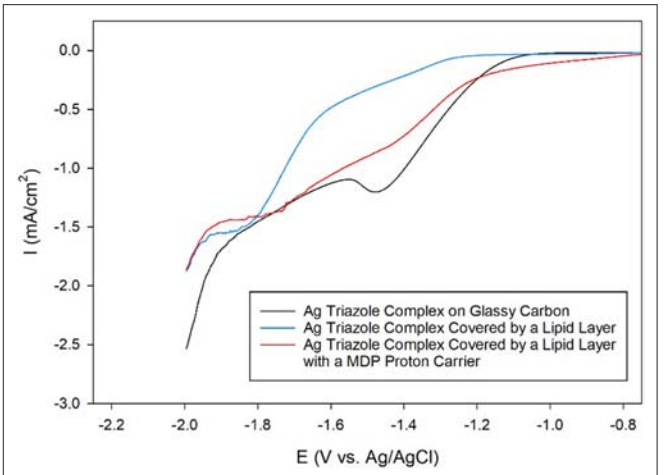

FIGURE 9 | Linear sweep voltammograms of CO_2 reduction by a glassy carbon electrode modified with the Ag complex of the amino-terminated triazole (black line) covered by a lipid membrane (blue line) with MDP proton carrier (red line) in pH 7 phosphate buffer at a scan rate of 10 mV/s.

First, the lack of a peak in the LSV under N_2 further confirms that the Ag triazole complex catalyzes CO_2 reduction. Second, the similarity of the LSV of the Ag triazole complex in N_2 to the other control experiments presented in **Figure 7** suggests that the cathodic current observed in these cases is due to the H_2 evolution reaction. In other words, a bare glassy carbon electrode or an electrode modified with only the triazole ligand does not significantly reduce CO_2 under these conditions.

Having established that the Ag triazole complex catalyzes CO_2 reduction, its catalytic performance was next measured using a membrane-modified electrode. When the catalyst is covered by a lipid monolayer (**Figure 2**, blue, $R_1 = -H$), the onset potential for catalysis shifts negative and the CO_2 reduction peak is not present (**Figure 9**, blue line), indicating that CO_2 reduction is significantly inhibited in this case. The lipid impedes access of protons to the catalyst, which are necessary for most CO_2 reduction processes (Costentin et al., 2013). Furthermore, the current density in the LSV with lipid only reaches about -1.9 mA/cm^2 at -2.0 V as compared to about -3.4 mA/cm^2 at -2.0 V for the Ag triazole complex without lipid in N_2 (**Figure 8**, red line). Since the Ag triazole complex without lipid in N_2 catalyzes the H_2 evolution reaction as discussed in the preceding paragraph, the decrease in the magnitude of current density observed for the lipid-modified catalyst indicates that the H_2 evolution reaction is suppressed. This finding is consistent with the idea that the lipid layer slows down proton transfer to the catalyst since the H_2 evolution reaction requires protons.

The addition of a proton carrier, either an alkyl phosphate, MDP, or an alkyl boronic acid, DBA, into the lipid layer (**Figure 2**, red, $R_1 = -H$) produces significant changes in the voltammetry of the Ag catalyst (**Figure 9**, red line and **Figure S5**, red line). For both proton carriers, there is more catalytic current in the regime of -1.2 to -1.8 V compared to the lipid-only case, and there are not significant differences in the integrity of the lipid layer as determined by blocking experiments (**Figure S6**). These results suggest that, compared to the lipid-only case, the activity of the CO_2 reduction catalyst is altered by the presence of the proton carrier, likely due to the enhancement of proton transfer rates to the catalytic active site. The amount of current enhancement observed depends upon the quantity of proton carrier added to the lipid layer (**Figure S7**), which dictates the rate of proton transfer to the catalyst. The LSVs of the Ag catalyst in the presence of proton carrier also depend upon temperature with greater current densities for CO_2 reduction observed as the temperature is increased (**Figure S8**).

The CO_2 reduction products obtained using the Ag triazole catalyst in different electrode environments at -1.75 V were quantified (**Figure 10**). The unmodified Ag triazole complex on glassy carbon produces nearly equal amounts of CO and HCOOH (∼15% Faradaic efficiency each) along with substantial quantities of H_2. These results confirm that the Ag triazole complex is an active CO_2 reduction catalyst. However, the catalyst also produces a larger amount of H_2 than is observed with Nafion-bound Ag triazole complexes (Tornow et al., 2012). The greater quantity of H_2 produced likely originates from exposed portions of the carbon surface that are not modified by the Ag triazole monolayer.

Covering the Ag triazole catalyst with a lipid layer decreases the Faradaic efficiency of H_2 production from ∼71 to ∼56%. The decreased quantity of H_2 produced is attributed to the hydrophobic nature of the lipid environment, which decreases the rate of proton transfer to the catalyst. With an impeded proton transfer rate, the catalyst has more time to bind and reduce CO_2 to either CO or HCOOH. This alteration in mechanism with a change in proton transfer rate is displayed schematically in **Figure S9**. The results indicate that the catalyst preferentially reduces CO_2 to CO (∼32%) over HCOOH (∼12%). Again, the hydrophobic nature of the lipid environment likely dictates product selectivity. Water is formed as a coproduct with CO, but not with HCOOH. We

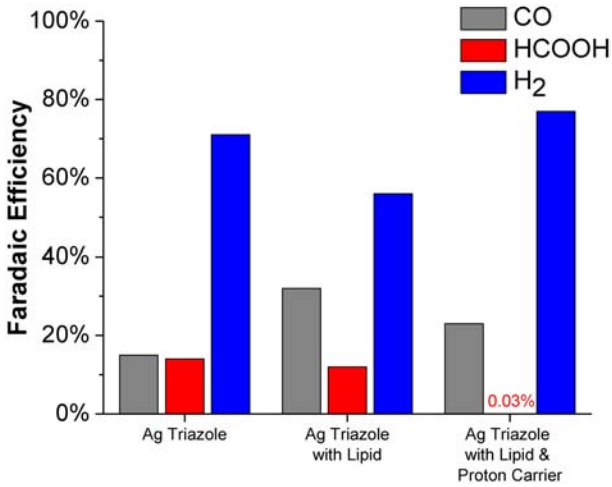

FIGURE 10 | Faradaic efficiencies for CO (gray), HCOOH (red), and H_2 (blue) production from the Ag triazole complex (left) with lipid (middle) and DBA proton carrier (right) obtained from chronoamperometry experiments at −1.75 V vs. Ag/AgCl.

hypothesize that the preference for CO formation is due to the favorable elimination of water out of the hydrophobic lipid interior, which shifts the reaction equilibria toward CO production.

The product selectively is further altered when a proton carrier is incorporated in the lipid layer. Specifically, the Faradaic efficiency for H_2 increases from ∼56 to ∼77% upon adding the proton carrier. The proton carrier increases proton transfer kinetics to the catalyst, which favors the production of H_2. Interestingly, the proton carrier drastically increases the ratio of CO to HCOOH generated and almost completely eliminates HCOOH production (∼0.03% Faradaic efficiency). The exact origin of this change in product selectivity is unknown, but possibly originates from interactions between the proton carrier and CO_2 reduction intermediates. The CO_2 reduction products of this system were also quantified as a function of temperature (**Figure S10**). Decreasing the reaction temperature to 1°C increases the Faradaic efficiency for HCOOH production to ∼3%. At this low temperature, previous studies have demonstrated that proton carriers cannot undergo flip-flop diffusion because the lipid layer is below its gel-phase transition temperature (Barile et al., 2014). Therefore, we anticipate that at 1°C, the Ag catalyst behaves as if there is no proton carrier. This hypothesis is supported by the observation that the ratio of CO to HCOOH production with proton carrier in the cold is similar to the lipid-only case at room temperature.

Lastly, the effect of voltage on the CO_2 product speciation was tested. The CO_2 products generated at −2 V are displayed in **Figure S11**. At this higher overpotential, the Ag triazole catalyst in the absence of lipid produces similar quantities of CO, HCOOH, and H_2 as compared to the −1.75 V case. However, when the catalyst contains a lipid layer with or without the proton carrier, the Faradaic efficiencies for CO and HCOOH both decrease to ∼2%, suggesting that the lipid layer inhibits CO_2 reduction at this higher overpotential.

CONCLUSIONS

We designed membrane-modified electrodes containing metal triazole complexes that electrocatalyze the reduction of O_2 and CO_2. For the O_2 reduction reaction, the complexes were anchored using SAMs on both Au and glassy carbon electrodes. By covering the catalysts in a lipid layer containing proton carriers, the kinetics of proton transfer to the complexes can be controlled on both substrates. The membrane-modified electrocatalytic systems developed on glassy carbon electrodes have a wider electrochemical window than those using Au, which enable the study of CO_2 reduction by lipid-covered catalysts. The results suggest that the relative rates of H_2, CO, and HCOOH production can be altered through the use of membranes.

Hydrogen production from humidity in the ambient air reduces the maintenance costs for sustainable solar-driven water splitting. We report a gas-diffusion porous photoelectrode consisting of tungsten trioxide (WO_3) nanoparticles coated with a proton-conducting polymer electrolyte thin film for visible-light-driven photoelectrochemical water vapor splitting. The gas–electrolyte–solid triple phase boundary enhanced not only the incident photon-to-current conversion efficiency (IPCE) of the WO_3 photoanode but also the Faraday efficiency (FE) of oxygen evolution in the gas-phase water oxidation process. The IPCE was 7.5% at an applied voltage of 1.2 V under 453 nm blue light irradiation. The FE of hydrogen evolution in the proton exchange membrane photoelectrochemical cell was close to 100%, and the produced hydrogen was separated from the photoanode reaction by the membrane. A comparison of the gas-phase photoelectrochemical reaction with that in liquid-phase aqueous media confirmed the importance of the triple phase boundary for realizing water vapor splitting.

INTRODUCTION

Large-scale deployment of photocatalytic and photoelectrochemical (PEC) water-splitting technologies, accompanied by fuel cells and energy carrier technologies, will allow the realization of the hydrogen (H_2) economy (Maeda and Domen, 2010). Separation of H_2 and oxygen (O_2) is easily achieved in PEC systems that use solid polymer electrolyte membranes (Pinaud et al., 2013; McKone et al., 2014). Laboratory-scale PEC studies are usually performed in aqueous electrolyte solutions using purified water without contamination. However, in practice, water resources are an issue for solar H_2 production. Stable supply of water might be problematic for large-scale solar H_2 production owing to limited rainfall in areas with low-cost land and abundant solar radiation such as deserts (Kumari et al., 2016). Another possible feedstock is seawater, but its use requires purification to avoid problems such as corrosion, poisoning, fouling, and byproduct formation. In contrast, gaseous water has been proposed as an attractive alternative to liquid water because an inexhaustible supply of water vapor from the ambient humid air is available at sea with high relative humidity (~80%) (Kumari et al., 2016). Gas-phase operations can significantly decrease maintenance costs because the natural convection of air can be used to feed the water vapor and

systems to purify and pump liquid water are not required (Rongé et al., 2014; Modestino et al., 2015).

Gas-phase water splitting by all-solid PEC systems has been studied using proton exchange membranes (PEMs) as a solid polymer electrolyte and n-type semiconductor electrodes as a photoanode (Georgieva et al., 2009, 2010; Iwu et al., 2013; Rong et al., 2013; Tsui et al., 2013; Rongé et al., 2014; Stoll et al., 2016, 2017; Verbruggen et al., 2017). PEC water oxidation is induced by photogenerated holes on the photoanode, which is in contact with the membrane, whereas the H_2 evolution reaction occurs on the cathode, which is located on the opposite side of the membrane. The PEM-based photoelectrolyzer (PEM-PEC cell) can be operated using gas-phase reactants such as water vapor and volatile organic compounds in air. However, the photon-to-current conversion efficiencies of the photoanodes are frequently low owing to the difficulties associated with designing electrodes for "gas–solid" PEC systems in contrast to those for conventional "liquid–solid" systems in aqueous electrolytes. The photoelectrode for a gas-phase reaction should exhibit gas diffusion properties for mass transport and proton conductivity for ion transport toward the membrane. It has been proposed that high-surface-area photoanodes need to be covered with a polymer electrolyte thin film to maximize the gas–electrolyte–solid phase contact area (Spurgeon and Lewis, 2011; Xiang et al., 2016). However, the effect of such a triple phase boundary has not been elucidated for gas–solid PEC systems. In addition, most studies have focused on TiO_2-based photoanodes under UV irradiation, and there are only a few reports on visible-light-responsive photoelectrodes for gas-phase reactions (Georgieva et al., 2009; Stoll et al., 2017). The use of narrow band gap semiconductors is necessary to achieve high solar-to-hydrogen efficiency because the number of photons is limited in the UV range. The maximum solar-to-hydrogen efficiency is only 1.7% even if all the UV light with wavelength shorter than 400 nm is utilized for water splitting reaction under AM1.5G spectrum (Abe, 2010; Hisatomi et al., 2015).

The aim of this study was to develop an all-solid PEC system with a triple phase boundary for water vapor splitting under visible-light irradiation. We selected tungsten trioxide (WO_3) as a blue-light responsive semiconductor with a narrow band gap of 2.6–2.7 eV (Amano et al., 2013). High-surface-area WO_3 nanoparticles were deposited on porous titanium microfiber felt (WO_3/Ti fiber), which was then covered with a perfluorosulfonic acid ionomer electrolyte thin film to improve its proton transport properties. The perfluorosulfonate ionomer, DuPont Nafion®, exhibits good proton conductivity at room temperature in hydrous conditions (Kusoglu and Weber, 2017). The Nafion ionomer thin film also has high chemical stability, moderate gas permeability, and moisture absorbency, which allows it to capture humidity in the gas phase (Modestino et al., 2015). We fabricated a membrane electrode assembly (MEA) by hot pressing the WO_3/Ti-fiber electrode onto a PEM with a platinum catalyst film on the opposite side. The effect of the ionomer thin film loading on the PEC performances of the WO_3/Ti fiber electrode was investigated in both humidified argon and liquid water using two-electrode and conventional three-electrode configurations.

MATERIALS AND METHODS

Preparation of WO_3 Gas Diffusion Electrode

Sintered Ti microfiber felt (thickness: 0.1 mm, Nikko Techno, Japan) was used as a macroporous conductive substrate to prepare a gas diffusion electrode composed of WO_3 nanoparticles (Homura et al., 2014; Amano et al., 2017). Ammonium metatungstate hydrate (20.4 g, Nippon Inorganic Colour & Chemical, Japan) and PEG 20,000 (10.0 g, Wako Pure Chemical, Japan) were dissolved in deionized water (40.0 g) as a solution for dip coating of the Ti microfiber felt. The dip coating process was performed three times. The precursor-coated Ti microfiber felt was dried at 353 K and calcined in air at 923 K for 2 h to achieve crystallization of WO_3. If required, the obtained WO_3/Ti fiber electrode was treated with a Nafion® perfluorosulfonic acid (PFSA) ionomer dispersion (5 wt% in mixture of lower aliphatic alcohols and water, contains 45% water, Sigma-Aldrich Japan, Japan) as a proton-conducting polymer. The dispersion was dropped on the electrode (10 μL cm^{-2}), and the wetted electrode was dried at 353 K. The loading amount of the Nafion ionomer was ∼0.6 mg cm^{-2}.

Preparation of Membrane Electrode Assembly

A carbon black-supported platinum nanoparticles (Pt/CB) was used as a cathode catalyst for H_2 evolution. A cathode catalyst ink was prepared by ultrasonication of a mixture of a Pt/CB (TEC10E50E, Pt loading: 46.6 wt%, Tanaka Kikinzoku Kogyo, Japan) and the Nafion ionomer dispersion. The weight ratio of the Nafion ionomer to Pt was adjusted to 1.0, and the loading amount of platinum was ∼0.1 mg cm^{-2}. The ionomer-mixed Pt/CB film and the WO_3/Ti fiber electrode were hot pressed onto a Nafion membrane N117 (thickness: 183 μm, DuPont, USA) at 15 kN and 413 K. The composition of the MEA was "WO_3/Ti fiber | Nafion membrane | ionomer-mixed Pt/CB."

Characterization

Scanning electron microscopy (SEM) observation and energy dispersive X-ray spectroscopy (EDS) analysis were performed on a JSM-7800F microscope (JEOL, Japan). The electrode was directly deposited on carbon tape. High-magnification SEM observation was performed on S-5200 microscope (Hitachi, Japan) with an operating voltage of 5 kV. Before the high-magnification observation, the sample deposited on carbon tape was coated with gold using an E-1030 ion sputter coater (Hitachi, Japan).

Nitrogen adsorption isotherms were recorded at 77 K in the relative pressure range between 0.05 and 0.30 with a BELSORP-mini system (MicrotracBEL, Japan). Before the measurements, the electrode was outgassed at 473 K for 2 h. The Brunauer–Emmett–Teller (BET) equation was used to calculate the surface area of WO_3/Ti fiber electrode. The BET specific surface area of the WO_3 particles was estimated from the measured surface area of the electrode and the loading amount of the WO_3 particles. The BET specific surface area of Ti microfibers was smaller than the measurement limit.

Photoelectrochemical Measurements

The PEC reaction was conducted at room temperature (298 K) and atmospheric pressure (0.1 MPa). The gas-phase water splitting reaction was performed using a dual compartment stainless-steel PEC reactor with an optical window, as shown in **Figure 1**. The compartments were separated by the Nafion membrane. Water vapor (3 vol%) was introduced into each compartment by passing argon at a flow rate of 20 mL min^{-1} through a bubbler filled with deionized water. The electrode area was 25 cm^2, but the light irradiation area was 16 cm^2 owing to the presence of a gold-coated copper plate as the current collector. Photoirradiation was performed using 3 W blue light-emitting diode lamps. The emission was centered at a wavelength (λ) of 453 nm with a full width at half maximum of 22 nm. The optical power was measured to be ~7 mW cm^{-2}. A 300 W xenon lamp with bandpass filters (bandwidth ~10 nm) was used to obtain the action spectrum for the incident photon-to-current conversion efficiency (IPCE), which is the ratio of the number of electric charges to the number of incident photons, as shown in equation (1).

$$\mathrm{IPCE} = (i_{\mathrm{photo}} \times 1240/\lambda)/I_0 \quad (1)$$

where i_{photo} is the steady-state photocurrent density [mA cm^{-2}], $1240/\lambda$ is the monochromatic photon energy [eV], and I_0 is the power of the incident monochromatic light [mW cm^{-2}]. The Faraday efficiency (FE), also known as the current efficiency, was calculated from the ratio of the electric current required for the formation of a product to the total electric current, as shown in equation (2).

$$\mathrm{FE} = (n_{\mathrm{e}} \times F \times r(x))/i_{\mathrm{photo}} \quad (2)$$

where n_{e} is the number of electrons required to form a product, F is the Faraday constant, and $r(x)$ is the formation rate of product x. The amounts of evolved O_2 and H_2 were analyzed using an online gas chromatograph equipped with a thermal conductivity detector and an MS-5A column with argon as the carrier gas. The n_{e} values of H_2 and O_2 are 2 and 4, respectively.

An H-type dual compartment glass reactor was used for the PEC measurements of small area electrodes (light irradiation area: 1 cm^2). The compartment separated by the Nafion membrane was filled with 3 vol% H_2O vapor in argon or an aqueous electrolyte of 0.1 mol L^{-1} sulfuric acid (pH = 1). A silver/silver chloride (Ag/AgCl) reference electrode (+195 mV vs. the standard hydrogen electrode) was used in the three-electrode configuration. The Nernst equation [equation (3)] can be used to convert the electrode potential vs. Ag/AgCl ($E_{\mathrm{Ag/AgCl}}$) to the potential vs. the reversible hydrogen electrode (E_{RHE}).

$$E_{\mathrm{RHE}} = E_{\mathrm{Ag/AgCl}} + 0.059\mathrm{pH} + 0.195 \quad (3)$$

RESULTS

Preparation of the Ionomer-Coated WO_3 Photoelectrode

To allow for gas diffusion and ion transport, the PEM-based PEC cell for gaseous reactants requires a three-dimensional porous electrode rather than a conventional planar dense electrode. We used a titanium microfiber felt that has a high porosity (67%) owing to its three-dimensional fibrous structures with diameters of 20 μm (Amano et al., 2017). The specific surface area of the Ti microfiber felt with a thickness of 0.1 mm was ~450 cm^2 g^{-1}, which is 90 times larger than that of a conventional two-dimensional Ti sheet with a thickness of 1.0 mm (5 cm^2 g^{-1}). The formation of a highly crystalline monoclinic WO_3 phase was confirmed by X-ray diffraction and Raman spectroscopy (Amano et al., submitted). The loading amount of WO_3 was 13 mg cm^{-2}, which corresponds to 27 wt% in the WO_3/Ti fiber electrode. SEM images of the WO_3/Ti fiber after gold sputtering (**Figure 2A**) revealed that monoclinic WO_3 formed nanoparticles with particle diameters of ~100 nm. The BET specific surface area of the WO_3 particles was measured to be 7.5 m^2 g^{-1}, which corresponds to the average diameter of 110 nm assuming that each particle was a sphere. The estimated particle size was similar to that of the WO_3 particles observed in SEM images. The PEC performance for water oxidation was tested in a conventional aqueous electrolyte solution (phosphate buffer, pH = 2.2). The performance of the WO_3/Ti fiber electrode was superior to that of a WO_3 particle electrode obtained by deposition of WO_3 nanoparticles on a two-dimensional substrate such as transparent conductive oxide-coated glass and a titanium sheet (Amano et al., 2017). The IPCE of the WO_3/Ti fiber electrode was ~60% at 1.0 V vs. Ag/AgCl under UV irradiation, and the FE of O_2 evolution was higher than 70%.

A Nafion ionomer dispersion was cast on the high-surface-area WO_3 nanoparticle electrode. **Figure 2B** shows a high-magnification SEM image of the WO_3/Ti fiber electrode after gold sputtering. The sputtered gold nanoparticles were clearly observed in the case of the ionomer-coated WO_3/Ti fiber, suggesting that the Nafion ionomer thin film induced the heterogeneous nucleation of the gold nanoparticles. This phenomenon would be a useful method to visualize the Nafion ionomer thin film in SEM observation. We found that the thin film covered the WO_3 particles, with some of the ionomer aggregated at the grain boundary. The thickness of the ionomer thin film was estimated to be ~3 nm by using the specific gravity of the Nafion membrane (1.98) assuming that the thin layer uniformly covers the surface of the WO_3 nanoparticles. EDS elemental analysis confirmed an increase in the content of carbon and fluorine after ionomer coating. The fluorine mapping shows that the ionomer was dispersed on the macroporous electrode, with some of the ionomer segregated in the void spaces of the Ti microfibers (**Figure 2C**). The ionomer-coated WO_3/Ti fiber photoanode (5 × 5 cm^2) and an ionomer-mixed Pt/CB cathode (5 × 5 cm^2) were pressed on both sides of a Nafion membrane (8 × 8 cm^2) to fabricate an MEA for a large stainless-steel PEC reactor (irradiated area: 16 cm^2).

Gas-Phase Water Splitting in the PEM-PEC Reactor

Figure 3A shows the photoresponse of the WO_3/Ti fiber photoanode with and without the ionomer in an argon flow with 3 vol% H_2O vapor (relative humidity: ~90%) under chopped

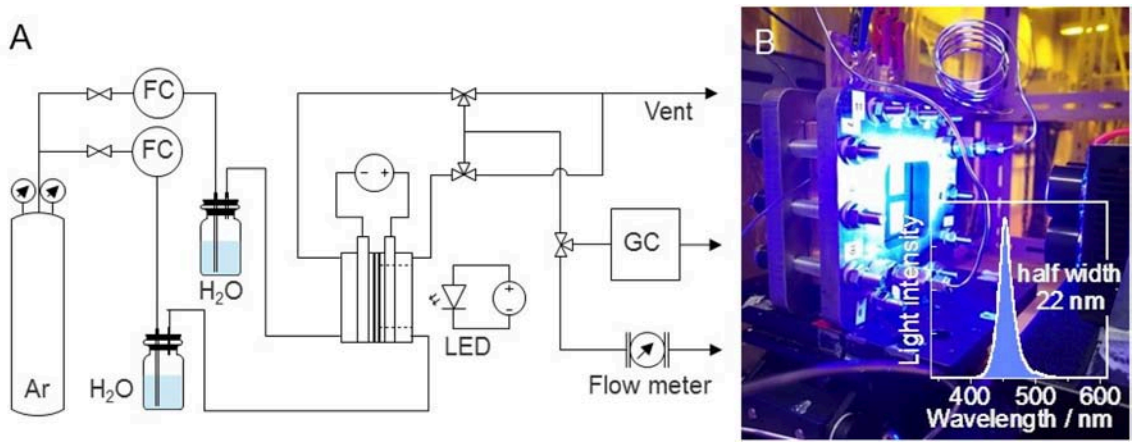

FIGURE 1 | Process flow for photoelectrolysis of water vapor (FC, flow controller; LED, light-emitting diode; GC, gas chromatograph). **(B)** Photograph of the photoelectrolyzer and blue LED (inset: spectrum of the blue light, centered at 453 nm).

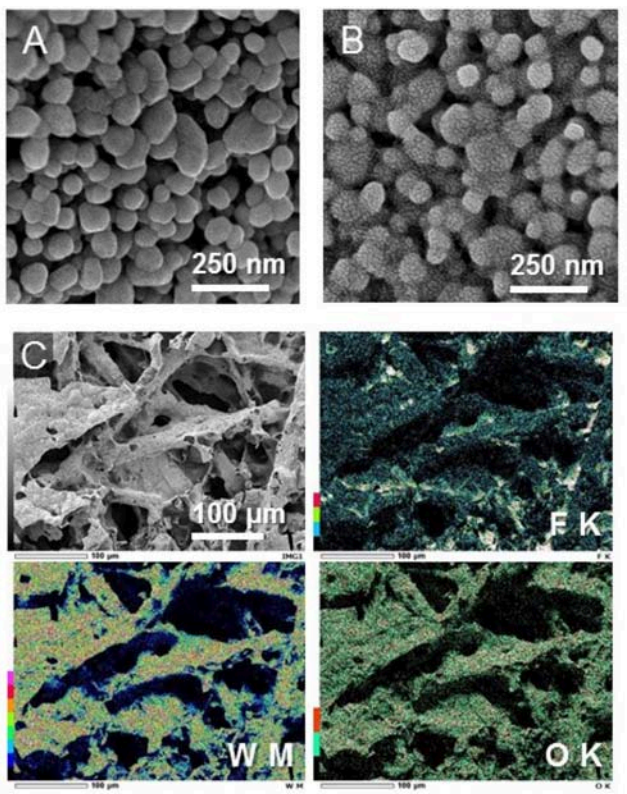

FIGURE 2 | SEM images of **(A)** the bare WO_3/Ti fiber electrode and **(B)** the ionomer-coated WO_3/Ti fiber electrode. The images were obtained after sputtering with gold. **(C)** EDS mapping images for F, W, and O elements of the ionomer-coated WO_3/Ti fiber electrode.

visible-light irradiation ($\lambda = 453$ nm). The two compartments of the large PEM-PEC cell were pre-purged with water vapor for more than 1 h. The applied voltage corresponds to the potential difference between the WO_3/Ti fiber photoanode and the ionomer-mixed Pt/CB cathode. The WO_3/Ti fiber electrode without the ionomer coating exhibited small photocurrent and a slow photoresponse during the gas-phase PEC measurements. The photocurrent was significantly decreased compared with that observed for the PEC performance test in a conventional aqueous electrolyte solution. In contrast, the ionomer-coated WO_3/Ti fiber electrode showed an increased photocurrent response in the gas-phase PEC measurements. The photocurrent at applied voltages higher than 0.2 V quickly increased when the UV light was turned on, and quickly decayed to the dark current level when the light was turned off. Thus, we found that the photoresponse of the WO_3/Ti fiber photoanode was accelerated by the Nafion ionomer coating, indicating that the electron transfer from water to WO_3 was accelerated. **Figure 3B** shows the time course of the photocurrent at 1.2 V. A Faraday current was not observed at steady state in the dark. The IPCE at 1.2 V was 7.6% for the ionomer-coated WO_3/Ti fiber photoanode, but the IPCE was only 3.8% in the absence of the ionomer coating. Moreover, an anodic current owing to water vapor oxidation was observed only under photoirradiation. Thus, the Nafion ionomer coating enhanced the steady-state photocurrent of the WO_3/Ti fiber electrode.

Figure 4 shows the outcome of the visible-light-induced gas-phase water-splitting reaction in the PEM-PEC reactor. The applied voltage was set to 1.2 V, which is less than the thermodynamic minimum voltage required for water electrolysis at room temperature (1.23 V). The reaction was repeated twice to check the evolved gasses in the photoanode and cathode compartments individually. In the first run, we analyzed the gas evolved from the cathode compartment. We detected continuous H_2 formation over the ionomer-mixed Pt/CB catalyst cathode when the photoanode was irradiated with blue light. The H_2 production rate in the cathode compartment was consistent with half of the electron flow in the outer circuit ($e^-/2$). The FE of H_2 evolution was close to 100%, assuming a two-electron reaction ($2H^+ + 2e^- \rightarrow H_2$). This result indicates that the photoexcited

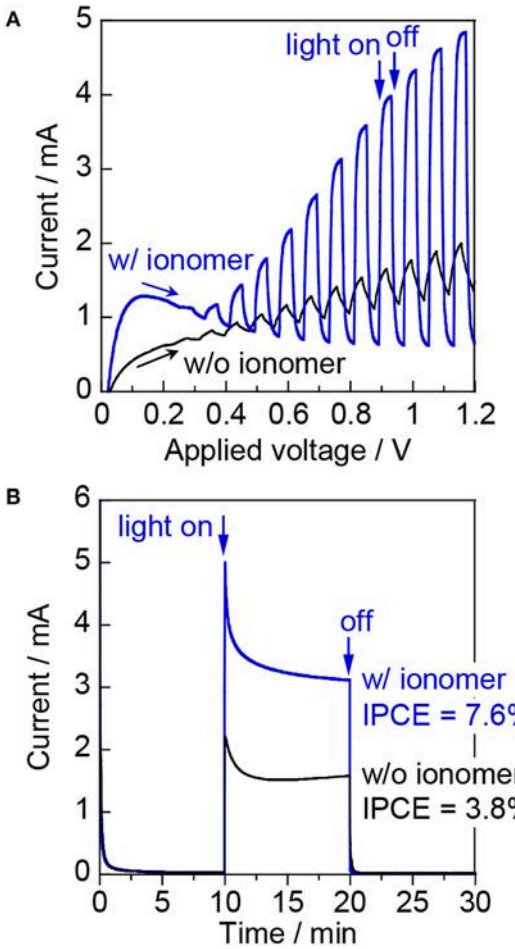

FIGURE 3 | (A) Linear sweep voltammetry curves at a scan rate of 20 mV s^{-1} under chopped irradiation (2 s intervals) and **(B)** current–time curves at an applied voltage of 1.2 V for WO_3/Ti fiber electrodes with and without the Nafion ionomer coating. Reaction conditions: 453 nm blue light, irradiance: 6.8 mW cm^{-2}, photoirradiation area: 16 cm^2, Ar/H_2O = 97/3, flow rate to each electrode: 20 mL min^{-1}.

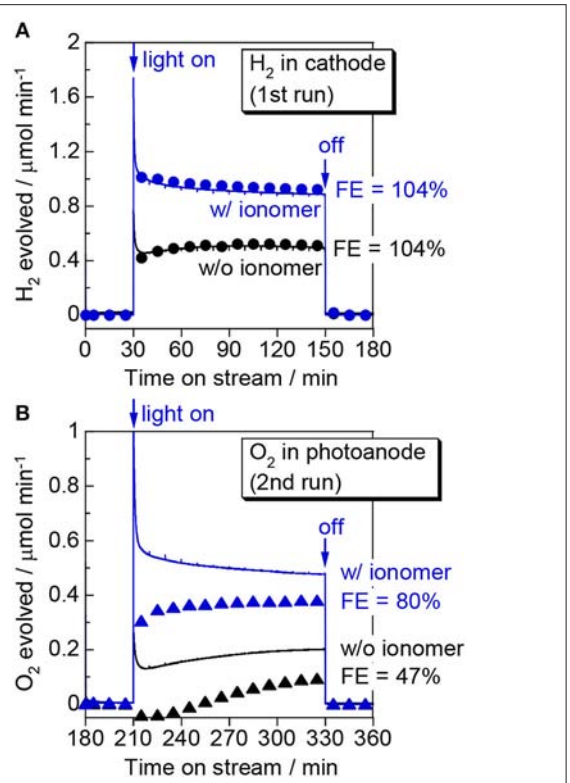

FIGURE 4 | Time course of **(A)** H_2 evolution in the first run and **(B)** O_2 evolution in the second run during gas-phase water splitting over WO_3/Ti fiber photoelectrodes with and without a Nafion ionomer coating. We measured the H_2 evolved in the cathode compartment in the first run and the O_2 evolved in the photoanode compartment in the second run. The symbols show the product formation rate determined by gas chromatography and the curves show the electron flow passing through the outer circuit ($e^-/2$ for H_2 and $e^-/4$ for O_2). Reaction conditions: 453 nm blue light, irradiance: 6.8 mW cm^{-2}, photoirradiation area: 16 cm^2, applied voltage: 1.2 V, Ar/H_2O = 97/3, flow rate to each electrode: 20 mL min^{-1}, temperature: 298 K, pressure: 0.1 MPa.

electrons in the conduction band of WO_3 are transported via the outer circuit to the counter electrode to reduce protons and evolve H_2. The visible-light-induced H_2 production rate was ~1.0 μmol min^{-1}.

In the second run, we analyzed the gas in the photoanode compartment. Although we confirmed that O_2 evolution occurred under photoirradiation, the O_2 formation rate was less than a quarter of the electron flow ($e^-/4$). It should be noted that the formation rate shows a net increase of O_2 because a small amount of O_2 was mixed in the flow from the ambient air. When the light was turned on, we observed an initial decrease in the O_2 concentration for the bare WO_3/Ti fiber photoanode, likely because the O_2 contaminant was consumed by a process such as photoabsorption under photoirradiation. The O_2 evolution rate gradually increased with the PEC reaction, but the FE of O_2 evolution was only 47%, even just before turning off the light. As the FE was calculated by assuming that four electrons are required for the O_2 evolution reaction, an FE of <100% indicates the presence of byproducts such as hydrogen peroxide in the photoanode compartment. The formation of hydrogen peroxide via a reaction requiring two electrons was reported for a PEC reaction over a WO_3 photoanode in an aqueous electrolyte (Santato et al., 2001). In contrast, the Nafion ionomer coating significantly enhanced the FE of O_2 evolution up to 80%. This result suggests that the proton-conducting thin film promoted the four-electron water oxidation reaction to evolve O_2. The visible-light-induced O_2 production rate with this electrode was ~0.4 μmol min^{-1} at an IPCE of 7.5% at 1.2 V.

Figure 5 shows a proposed schematic mechanism for water vapor oxidation over the ionomer-coated WO_3/Ti fiber photoanode. The O_2 evolution reaction ($2H_2O \rightarrow O_2 + 4H^+ + 4e^-$) is recognized as a proton-coupled electron transfer process (Surendranath et al., 2010; Warren et al., 2010). Photocatalysis processes over TiO_2 and ZnO have also been confirmed as proton-coupled electron transfer reactions (Schrauben et al., 2012). The photogenerated holes in the valence band induce

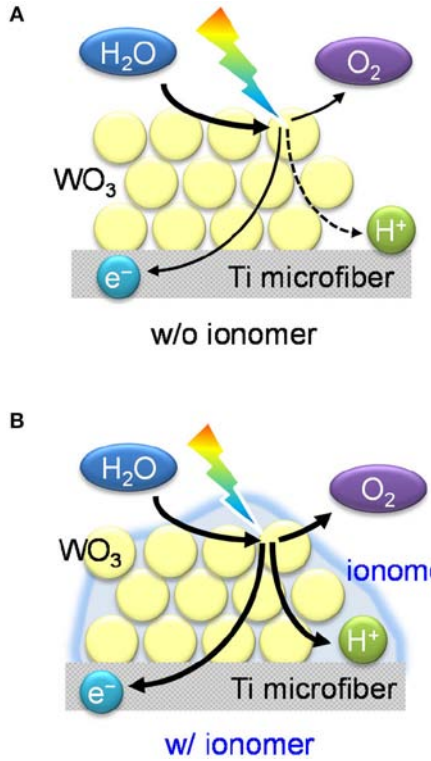

FIGURE 5 | Schematic illustrations of **(A)** the interfaces of the WO_3/Ti fiber electrode without the ionomer coating and **(B)** the photoelectrochemical triple phase boundary of the ionomer-coated WO_3/Ti fiber electrode.

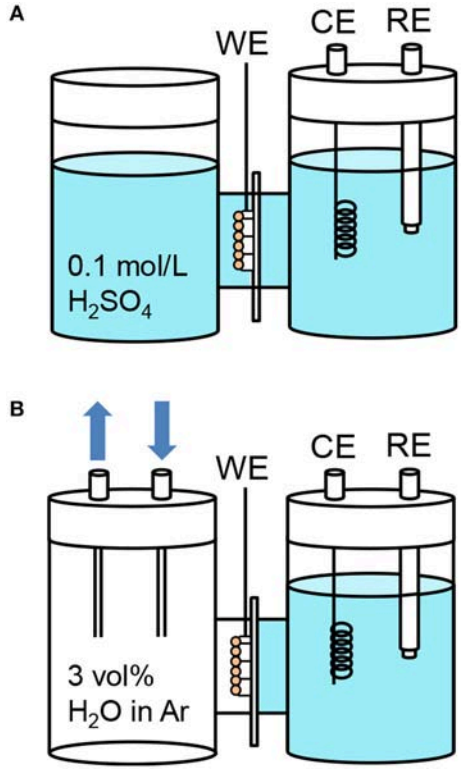

FIGURE 6 | Schematic illustrations of the H-type dual compartment glass reactors used for testing the PEC performance of **(A)** "liquid | solid | liquid" interfaces and **(B)** "gas | solid | liquid" interfaces in the three-electrode configuration. (WE: 1 cm^2 working electrode pressed on a Nafion membrane, CE: Pt counter electrode, RE, Ag/AgCl reference electrode). The gas flow was argon with 3 vol% water vapor. The aqueous electrolyte was 0.1 mol L^{-1} sulfuric acid (pH =1).

four-electron oxidation of water to evolve O_2. The concerted transfer process enhances the reaction rate because the transfer of multiple electrons and protons at the same time avoids the formation of the high-energy intermediates obtained during stepwise reactions. However, proton transfer at the gas–solid interface will be difficult in the absence of an aqueous electrolyte, which acts as an ion conductor. Therefore, the proton-coupled electron transfer is the rate-determining step of water vapor oxidation over the bare WO_3/Ti fiber electrode. However, we found that the proton-conducting ionomer thin film promotes the gas-phase PEC reaction over the WO_3/Ti fiber electrode. These results clearly indicate the importance of the gas–electrolyte–solid triple phase boundary for the PEC water vapor splitting reaction.

PEC Measurements in the Three-Electrode Configuration

We aimed to investigate the role of the triple phase boundary on the gas-phase PEC reactions. A small H-type glass cell (irradiated area: 1.0 cm^2) was used to compare the PEC performance under different conditions. **Figure 6** shows the setup for the PEC measurements in the three-electrode configuration using a platinum wire counter electrode and a Ag/AgCl reference electrode. The two compartments were separated by a Nafion membrane. We filled the cathode compartment with an aqueous electrolyte to maintain electrical neutrality between the membrane, the counter electrode, and the reference electrode. The WO_3/Ti fiber photoanode, which was in contact with the Nafion membrane, was exposed to the other compartment. We investigated two different photoanode conditions. In the first, the photoanode was immersed in an aqueous electrolyte (**Figure 6A**), whereas in the second, the photoanode was exposed to an argon flow with 3 vol% water vapor (**Figure 6B**). These setups are denoted as "liquid | solid | liquid" and "gas | solid | liquid" interfaces, respectively.

Figure 7A shows the photocurrent density at 1.0 V vs. Ag/AgCl for the "liquid | solid | liquid" interfaces. The photocurrent exhibited by the bare electrode was higher than that of the ionomer-coated electrode during the liquid-phase water splitting reaction. This observation indicates that the Nafion ionomer coating retards the oxidation of water, probably by interrupting water adsorption and/or O_2 desorption on the WO_3 surface. **Figure 7B** shows the photocurrent density at 1.0 V vs. Ag/AgCl for the "gas | solid | liquid" interfaces. The IPCE decreased from 28.1 to 10.7% when the photoanode cell was changed from the liquid phase to the two-phase environment. This decrease indicates that the penetration of

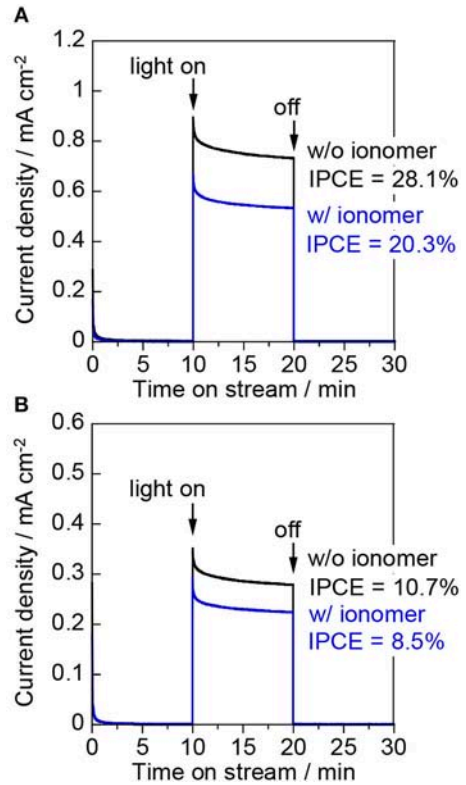

FIGURE 7 | Current–time curves of **(A)** the "liquid | solid | liquid" interfaces and **(B)** the "gas | solid | liquid" interfaces at an applied potential of 1.0 V vs. Ag/AgCl in a three-electrode configuration. The working electrodes were WO_3/Ti fiber electrodes with and without a Nafion ionomer coating. The irradiation source was 453 nm blue light.

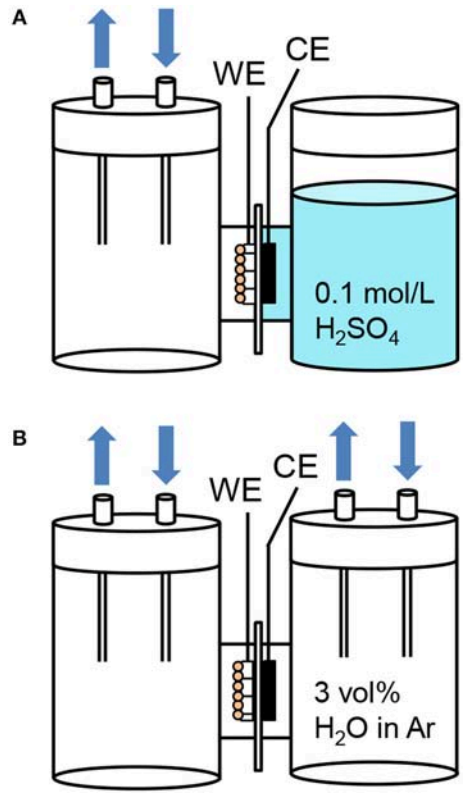

FIGURE 8 | Schematic illustrations of the H-type dual compartment glass reactors using for testing the PEC performance of **(A)** "gas | solid | liquid" interfaces and **(B)** "gas | solid | gas" interfaces in the two-electrode configuration. the aqueous electrolyte into the interconnected mesopores of the WO_3 nanoparticles is very important for enhancing the proton-coupled electron transfer process during water oxidation. The photocurrent of the bare electrode decreased more than that of the ionomer-coated electrode when the liquid phase was changed for the two-phase environment. However, the photocurrent of the bare electrode was still higher than that of the ionomer-coated electrode. This is because the Nafion membrane remained fully hydrated when one part of it was in contact with the aqueous electrolyte in the other compartment. Therefore, the bare WO_3 electrode was also coated with a thin layer of the aqueous electrolyte because it was in contact with the wetted Nafion membrane.

PEC Measurements in the Two-Electrode Configuration

We further investigated the PEC performance of the WO_3/Ti fiber photoanodes in the two-electrode configuration to compare two different cathode conditions as shown in **Figure 8**. The ionomer-mixed Pt/CB film was used as a counter electrode in place of the platinum wire in the three-electrode configuration. The WO_3/Ti fiber and the ionomer-mixed Pt/CB film were in contact with a Nafion membrane. For the "gas | solid | liquid" interfaces, the WO_3/Ti fiber photoanode was exposed to the gas phase and the ionomer-mixed Pt/CB cathode was immersed in an aqueous electrolyte (**Figure 8A**). For the "gas | solid | gas" interfaces, both the photoanode and the cathode were exposed to the gas phase (**Figure 8B**). The electrode potential of 1.0 V vs. Ag/AgCl at pH = 1 corresponds to 1.25 V vs. RHE. Therefore, we set the applied voltage to 1.20 V in the two-electrode configuration.

Figure 9A shows the results for the "gas | solid | liquid" interfaces in the two-electrode system. The photocurrent densities at an applied voltage of 1.2 V were similar to those at 1.0 V vs. Ag/AgCl in the three-electrode configuration. This result indicates that the cathodic polarization distributed from the applied voltage was small on the ionomer-mixed Pt/CB catalyst electrode owing to the low overpotential for the H_2 evolution reaction. The performance of a polymer electrolyte fuel cell is significantly increased by a good network of the perfluorosulfonate ionomers contacting with Pt nanoparticles (Uchida et al., 1995). The ionomer is also necessary to prepare the viscous catalyst ink for the Pt/CB catalyst layer with good bonding. **Figure 9B** shows the photocurrent density at the "gas | solid | gas" interfaces in the two-electrode system. The IPCE of the bare WO_3/Ti fiber decreased from 8.2 to

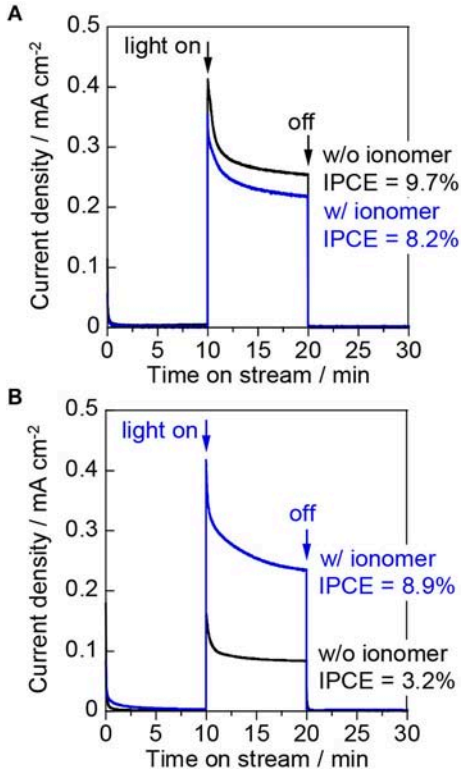

FIGURE 9 | Current–time curves of **(A)** the "gas | solid | liquid" interfaces and **(B)** the "gas | solid | gas" interfaces at an applied voltage of 1.2 V in the two-electrode configuration. 3.2% by changing from the two-phase condition to the gas-phase condition. In contrast, the photocurrent densities of the ionomer-coated WO_3/Ti fiber were the same for the "gas | solid | liquid" and the "gas | solid | gas" interfaces. As a result, the IPCE of the ionomer-coated WO_3/Ti fiber was 180% higher than that of the bare WO_3/Ti fiber electrode in the gas-phase PEC reaction.

Figure 10 shows the IPCE action spectrum of the ionomer-coated WO_3/Ti fiber electrode in the "gas | solid | liquid" interfaces. A visible-light response was observed at ∼460 nm, which is consistent with the optical band gap of monoclinic WO_3 nanoparticles (2.67 eV) estimated from the Tauc plot of the diffuse reflectance spectrum (Amano et al., 2017). In this study, the photocurrent response was investigated under blue light irradiation at 453 nm, which is very close to the threshold wavelength. This is the reason for the relatively low IPCE values under blue light. We found that the IPCE at 1.0 V vs. Ag/AgCl was higher than 40% under UV irradiation at wavelengths <400 nm. Moreover, the IPCE value was much higher than that of an ionomer-coated TiO_2/Ti fiber (IPCE = 26% at 1.2 V under 365 nm UV irradiation) for gas-phase water oxidation (Amano et al., in press). To the best of our knowledge, this IPCE value is the highest among those reported for photoanodes in PEM-PEC systems.

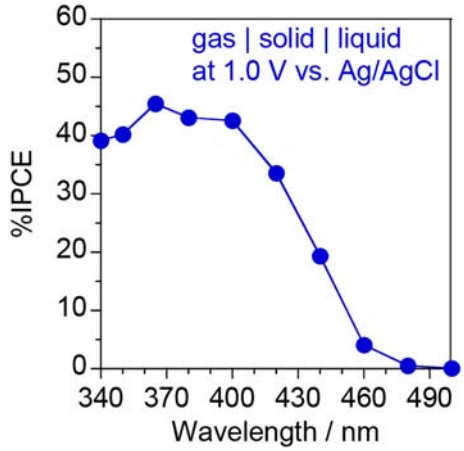

FIGURE 10 | IPCE action spectrum of the ionomer-coated WO_3/Ti fiber photoanode at 1.0 V vs. Ag/AgCl using the "gas | solid | liquid" interfaces shown in **Figure 8A**.

DISCUSSION

We found that a proton-conducting ionomer coating enhanced the PEC oxidation of water in the gas phase, although this effect was not observed in aqueous media. The IPCE of the bare WO_3/Ti fiber decreased from 28.1% in the liquid phase to 9.7–10.7% in the two-phase system and to 3.2% in the gas phase. This behavior indicates that an aqueous electrolyte is essential for PEC reactions that involve proton-coupled electron transfer. In the case of the gas-phase PEC reaction, the hydrated Nafion ionomer thin film plays the role of a solid electrolyte with good proton conductivity at room temperature. The ionomer coating also can absorb water molecules from the gas phase to enhance the hydration of the electrode surface. The Nafion ionomer membrane must be hydrated to maintain the high proton conductivity (Spurgeon and Lewis, 2011). The investigation of the PEC reaction in aqueous media revealed that the ionomer thin film slightly retards the transport of materials, which affects water adsorption and/or O_2 desorption on the WO_3 surface. However, the gas permeability of the thin film is sufficient to create a gas–electrolyte–solid triple phase boundary, where gaseous reactants and products are accessible.

Recently, we found that TiO_2 electrodes without a Nafion ionomer coating exhibit negligible photocurrents for the PEC oxidation of gas-phase water vapor (Amano et al., in press). In contrast, the bare WO_3/Ti fiber electrode exhibited a moderate photocurrent density during the gas-phase PEC reaction. This difference in behavior can be attributed to the proton conductivity of the oxide surfaces. The Nafion ionomer is a perfluorosulfonic acid with strong acidity, and WO_3 is an acidic oxide with an isoelectric point at pH 1.5 (Anik and Cansizoglu, 2006). In contrast, TiO_2 is a neutral oxide with an isoelectric point at pH 5–7 (Maeda and Domen, 2010). Thus, the acidic nature of the WO_3 surface can slightly promote proton transport at room temperature. However, the proton conductivity of the bare electrode was not sufficient for the gas-phase PEC reaction.

The Nafion ionomer coating enhanced the photocurrent density for the oxidation of water vapor to evolve O_2. The FE of O_2 evolution was enhanced to 80%, suggesting that the majority of the photogenerated holes were consumed by a four-electron reaction involving proton-coupled electron transfer.

The fabricated PEM-PEC cell shows a H_2 evolution rate of $\sim$1.0 μmol min^{-1} at 1.2 V under visible-light irradiation (λ = 453 nm, $I_0 = 6.8$ mW cm^{-2}). The rate of H_2 evolution was much higher than that of the previously reported PEM-PEC systems (Stoll et al., 2016, 2017). The IPCE of 40% in the UV range was also the highest value in the gas-phase water photoelectrolysis reaction. This work highlights that the gas–electrolyte–solid triple phase boundary sustained by solid polymer electrolyte plays a significant role in enhancing the photocurrent in the absence of liquid water. To implement solar water splitting technologies, it is necessary to decrease the applied bias voltage and increase the IPCE in the visible light region.

In conclusion, we have successfully fabricated a PEC system consisting of WO_3 nanoparticles for water vapor splitting under visible-light irradiation. A high-surface-area WO_3/Ti fiber gas diffusion electrode was coated with a perfluorosulfonate electrolyte thin film to improve the proton conductivity. Under gas-phase conditions, the ionomer coating significantly enhanced the IPCE as well as the current efficiency of the O_2 evolution reaction by four-electron oxidation of water vapor. The gas–electrolyte–solid triple phase boundary on the high-surface-area photoanode enhanced the extent of proton-coupled electron transfer between the photogenerated holes and the adsorbed water, which was fed from the gas phase. The concept provides insights into the features necessary for successful gas-phase operation, which is a promising approach for low-cost, large-scale H_2 production under solar irradiation.

Templated Growth of Crystalline Mesoporous Materials: From Soft/Hard Templates to Colloidal Templates

Lei Zhang[1,2], *Lei Jin*[2], *Ben Liu*[1]* and *Jie He*[2,3]*

[1] Jiangsu Key Laboratory of New Power Batteries, Collaborative Innovation Center of Biomedical Functional Materials, School of Chemistry and Materials Science, Nanjing Normal University, Nanjing, China, [2] Department of Chemistry, University of Connecticut, Mansfield, CT, United States, [3] Institute of Materials Science, University of Connecticut, Mansfield, CT, United States

Mesoporous non-siliceous materials, in particular mesoporous transition metal oxides (*m*-TMOs), are of interest due to their fascinating electronic, redox, and magnetic properties for a wide range of applications in catalysis and energy storage. Control of the porosity (e.g., pore size, wall thickness, and surface area) and the crystalline degree (e.g., phase composition, crystallinity, and crystal grain size) of *m*-TMOs are critical for those applications. To crystallize TMOs, high temperature annealing is often needed to remove the amorphous defects and/or tune the compositions of different crystalline phases. This has brought many challenges to surfactant or block copolymer templates used in the process of evaporation-induced-self-assembly to prepare *m*-TMOs. In this review, we summarize the most recent achievements including the findings in our own laboratory on the use of organosilicate-containing colloids for the templated growth of mesoporous materials. We review a few key examples of preparing crystalline mesoporous oxides using different templating methods. The colloidal templating method by which mesoporous nanostructures can be stabilized up to 1,000°C is highlighted. The applications of *m*-TMOs and meso metal-oxide hybrids synthesized using organosilicate-containing colloidal templates in photocatalysis and high-temperature catalysis are also discussed.

INTRODUCTION

Mesoporous materials are porous materials with periodically ordered pores in the range of 2∼50 nm. They have large accessible surface areas and tunable pore sizes, which are of particular benefit for mass transport and dispersion of electrons/reactants. Therefore, mesoporous materials show great potential in electrocatalysis (Wu et al., 2012; Ren et al., 2013; Xin et al., 2018), photocatalysis (Li et al., 2007; Onozuka et al., 2012; Joo et al., 2013; Liu et al., 2015b) and energy storage, and conversion (Li et al., 2015, 2016; Fang et al., 2016; Le et al., 2017). Since ordered mesoporous silica such as MCM-41 were discovered in 1992 (Kresge et al., 1992), extensive efforts have been devoted to the development of many other mesoporous silica such as SBA-15/16 (Zhao et al., 1998a,b; Sakamoto et al., 2000), KIT-6 (Kleitz et al., 2003), AMS (Qiu and Che, 2011; Han and Che, 2013), and FDU-12 (Fan et al., 2003, 2005). These mesoporous silica with ordered and

interconnected nanopores as well as excellent thermal stability have been broadly used as support for metal nanocatalysts. Other than mesoporous silica, there has been a substantial amount of interest in mesoporous transition metal oxides (*m*-TMOs) due to their unique *d*-shell electrons, resulting in a redox active surface on top of the nanosized pores (Schüth, 2001). Compared to amorphous mesoporous silica, *m*-TMOs exhibit enhanced electronic and optical properties (Kondo and Domen, 2008), which have been proven to be essential in the applications such as photocatalysis (Kuo et al., 2015; Liu et al., 2015b), electrocatalysis (Burke et al., 2015; Song et al., 2018), and battery materials (Su et al., 2016; Zheng et al., 2018).

The crystallinity of *m*-TMOs is of critical importance for some of their applications. Since high-temperature annealing is the most common way to increase the crystallinity and tune the crystalline phases of *m*-TMOs (Lee et al., 2008; Zhang et al., 2010; Liu et al., 2015b), how to stabilize porous frameworks under high temperature is the key to producing highly crystalline *m*-TMOs. Using photocatalysis as an example, TiO_2 is one of the most well-studied photocatalysts. The low-crystalline TiO_2 with amorphous domains is known to effectively trap photo-excited electrons and holes that lower the overall utilization of photoexcitation (Ohtani et al., 1997). TiO_2 has two common crystalline structures, including rutile and anatase. As a photocatalyst, anatase shows much better activity compared to rutile. Interestingly, TiO_2 with mixed phases outperforms both pure phases (Cong and Xu, 2011; Zhao et al., 2013; Siah et al., 2016). P25 (Degussa) consisting of ∼80% of anatase and ∼20% of rutile has often been used as a benchmark TiO_2 photocatalyst. Since there is a type II band alignment of ∼0.4 eV (the energy of valance band) (Scanlon et al., 2013), TiO_2 with a mixture of phases shows enhanced charge separation efficiency at the interface of rutile and anatase (Kawahara et al., 2002; Miyagi et al., 2004). Converting anatase or non-crystalline to rutile TiO_2 requires high-temperature annealing, e.g., at 800°C, although the rutile TiO_2 is more stable. When the annealing is carried out in a mesoporous TiO_2, the collapse of the porous framework occurs before the phase transition due to the overgrowth of crystal grains (Schüth, 2001; Yun et al., 2001). Another example is the formation of crystalline mixed oxides in order to control the optical properties. Carter et al. have proposed the MnO:ZnO alloys that potentially shift the band energy of MnO dramatically (Kanan and Carter, 2012, 2013). MnO as an n-type semiconductor has a large bandgap of 4.0 eV but, when forming alloys with ZnO, its band energy can be shifted largely to a bandgap of 2.6 eV, which is potentially useful for photocatalytic water splitting or CO_2 reduction. The formation of mixed oxides of MnO:ZnO needs high-temperature treatment at 700°C (Song et al., 2015). The synthesis of such binary or ternary oxides (e.g., copper tungstate and perovskites) in mesoporous form will be very difficult because of the poor thermal stability of porous frameworks. Overall, the control of crystallinity and crystal phases is critical in tuning the physicochemical properties of *m*-TMOs.

In this review, we summarize the synthetic methods in recent years for the preparation of highly crystalline *m*-TMOs. The synthesis will be discussed by classifying the synthetic methods based on the templates (**Figure 1**), including hard templates, soft templates, and colloidal templates. There are a number of excellent review papers on the synthesis of mesoporous materials such as TiO_2 (Li et al., 2013), non-siliceous oxides (Gu and Schuth, 2014), and metal oxides (Ren et al., 2012) by mainly soft-templating and hard-templating methods. We intend to highlight a few key examples in control of the crystallinity of *m*-TMOs by different methods, with a focus on the findings in our own laboratory on the use of organosilicate-containing colloids for the templated growth of mesoporous materials. The applications of colloidal-templated porous oxides and metal-oxide hybrids in photocatalysis will be included. At the end of this review, we include a short perspective in this area. We hope that this review will help readers to understand the challenges and solutions in the rational design and application of crystalline *m*-TMOs.

HARD-TEMPLATING METHOD

The hard-templating method, also known as nanocasting, provides the most accessible strategy to synthesize crystalline mesoporous materials. Nanocasting is to make use of a rigid mold with defined porous structures on the nanometer scale where the target materials or their precursors are added to fill the pore of the mode, and the primary mold is subsequently removed after the formation of target materials (Lu and Schüth, 2006). In detail, nanocasting of *m*-TMO includes three steps: (1) synthesis of mesoporous replicas (e.g., silica, carbons, and aluminates); (2) infiltration of metal precursors and further decomposition to form crystalline materials; and (3) removal of the hard template to release the pores. Upon removal of the mold, the yielded *m*-TMO will replicate the complementary mesostructures of the hard template. For instance, silica templates equipped with ordered cylindrical channels can produce nanowires or nanoarrays (Lu and Schüth, 2005), while the template with spherical pores can prepare the nanosphere arrays (Lu and Schüth, 2006), and the template with bicontinuous pores results in bicontinuous mesostructured duplicates with periodically and helically twisted nanowires (Yang and Zhao, 2005). The framework thickness of the mesoporous silica is usually in the range of 2–11 nm; thus, the pore size of derived replicas of *m*-TMO is also in the same range (Schüth, 2001).

Ideally, all crystalline mesoporous materials can be synthesized using the hard-templating method if the corresponding metal precursors can be filled into the pore of the mold. So far, among numerous hard templates, mesoporous silica (e.g., SBA-15 and KIT-6) are commonly used for the preparation of mesoporous materials due to their diverse pore architectures and extremely uniform pore size/size distribution. SBA-15 has uniform hexagonal pores with the pore diameter in the range of 5–15 nm (Zhao et al., 1998a,b; Sakamoto et al., 2000). KIT-6 shows a bicontinuous structure as a gyroid cubic symmetry Ia3d with a pore diameter in the range of 4–12 nm (Kleitz et al., 2003). When using mesoporous silica as a template, the removal of silica to release the pore usually relies on the etching by concentrated NaOH or HF. One can also consider the use of mesoporous carbon as a template to prepare *m*-TMO, where the carbon template can simply be oxidized by low-temperature annealing

in air (Lu et al., 2002; Roggenbuck and Tiemann, 2005; Polarz et al., 2007; Liang et al., 2008).

Given the hard templates that can support and confine the grain growth of TMOs, the crystalline phases and pore features of metal oxides can be rationally designed. Taking manganese oxides as an example, Bruce's group synthesized mesoporous β-MnO_2, Mn_2O_3, and Mn_3O_4 by high-temperature calcination at different temperatures or in the assistance of H_2, using KIT-6 as the hard template (Jiao and Bruce, 2007; Jiao et al., 2007). All the materials possessed similar mesoporous frameworks and well-controlled crystalline phases of Mn oxides (**Figures 2A–C**). Similarly, iron oxides (Jiao et al., 2006) and cobalt oxides (Jiao et al., 2005a) with different crystalline phases were also obtained using the same strategy (Ren et al., 2009). Furthermore, bicontinuous mesoporous nanochannels of KIT-6 can also be utilized to tailor the final porosity of the materials. By selectively filling in different sets of nanochannels, mesoporous oxides with different pore sizes and even pore hierarchies (macropore, mesopore, and micropore) were successfully synthesized (**Figures 2D–F**) (Ren et al., 2013). The hard-templating synthesis of mesoporous materials is also extendable to metal sulfides and phosphides (Fu et al., 2016; Jin et al., 2017).

The hard-templating method shows limited control over the mesoporous structures but, in KIT-6 template, the distribution, and adjustable ratio of the two different pores can be achieved by hydrothermal synthetic conditions (**Figure 3**) (Jiao et al., 2008; Ren et al., 2010). Using mesoporous NiO as an example, an alcoholic solution of $Ni(NO_3)_2$ was mixed with KIT-6 and then redispersed in hexane to achieve a very high degree of pore filling. Followed by calcination at 550°C and removal of KIT-6 via etching with NaOH, mesoporous NiO with a specific surface area of 108.6 m^2 g^{-1} can be synthesized. KIT-6 has two sets of pores

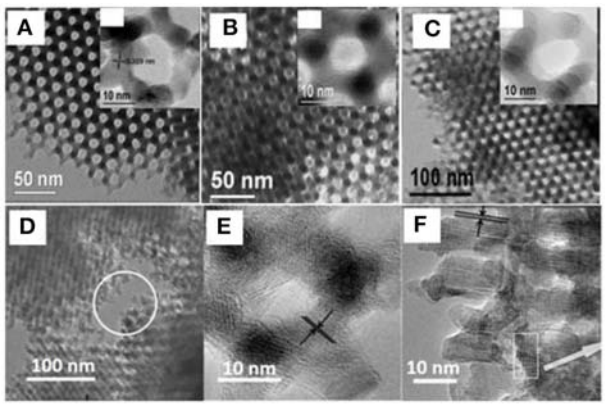

FIGURE 2 | Control of crystallinity and mesostructures of Mn oxides. with bicontinous channels and the development of these channels varies along with the hydrothermal synthetic conditions of KIT-6. At a higher hydrothermal temperature (>130°C), the existence of interconnected porous channels in KIT-6 favors complete growth of NiO across both sets of mesopores, leading to the formation of mesoporous NiO with a pore diameter (∼3.3 nm) similar to the wall thickness of KIT-6 (**Figure 3**). On the other hand, with less interconnected pores at a lower hydrothermal temperature, the growth of mesoporous NiO within only one set of mesopores was observed. The resultant mesoporous NiO has a pore size of ∼11 nm, equivalent to the dimension of two walls plus the pore

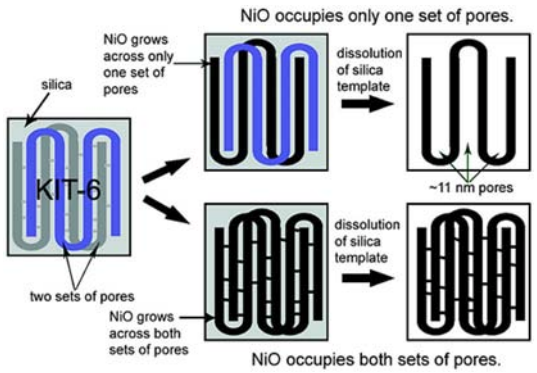

FIGURE 3 | Scheme illustrating the synthesis of *m*-TMO with two pore size distributions by using KIT-6 as the template. Reprinted with permission from Jiao et al. (2008). Copyright 2008 American Chemical Society.

size of KIT-6. Through this method, mesoporous β-MnO_2 and NiO with large (∼11 nm) and small (∼3.3 nm) controllable pore sizes can be prepared.

Using SBA-15 as a template, *m*-TMO with ordered cylindrical channels can be prepared. Zhu et al. reported the highly crystalline Cr_2O_3 using aminopropyl-triethoxysilane (APTS)-modified SBA-15 (Zhu et al., 2003). The formation of crystalline Cr_2O_3 needs calcination of the Cr_2O_3@SBA above 350°C. After the removal of SBA-15, the mesoporous Cr_2O_3 possesses a specific surface area of 58.1 m^2 g^{-1} and an average pore size of 3.4 nm. Other mesoporous *m*-TMOs with cylindrical pores can be prepared through a similar route (Chen et al., 2003; Jiao et al., 2005b; Yue et al., 2005). Our group also demonstrated mesoporous Co_3O_4, NiO, and their binary oxides by using bicontinuous KIT-6 as the template. Through a solid-phase sulfurization method based on sulfur, bicontinuous mesoporous CoS_2, NiS_2, and their binary sulfides can be further synthesized (Jin et al., 2017). When using the double templates, more sophisticated nanostructures can be designed. For example, if coated with thin carbon on the SBA channels first, the further growth of metal oxides will be confined in the hollow carbon nanotubes within SBA-15. Zhao et al. showed the synthesis of a mesoporous Co_3O_4@ carbon nanotube using double templates of silica and carbon. The resultant oxide-in-tube nanostructures possess a specific surface area up to 750 m^2 g^{-1} and a controllable size of Co_3O_4 between 3 and 7 nm.

The synthetic challenge of the hard-templating method is to completely fill the pores of the template due to the slow mass transfer at nanoscale (Yang and Zhao, 2005). Mostly, only small pieces of mesoporous replicas can be yielded. Despite functionalized mesoporous templates with binding groups (e.g., $-NH_2$, -OH, $-CH=CH_2$) (Zhu et al., 2003; Tian et al., 2004; Wang et al., 2005), metal precursors still inevitably nucleate and grow in the outside of template pores, in particular under high temperature. Additionally, the pore size of resultant replicas that is determined by the thickness of the framework is usually small and less adjustable in both SBA series and KIT-6. Meanwhile, the nanocasting method is high-cost and time-consuming (Lu and Schüth, 2005, 2006; Yang and Zhao, 2005).

SOFT-TEMPLATING METHOD

The soft-templating method usually uses unrigid nanostructures formed by intermolecular interaction force as templates. Followed by the deposition of inorganic sources on the surface and interior of the unrigid soft templates, the formation of mesostructures with defined pore structures and sizes can occur. Generally, soft templates include soft matter, including organic surfactants and/or block copolymers, that can interact with metal ions and self-assemble into liquid crystal phases to template the sol-gel process. The assembled process between metal ions and soft matter is driven by weak non-covalent bonds, such as hydrogen bonds, van der Waals forces, and electrostatic interaction. In addition, cooperative assembly between metal ions and soft matter is mostly involved in facilitating this process. Mesostructures with open pores can be obtained after the removal of soft template through calcination. The soft-templating method offers a large room of controllability in terms of the pore structures and pore sizes compared to the hard-templating method. The key of the soft-templating method is the control over the sol-gel transition of precursors along the self-assembly of soft templates, i.e., surfactants/block copolymers (Meng et al., 2005; Li et al., 2013; Lokupitiya et al., 2016). By rationally tuning the cooperative assembly between precursors and templates, mesoporous materials can be obtained through either a solution-phase synthesis or evaporation-induced self-assembly (EISA) process. The first report on solution-phase synthesis of mesoporous oxides and phosphates by a similar route for MCM silica was in Huo et al. (1994). Due to the straightforwardness of tunability in size and self-assembled mesophases of surfactants/block copolymer, the soft-templating method has been widely used to tailor the mesoporous sizes and framework nanostructures of *m*-TMOs.

However, it is difficult to release mesopores by removing the surfactant because of the disruption and collapse of these porous frameworks during the crystallization of *m*-TMOs. Ying et al. first reported the ordered mesoporous TiO_2 with open pores using titanium acetylacetonate tri-isopropoxide as Ti precursor and tetradecylphosphate as the template (Antonelli and Ying, 1995). The presence of acetylacetone slowed down the sol-gel transition, which allowed further interaction and co-assembly with Ti and the template. The resultant mesoporous TiO_2 had a surface area of 200 m^2 g^{-1} after calcination. Her group has extended this solution synthetic method to synthesize the ordered mesoporous Nb_2O_5 (Antonelli et al., 1996), VO_x (Liu et al., 1997), and ZrO_2 (Wong et al., 1997; Antonelli, 1999).

Yang and Zhao creatively developed Pluronic polymers (commercial PEO-PPO-PEO triblock copolymers) as soft templates in non-aqueous solution to synthesize a series of mesoporous silica and metal oxide, including TiO_2, ZrO_2, Al_2O_3, Nb_2O_5, Ta_2O_5, WO_3, HfO_2, SnO_2, and mixed oxides $SiAlO_{3.5}$, $SiTiO_4$, $ZrTiO_4$, Al_2TiO_5, and ZrW_2O_8 (Yang et al., 1998, 1999). Pluronic polymers have a long flexible poly(ethylene oxide)

(PEO) chain that can coordinate with transitional metal ions via weak coordination bonds. The absence of water enabled a controllable sol-gel, i.e., hydrolysis and condensation of metal precursors. These resulted in the optimal co-assembly at inorganic/organic interfaces; therefore, Pluronic polymers further templated the growth of a number of *m*-TMOs with periodically ordered mesoporous nanostructures. Through EISA, Sanchez et al. used PEO-based surfactants (e.g., Pluronic F127, Pluronic P123, Brij 56, and Brij 58) as templates to synthesize highly ordered *m*-TMOs (Grosso et al., 2001; Crepaldi et al., 2003). However, since the conventional EISA method usually employed Pluronic polymers as templates, the pore size of *m*-TMOs is usually <15 nm owing to the short hydrophobic PPO segments (Yang et al., 1998). Furthermore, both PEO and PPO polymers are thermally unstable. When annealing those *m*-TMOs to remove the template, the mesoporous nanostructures ineluctably undergo structural reconstruction for crystallization, leading to the overgrowth of crystal grains, and even collapse of mesoporous frameworks (Schüth, 2001; Yun et al., 2001).

More recently, Suib's group has developed a universal strategy to synthesize the thermally stable and crystalline *m*-TMOs (Poyraz et al., 2013). As illustrated in **Figure 4A**, the inverse micelle formed by Pluronic P123 served as a nanoreactor where the positively charged transition metal-oxo clusters were confined via hydrogen bonding interaction. As stabilized by P123, the uncontrolled aggregation of the clusters was reduced and hindered. The addition of 1-butanol, the solvent and interface modifier, further enhanced the physical barrier between the oxo-clusters and prevented condensation. The essential presence of nitric acid in this system enabled the penetration of the positively charged metal-oxo clusters into the micelles, simultaneously increasing the solubility of P123 and hydrating the core. Interestingly, the decomposition of the nitrate ions into nitric oxides (NO_x) played a critical role in the consecutive heat treatment by adsorption onto metal oxo-clusters, therefore impeding the uncontrolled condensation. After the removal of P123 by calcination at different temperatures ranging from 150 to 550°, the *m*-TMOs were readily obtained with tunable pore size distribution. For example, the mesoporous MnO_2 evolved from amorphous materials with higher specific surface area (255 $m^2\ g^{-1}$) and smaller pore size (2 nm) at a low temperature of 150° (**Figures 4B,C**), to the ordered crystalline Mn_2O_3 with lower specific surface area (35 $m^2\ g^{-1}$), and enlarged pore size (12.3 nm) at an elevated temperature of 550° (**Figures 4D,E**). This method allows the general syntheses to a range of *m*-TMOs including nickel, cobalt, iron oxides etc (Poyraz et al., 2013, 2014; Song et al., 2014; Jiang et al., 2015; Wasalathanthri et al., 2015). It is worth mentioning that the series of the *m*-TMOs are highly resistant to elevated temperatures up to 400∼550°, showing superior thermal stability. This unique stable mesoporous structure affords the development of more efficient and heat-tolerant catalysts in high-temperature reactions (Poyraz et al., 2013; Lu et al., 2015; Vovchok et al., 2018).

As mentioned above, the crystallinity of TiO_2 determines the surface amorphous defects that plays a critical role in photocatalysis. The high temperature treatment for a typical *m*-TiO_2 obtained using Pluronic polymers as templates, usually causes structural collapse of the ordered mesoporous frameworks (Schüth, 2001; Yun et al., 2001). To solve the thermal stability challenges in soft-templating, Wiesner's group developed the combined assembly by soft and hard chemistries (so-called CASH, **Figure 5a**) method to fabricate mesoporous metal oxides (*m*-TiO_2 and *m*-Nb_2O_5) with excellent thermal stability and crystallinity (Lee et al., 2008). In the CASH method for the synthesis of *m*-TiO_2 (**Figure 5a**), titanium chloride firstly reacted with titanium isopropoxide to form the metal oxide clusters and corresponding alkyl halide, which was added into the tetrahydrofuran (THF) solution of the block copolymer of poly(isoprene-block-ethylene oxide) (PI-*b*-PEO, $M_n = 27{,}220\ g\ mol^{-1}$). The hydrophilic PEO selectively bound the metal oxide sol, which generated an amorphous hybrid material under evaporation of a PI-*b*-PEO/metal oxide solution in air (the obtained hybrid in **Figure 5b**). Secondly, the as-made PI-*b*-PEO/metal oxide hybrids were annealed at 700°C in argon to achieve the highly crystalline materials. The metal oxide crystals nucleate, grow, and sinter into porous frameworks and PEO was removed by thermal decomposition, while the PI segments can be transformed *in situ* into a carbon scaffold inside the pore channels due to the existence of sp^2 hybridized carbon atoms in the PI segments of PI-*b*-PEO (the TiO_2-C composite in **Figure 5c**). The generated carbon scaffold acts as a hard template *in situ* to prevent the collapse of mesoporous frameworks while crystallizing under high temperature treatment (700°C). Thus this generated highly crystalline TiO_2 (Lee et al., 2008). Finally, the carbon inside TiO_2-C composite could be removed by heating in air, yielding a well-organized, highly crystalline mesoporous TiO_2 (**Figure 5d**) with a pore size of 23.6 nm and a specific surface area of 75 $m^2\ g^{-1}$. Other polymers, like poly(ethylene oxide)-*b*-polystyrene (PEO-*b*-PS), which includes sp^2 hybridized carbon atoms and can be carbonized under inert atmosphere, potentially are useful to obtain highly crystalline *m*-TMOs using the CASH method (Zhang et al., 2011).

Other than carbonization thermally, Zhao's group developed a simple sulfuric acid (H_2SO_4) carbonization method to generate a highly crystalline, ultra-stable ordered *m*-TiO_2 by using Pluronic polymers (P123, F127, and F10) as templates (**Figure 6A**) (Zhang et al., 2010). In the process of EISA with titanium isopropoxide (TIPO), a mixture of HCl, and H_2SO_4 as the acidic catalyst carbonized the polymer template to form amorphous carbon in the original pore channels. The *in situ*-formed carbon templates can stabilize the mesoporous structures during crystallization (650°C) in N_2. After burning off the carbon at 450°C in air, the resultant *m*-TiO_2 with a specific surface area of 193 $m^2\ g^{-1}$ and a pore size of 4.6 nm was generated, which also possessed a high crystallinity of anatase and thermal stability (**Figures 6B,C**). To keep the structural order of *m*-TMOs, Zhou et al. synthesized the well-ordered mesoporous *m*-TiO_2 with improved crystallinity and remarkably thermal stability through the EISA method assisted with encircling ethylenediamine (EN) protectors to retain the mesoporous structure (Zhou et al., 2011). The EN species could tightly interact and bind on the surface of TiO_2 while prohibiting undesirable grain growth and structure transformation during calcination. Thus, the

mesoporous TiO_2 obtained in this method is stable up to 700°C; and it has a specific surface area of 122 m^2 g^{-1} and a pore size of 10 nm.

COLLOIDAL-TEMPLATING METHOD

The examples highlighted in the soft-templating method share a key idea, i.e., to improve the stability of hydrocarbon-based polymer templates and to confine the crystal growth during thermal treatment. Even though the carbonization of polymer templates enhances thermal stability, it is limited to some extent. The carbonized polymer templates require the thermal annealing with extra caution, for example, under inert gas atmosphere and without extremely long annealing time. Otherwise, the carbonized polymer templates can be oxidized, further resulting in the collapse of porous frameworks.

One ultimate solution to the thermal stability of templates is to introduce inorganic components, including inorganic nanoparticles (NPs) or non-hydrocarbon-based elements to polymer templates. Inorganic NPs have an inherently much higher thermal stability compared to organic polymers, while some of non-hydrocarbon-based elements, e.g., Si, can convert into inorganic oxides that are known to be thermally stable

as well. By coupling inorganic templates with polymers, the advantages from soft-templating and hard-templating methods can be said to emerge as the "colloidal-templating" method. Colloidal templates are composed of an inorganic NP core tethered with flexible polymer tails. In view of the topology of colloidal templates, they are extremely like polymer micelles, which have been used in the soft-templating method to grow mesoporous materials (Bastakoti et al., 2014, 2016; Jiang et al., 2017, 2018; Tanaka et al., 2018). In the colloidal-templating method, polymers as soft templates are responsible for coordinating inorganic metal ions to self-assemble into nanostructures, similar to that of the soft-templating method. The inorganic NPs, on the other hand, serve as hard templates to offer thermal stability and nanoconfinement to crystallize the framework under high-temperature annealing. Colloidal templates similar to the surfactants/block copolymers can form periodically ordered nanostructures in the course of sol-gel to fabricate mesoporous materials.

One example of colloidal templates by Dong et al. is to synthesize mesoporous graphene using oleic acid (OA)-capped Fe_3O_4 nanocrystals (Jiao et al., 2015). The self-assembled OA-capped Fe_3O_4 first formed the ordered 3D Fe_3O_4 nanocrystal superlattices. The superlattices were further calcined at 1,000°C under argon. As inorganic components, Fe_3O_4 nanocrystals are thermally very stable with respect to annealing, while OA can be carbonized to form continuous carbon frameworks. Followed by the removal of Fe_3O_4 nanocrystals using HCl, the ordered mesoporous carbon was derived and then transformed into highly ordered mesoporous graphene with *fcc* symmetric mesoporosity. However, such a colloidal template is difficult to extend to the synthesis of *m*-TMO, since mixed metal oxides can be formed under high-temperature annealing.

Organosilicate-containing colloidal templates are also utilized as soft-hard templates to synthesize highly crystalline mesoporous materials, which is largely beyond the capacity of the traditional soft-templating method. It is worth noting that the phase transition of TiO_2 requires high temperature calcination (>800°C). Traditional carbon-based soft templates are unlikely to be stable at such a high temperature to support the mesoporous frameworks. Our group recently developed a new series of colloidal templates consisting of a silica-containing inorganic core and PEO shell (Liu et al., 2015b). The synthesis of such colloidal templates is based on the self-assembly of amphiphilic block copolymers in water (**Figure 7**). Briefly, a diblock copolymer of poly(ethylene oxide)-*block*-poly[3-(trimethoxysilyl)propyl methacrylate] (PEO-*b*-PTMSPMA) can form polymer micelles in the mixture solvent of water and ethanol. The micelles are highly uniform with an average diameter of 25 ± 2 nm. The hydrophobic PTMSPMA block contains trimethoxysilyl moieties that can hydrolyze to form polysilsesquioxane. Upon the addition of transition metal precursors, the coordination interaction between PEO and metal ions, similar to that in the soft-templating method, can result in the co-assembly of colloidal templates with metal precursors along with sol-gel transition during EISA. When annealing at high temperature, the polysilsesquioxane cores of colloidal templates further convert into rigid silica nanoparticles to support the structural integrity of the mesoporous framework, while the PEO will be burned off. Since silica is stable up to an air temperature of 1,000°C, the porous materials can be directly annealed at 1,000°C without disrupting their mesostructures. Therefore, the colloidal-templating method offers an ideal solution to the disadvantages of traditional soft templates, having poor thermal stability, and low mechanical strength.

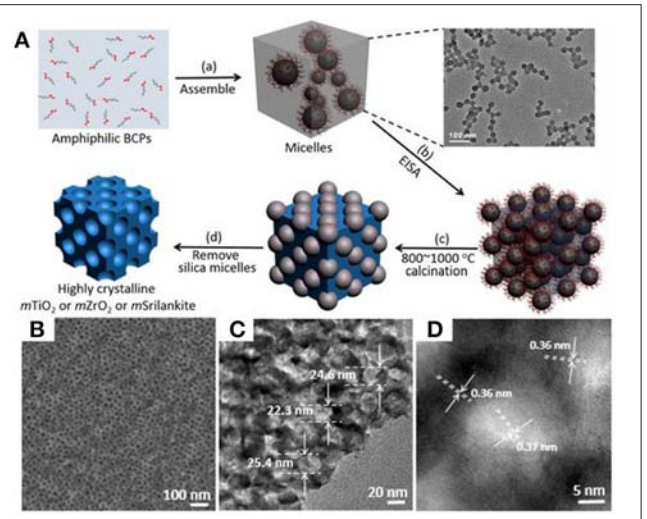

FIGURE 7 | (A) Schematic illustration of highly crystalline *m*-TMOs based on the colloidal amphiphile-templating method. **(B)** SEM, and **(C,D)** TEM images of as-resultant *m*-TiO_2 with uniform mesopores. Using *m*-TiO_2 as an example, our group demonstrated that *m*-TiO_2 synthesized with colloidal templates could be recrystallized at 900°C under air without further pretreatment (**Figure 7B**). *m*-TiO_2 has a pore size of 21 nm and a specific surface area of 54.5 $m^2\ g^{-1}$. Importantly, calcination at 900°C can lead to the formation of TiO_2 with mixed anatase and rutile, similar to that of P25. Crystallization of mesoporous TiO_2 is rationally tailored by calcination temperature or time, which exhibit dramatically enhanced activity toward photocatalysis (discussed below). In addition, the colloidal-templating method can be extended to synthesize the other *m*-TMOs, such as group-V *m*-ZrO_2 and group-IV/group-V mixed transition-metal oxide, $Zr_{0.33}Ti_{0.67}O_2$ (*m*-Srilankite). In particular, highly crystalline *m*-ZrO_2 and *m*-Srilankite with uniform pore sizes can be obtained at 800°C.

Following the similar synthetic strategy, the colloidal templating method can used to prepare mesoporous carbon or TMO supported on carbon. To do so, the colloidal templates can template the oxidative self-polymerization of dopamine to polydopamine (PDA) nanospheres Liu et al. (2017b). In this case, the hydrogen bonds between dopamine with the PEO shell of colloidal templates drive the co-assembly. Since there are abundant functional groups (e.g., catechol and amine) of PDA to strongly coordinate metal ions (e.g., Co^{2+}), the hybrids of PDA, and colloidal templates can physically absorb Co^{2+} ions. When annealing at 650°C under N_2, the PDA backbone could be transformed into hierarchical porous

carbon frameworks by pyrolysis while Co^{2+} ions were reduced metallic Co nanoparticles (2–7 nm) (Liu et al., 2017b). Here, the mechanically strong colloidal templates not only supported the porous carbon frameworks, but also confined the growth of Co NPs to restrain their overgrowth. Our group also extended this universal colloidal-templating method to develop a series of mesoporous hybrid nanostructures of metal-oxides and metal-carbons (Liu et al., 2016, 2017a,b, 2018).

In addition, the use of colloidal templates can bring unexpected functionalities of inorganic NP to oxides, e.g., optical and/or catalytic properties, when replacing the silica cores of the colloidal template with noble metal NPs (Joo et al., 2009). One intriguing report from Mirkin's group shows that DNA-modified Au NPs as colloidal templates can guide the synthesis of mesoporous silica (**Figure 8a**) (Auyeung et al., 2015). To do so, the citrate-capped 5 nm Au NPs were first modified by thiolated DNA sequences (∼25 dsDNA per NP). Other DNA strands complementary to the DNA ligands on Au NPs were added into the mixture solution (1:1 ratio) of Au to initiate rapid aggregation. The disordered aggregates were subsequently slow-cooled from 60 to 25°C at a rate of 0.1°C/10 min to get spatially organized Au superlattices. The Au superlattices were further utilized as templates to grow silica in the DNA domain. Upon the removal of DNA by calcination, Au NP superlattices within porous silica supports could be synthesized. Due to the confinement of silica, Au NPs have high thermal stability without sintering. The obtained hybrids show a typical Type-IV isotherm with a specific surface area of 210 $m^2 g^{-1}$ (**Figures 8b,c**). The porous Au NP superlattices with available channels are catalytically active in alcohol oxidation.

Co-assembly of two sets of colloidal templates into mesoporous materials also provides a new strategy to encapsulate functional NPs, especially noble metal NPs, within mesoporous frameworks of TMOs. Recently, two sets of colloids, including PS-*b*-PEO-tethered Au (Au-PS-PEO) and spherical colloidal of self-assembled PS-*b*-PEO, were utilized as co-templates for the growth of Au/*m*WO_3 hybrid materials (Liu et al., 2015a). The two sets of colloidal templates share similar structural and chemical features and can co-assemble during the growth and crystallization of WO_3, thus resulting in the homogeneous dispersion of Au NPs within *m*WO_3. The porous frameworks can limit the mobility of Au NPs to enhance thermal stability, while the Au NPs confined by *m*-TMOs essentially exert plasmonic enhancement for the photocatalytic performance of *m*-TMOs. More importantly, because Au NPs are pre-synthesized, this method thus paves the first way to rationally control loading sizes and amounts of noble metal NPs within mesoporous oxides. The same strategy is also extendable to encapsulate noble metal NPs within *m*TiO_2m (Liu et al., 2017a). Furthermore, two sets of the colloidal templates with different structural features are also successful in the formation of noble metal-oxide hybrid materials. For example, Au-PEO colloids and P123 have been used as co-templates to disperse Au NPs with mesoporous silica, which exhibited dramatically enhanced thermal stability of Au NPs for the high-temperature reaction (discussed later).

APPLICATIONS

Crystalline *m*-TMOs with high surface areas, uniform pore sizes, and accessible interspaces exhibited great potential in many applications. We highlight a few examples on the applications of *m*-TMOs synthesized via the colloidal-templating method. The first example of the application is *m*-TiO_2 synthesized by organosilane-containing colloids for photocatalytic degradation of organic dye (Liu et al., 2015b). As discussed above, having thermally stable colloidals as the soft-hard templates renders the resultant *m*-TiO_2 with the precisely tunable crystalline phase of anatase and rutile by tuning the calcination temperature. The percentage of anatase and rutile can be controlled by calcination temperature and annealing time. The mesoporous TiO_2 obtained at 1,000°C for 1 h has ∼39% of rutile and ∼61% of anatase. In contrast, the mesoporous TiO_2 obtained below 800°C has almost 100% anatase phase. Both crystallinity and controllable anatase/rutile interface play an important role in the enhancement of photocatalytic activity. We used the photo decomposition of organic dye (Rhodamine B, RhB) to evaluate the photocatalytic performance of different *m*-TiO_2 obtained from different calcination conditions. The

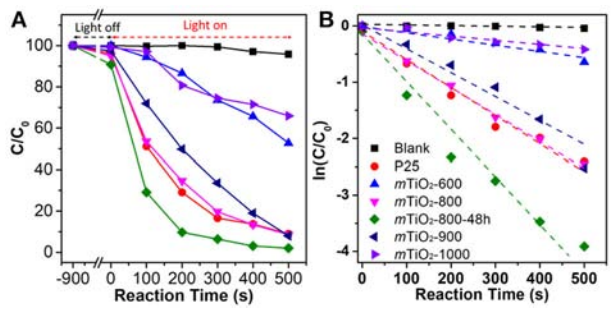

FIGURE 9 | Photocatalytic activity of *m*-TiO_2. **(A)** Photocatalytic degradation of RhB and **(B)** the fitting of the rate constant by using different mesoporous TiO_2 (*m*TiO_2) obtained at different calcination temperatures. photocatalytic decomposition results of RhB were obtained from the change of absorption intensity in the corresponding UV-vis spectra (**Figure 9A**). In addition, **Figure 9B** displays the kinetic fitting results by plotting ln (C/C_0) against the reaction time. The control experiment without a catalyst showed a very slow decomposition rate of RhB, with a rate constant of 9 $\times$ 10^{-5} s^{-1}. *m*-TiO_2 obtained at 800 and 900°C exhibited an increased photocatalytic activity with rate constant of 5.1 $\times$ 10^{-3} s^{-1} and 4.4 $\times$ 10^{-3} s^{-1}, respectively. The photo-decomposition activity of *m*-TiO_2 obtained at 800°C for 48 h with the highest activity showed 1.7 times higher than that of commercial P25. The above results indicate that the importance of mesoporous nanostructures and the interface of anatase and rutile phases for their photocatalytic activity. The change of photocatalytic activity is closely related to the crystallinity and controllable interface of anatase/rutile. The highly crystalline *m*-TMOs also can be prepared by using the CASH method (Lee et al., 2008), which decreased the defects to improve performance in photocatalysis.

The colloidal-templating method provides a new avenue to stabilize the noble metal NPs within a mesoporous framework, especially with amorphous SiO_2 as the support. Using KIT-6-typed SiO_2 with the framework and mesochannels smaller than the size of Au NPs could dramatically enhance the thermal stability of Au under high temperature, while Au NPs confined by mesoporous frameworks remain accessible and catalytically active (Liu et al., 2017a). We evaluated the high temperature catalytic performance of Au@*m*SiO_2 (**Figures 10A,B**) for CO oxidation. As shown in **Figure 10C**, when the catalytic temperature reached 275°C (light-off temperature), the CO conversion of *m*SiO_2-AuNP hybrids show catalytic activity for CO oxidation and achieved 100% of CO conversion at 400°C. In contrast, *m*SiO_2 without Au NPs showed no CO oxidation activity even at 450°C. The high temperature stability of *m*SiO_2-AuNP hybrids is further investigated in **Figure 10D**. No decrease in activity was observed for more than 130 h of continuous operation, indicating that *m*SiO_2-AuNP hybrid catalysts have outstanding stability under high temperature. Not only the mesoporous structure of Au@*m*SiO_2, but also Au NPs displayed extraordinary stability after CO oxidation for 130 h, further indicating the superior thermal stability of Au endowed by the nanoconfinement effect of mesoporous oxide supports. Moreover, these mesoporous metal-oxide hybrids are also potentially useful for other high temperature catalysis such as the oxidation of methane to methanol (Agarwal et al., 2017; Williams et al., 2018).

SUMMARY AND PERSPECTIVES

Advances in the rational design and formation of highly crystalline *m*-TMOs with controlled crystallinity and functions largely broaden their practical applications in catalysis and energy storage/conversion. The development of new synthetic methods is the key for all those applications. In this review, we summarize the current synthetic methodologies of *m*-TMOs, including soft-templating, hard-templating, and colloidal-templating methods, and briefly discuss their advantages/disadvantages for the synthesis of *m*-TMOs. Special focus is given to the colloidal-templating synthesis of *m*-TMOs and hybrid materials of porous metal-oxides, beyond the capability of other traditional synthetic methods. Several typical examples are provided to highlight the potential applications of *m*-TMOs and porous metal-oxides synthesized by colloidal-templating method.

Despite much progress made in the synthesis of crystalline *m*-TMOs, there are still unmet synthetic challenges, particularly for the colloidal-templating method. First, no example has been documented on crystalline perovskites using soft-templating or

colloidal-templating methods. Perovskites, as a complex oxide consisting of two or more simple oxides, have a cubic structure with a general formula of ABO_3; and they have been studied extensively due to the interesting electronic and catalytic activity, e.g., as a solid electrolyte (Zhou et al., 2016) and cathode materials for fuel cells (Skinner, 2001; Suntivich et al., 2011). The synthesis of perovskites usually relies on the solid-state annealing of the mixture of oxides at >700°C (Zhu et al., 2014). Because of the slow diffusion in solid states, the synthesis of perovskites can take a few hours to days to anneal the oxide mixtures. With the new CASH or organosilicate-containing colloidal-templating methods, it will be of interest to extend the current synthetic capacity to crystalline perovskites. Secondly, encapsulating noble metal NPs within highly crystalline *m*-TMOs is also unresolved. There is an extensive literature on the strong metal-oxide interaction (Tauster, 1987; Farmer and Campbell, 2010), known to be critical for catalytic activity of metal-oxide hybrids. The formation of the strong metal-oxide interaction (or strong metal-support interaction, SMSI) requires the annealing under reductive atmosphere. Control of metal-oxide interaction in the context of mesoporous hybrids has rarely been reported in previous research. In addition, we expect that more achievements from other fields, including macromolecules, electronics, and biomedical, can be incorporated in further developments of the synthesis and applications of *m*-TMOs. For example, new colloidal templates with different topologies assembled from different amphiphilic block copolymers (Yao et al., 2015) can add more structural hierarchies to crystalline *m*-TMOs. The interdisciplinary aspects that bring the new knowledge across fields will create new opportunities in solving those synthetic challenges.

Inorganic Chemistry

Timothy R. Cook

Timothy R. Cook is an Assistant Professor at the University of Buffalo's Department of Chemistry. His research focuses on several aspects of materials science, including self-assembly and characterization of discrete inorganic metallacycles and cages, energy harvesting, transport and storage in photo- and redox-active molecular materials, as well as polynuclear catalysts for small molecule activations of relevance to renewable energy schemes. Professor Cook completed his PhD at the Massachusetts Institute of Technology (MIT), followed by postdoctoral and Research Assistant Professor positions at the University of Utah.

Bo Zhou

Prof. Bo Zhou obtained his PhD degree in Optics from the City University of Hong Kong in 2011, and then worked as a postdoctoral researcher at the Hong Kong Polytechnic University and Institute of Materials Research and Engineering, A*STAR, Singapore. Since 2017, he has been a full Professor at South China University of Technology. His research interests focus on luminescence mechanism of lanthanides, upconversion nanomaterials, glass materials and fibers, and nanophotonics. He has authored and co-authored over 50 peer-reviewed papers in journals including Nature Nanotechnology, Advanced Materials, Angewandte Chemie, Advanced Functional Materials, Advanced Science, and Progress in Materials Science.

Oleksandr A. Savchuk

Oleksandr Savchuk has a Master's degree in physics of semiconductors and nanostructures at Chernivtsi National University, Ukraine. His Master's thesis was focused on the synthesis of ZnO nanoparticles by pulsed laser ablation technique in liquid media. In 2016, he finished his doctorate studies at the University Rovira i Virgili, Tarragona, Spain, where he completed his thesis work conducted in the Physics and Crystalography of Materials and Nanomaterials laboratories, at the Department of Physical and Inorganic Chemistry. Currently, Oleksandr is a research fellow at the International Iberian Nanotechnology Laboratory (INL) Braga, Portugal, working on intracellular temperature measurements using luminescence nanothermometry for hyperthermia treatment.

Xiaoji Xie

Xiaoji Xie earned his BSc degree in Chemistry from Nanjing University in 2009. He obtained his PhD in 2013 at the National University of Singapore with Prof. X. Liu. He then became a postdoctoral researcher working in collaboration with Prof. X. Liu. He joined the Institute of Advanced Materials (IAM) at Nanjing Tech University, China in 2014. His current research involves the investigation of inorganic functional nanomaterials such as upconversion nanoparticles for bioapplications, catalysis ,and sensing.

Eduardo D. Martínez

Eduardo D. Martínez is an assistant researcher at the Institute of Nanoscience and Nanotechnology-CONICET located in the city of Bariloche, Argentina. He has a degree in materials engineering and a PhD in chemistry from the University of San Martín, Argentina. He performed a postdoctoral fellowship in his present institution developing nanocomposite materials for microfabrication and a second postdoc at the Universidad Estadual de Campinas, (UNICAMP), Brazil, devoted to upconverting nanoparticles. His expertise lies in the field of nanomaterials and nanocomposites, focused on plasmonics and photonics. Specifically, he works in the chemical synthesis of nanoparticles and their assembly into nanostructures and devices by combining bottom-up and top-down approaches.

Jérôme Long

Jérôme Long received his PhD from Pierre and Marie Curie University (Paris VI) in 2009 under the supervision of Dr Valérie Marvaud. He undertook postdoctoral research at the University of Ottawa with Prof. M. Murugesu before joining the University of Montpellier as an Assistant Professor in 2010. His current research is oriented towards the design and characterization of multifunctional molecular materials at bulk and nano-scales.

Laleh Tahsini

Dr Laleh Tahsini completed her PhD work at Sharif University of Technology (SUT), Iran, and the University of Manchester, UK. In 2009, She joined the MOBIC group in Ewha Woman's University, South Korea and worked as a postdoctoral researcher with Professors Kenneth D. Karlin (Johns Hopkins University) and Shunichi Fukuzumi (Osaka University). In 2011, she joined Prof. Linda Doerrer's group at Boston University, where she worked on electrocatalytic water oxidation. Dr Tahsini became an Assistant Professor at the chemistry department of Oklahoma State University in Fall 2014. The research theme of her group is inorganic and organometallic chemistry: synthesis, reactivity, and application.

Carlos D. S. Brites

Carlos DS Brites completed his PhD in Physics in the MAP-FIS joint program in 2012 at CICECO (University of Aveiro, Portugal) and at ICMA (University of Zaragoza, Spain), within the groups of Prof. F. Palacio and Dr A. Millan. His research interests focus on the luminescent properties of trivalent lanthanide as sensors and as functional molecular devices. He has authored 40 publications (h index 20, >2000 citations) and holds three international patents. He is currently a Researcher at CICECO as a member of the PHANTOM-G group, headed by prof. L. D. Carlos.

Kevin R. Kittilstved

Kevin Kittilstved was born in Spokane, Washington and graduated with degrees in chemistry from Gonzaga University (BSc) and the University of Washington (PhD). He held postdoctoral positions at the Université de Genève and the University of Washington prior to joining the University of Massachusetts Amherst as an Assistant Professor. Kevin is the recipient of the NSF CAREER Award and was recently promoted to Associate Professor. His research program focuses on understanding and exploiting the defect chemistry of inorganic materials to control physical properties and electronic structures from the molecular to the bulk.

Thomas L. Gianetti

Dr Gianetti is an Assistant Professor at the University of Arizona since September 2017. He was born in Marseille, south of France, where he completed his initial education. He graduated in 2009 from CPE Lyon, an engineering school in France, with a BSc and MSc degree in chemistry and chemical engineering. He then pursued his PhD studies at the University of California, Berkeley under the guidance of Profs Arnold and Bergman, followed by a post-doctoral position at the ETH Zürich with Prof. Grützmacher. His current work focuses on developing new catalytic systems for energy conversion and the removal of environmentally dangerous chemicals.

Coordination-Driven Self-Assembly of Silver(I) and Gold(I) Rings: Synthesis, Characterization, and Photophysical Studies

Cressa Ria P. Fulong[1], *Sewon Kim*[1], *Alan E. Friedman*[2] *and Timothy R. Cook*[1]*

[1] *Department of Chemistry, University at Buffalo, The State University of New York, Buffalo, NY, United States,* [2] *Department of Materials Design and Innovation, University at Buffalo, The State University of New York, Buffalo, NY, United States*

In this work, we investigate the self-assembly between Ag(I) and Au(I) centers and pyridyl donors to form hexagonal metallacycles and related linear complexes. The precipitation of hexagonal metallacycles upon assembly in chloroform/methanol mixtures results in high solid-state photo-stability. Whereas, the Ag(I) species have fast kinetics and high formation constants in acetone, this solvent interferes in the formation of the analogous Au(I) complexes. The photophysical properties of this suite of metallacycles was investigated including steady-state absorption, emission, and time-resolved lifetime measurements. All ligands and hexagons exhibited ligand-centered singlet emissions with ground-state absorption and emission perturbed upon coordination. The ligand-based fluorescent photoluminescence was affected by the heavy-atom effect when halide or metals are present, attenuating quantum yields as evidenced by increases in the experimentally measured non-radiative rate constants. The formation of group 11 metallacycles is motivated by their potential applications in mixed-matrix materials wherein metal ions can interact with substrate to facilitate separations chemistry with reduced energy requirements, in particular the isolation of ethylene and light olefins. Existing processes involve cryogenic distillation, an energy intensive and inefficient method.

Keywords: self-assembly, coordination, metallacycle, silver hexagon, gold hexagon

INTRODUCTION

Coordination-driven self-assembly (Leininger et al., 2000) is a valuable strategy for the design and synthesis of discrete molecular complexes such as metallacycles and metallacages for biomedical (Cook et al., 2013; Casini et al., 2017) catalytic (Ito et al., 2000; Brown et al., 2009; Smulders and Nitschke, 2012; Vardhan and Verpoort, 2015; Kuijpers et al., 2016), molecular sensing (Tashiro et al., 2005; Kim and Ahn, 2008; Wang et al., 2011; Zwijnenburg et al., 2016; Cao et al., 2017), and small molecule adsorption and separation applications (Sudik et al., 2005; Zhao et al., 2010; Riddell et al., 2011; Amayuelas et al., 2016). This strategy exploits pre-programmed directionality information on metal acceptor and ligand donor building blocks to form complex architectures driven by metal-ligand coordination (Cook and Stang, 2015). A careful design of building blocks coupled with thermodynamic driving forces favors the convergent formation of discrete molecular

complexes over divergent coordination polymers a.k.a. metal-organic frameworks (MOFs) (Fujita et al., 2001).

Inspired by previous reports on hexagonal self-assemblies from *trans*-capped Pt(II) precursors (Yang et al., 2007) and 120° bidentate pyridine-type ligands, which are known for their luminescent properties, and other luminescent Pt(II)-based metallacycles (Huang et al., 2017; Tang et al., 2018), we now report the self-assembly of hexagonal metallacycles from the same class of ligand donors and Ag(I) and Au(I) metal acceptors. There have been few reports on linear Ag(I) (Del Piero et al., 2008) and Au(I) (Fernández et al., 2007) complexes, and Ag(I) metallacycles (Shin et al., 2003; Chen and Mak, 2005; Fromm et al., 2005; Ren et al., 2006; Kim et al., 2009; Wan and Mak, 2011; Kole et al., 2012; Wei et al., 2012; Chevrier et al., 2013) with pyridine-type ligands, but these are the first Ag(I) and Au(I) hexagonal rings. We also synthesized Ag(I) and Au(I) monomeric complexes using analogous monodentate pyridine-type ligands. Having both linear monomeric complexes and hexagonal metallacycles enables the comparison of solid- and solution-state structures, organic solvent solubilities, photophysical properties, as well as light-stabilities. These self-assembled Ag(I) and Au(I) hexagons have limited solubility in organic solvents. Efforts are ongoing to improve the solubilities of these metallacycles including but not limited to pre- and post-assembly ligand modification.

We have an ongoing interest in incorporating these metallacycles and metallacages as filler materials in mixed-matrix materials (MMMs) (Fulong et al., 2018). MMMs are a type of thin-film composite material typically composed of a highly porous inorganic/organic filler and an organic polymer binder. The significance of MMMs in the medical and small molecule purification industries has been steadily increasing in the past decade and contemporary research is largely focused on MOFs as a filler material (Dechnik et al., 2017). We have previously shown the importance of solubilizing the filler material into the polymer solution to fabricate thin, flexible, homogeneous, and highly permeable MMMs (Fulong et al., 2018). Along these lines, we highlighted the advantage and ease of using discrete coordination cages over MOFs as MMMs filler material due to the former's solubility in a range of solvents. For certain separations the filler material introduces sites for intermolecular interactions with substrate, which enables active separation rather than just size-selective sieving. As a result, the design of fillers with unsaturated metals or other binding sites enables the fabrication of MMMs with improved permeability and selectivity. Since a variety of metal centers may be used as nodes in coordination-driven self-assembly, properly matching metal ions to a separation of interest is an important first-principle in the design of new metal-organic materials (Dechnik et al., 2017).

The incorporation of silver salts has been identified as an effective strategy for increasing the selectivity of olefin/paraffin membranes based on the ability of electron-rich olefins to interact with metal ions, an attractive technology given the scope of the petrochemical industry wherein ethylene is used a primary building block (Eldridge, 1993). These materials suffer from the instability of Ag(I) ions that react with oxygen and leach from the material. We hypothesized that Ag(I) ions may be stabilized by a linear L–Ag(I)–L environment that still enables equatorial interactions with substrate (Fox et al., 2002; Gimeno, 2009). Other transition metals with coordination numbers of three or more require capping ligands to prevent divergent framework formation (Fujita, 1998; Fujita et al., 2001). For Ag(I) and Au(I), with linear coordination environments, capping ligands are not required and coordination with bent ditopic donors may furnish discrete metallacycles.

MATERIALS AND METHODS

All reagents and solvents were reagent grade and used as received without further purification unless noted. Methanol (CH_3OH), acetone, dichloromethane (DCM), ethyl acetate (EtOAc), n-hexanes, toluene, diethyl ether, petroleum ether, potassium hydroxide (KOH), sodium sulfate (Na_2SO_4) and potassium carbonate (K_2CO_3) were purchased from Fisher Scientific. N,N-dimethylformamide (DMF) was purchased from Macron Fine Chemicals. Tetrahydrofuran (THF), triethylamine (NEt_3), and chloroform ($CHCl_3$) were purchased from EMD Millipore. Ethanol (EtOH, 200 proof) was purchased from Decon Labs, Inc. Tetrakis(triphenylphosphine)palladium(0) ($Pd(PPh_3)_4$), and bis(triphenylphosphine)palladium(II) chloride ($Pd(PPh_3)_2Cl_2$), and 1,3-dibromobenzene were purchased from Matrix Scientific. 4-pyridinylboronic acid ($pyB(OH)_2$) was purchased from AK Scientific. Copper (I) iodide (CuI) was purchased from Strem Chemicals. Tetrahydrothiophene (tht) was purchased from Aldrich. Silver(I) hexafluorophosphate ($AgPF_6$) was purchased from Oakwood Chemical. Hydrogen tetrachloroaurate(III) trihydrate ($HAuCl_4{\cdot}3H_2O$) was purchased from J&J Materials Inc. 4-ethynylpyridine hydrochloride and 1,3,5-tribromobenzene were purchased from Ark Pharm Inc. Deionized water was used whenever water was needed. THF was purified and dried through a Pure Process Technology free standing solvent purification system. NEt_3 was purified and dried by distillation in KOH. DMF was filtered and dried using activated molecular sieves under N_2 and freeze-pump-thawed with water before use for synthesis.

^{1}H Nuclear Magnetic Resonance (NMR) spectra were recorded on either Varian 300 or 400 MHz spectrometer. Chemical shifts (δ) are reported in parts per million (ppm) referenced using the residual protio-solvent peaks as internal standards. Coupling constants (J) are quoted in Hertz (Hz), and the following abbreviations are used to describe the signal multiplicities: s (singlet); d (doublet); t (triplet); q (quartet); m (multiplet). Fourier Transform-Ion Cyclotron Resonance (FT-ICR) mass spectra were acquired using a Bruker Daltonics SolariX 12T FT-ICR Mass Spectrometer that was calibrated with > 90% Angiotensin I purchased from Sigma Aldrich under either Electrospray Ionization (ESI) or Laser Desorption Ionization (LDI) modes. Single Crystal X-ray Diffraction (SC-XRD) Crystallography was performed using a Bruker D8 Venture diffractometer in a fixed-chi geometry, equipped with a Photon-100 CMOS area detector, Oxford Cryosystems cryostat, a molybdenum

source (Mo, λ = 0.71073 Å), and a graphite monochromator. Fourier Transform Infrared Resonance (FT-IR) spectra were collected from a Perkin Elmer 1760 FT-IR spectrometer equipped with horizontal attenuated total reflectance (HATR) from 4,000 to 500 cm^{-1} wavenumbers (ν). The following abbreviations are used to describe signal intensities: w (weak); m (medium); s (strong). All UV-Vis absorption spectra were acquired from an Agilent Cary 8454 UV-Vis Diode Array system. Blank spectra with pure solvents were acquired before each run. All emission spectra were collected using a Horiba Scientific FluoroMax-4 Spectrofluorometer equipped with Quanta-φ Integrating light sphere with Spectralon coating for quantum yield (Φ) measurements and Delta-Hub DH-HT High Throughput Time-correlated Single Photon Counting (TCSPC) Controller and Nano-LED NL-C2 pulsed-diode controller with N-350 NanoLED Source for lifetime measurements. All solution-state absorbance and emission spectra were collected using a 10-mm rectangular quartz cuvette from Starna Cells Inc.

Synthesis of Ag(I) Complex ($AgL1_2$)

Ag**L1**$_2$ complex was self-assembled using a modified literature procedure (Chen et al., 2013). In a foil-covered 200-mL round-bottom flask, 0.800 g (3.1 mmol) **L1** was dissolved in 80.0 mL $CHCl_3$. In another foil-covered 100-mL round-bottom flask, 0.720 g (2.85 mmol) $AgPF_6$ was dissolved in 80.0 mL MeOH then layered over the **L1** solution. After 48 h, white needle-like crystals form. These crystals were filtered and washed with 10-mL portions of $CHCl_3$ (3x) to afford 1.19 g (100% yield) isolated product. ^{1}H NMR (400 MHz, acetone-d_6, 25°C): δ (ppm) = 8.81 (d, ^3J = 5.2 Hz, 4H, pyridyl H_α), 7.82 (s, 2H, phenyl H), 7.77 (d, ^3J = 6.3 Hz, 4H, pyridyl H_β), 7.71 (d, ^3J = 8.1 Hz, 2H, phenyl H), 7.65 (d, ^3J = 7.8 Hz, 2H, phenyl H), 7.46 (t, ^3J = 7.9 Hz, 2H, phenyl H). FT-IR (ATR, cm^{-1}): 3069 (w), 2235 (w), 2187 (w), 1609 (m), 1558 (w), 1506 (w), 1470 (w), 1433 (w), 1405 (w), 1223 (w), 1152 (w), 1070 (w), 1031 (w), 991 (w), 915 (w), 881 (m), 815 (m), 775 (m), 757 (m), 743 (m), 678 (m), 663 (m), 553 (m), 531 (m).

Synthesis of ({AgL2}$_6$) Ag(I) Hexagon

{Ag**L2**}$_6$ hexagon, was self-assembled using a modified literature procedure (Chen et al., 2013). In a foil-covered 20-mL scintillation vial, 0.050 g (0.14 mmol) **L2** was dissolved in 5.0 mL $CHCl_3$. In another foil-covered 20-mL scintillation vial, 0.035 g (0.14 mmol) $AgPF_6$ was dissolved in 5.0 mL MeOH then layered over the **L2** solution. After 48 h, white powdered product formed which was filtered and washed with 10-mL portions of $CHCl_3$ (3x) to afford 0.062 g (73% yield) isolated product. ^{1}H NMR (400 MHz, acetone-d_6, 25°C): δ (ppm) = 8.72 (d, ^3J = 5.9 Hz, 24H, pyridyl H_α), 7.90 (s, 11H, phenyl H), 7.83 (s, 6H, phenyl H), 7.62 (d, ^3J = 6.0 Hz, 24H, pyridyl H_β). FT-IR (ATR, cm^{-1}): 3076 (w), 2219 (w), 1613 (m), 1557 (w), 1507 (w), 1435 (m), 1338 (w), 1291 (w), 1221 (m), 1174 (w), 1162 (w), 1136 (w), 1107 (w), 1066 (w), 1028 (w), 993 (w), 964 (w), 864 (m), 821 (s), 748 (w), 736 (w), 663 (m), 573 (w), 552 (s).

Synthesis of ({AgL3}$_6$) Ag(I) Hexagon

{Ag**L3**}$_6$ hexagon, was self-assembled using a modified literature procedure (Chen et al., 2013). In a foil-covered 20-mL scintillation vial, 0.050 g (0.18 mmol) **L3** was dissolved in 5.0 mL $CHCl_3$. In another foil-covered 20-mL scintillation vial, 0.045 g (0.18 mmol) $AgPF_6$ was dissolved in 5.0 mL MeOH then layered over the **L3** solution. After 48 h, white powdered product formed which was filtered and washed with 10-mL portions of $CHCl_3$ (3x) to afford 0.096 g (100% yield) isolated product. ^{1}H NMR (400 MHz, acetone-d_6, 25°C): δ (ppm) = 8.74 (d, ^3J = 6.0 Hz, 24H, pyridyl H_α), 7.86 (s, 6H, phenyl H), 7.74 (d, ^3J = 9.3 Hz, 12H, phenyl H), 7.66 (d, ^3J = 6.1 Hz, 23H, pyridyl H_β), 7.63 – 7.56 (m, 7H, phenyl H). FT-IR (ATR, cm^{-1}): 3107 (w), 2203 (w), 1615 (m), 1543 (w), 1501 (w), 1431 (w), 1227 (w), 1167 (w), 1064 (w), 1025 (w), 878 (w), 821 (m), 752 (w), 733 (w), 682 (w), 556 (m), 541 (m).

Synthesis of ({AgL4}$_6$) Ag(I) Hexagon

{Ag**L4**}$_6$ hexagon, was self-assembled using a modified literature procedure (Chen et al., 2013). In a foil-covered 20-mL scintillation vial, 0.025 g (0.11 mmol) **L4** was dissolved in 2.0 mL $CHCl_3$. In another foil-covered 20-mL scintillation vial, 0.027 g (0.11 mmol) $AgPF_6$ was dissolved in 2.0 mL MeOH then layered over the **L4** solution. After 48 h, white powdered product formed which was filtered and washed with 10-mL portions of $CHCl_3$

Synthesis of Au(I) Complex (Au$L1_2$)

Au**L1**$_2$ complex was self-assembled using a modified literature procedure (Lin et al., 2008). In a foil-covered 2-dram vial, 0.020 g (0.078 mmol) **L1**, 0.025 g (0.078 mmol) Au(tht)Cl were dissolved in 6.0 mL acetone. After 6 h, the solution was concentrated in vacuo and the collected solid was washed with 6-mL portions of $CHCl_3$ (3x) to afford 0.007 g (20% yield) isolated product. ^{1}H NMR (300 MHz, acetone-d_6, 25°C): δ (ppm) = 8.84 (d, ^{3}J = 6.0 Hz, 4H, pyridyl H_α), 7.89 (d, ^{3}J = 7.0 Hz, 5H, pyridyl H_β), 7.80 (s, 2H, phenyl H), 7.68 (td, ^{3}J = 16.3, 15.7, 7.8 Hz, 10H), 7.50 – 7.40 (m, 3H, phenyl H). FT-IR (ATR, cm^{-1}): 3044 (w), 2918 (w), 2856 (w), 2218 (m), 2187 (w), 1943 (w), 1801 (w), 1614 (m), 1588 (m), 1558 (w), 1496 (w), 1463 (w), 1429 (w), 1404 (w), 1261 (w), 1234 (w), 1217 (w), 1158 (w), 1105 (w), 1088 (w), 1060 (w), 1038 (w), 987 (w), 906 (w), 876 (w), 836 (m), 814 (w), 789 (m), 747 (w), 713 (w), 691 (w), 680 (m), 655 (m), 565 (w), 535 (m).

Synthesis of Au(I) Hexagons ({AuL2}$_6$)

{Au**L2**}$_6$ hexagon was self-assembled using a modified literature procedure (Lin et al., 2008). In a foil-covered 2-dram vial, 0.028 g (0.078 mmol) **L2**, 0.025 g (0.078 mmol) Au(tht)Cl were dissolved in 6.0 mL $CHCl_3$. After 24 h, the solution was concentrated in vacuo and the collected yellow solid was washed with 6-mL portions of $CHCl_3$ (3x) to afford 0.025 g (78% yield) isolated product. ^{1}H NMR (400 MHz, CD_3NO_3, 25°C): δ (ppm) = 8.84–8.71 (m, 24H, pyridyl H_α), 8.09 – 7.82 (m, 40H, pyridyl H_β and phenyl H). FT-IR (ATR, cm^{-1}): 3100 (w), 3044 (w), 2210 (m), 1615 (s), 1553 (w), 1496 (w), 1430 (m), 1336 (w), 1288 (w), 1211 (m), 1171 (w), 1134 (w), 1105 (w), 1063 (m), 1046 (w), 992 (w), 966 (w), 863 (m), 826 (m), 761 (w), 721 (w), 672 (m), 587 (w), 574 (m), 527 (w).

Synthesis of Au(I) Hexagons ({AuL3}$_6$)

{Au**L3**}$_6$ hexagon was self-assembled using a modified literature procedure (Lin et al., 2008). In a foil-covered 2-dram vial, 0.022 g (0.078 mmol) **L3**, 0.025 g (0.078 mmol) Au(tht)Cl were dissolved in 6.0 mL $CHCl_3$. After 24 h, the solution was concentrated in vacuo and the collected yellow solid was washed with 6-mL portions of $CHCl_3$ (3x) to afford 0.026 g (89% yield) isolated product. ^{1}H NMR (400 MHz, CD_3NO_3, 25°C): δ (ppm) = 8.76 (d, ^{3}J = 5.0 Hz, 24H, pyridyl H_α), 8.08 – 7.70 (m, 41H, pyridyl H_β and phenyl H), 7.66–7.57 (m, 7H, phenyl H). FT-IR (ATR, cm^{-1}): 3092 (w), 3029 (w), 2203 (m), 1943 (w), 1609 (s), 1529 (w), 1492 (w), 1427 (w), 1324 (w), 1213 (w), 1162 (w), 1150 (w), 1125 (w), 1093 (w), 1065 (w), 1042 (w), 991 (w), 942 (w), 902 (w), 831 (m), 792 (w), 754 (w), 729 (w), 666 (w), 569 (w), 544 (w).

Synthesis of Au(I) Hexagons ({AuL4}$_6$)

{Au**L4**}$_6$ hexagon was self-assembled using a modified literature procedure (Lin et al., 2008). In a foil-covered 2-dram vial, 0.018 g (0.078 mmol) **L4**, 0.025 g (0.078 mmol) Au(tht)Cl were dissolved in 6.0 mL $CHCl_3$. After 24 h, the solution was concentrated in vacuo and the collected white solid was washed with 6-mL portions of $CHCl_3$ (3x) to afford 0.027 g (100% yield) isolated product. ^{1}H NMR (400 MHz, CD_3NO_3, 25°C): δ (ppm) = 8.82 (d, ^{3}J = 6.7 Hz, 24H, pyridyl H$_\alpha$), 8.35 (s, 7H, phenyl H), 8.22 (d, ^{3}J = 6.3 Hz, 22H, pyridyl H$_\beta$), 8.11 (d, ^{3}J = 9.4 Hz, 14H, phenyl H), 7.86 (t, ^{3}J = 7.6 Hz, 7H, phenyl H). FT-IR (ATR, cm^{-1}): 3060 (w), 1611 (s), 1546 (w), 1508 (w), 1472 (w), 1443 (w), 1427 (w), 1398 (m), 1340 (w), 1318 (w), 1266 (w), 1231 (m), 1186 (w), 1109 (w), 1076 (m), 1034 (w), 970 (w), 935 (w), 915 (w), 857 (w), 832 (m), 786 (s), 761 (w), 732 (m), 687 (w), 667 (w), 645 (m), 632 (w), 606 (w), 535 (s).

RESULTS AND DISCUSSION

Self-Assembly of Ag(I) and Au(I) Complexes and Hexagons

Four pyridyl ligands, 1-bromo-3(4-ethynylpyridyl)benzene (**L1**), 5-bromo-1,3-bis(4-ethynylpyridyl)benzene (**L2**), 1,3-bis(4-ethynylpyridyl)benzene (**L3**), and 1,3-bis(4-pyridyl)benzene (**L4**), were prepared as donors for self-assembly reactions. As illustrated in **Scheme 1**, **L1**, **L2**, and **L3** were prepared following a typical Sonogashira coupling reaction while **L4** was prepared following a typical Suzuki coupling reaction. The ^{1}H NMR spectra of **L1**, **L2**, **L3**, and **L4** in acetone-d$_6$ are summarized in **Supplementary Figures 1A–D**, respectively. The **L1** ^{1}H spectrum shows the pyridyl-H doublets at 8.63 and 7.49 ppm and the benzyl-H singlet at 7.78 ppm, two doublets at 7.65 and 7.60 ppm, and triplet at 7.42 ppm. The **L2** spectrum shows the pyridyl-H doublets at 8.66 and 7.53 ppm and the benzyl-H singlets at 7.87 and 7.82 ppm. The **L3** spectrum shows the pyridyl-H doublets at 8.65 and 7.51 ppm and the benzyl-H singlet at 7.83 ppm, doublet at 7.69 ppm, and triplet at 7.56 ppm. The **L4** spectrum shows the pyridyl-H doublets at 8.68 and 7.78 ppm and the benzyl-H singlet at 8.17 ppm, doublet at 7.89 ppm, and triplet at 7.70 ppm.

L1 was used to synthesize linear Ag(I) and Au(I) complexes, while **L2**, **L3**, and **L4** were used to self-assemble Ag(I) and Au(I) hexagonal metallacycles. The general method used to self-assemble the complexes and hexagons is shown in **Figure 1**. All self-assembly reactions were performed in the absence of light to ensure no loss in Ag(I) and Au(I) precursors. The monomeric Ag(I) complex, Ag**L1**$_2$, was prepared by layering one equivalent of $AgPF_6$ in MeOH over two equivalents of **L1** in $CHCl_3$. This resulted in the crystallization of Ag**L1**$_2$ after 48 h. Ag(I) hexagons, {Ag**L**}$_6$ where **L** = **L2**, **L3**, and **L4**, were prepared by layering one equivalent of $AgPF_6$ in MeOH over one equivalent of **L** in $CHCl_3$. The hexagons precipitated at almost quantitative yields as white powders after 48 h. The gold analogs, Au(I) hexagons, {Au**L**}$_6$ where **L** = **L2**, **L3**, and **L4**, were prepared by mixing 1:1 equivalents of Au(tht)Cl and **L** in $CHCl_3$. After 24 h, powdered metallacycles were isolated upon solvent removal and $CHCl_3$ washing. In the case of the monomeric Au(I) complex, Au**L1**$_2$, previous attempts using pure $CHCl_3$ or 1:1 (v/v) $CHCl_3$/MeOH did not result in any complex formation. However, the complex was isolated at a relatively low yield by mixing 1:1 equivalents of Au(tht)Cl and **L1** in acetone.

^{1}H NMR of Ag(I) and Au(I) Complexes and Hexagons

A notable challenge in characterizing these self-assembled Ag(I) and Au(I) complex and hexagons is their limited solubilities. Coordinating solvents such as acetonitrile (MeCN) and *N,N*'-dimethylsulfoxide (DMSO), which are typically used in solution-state structural analyses of Ag(I) and Ag(I) complexes proved to be unsuitable for our complexes and hexagons (Laye, 2007; Lin et al., 2008). In all cases, we observed ligand dissociation upon addition of MeCN or DMSO.

Nonetheless, we were able to detect the intact Ag(I) complexes and hexagons (**Figure 2**) as well as Au(I) complex (**Figure 3**) in acetone. The coordination of the pyridyl ligands to Ag(I) and Au(I) is exemplified by the characteristic downfield shifts in ^{1}H NMR peaks as well as peak integration agreements (**Supplementary Figures 2, 3A**). In addition, the same peak splitting patterns between

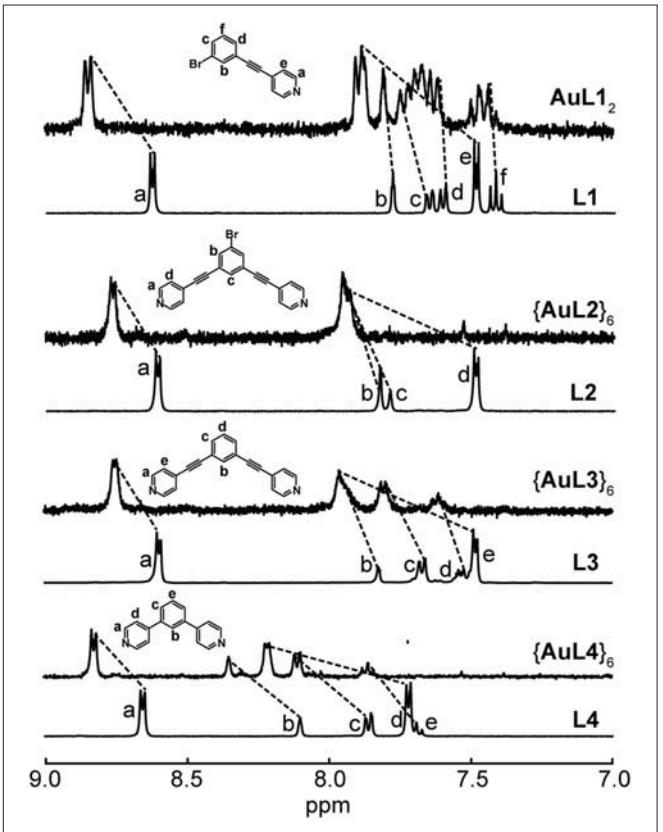

FIGURE 3 | ^{1}H NMR spectra of **L1** and Au**L1**$_2$ in acetone-d$_6$, **L2** and {Au**L2**}$_6$, **L3** and {Au**L3**}$_6$ and **L4** and {Au**L4**}$_6$ in nitromethane-d$_3$.

the ligand and the complex/hexagon were expected due to the C_{2v} symmetry of both Ag**L1**$_2$ and Au**L1**$_2$ complexes and the D_{6h} symmetry of all {Ag**L**}$_6$ hexagonal metallacycles.

For the Au(I) hexagons, ligand dissociation occurs when MeCN, DMSO, and acetone were used as solvents. These hexagons are insoluble in all other solvents except for nitromethane, in which we were able to observe intact Au(I) hexagons. **Figure 3** summarizes the ^{1}H NMR spectra of {Au**L2**}$_6$, {Au**L3**}$_6$, and {Au**L4**}$_6$. The full spectra of each Au(I) hexagon are shown in **Supplementary Figures 3B–D**. Similar to the Ag(I) hexagons, the downfield shifts of all ^{1}H NMR peaks, the peak integration agreements, and the similarity in peak splitting patterns indicate the formation of pure Au(I) hexagonal metallacycles. Although the solubility of these species is limited, our identification of NMR-suitable solvents rules out the formation of polymeric species as such coordination polymers are fully insoluble. ESI-MS (see below) further confirms the stoichiometries of self-assembly.

Formation of Ag(I) and Au(I) Complexes and Hexagons in Acetone

All of these complexes were synthesized in pure $CHCl_3$ or in $CHCl_3$ mixtures with MeOH. MeCN and DMSO competitively coordinate with the Ag(I) and Au(I) resulting in ligand dissociation. Acetone was a suitable solvent for the building blocks, as well as the final assemblies, enabling the study of complex formation. Using ^{1}H NMR methods, we initially acquired a series of spectra for a solution containing 1:1 equivalents of Ag:**L** in acetone upon mixing and after 24 h (**Supplementary Figure 4**). We observed that the thermodynamic products formed immediately upon mixing with no significant changes observed after 24 h. This suggests a fast

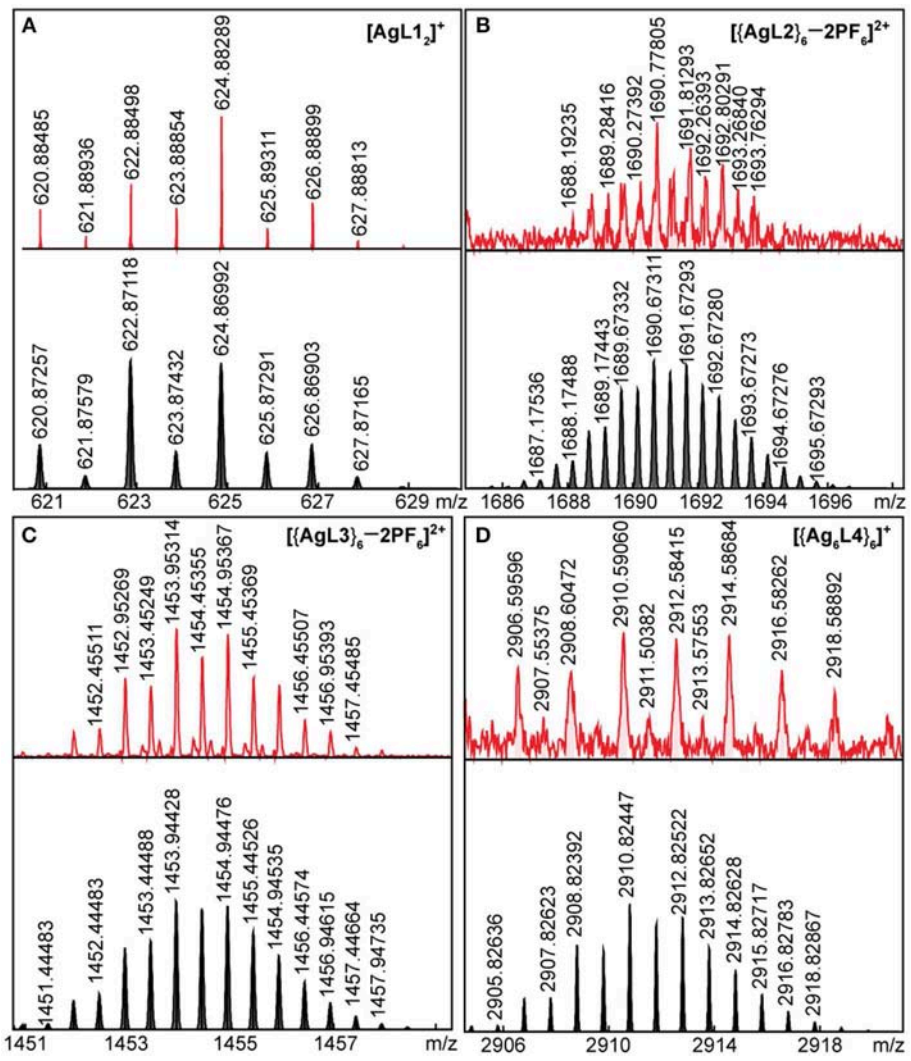

FIGURE 4 | ESI-FT-ICR MS spectrograms of intact **(A)** Ag**L1**$_2$, **(B)** {Ag**L2**}$_6$, **(C)** {Ag**L3**}$_6$, and **(D)** LDI-FT-ICR MS spectrum of intact {Ag**L4**}$_6$ (top = experimental, bottom = simulated).

kinetics with a large formation constant for all Ag(I) complex and hexagons in acetone.

Similarly, we wanted to study the solution formation of the Au(I) complex and hexagons. In this case, we prepared solutions containing 1:1, 2:1, and 3:1 equivalents of Au:**L** in acetone to ensure complete ligand coordination. The acquired ^{1}H NMR spectra at 0 (upon mixing), 6, 24, and 48 h were summarized in **Supplementary Figures 5–7** for 1:1, 2:1, and 3:1 solutions, respectively. It was observed that the Au**L1**$_2$ complex self-assembles within 6 h then partially dissociates thereafter. In the case of both {Au**L2**}$_6$ and {Au**L3**}$_6$, an equilibrium was established immediately upon mixing that stays up to at least 48 h. Products of {Au**L4**}$_6$ hexagon assembly crash out of solution immediately upon mixing such that we only observe uncoordinated **L4** and partially dissolved products. In all cases, the initial coordination is fast; however, quantitative analyses of the NMR peaks is not straightforward using a one-step metal-ligand binding model. There are reports on the mechanism and reducing ability of acetone to form Au nanoparticles from Au(III) and Au(I) (Marin et al., 2008). Thus, we think that there is a possibility of either Au(I) slowly being released as Au(0) from the hexagonal metallacycle into the acetone solution or acetone competitively coordinating to Au(I) to form other products.

FT-ICR MS of Ag(I) and Au(I) Complexes and Hexagons

High-resolution mass spectrometry (HRMS) was used to probe the stoichiometry of our self-assemblies. We used Fourier transform-ion cyclotron mass spectrometry (FT-ICR MS) with electrospray ionization (ESI) for soluble complexes and hexagons, while laser desorption ionization (LDI) was used for hexagons that are unstable in acetone. ESI, as a soft

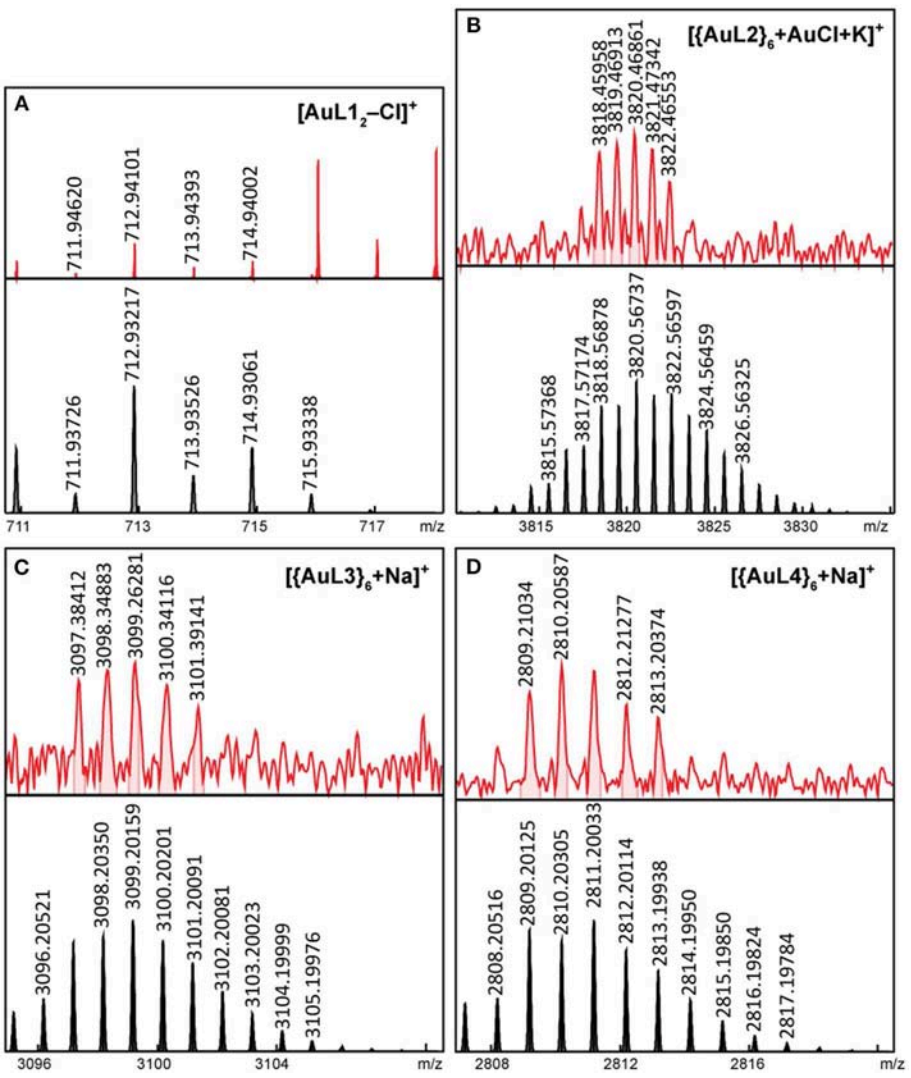

FIGURE 5 | ESI-FT-ICR MS spectrogram of intact **(A)** Au**L1**$_2$ and LDI-FT-ICR MS spectrograms of intact **(B)** {Au**L2**}$_6$, **(C)** {Au**L3**}$_6$, and **(D)** {Au**L4**}$_6$ (top = experimental, bottom = simulated).

ionization technique, is advantageous and popularly used in detection of intact coordination complexes and cages with high molar masses (Vikse and Scott McIndoe, 2018). Typical of soft ionization methods, molecules are ionized by either loss of ions or association with low-valent ions. In the case of our Ag(I) and Au(I) complexes and hexagons, loss of counter-ions results in multiply-charged compounds that are easily detectable by HR-MS at lower m/z. In cases wherein the hexagon is not stable in acetone, we opted to use matrix-free LDI, which uses high-energy lasers to ionize samples in the solid state. LDI is not popularly used in coordination chemistry due to formation of singly-charged fragment ions (Mandal et al., 2019). We, nonetheless, successfully identified intact hexagons in their solid state.

The mass spectrograms for Ag(I) complex and hexagons and for Au(I) complex and hexagons are shown in **Figures 4**, **5**, respectively. For the Ag(I) complex and hexagons, we were able to detect the intact $[Ag\mathbf{L1}_2]^+$ complex (**Figure 4A**) as well as $[\{Ag\mathbf{L2}\}_6 - 2PF_6]^{2+}$ hexagon (**Figure 4B**) and $[\{Ag\mathbf{L3}\}_6 - 2PF_6]^{2+}$ hexagon (**Figure 4C**) by ESI-FT-ICR MS. A loss of one PF_6^- counter-ion was observed for the complex and two PF_6^- were observed for both hexagons. $[\{Ag\mathbf{L4}\}_6]^+$ hexagon (**Figure 4D**), which has low solubility in acetone, was detected by LDI-FT-ICR MS.

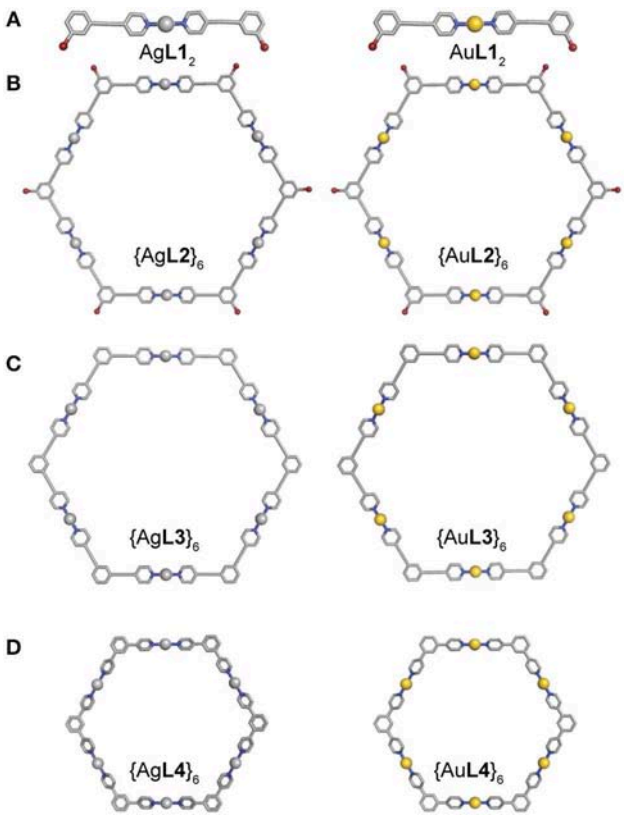

FIGURE 6 | Molecular models from crystal structure of **(A)** Ag**L1**$_2$ (CCDC 1879931) and Universal Force Field (UFF) optimized structures of Au**L1**$_2$, **(B)** {Ag**L2**}$_6$ and {Au**L2**}$_6$, **(C)** {Ag**L3**}$_6$ and {Au**L3**}$_6$, and **(D)** {Ag**L4**}$_6$ and {Au**L4**}$_6$ (C = gray, N = blue, Br = maroon, Ag = silver, and Au = gold).

For the Au(I) complex and hexagons, we were able to detect the intact $[Au\mathbf{L1}_2]^+$ complex (**Figure 5A**) with a loss of Cl^- counter-ion by ESI-FT-ICR MS. The Au(I) hexagons, which are unstable is acetone were detected by LDI-FT-ICR MS. We were able to detect singly-charged intact $[\{Au\mathbf{L2}\}_6+AuCl+K]^+$ hexagon (**Figure 5B**), $[\{Au\mathbf{L3}\}_6+Na]^+$ hexagon (**Figure 5C**), and $[\{Au\mathbf{L4}\}_6+Na]^+$ hexagon (**Figure 5D**). Each of these hexagons have six chloride counter-ions. We also observed $\{Au\mathbf{L}\}_6$ fragments (**Supplementary Figures 12–15**) with chloride counter-ions by ESI-FT-ICR MS, which further confirms the presence of chloride counter-ions in the Au(I) hexagons.

In all cases, we were able to confirm the presence of intact complexes and cages from the agreement of molecular ion m/z and isotopic distribution pattern between the simulated and experimental spectrograms. The presence of complex and hexagon fragmentation (**Supplementary Figures 8–11** for Ag(I) and **Supplementary Figures 12–15** for Au(I) complexes and hexagons) in the mass spectra further confirmed the structure and counter-ions of the linear complex and hexagonal self-assemblies since these fragments were not detected in the NMR studies.

Structures of Ag(I) and Au(I) Complexes and Hexagons

Single-crystal X-ray diffraction was attempted to further elucidate the structures of the Ag(I) and Au(I) complexes and hexagons. Slow evaporation of acetone solutions resulted in very fine needle-like crystals. Only crystals of Ag**L1**$_2$ gave a tractable data set. The asymmetric unit contains two formula units ($Z' = 2$) held in a cofacial conformation as well as a single chloroform molecule. Each Ag(I) center possess a coordination number of 2 with near ideal 180° geometries (**Figure 6A** and **Supplementary Figure 16** and **Table S1**). The PF_6- counter ion is outer sphere with a closest contact of approximately 3 Å. It is apparent that non-covalent interactions are a strong driving force in the resulting crystal structure of this compound. An apparent argentophilic Ag(I)—Ag(I) interaction leads to the interesting cofacial conformation (∼3.5 Å). Furthermore, interaction between the electron-rich Br atoms and the H atoms (average separation 3.60(9) Å) of the corresponding formula unit further contribute to the observed structure.

Molecular mechanics geometry optimizations were carried out on the Au(I) complex and the Ag(I) and Au(I) hexagons (**Figures 6B–D**). These structures were optimized using Universal Force Field (UFF) as implemented in ArgusLab. All hexagons formed from **L2** and **L3** preserved ligand planarity. In contrast, the hexagons from **L4** have pyridyl groups that are rotated by 40° from the central phenyl due to the steric strain of the protons on neighboring aromatic rings.

Solid-State Light Stability of Ag(I) and Au(I) Complexes and Hexagons

Solid-state IR spectroscopy is another useful tool to confirm the coordination of the pyridyl ligands to Ag(I) and Au(I) metal acceptors and study the solid-state photostability of the complexes and hexagons. We acquired FT-IR spectra of the

ligands, complexes and hexagons as synthesized. After a week of storing the complexes and hexagons under room light at ambient conditions, we re-acquired the FT-IR spectra of each compound. The ligand IR spectra are shown in both **Figures 7**, **8**, where the characteristic aromatic -CH stretching at 3,000–3,100 cm^{-1}, aromatic -CC- stretching at 1,400–1,600 cm^{-1}, and aromatic -CN- stretching at 1,600 cm^{-1} are present in all ligands (Katritzky and Hands, 1958; Schrader, 2007). The characteristic alkyne -CC- stretching at 2,100 cm^{-1} are also present in **L1**, **L2**, and **L3**.

In all cases, there is a slight shift to higher wavenumbers upon Ag(I) or Au(I) coordination, most notably for the -CN- stretching peaks at 1,600 cm^{-1}. We observe no change in both the functional group and the fingerprint regions after exposure of the complexes and hexagons to room light for one week, which confirms the improved photo-stability of Ag(I) and Au(I) upon coordination into both linear complex and hexagonal metallacycle.

Photophysical Properties of Ag(I) and Au(I) Complexes and Hexagons

The photophysical properties of these self-assembled complexes and hexagons were studied using steady-state and time-resolved methods. Studies of Ag(I) (Zhou et al., 2006; Laye, 2007; Yeşilel et al., 2012; Mei et al., 2015a; Jenkins and Assefa, 2017) and Au(I) (Lin et al., 2008; Langdon-Jones and Pope, 2014; Shakirova et al., 2017) complexes and metallacycles with N-donor heterocyclic ligands demonstrate interesting luminescent properties, which assigned to metal-to-ligand charge transfers (MLCT), ligand-based charge transfers, or metal-perturbed ligand-based charge transfers in part due to argentophilic or aurophilic interactions.

We studied both the solution- and solid-state photoluminescence of all Ag(I) and Au(I) complexes and hexagons; however, the acetone instability of some compounds limited our solution-state studies to the photoluminescence of Ag(I) complexes and hexagons and the mononuclear Au(I) complex in acetone. The solution-state absorption and emission of the free ligands, Ag(I) and Au(I) complexes, and Ag(I) hexagons are summarized in **Figure 9**. Several UV-vis absorption features were masked by the UV-cutoff of acetone. Nonetheless, the high energy band due to $\pi \rightarrow \pi^*$ ligand-centered transitions that is typical of aromatic and alkynyl-containing ligands (Shakirova et al., 2017) were prominent in **L1**, **L2**, and **L3** and less so in **L4** due to the absence of ethynyl spacer in this ligand. We see a slight red-shift in the absorption of Ag**L1**$_2$ (**Figure 9A**) but not in Au**L1**$_2$ (**Figure 9E**) or any of the Ag(I) hexagons (**Figures 9B–D**) suggesting ligand-centered transitions for the Au(I) complex and Ag(I) hexagons and metal-perturbed ligand-centered transition for the Ag(I) complex, which is supported by the presence of argentophilic interactions in the crystal structure (**Figure 6**).

Table 1 shows the summary of all measured quantum yields (Φ, **Supplementary Figures 17–22**) and lifetimes (τ, **Supplementary Figures 23–25**) and all calculated radiative (k_r) and non-radiative (k_{nr}) decay rate constants. At 330 nm

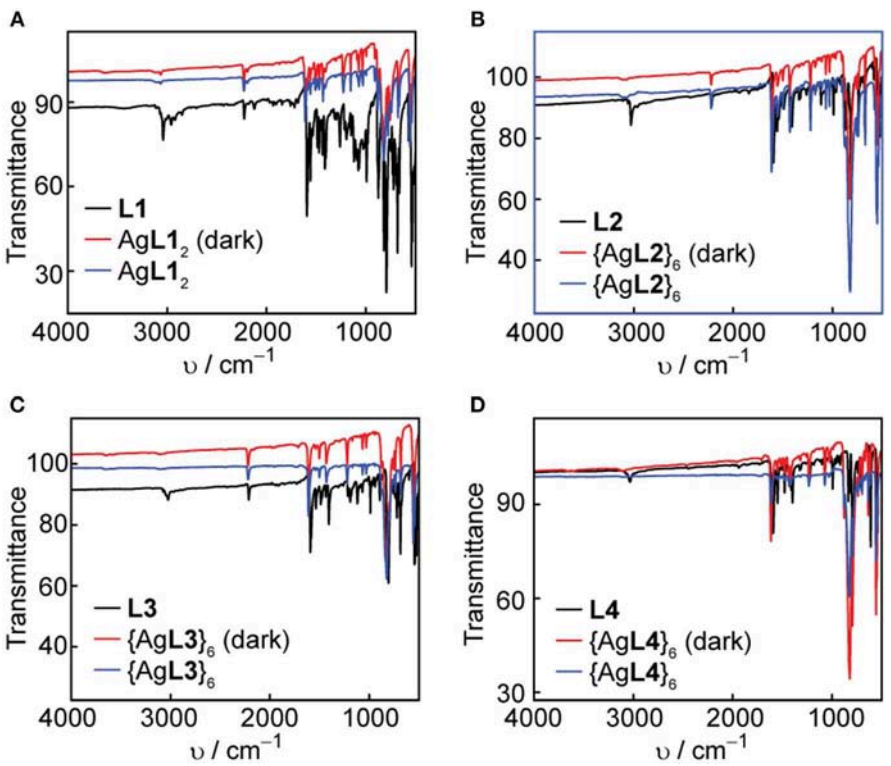

FIGURE 7 | Comparison of FT-IR spectra in the dark and under room light conditions for **(A) L1** and Ag**L1**$_2$, **(B) L2** and {Ag**L2**}$_6$, **(C) L3** and {Ag**L3**}$_6$, and **(D) L4** and {Ag**L4**}$_6$.

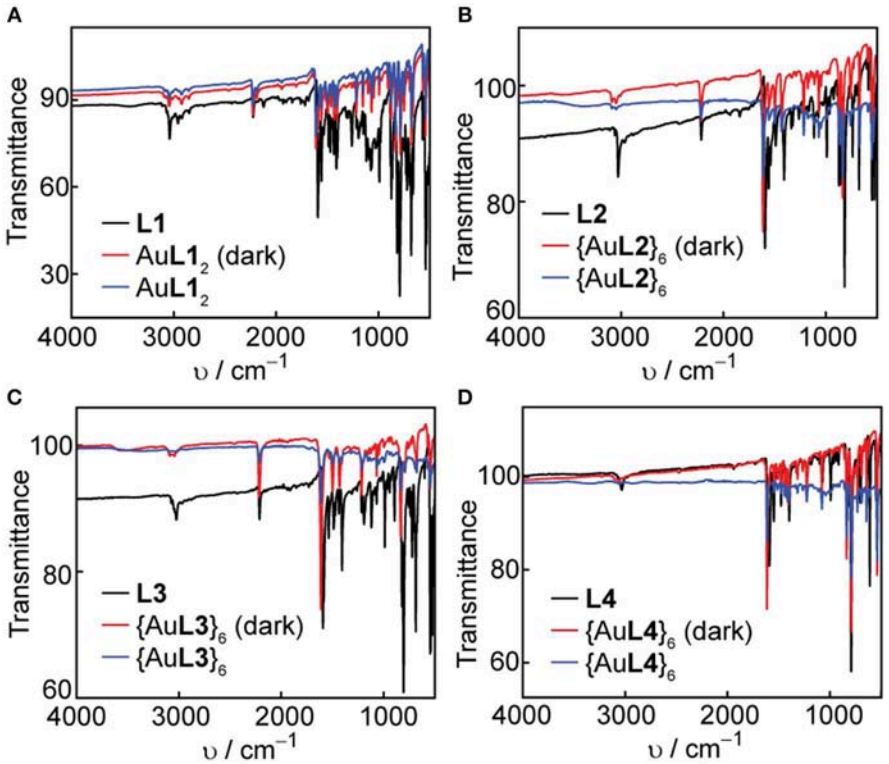

FIGURE 8 | Comparison of FT-IR spectra in the dark and under room light conditions for **(A) L1** and Au**L1**$_2$, **(B) L2** and {Au**L2**}$_6$, **(C) L3** and {Au**L3**}$_6$, and **(D) L4** and {Au**L4**}$_6$.

excitation, fluorescence emission bands centered at 375 nm (**Figures 9A–C**) were observed for **L1**, **L2**, and **L3** in acetone at 3.82, 0.800, and 7.76% quantum yields and 0.11, 0.12, 0.49 ns lifetimes, respectively (**Table 1**). These ligands have ethynyl spacers that connect the central phenyl group to the pyridyl group/s, which helps rigidify the structure and enhance emission. The highest quantum yield and longest lifetime was observed in **L3**, which is not affected by heavy-atom effects, unlike **L1** and **L2** wherein bromide was present. In addition, the four-fold increase in k_{nr} for **L1** (8.91×10^9 s^{-1}) and **L2** (8.00×10^9 s^{-1}) as compared to **L3** (1.89×10^9 s^{-1}), further supports the enhancement of inter-system crossing (ISC) for the bromine-containing ligands. On the other hand, a weak fluorescence band centered at 400 nm (**Figure 9D**) was observed for **L4** but has a quantum yield and lifetime below the limit of our instrumental detection. By placing an upper bound on quantum yield and lifetime of **L4** based on instrumental detection limits, we estimated an upper limit to k_r and a lower limit to k_{nr} as shown in **Table 1**. The absence of the ethynyl spacer in **L4** introduces rotational freedom that enhances internal conversion resulting in very weak emission of the ligand.

Similar to the absorption profiles, we also observe a red-shift in the emission band of Ag**L1**$_2$ centered at 400 nm (**Figure 9A**) but not in Au**L1**$_2$ (375 nm, **Figure 9E**) or any of the Ag(I) hexagons, {Ag**L2**}$_6$ (375 nm, **Figure 9B**), {Ag**L3**}$_6$ (375 nm, **Figure 9C**), and {Ag**L4**}$_6$ (400 nm, **Figure 9D**). These emission profiles are similar to that of the ligand with significant reduction in quantum yields and lifetimes upon ligand coordination to Ag(I) and Au(I) suggesting ligand-centered singlet emissions with some perturbations from Ag(I) argentophilic interactions for the Ag(I) complex. Although not as common, fluorescent transition metal complexes are known (Chia and Tay, 2014). The lack of triplet emissions in these complexes can be attributed to either lack of metal-ligand interaction resulting in small metal contribution at the excited state or larger rate constant for fluorescence compared to that of ISC, which is reasonable given the fluorescence emission of the free ligand. Based on our decay rate constant calculations for the Ag(I) and Au(I) complexes and Ag(I) hexagons, k_{nr} is always higher than k_r which implies poor metal-ligand interaction as the main reason for lack of phosphorescence in these compounds.

We also reported the solid-state quantum yields of all ligands, Ag(I) and Au(I) complexes, and hexagons in **Table 1**. Similar to the solution-state quantum yields, the highest and lowest quantum yields are observed for **L3** are **L4**, respectively. Upon ligand coordination to either Ag(I) and Au(I), we see a general decrease in quantum yields except for {Ag**L2**}$_6$, {Ag**L4**}$_6$, and {Ag**L4**}$_6$. These quantum yield enhancement may be due to aggregation induced emission (Fan et al., 2015; Mei et al., 2015b), particularly in metallacycles containing **L4**, which in itself is weakly emissive, wherein

CONCLUSION

Silver(I) and gold(I) mononuclear complexes and hexagonal rings were self-assembled from $AgPF_6$ and Au(tht)Cl precursors and mono- and bidentate pyridyl ligands. These coordination resulting in self-assembly and complex formation was evidenced by the downfield ^{1}H NMR peak shifts of the ligand pyridyl H peaks and FT-ICR MS peaks with isotopic distributions and mass-to-charge ratios consistent with intact [6 + 6] cores that ionized by the loss of counterions.

Longer-term photostability of all complexes and hexagons in the solid-state were confirmed by FT-IR. Significant peak shifts to higher wavenumbers were observed upon coordination of the ligands to either Ag(I) or Au(I). No changes to the spectra were observed after storing the compounds at ambient conditions under room light for one week.

Ligand-centered fluorescence emission was observed for many of these complexes. In both the solid- and solution-state, **L3** and **L4** were the most and least emissive ligands, respectively. In the solid-state, all complexes and hexagons have diminished emission except for $\{Ag\mathbf{L2}\}_6$, $\{Ag\mathbf{L4}\}_6$, and $\{Au\mathbf{L4}\}_6$ wherein aggregation-induced emission was observed. In the solution-state, all ligands and hexagons exhibited ligand-centered singlet emissions while $Ag\mathbf{L1}_2$ and $Au\mathbf{L1}_2$ both exhibited metal-perturbed ligand-centered singlet emissions.

This work establishes that Ag(I) and Au(I) centers are effective linear nodes for self-assembly reactions with dipyridyl ligands and that the resultant materials stabilize these ions with respect to oxidation and photodecomposition. Due to the modular nature of coordination-driven self-assembly, efforts are ongoing to exploit ligand-tuning to incorporate functional groups that will enhance metallacycle solubility to improve their processability for incorporation into mixed-matrix materials.

DATA AVAILABILITY

The dataset $Ag\mathbf{L1}_2$ (CCDC No. 1879931) for this study can be found in the Cambridge Crystallographic Data Centre https://www.ccdc.cam.ac.uk/solutions/csd-system/components/csd/.

AUTHOR CONTRIBUTIONS

CF designed and carried out the experiments and wrote the manuscript. SK assisted in ligand synthesis. AF carried out the mass spec characterization. TC designed the project and wrote the manuscript.

FUNDING

The project described was supported by Award Number S10RR029517 from the National Center For Research Resources.

Understanding the Role of Yb^{3+} in the Nd/Yb Coupled 808-nm-Responsive Upconversion

Nan Song, Bo Zhou, Long Yan, Jinshu Huang and Qinyuan Zhang**

State Key Laboratory of Luminescent Materials and Devices, Guangdong Provincial Key Laboratory of Fiber Laser Materials and Applied Techniques, Institute of Optical Communication Materials, South China University of Technology, Guangzhou, China

The realization of upconversion at 808 nm excitation has shown great advantages in advancing the broad bioapplications of lanthanide-doped nanomaterials. In an 808 nm responsive system, Nd^{3+} and Yb^{3+} are both needed where Nd^{3+} acts as a sensitizer through absorbing the excitation irradiation. However, few studies have been dedicated to the role of Yb^{3+}. Here, we report a systemic investigation on the role of Yb^{3+} by designing a set of core-shell-based nanostructures. We find that energy migration over the ytterbium sublattice plays a key role in facilitating the energy transportation, and moreover, we show that the interfacial energy transfer occurring at the core-shell interface also has a contribution to the upconversion. By optimizing the dopant concentration and surface anchoring the infrared indocyanine green dye, the 808 nm responsive upconversion is markedly enhanced. These results present an in-depth understanding of the fundamental interactions among lanthanides, and more importantly, they offer new possibilities to tune and control the upconversion of lanthanide-based luminescent materials.

Keywords: upconversion, energy migration, interfacial energy transfer, Nd/Yb coupled system, mechanistic study

INTRODUCTION

Recently, substantial attention has been devoted to the lanthanide-doped nanoparticles due to their great infrared-to-visible photon upconversion performance (Auzel, 2004; Haase and Schafer, 2011; Zhou et al., 2015), which shows potential applications ranging from bioimaging (Zhu et al., 2017) to photodynamic therapy (Xu et al., 2017), 3D display (Deng et al., 2015), security (Lu et al., 2014), anti-counterfeiting (Li et al., 2016), and super-resolution nanoscopy (Liu et al., 2017). The unique 4f electronic configuration with abundant energy levels allows us to easily realize multi-wavelength upconversion emission bands upon infrared excitations (Chen et al., 2014; Dong et al., 2015; Zheng et al., 2015). By taking advantage of strategies including development of new host materials (Lei et al., 2017), control of local structure (Fischer et al., 2016), mechanistic exploration of new pathways using energy migration (Wang et al., 2011; Chen et al., 2017), cross-relaxation (Liu et al., 2017) and interfacial energy transfer (Zhou et al., 2016, 2018), efficient upconversion from a set of lanthanides such as Er^{3+}, Tm^{3+}, Ho^{3+}, Tb^{3+}, and Eu^{3+} was obtained. However, the most used upconversion systems are based on a Yb-sensitized design with 980 nm excitation, which makes the upconversion nanoparticles unsuitable for biological application because of the strong absorption

of water at this wavelength region (Weissleder, 2001; Kobayashi et al., 2011; Zhu et al., 2017). Therefore, developing new classes of upconversion materials would be of great importance for their biomedical applications.

Interestingly, recent works suggest that Nd^{3+} is a possible sensitizer to move the excitation wavelength from 980 to 808 nm due to its $^4F_{5/2} \leftarrow {}^4I_{9/2}$ absorption transition at this wavelength region (Liu et al., 2017; Xie et al., 2017) together with efficient energy transfer from Nd^{3+} to Yb^{3+} (Parent et al., 1986). More importantly, the absorption of excitation energy by water in biological tissues can be effectively minimized. To date, the 808 nm pumped upconversion from a series of lanthanides (e.g., Er and Tb) has been realized (Zhong et al., 2014; Zhou et al., 2018). In the Nd-sensitized upconversion system, Yb^{3+} is also employed to facilitate the energy transfer from Nd^{3+} to the lanthanide emitter, and the typical processes involved in this system can be schematically illustrated in **Figure 1A**. So far, there are four typical core-shell schemes can be used to obtain the upconversion, and typical sample forms for Er^{3+} are $NaYF_4$:Yb/Er/Nd(20/2/1 mol%)@$NaYF_4$, $NaYF_4$:Yb/Er/Nd(20/2/1 mol%)@$NaYF_4$:Nd(30 mol%), $NaYF_4$:Yb/Er@$NaYF_4$:Nd(30 mol%), and $NaYF_4$:Yb/Er(20/2 mol%)@$NaYF_4$:Nd/Yb(30/10 mol%), among which the last one shows the best upconversion behavior (**Figure 1B**). However, few studies have explored the role of Yb^{3+}, which is necessary in the 808 nm pumped upconversion systems, and the mechanism of the luminescence physics occurring in the Nd/Yb coupled upconversion is still not clear.

In this study, we performed a mechanistic investigation on the role of Yb^{3+} in the Nd/Yb coupled 808 nm responsive upconversion. We demonstrated that energy migration over the Yb-sublattice plays a key role in facilitating the energy transportation from the Nd^{3+} sensitizer to the lanthanide emitter. More importantly, we showed that the interfacial energy transfer from Yb^{3+} in the shell to the lanthanide emitter in the core across the core-shell interface also contributes to the upconversion. Such an 808 nm responsive upconversion can be markedly enhanced by optimizing the sample structure together with surface anchoring the infrared indocyanine green (ICG) dye. Our results present an in-depth understanding of the luminescence mechanism involving the Nd/Yb coupled upconversion nanomaterials, which would contribute to both fundamental research and practical applications of lanthanide-doped luminescent materials.

EXPERIMENTAL

Materials

The materials including yttrium(III) acetate hydrate (99.9%), erbium(III) acetate hydrate (99.9%), ytterbium(III) acetate hydrate (99.99%), thulium(III) acetate hydrate (99.9%), holmium(III) acetate hydrate (99.9%), neodymium(III) acetate hydrate (99.9%), oleic acid (90%), 1-octadecene (90%), sodium hydroxide (NaOH; >98%), and ammonium fluoride (NH_4F; >98%) were all purchased from *Sigma-Aldrich*. The nitrosonium tetrafluoroborate ($NOBF_4$; 98%) was purchased from *Alfa Aesar* and indocyanine green ($C_{43}H_{47}N_2NaO_6S_2$), N,N-dimethylformamide (DMF; anhydrous, 99.8%) were purchased from *Energy Chemical*. All these materials were used as received unless otherwise noted.

Sample Synthesis

The core-shell based nanoparticles were synthesized using a coprecipitation chemical method, which was shown to be a good way for the preparation of core only and core-shell based nanoparticles (Wang et al., 2011). The core nanoparticle samples were pre-synthesized as the seeds for growth of the core-shell structure. In a typical procedure for the synthesis of $NaYF_4$:Yb/Er core nanoparticles, to a 50-mL flask containing oleic acid (3 mL) and 1-octadecene (7 mL) was added a water solution containing $Y(CH_3CO_2)_3$, $Yb(CH_3CO_2)_3$, and $Er(CH_3CO_2)_3$ at designed ratios (e.g., 78:20:2 mol%) with a total amount of 0.4 mmol. The resulting mixture was heated at 150°C for 1 h and then cooled down to room temperature. Subsequently, a methanol solution containing NaOH (1 mmol) and NH_4F (1.6 mmol) was added and stirred at 50°C for 0.5 h, and then heated at 290°C under an argon flow for 1.5 h before cooling down to room temperature. The resulting core nanoparticles were collected by centrifugation, washed with ethanol, and finally dispersed in cyclohexane. Other control core nanoparticles were synthesized using a similar procedure except for the use of different lanthanide precursors.

Next, the core-shell nanoparticles were prepared with a two-step coprecipitation method using the pre-synthesized core nanoparticles as seeds for shell layer growth. Typically, for the synthesis of $NaYF_4$:Yb/Er@$NaYF_4$:Nd/Yb core-shell nanoparticles, to a 50-mL flask containing oleic acid (3 mL) and 1-octadecene (7 mL) was added a water solution containing $Y(CH_3CO_2)_3$, $Nd(CH_3CO_2)_3$, and $Yb(CH_3CO_2)_3$ at designed ratios (e.g., 40:50:10 mol%) with a total amount of 0.4 mmol. The resulting mixture was heated at 150°C for 1 h and then cooled down to room temperature. Subsequently, the pre-synthesized $NaYF_4$:Yb/Er particles were added as seeds along with a methanol solution containing NaOH (1 mmol) and NH_4F (1.6 mmol) was added and stirred at 50°C for 0.5 h, and then heated at 290°C under an argon flow for 1.5 h before cooling down to room temperature. The resulting nanoparticles were collected by centrifugation, washed with ethanol, and finally dispersed in cyclohexane. The core-shell-shell nanoparticles were prepared through a three-step coprecipitation method with a similar procedure except for using pre-synthesized core-shell particles as the seeds for the outermost shell layer growth.

The following synthetic procedure was used to prepare dye-decorated nanoparticles. Firstly, the sub-nanometer ligands of $NOBF_4$ were used to exchange the oleic acid ligands for the nanoparticles by coprecipatition method. The nanoparticles despersed in cyclohexane were mixed with the DMF solution of $NOBF_4$ (0.1 M) at room temperature, and the mixture was shaken gently for minutes to extract nanoparticles from upper cyclohexane layer into the bottom DMF layer. The bottom layer solution was then centrifuged at 11,000 rpm for 25 min, and the precipitated nanoparticles were weighted and re-dispersed in DMF (~60 mg/mL) for NIR dye sensitization experiment. Subsequently, a suitable amount of the ICG dyes dissolved DMF

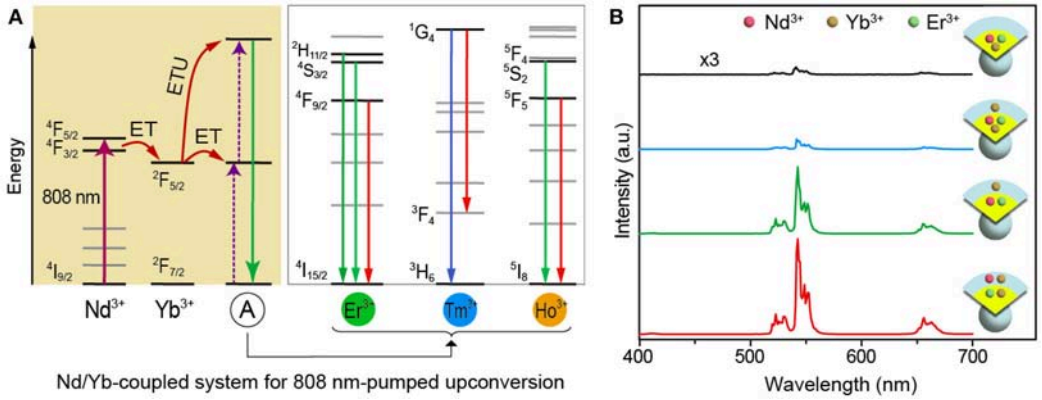

FIGURE 1 | (A) Schematic illustration of energy transportation processes involving the Nd/Yb coupled upconversion system. The typical upconverted visible transitions from Er^{3+}, Tm^{3+}, and Ho^{3+} are marked in the right panel. ET and ETU stand for energy transfer and energy transfer upconversion, respectively. **(B)** Upconversion emission spectra from the four types of core-shell samples of $NaYF_4$:Yb/Er/Nd(20/2/1 mol%)@$NaYF_4$, $NaYF_4$:Yb/Er/Nd(20/2/1 mol%)@$NaYF_4$:Nd(30 mol%), $NaYF_4$:Yb/Er(20/2 mol%)@$NaYF_4$:Nd(30 mol%), and $NaYF_4$:Yb/Er(20/2 mol%)@$NaYF_4$:Nd/Yb(30/10 mol%) under 808 nm excitation.

solution (1 μg/mL) was added to the nanoparticle dispersed DMF solution. This mixture was stirred overnight at room temperature to produce the ICG dyes sensitized nanoparticles in DMF solution.

Characterization

The powder X-ray diffraction (XRD) data were recorded on a Philips Model PW1830 X-ray powder diffractometer with Cu Kα radiation (λ = 1.5406 Å). The upconversion emission spectra and infrared emission spectra were measured by a Jobin-Yvon Triax 320 spectrofluorometer equipped with an 808-nm laser diode with power density of 27.9 W/cm^2. A 980-nm laser diode with identical power density was also used for the excitation of control samples. The decay curves were measured with the same spectrofluorometer using the pulsed lasers as excitation sources. The low- and high-resolution transmission electron microscopy (TEM) measurements, together with elements mappings, were performed on a JEM 2100F with an acceleration voltage of 200 kV. The upconversion emission photographs were taken with a digital camera.

RESULTS AND DISCUSSION

We firstly made an optimization of the upconversion from the $NaYF_4$:Yb/Er@$NaYF_4$:Nd/Yb core-shell nanoparticles at 808 nm excitation. Here the typical $NaYF_4$:Yb/Er(20/2 mol%) nanoparticles were used as core seeds because of their good upconverted luminescence (**Figure S1**). The as-synthesized core-shell nanoparticles showed good monodispersive characteristic (**Figures 2A,B**) and are in hexagonal phase according to the XRD diffraction profile (**Figure S2**). As shown in **Figure 2C**, the increment of Nd^{3+} concentration in the shell layer contributes to an enhancement of the visible upconversion of Er^{3+} and the optimal concentration of Nd^{3+} is found to be 50 mol%. It is easily understood that heavier dopant concentration of sensitizer can result in a higher absorption of the incident excitation irradiation. The upconversion as a function of Yb^{3+} concentration in the shell was also investigated, and the result is shown in **Figure 2D**. The presence of Yb^{3+} in the shell layer indeed leads to the enhancement of upconversion; however, a higher dopant concentration can cause a serious luminescence quenching, and a concentration of 10 mol% is found to be the optimized value with 12.3 times enhancement (**Table S1**). Thus, the optimal concentration of dopants in the shell layer for Nd-Yb pair is determined to be 50 and 10 mol%, respectively. The upconversion performance from Tm^{3+} and Ho^{3+} was also measured by preparing the $NaYF_4$:Yb/A(A=Tm,Ho)@$NaYF_4$:Nd/Yb core-shell samples, and typical upconversion emission profiles were obtained (**Figure S3**). Because Er^{3+} exhibits the most intensive upconversion emission, it was used in the following experiments.

In order to investigate the possible energy migration involving the Nd/Yb coupled upconversion system, we propose a core-shell-shell trilayer nanostructure by inserting the Yb-doped interlayer into the $NaYF_4$:Yb/Er(20/2 mol%)@$NaYF_4$:Nd/Yb(50/10 mol%) core-shell nanostructure, as schematically shown in **Figure 3A**. In this case, the upconversion of Er^{3+} from the core should be closely dependent on the content of Yb^{3+} in the interlayer since it acts as a bridge to facilitate the energy transportation from the outermost shell layer to the core under 808 nm irradiation. These nanoparticles were successfully prepared using the three-step co-precipitation method (**Figure 3B**) and their upconversion emission spectra are shown in **Figure 3C**. It is clearly observed that the upconverted emission from Er^{3+} produces an initial increase and then a decline with the increase of Yb^{3+} content. More importantly, almost no Er^{3+} upconversion is observed for the sample without Yb^{3+} doping in the interlayer. These results clearly confirmed the occurrence of energy migration among Yb-sublattice, and the optimal Yb^{3+} content is at around 20 mol%. On the other hand, intense infrared emission bands of Yb^{3+} were also recorded, see **Figure 3D**. This indicates that the spontaneous $^2F_{5/2} \rightarrow {}^2F_{7/2}$

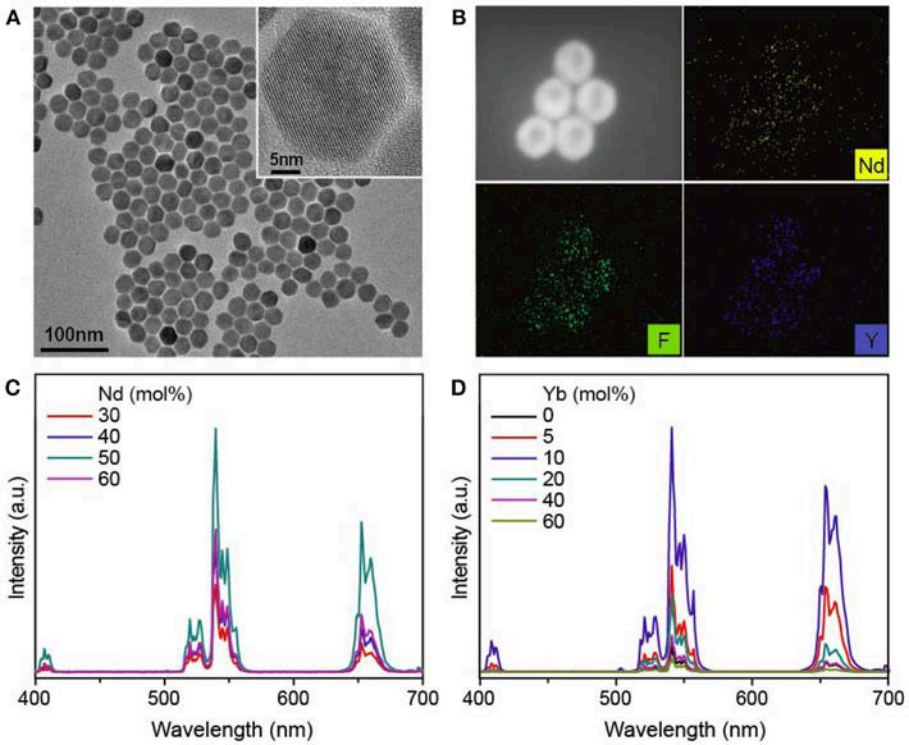

FIGURE 2 | (A) TEM image of the as-synthesized $NaYF_4$:Yb/Er(20/2 mol%)@$NaYF_4$:Nd/Yb(50/10 mol%) core-shell nanoparticles. Inset shows the high-resolution TEM image of a single nanoparticle. **(B)** STEM image of the **(A)** sample and the element mappings of Y, Nd, and F. **(C,D)** Upconversion emission spectra from **(C)** $NaYF_4$:Yb/Er(20/2 mol%)@$NaYF_4$:Nd/Yb(x/10; $x =$ 30∼60 mol%) and **(D)** $NaYF_4$:Yb/Er(20/2 mol%)@$NaYF_4$:Nd/Yb(40/y; $y =$ 0∼60 mol%) core-shell nanoparticles under 808 nm excitation.

transition is also a leading de-excitation channel for Yb^{3+} ions apart from energy migration.

We recently discovered that Yb-mediated interfacial energy transfer is an efficient process for enabling the upconversion from lanthanides (Zhou et al., 2018). Thus, there might exist a channel to activate the lanthanide emitter through a way of interfacial energy transfer in addition to the energy migration involving Yb-sublattice, as schematically illustrated in **Figure 4A**. Then two control core-shell samples of $NaYF_4$:Er@$NaYF_4$:Nd/Yb and $NaYF_4$:Er@$NaYF_4$:Nd were synthesized to check the role of Yb^{3+} in the shell layer. Note that no Yb^{3+} was incorporated into the core aiming to remove the possible interference of Yb^{3+} from the core on the resultant upconversion. Interestingly, the upconverted emission of Er^{3+} was markedly enhanced for the core-shell sample after the presence of Yb^{3+} in the shell layer (**Figure 4B**). This observation confirmed that the Yb^{3+} in the shell layer plays a key role in transporting the excitation energy from the shell layer to the core, and more importantly, it verified that the interfacial energy transfer from the Yb^{3+} in the shell to the Er^{3+} in the core indeed occur. Therefore, it can be concluded that both processes of energy migration and interfacial energy transfer contribute to the observation of efficient upconversion from the Nd/Yb coupled nanosystem.

Such an 808 nm enabled upconversion allows for a further enhancement of the upconversion by introducing the infrared dyes which have much higher absorption ability than Nd^{3+} at 808 nm wavelength region (**Figure 5A**), and the subsequent energy transfer from dye to Nd^{3+} could help greatly enhance the upconversion in this system (Zou et al., 2012; Wu et al., 2016; Wang et al., 2017). Considering the high absorption cross section ($\sim 6 \times 10^{-16}$ cm^2) of indocyanine green (ICG) dye which is ∼5,000 times higher than that of Nd^{3+} (1.2×10^{-19} cm^2) at around 800 nm (Kushida et al., 1968; De Boni and Mendonca, 2011), here we used it to sensitize the upconversion from the present $NaYF_4$:Yb/Er@$NaYF_4$:Nd/Yb core-shell nanoparticles (Wang et al., 2018). As shown in **Figures 5B,C**, the emission intensity is markedly enhanced when using the ICG dye amount of 150 μL (1 μg/mL), confirming the effectiveness of the construction in **Figure 5A**. The detail of energy transportation was shown in **Figure S4**. It should be pointed out that this dye-sensitized upconversion is 210 times more enhanced than that from $NaYF_4$:Yb/Er/Nd@$NaYF_4$:Nd core-shell nanoparticles (**Figure 5D**) when ICG used is 150 μL, at which the number of ICG per particle is estimated to be 32.8 given a full attachment of them at the surface. This result would greatly contribute to the diversity of frontier biological applications.

On the other hand, recent studies showed that a control of energy migration involving Yb-sublattice present a novel and efficient approach to tuning and enhancing upconversion

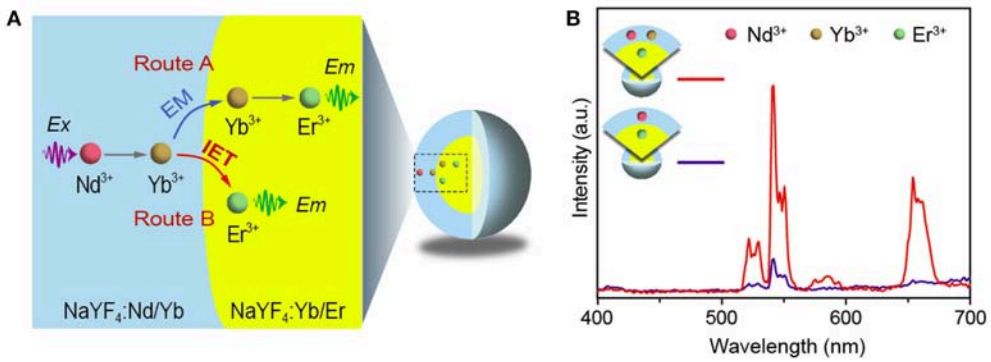

FIGURE 4 | (A) Schematic of possible energy migration (EM; Route A) and interfacial energy transfer (IET; Route B) in the design of $NaYF_4$:Yb/Er@$NaYF_4$:Nd/Yb core-shell nanostructure. Ex and Em stand for excitation and emission, respectively. **(B)** Upconversion emission spectra from control samples of $NaYF_4$:Er(2 mol%)@$NaYF_4$:Nd/Yb(50/10 mol%) and $NaYF_4$:Er(2 mol%)@$NaYF_4$:Nd(50 mol%) under 808 nm excitation.

performance of lanthanides (Chen et al., 2016; Liu et al., 2018). In the present work, the presence of Yb^{3+} into the shell layer indeed leads to a decline of the upconversion (**Figure S5**). We then designed a $NaYF_4$:Yb/Er@$NaNdF_4$:Yb@$NaYF_4$:Nd core-shell-shell nanostructure to improve the upconversion at 808 nm irradiation by making a fine tuning of the Yb^{3+} concentration in the Nd-sublattice (**Figure 6A**). It was found that 50 mol% Yb^{3+} in the $NaNdF_4$ interlayer is the optimal value for balancing the absorption and further transportation of the incident 808 nm excitation energy. Note that this Yb^{3+} content (50 mol%) in the interlayer is much higher than that from the $NaYF_4$:Yb/Er@$NaYF_4$:Nd/Yb core-shell nanostructure (10 mol%), revealing that there might exist a possibility of energy migration over to the surface which can quench the upconversion. In this case, the designs with high doping of migratory lanthanides need an optically inert shell layer to isolate the interactions between lanthanide emitter and surface quencher (Liu et al., 2018; Yan et al., 2018). Notably, the

Inset shows their emission photographs under 808 nm irradiation.

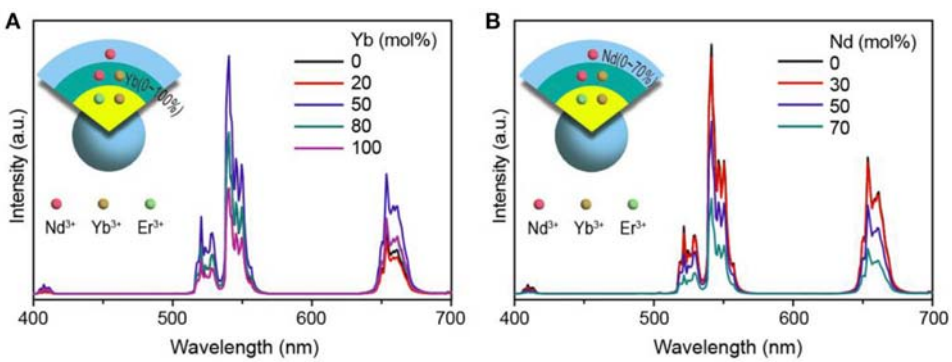

FIGURE 6 | Upconversion emission spectra from the **(A)** $NaYF_4$:Yb/Er(20/2 mol%)@$NaNdF_4$:Yb(0~100 mol%)@$NaYF_4$:Nd(50 mol%) and **(B)** $NaYF_4$:Yb/Er(20/2 mol%)@$NaNdF_4$:Yb(50 mol%)@$NaYF_4$:Nd(0~70 mol%) core-shell-shell samples under 808 nm excitation. Insets show the structure of the trilayer samples.

upconversion emission intensity is much weaker for these samples without the outermost shell layer (**Figure S6**). We further investigated the role of Nd^{3+} in the outermost shell layer. And the spectral result shows that a doping of it in the shell layer caused a slight decline in the upconversion intensity (**Figure 6B**) and lifetime (**Figure S7**). It should be noted that the near infrared emission from Yb^{3+} can be well improved (**Figure S8**).

CONCLUSIONS

In conclusion, the role of Yb^{3+} in the Nd/Yb coupled upconversion system was mechanistically investigated. By designing a $NaYF_4$:Yb/Er@$NaYF_4$:Yb@$NaYF_4$:Nd/Yb core-shell-shell nanostructure with a Yb^{3+} content tuneable interlayer, we have confirmed that the energy migration over the ytterbium sublattice plays a critical role in facilitating the energy transportation from the sensitizer in the shell to the lanthanide emitter in the core. Interestingly, the direct interfacial energy transfer from Yb^{3+} in the shell to the emitter in the core also contributes to the upconversion. By further sensitization through using the infrared dyes, the upconversion luminescence intensity was markedly enhanced. These results on dynamics in the 808 nm pumped upconversion systems provide an in-depth mechanistic understanding of the energy interactions occurred in lanthanides, and more importantly, the markedly enhanced upconversion performance shows great promise in the diversity of biological applications.

AUTHOR CONTRIBUTIONS

BZ conceived and designed the experiments. NS, LY, and JH performed the experiments. BZ and QZ supervised the project. BZ wrote the manuscript with input from all authors.

Front. Chem. 7:88. doi: 10.3389/fchem.2019.00088

This study analyzes the mapping of temperature distribution generated by graphene in a glass slide cover after illumination at 808 nm with a good thermal resolution. For this purpose, Er,Yb:$NaYF_4$ nanoparticles prepared by a microwave-assisted solvothermal method were used as upconversion luminescent nanothermometers. By tuning the basic parameters of the synthesis procedure, such as the time and temperature of reaction and the concentration of ethanol and water, we were able to control the size and the crystalline phase of the nanoparticles, and to have the right conditions to obtain 100% of the β hexagonal phase, the most efficient spectroscopically. We observed that the thermal sensitivity that can be achieved with these particles is a function of the size of the nanoparticles and the crystalline phase in which they crystallize. We believe that, with suitable changes, these nanoparticles might be used in the future to map temperature gradients in living cells while maintaining a good thermal resolution.

Keywords: green synthesis, upconversion nanoparticles, graphene, nanothermometry, thermal mapping

INTRODUCTION

Carbon-based materials have emerged as promising photothermal agents due to their wideband optical absorption that allows the absorption of light at various wavelengths leading to an efficient heat conversion (Han et al., 2018). The extraordinary properties of graphene propelled its application in many fields of science, including its use as photothermal conversion agent (Savchuk et al., 2016). The excellent performance of graphene as a photothermal conversion material has allowed its use in photothermal therapy, usually in combination with other functional materials with complementary properties (Zhu et al., 2010). However, we are not aware of the existence of studies on the thermal mapping of graphene films.

With the development of nanotechnology, the determination of temperature in a given system with submicrometric spatial resolution became possible. This has led to the development of a new

subfield of thermometry, named nanothermometry, which studies the measurement of temperature at the nanoscale level (Lee and Kotov, 2007). Luminescence thermometry is considered to be one of the most promising non-contact techniques for temperature determination at the sub-micrometer and nanometer scale due to its very high spatial, thermal, and temporal resolutions, large measurement ranges and affordable costs (Brites et al., 2012; Jaque and Vetrone, 2012). A big number of materials has been studied for luminescence nanothermometry applications, including quantum dots (Maestro et al., 2010, 2014; Vlaskin et al., 2010; Benayas et al., 2015), organic dyes (Peterman et al., 2003; Steinegger et al., 2017; Xie et al., 2017), gold nanoparticles (Bomm et al., 2012; Shang et al., 2013), polymers (Graham et al., 2010; Okabe et al., 2012; Hannecart et al., 2015), and lanthanide doped materials (Cheng et al., 2013; Zheng et al., 2014; Cerón et al., 2015; Piñol et al., 2015; Zhu et al., 2016; Balabhadra et al., 2017). The different measurement techniques used, and based on changes in radiative lifetimes, intensity variations, spectral position shifting, and broadening of emission lines induced by temperature, have proved to be potential tools for temperature determination even in biosystems (Vetrone et al., 2010; Fischer et al., 2011; Du et al., 2014; Zhu et al., 2016; Li et al., 2017).

However, some of these materials attracted more attention because of their interesting advantages for luminescent nanothermometry. These materials are the Ln^{3+}-doped upconversion nanoparticles (Ln^{3+}-UCNPs). This kind of material absorbs light in the near-infrared (NIR) region of the electromagnetic spectrum, while emitting light in the visible range (Haase and Schäfer, 2011). Pumping in the NIR allows to overcome problems related to the background fluorescence arising from biological tissues, and the potential damage that ultraviolet (UV) light can generate in them (Diao et al., 2015), for instance. Finally, the use of NIR radiation also preserves the operative lifetime of the phosphors used in comparison with those illuminated with UV light, usually damaged by this radiation, that shortens their operational lifetimes (Rapaport et al., 2006).

Er^{3+} is the most used lanthanide ion for luminescence thermometry purposes in UCNPs because of its intense green emission that consists of two luminescence bands centered at 520 and 540 nm and assigned to the $^2H_{11/2} \rightarrow {}^4I_{15/2}$ and $^4S_{3/2} \rightarrow {}^4I_{15/2}$ radiative transitions, respectively. These two energy levels, from which the emission arises, are thermally coupled and, thus, the relative emission intensity of these two luminescence bands shows a strong temperature dependence (Vetrone et al., 2010; Fischer et al., 2011; Du et al., 2014; Zhu et al., 2016; Li et al., 2017). Among the potential crystalline matrices that can host Er^{3+}, $NaYF_4$ emerged as the most promising one (Krämer et al., 2004; Wang et al., 2010).

However, $NaYF_4$ can crystallize in two polymorphic phases: the α-$NaYF_4$ phase with $Fm\bar{3}m$ space group and the hexagonal β-$NaYF_4$ phase with $P\frac{6_3}{m}$ space group (Wang et al., 2010). High reaction temperatures and long reaction times can induce the phase transformation from the metastable α phase to the thermodynamically stable β phase (Zhou et al., 2013). Thus, the synthesis of $NaYF_4$ phosphors has been extensively studied, especially to explore the best conditions to obtain the pure β phase with a high production yield. Microwave-assisted hydrothermal synthesis emerged as an efficient method for the synthesis of monodispersed and highly luminescent $NaYF_4$ nanoparticles (Wang and Nann, 2009), since it allows for a fast and uniform heating in an eco-friendly and energy-efficient way. However, those procedures still suffer from poor yields (Wang and Nann, 2009), production of mixtures of α and β phases (Mi et al., 2011), limited to microtubes (Chen et al., 2009; Tong et al., 2017), and nanowires (Wawrzynczyk et al., 2015), as well as micron-size particles (Som et al., 2016).

Here, we report the synthesis of Er,Yb:$NaYF_4$ nanoparticles by a microwave-assisted solvothermal method which allowed us to obtain these nanoparticles in short times and at low temperatures. Furthermore, by tuning the basic parameters of the synthesis process, such as temperature and time of reaction, we succeeded in obtaining nanoparticles with different sizes and in isolating the different crystalline phases. We have been able to get the right conditions to obtain 100% of the pure β-$NaYF_4$ phase with a production yield ranging from 64 to 98%. We also analyzed the temperature dependence of the luminescence of these nanoparticles. Nanoparticles with bigger sizes belonging to the hexagonal β phase showed a higher relative sensitivity than those with smaller sizes or those belonging to the cubic α phase. Finally, we used these nanoparticles to map the temperature distribution generated by the laser-induced heating of graphene deposited on a glass cover slide generated by a photothermal conversion process.

EXPERIMENTAL SECTION

Synthesis of Er,Yb:$NaYF_4$ Nanoparticles

Yb (20 mol. %), Er (2 mol. %) co-doped $NaYF_4$ nanoparticles were synthesized by a microwave-assisted solvothermal method. High purity Y_2O_3, Yb_2O_3, and Er_2O_3, analytical reagents, trisodium citrate ($Na_3C_6H_5O_7$), sodium fluoride (NaF), and ammonium fluoride (NH_4F) were used as raw starting reagents. $RE(NO_3)_3$ (RE = Y, Yb, Er) were prepared by dissolving the corresponding RE_2O_3 in 10 ml of hot nitric acid (HNO_3). After the evaporation of the nitric acid, 15–65.5 ml of ethanol (depending on the experiment) in which 8.1–24.7 g of trisodium citrate (depending on the experiment) were dissolved, were added and stirred for 60 min. In another vessel, 0.08–0.36 g of NaF and 0.45–3.62 g of NaH_4F were dissolved in 7.5–60 ml of hot water, depending on the experiment. Then, the two solutions were mixed together. After a vigorous stirring for 2 h, the solution was transferred to a Teflon reactor with a total volume of 70 ml. This reactor was placed in a Milestone ETHOS-TOUCH CONTROL laboratory microwave autoclave, where it was maintained at a temperature between 393 and 453 K under continuous stirring during a period of time ranging from 3 to 6 h, depending on the experiment. Finally, the solution was cooled down naturally, and the precipitated nanoparticles were washed with ethanol and deionized water three times. **Table 1** summarizes the synthesis conditions for the different experiments we performed.

Structural and Morphological Characterization

The crystalline structure of the obtained Er,Yb:$NaYF_4$ nanoparticles was investigated by means of X-ray powder diffraction analysis using a Bruker-AXS D8-Discover diffractometer using Cu Kα radiation. The crystallite size was calculated with the data corresponding to all the reflections in the diffraction pattern using the Scherrer equation. The crystallite size is also listed in **Table 1**.

The morphology of the Er,Yb:$NaYF_4$ nanoparticles obtained by the microwave-assisted solvothermal method was investigated using an environmental scanning electron microscope (ESEM) FEI Quanta 600 and a transmission electron microscope (TEM) JEOL 1011.

Temperature-Dependent Luminescence Measurements

For temperature dependent luminescence measurements, the Er,Yb:$NaYF_4$ nanoparticles were placed in a Linkam THMS 600 heating stage equipped with a BN disk that allowed an improved temperature distribution in the chamber. The nanoparticles were excited by a fiber-coupled diode laser emitting at 980 nm with a power of 10 mW, so that the contribution of the excitation laser to the heating of the nanoparticles is negligible. The laser beam was focused on the sample with a 40× microscope objective with a numerical aperture N.A. = 0.6, providing a spot size of around 100 μm on the sample. The visible emission arising from the nanoparticles was registered by the same microscope objective, and after passing a dichroic filter to eliminate the excitation radiation, it was fiber coupled to an AVANTES AVS-USB2000 spectrometer for the recording of the emission spectra. These spectra were recorded at temperatures between RT and 333 K.

Thermal Mapping of Heat Transfer Through a Graphene-Coated Glass

Hundred microliters of a graphene solution in dymethylformamide (DMF) with a concentration of 1 mg ml^{-1} were deposited on a microscope slide cover glass with a thickness of 100 μm. The solvent was evaporated letting it dry at 353 K, generating a film with a thickness ranging between 700 nm and 1.2 μm, determined with a SENSOFAR PLμ 2300 confocal microscope. On the other side of the same microscope slide cover glass 100 μl of a dispersion of the Er,Yb:$NaYF_4$ nanoparticles in ethanol with a concentration of 10 mg ml^{-1} was deposited. A fiber-coupled diode laser emitting at 808 nm with powers ranging from 20 to 200 mW, depending on experiments, was focused on the graphene-coated cover glass using a 60× microscope objective (N. A. = 0.7), generating a beam with a diameter of 9 μm on the sample. Graphene efficiently absorbs the 808 nm laser light and converts it into heat (Savchuk et al., 2016). The temperature generated was then determined

through the analysis of the upconversion emission spectra of Er,Yb:$NaYF_4$ nanoparticles.

RESULTS AND DISCUSSION

Microwave-Assisted Solvothermal Synthesis of Er,Yb:$NaYF_4$ Nanoparticles

Er,Yb:$NaYF_4$ nanoparticles were synthesized with the microwave-assisted solvothermal method. The scheme of the synthesis process is shown in **Scheme 1**. Compared to other conventionally heated hydrothermal methods, microwave heating is a greener approach to the synthesis of materials, since it allows for a shortening of the reaction times, a reduction of the reaction temperature and thus, for a reduction of the energy consumption (Komarneni et al., 1992; Sánchez et al., 2013; Granados-Reyes et al., 2014). By changing the reaction temperature, the reaction time and the ethanol and water volumes, we obtained nanoparticles with different sizes and crystallizing in different crystalline phases, as listed in **Table 1**, identifying the conditions to obtain pure α- and β-$NaYF_4$ nanoparticles. TEM and ESEM images of all the nanoparticles obtained are presented in **Figure S1**.

Since the β phase allows to obtain a higher up-conversion emission intensity, we focused our efforts in maximizing the production of this phase.

In the case of nanoparticles synthesized at 453 K for 6 h, the pure β-$NaYF_4$ phase was obtained for solutions containing ethanol concentrations between 40 and 70%, while a mixture of the α and β phases (α phase with a lower concentration than the β phase) was obtained in solutions with a lower ethanol content. These solutions with a lower ethanol content were avoided in the remaining experiments. When the reaction time was reduced to 3 h, while keeping the reaction temperature at 453 K, the pure β phase was obtained for all the solutions analyzed. When the temperature was reduced to 423 K, the pure β phase was obtained for all the solutions analyzed, expect for the one formed by 90% ethanol and 10% water, in which we obtained the pure α phase. This solution composition was not used in the last experiment, in which the temperature was reduced to 393 K, while the reaction time was kept at 3 h. Under these conditions, we were able to obtain the pure β phase again for all the solutions analyzed.

The yields of production of the β phase were high in all cases, between 64 and 98%, as listed in **Table 1**. The production yields are higher for the samples prepared in solutions containing a higher ethanol content, and this does not seem to depend on the synthesis temperature. However, as the reaction time increased, the production yields decreased, which would indicate that the products formed tend to dissolve again with a long exposure to the solution.

The crystallite size of these nanoparticles was calculated using the Scherrer equation (Patterson, 1939). The results are listed in **Table 1**. Comparing the crystallite size of the nanoparticles obtained from solutions containing the same ethanol concentrations at different temperatures and reaction times, we observed that the smallest crystallite sizes were obtained for the nanoparticles synthesized at 453 K for 3 h, while, even when the temperature was reduced to 423 or 393 K, the crystallite size increased again.

If we take a look to the shape of the nanoparticles obtained, we can observe that at low synthesis temperatures we obtained short rods, but as the temperature increased these rods tended to transform toward more irregular or spherical shapes. However, the surfaces of these nanoparticles are not smooth, indicating that probably they are formed by the agglomeration of the smaller short rod units. Also, when the reaction time was increased from 3 to 6 h, sub-micrometric size particles exhibiting a long rod shape were obtained. Finally, comparing the shape of the nanoparticles obtained using different ethanol concentrations, we observed that as the ethanol concentration increased, the nanoparticles tended to show more irregular, spherical or long rod shapes, depending on the synthesis temperature and the reaction time used.

As explained in the Introduction of this article, microwave-assisted hydrothermal methods have been previously used for the synthesis of $NaYF_4$ phosphors. Wang and Nann used sodium trifluoroacetate (TFA), yttrium-TFA, ytterbium-TFA, and erbium-TFA as initial reagents dissolved in oleic acid and 1-octadecene to obtain $NaYF_4$ nanocrystals. They used a microwave-assisted process at 563 K for 5 min, obtaining cubic α-$NaYF_4$ nanoparticles with very small sizes (11 nm in diameter) with a poor yield (Wang and Nann, 2009). Chen et al. (2009) used NaF, NH_4HF_2, and Y, Yb, and Tm nitrates as initial reagents dissolved in water to obtain $NaYF_4$, adjusting the pH with HF, and heating the solution at 453 K for 4 h in a microwave synthesizer. They obtained β-$NaYF_4$ microtubes, 0.5 μm in diameter and 2–3 μm long. Similar microtubes were obtained

by Tong et al. (2017) using a similar methodology. Later, Mi et al. (2011) used rare earth acetates, such as NH_4F and NaCl, and fluorine and sodium sources, respectively, dissolved in a mixture of water and ethylene glycol, and treated thermally in a microwave autoclave at 433 K for 1 h. Under these conditions they obtained a mixture of the α and β phases with average sizes of around 40 nm. More recently, Wawrzynczyk et al. (2015), using a microwave flash-heating method, obtained $NaYF_4$ nanowires 1.5 mm long and 100 nm in diameter. On the other hand, Som et al. (2016) prepared Er,Yb:$NaYF_4$ phosphors using rare earth nitrates and NaF dissolved in water, and adding ethylenediamine tetra acetic acid (EDTA) as chelating agent. They adjusted the pH of the solution with NaOH in a microwave digestion unit at 453 K for different time periods extending from 10 min to 2 h. The samples obtained at shorter times crystallized in the α metastable phase with small amounts of YF_3, indicating that the reaction was not complete. For intermediate times they obtained mixtures of the α and β phases, while the samples obtained at longer times exhibited only the pure β-$NaYF_4$ phase with a hexagonal prism shape, with a mean diameter of 1.0 μm and a length of 5.5 μm. More recently, Palo and co-workers obtained $NaYF_4$ nanoparticles using a microwave-assisted solvothermal method at relatively low temperatures (413–458 K) and long times (4–12 h) (Palo et al., 2016). However, the resulting nanoparticles are a mixture of the two phases with different morphologies (spherical, large cubes, and rods). Wang et al., in their study, synthesized β-$NaYF_4$ nanoparticles uniform in size and with s strong fluorescence using a solvothermal method. The nanoparticles prepared using the synthesis optimal conditions (453 K, 24 h, and 5 ml of oleic acid) were used as fluorescent labels for fingerprint applications (Wang et al., 2015).

Thus, when comparing the results previously reported with the ones we obtained, we can conclude that the microwave-assisted solvothermal method we developed allows obtaining pure β-$NaYF_4$ nanoparticles with smaller sizes and at lower temperatures and shorter reaction times. Also, we avoided the appearance of microtubes or nanowires. Furthermore, the synthesis procedure we present here avoids the use of organic ligands like oleic acid (Wang and Nann, 2009; Wang et al., 2015) or EDTA (Som et al., 2016), which confer a hydrophobic character to the nanoparticles obtained and are difficult to eliminate at the end of the reaction. With our synthesis procedure, the production yields obtained ranged from 64 to 98%, as can be seen in **Table 1**. Thus, the methodology presented here shows several advantages over the technologies previously reported in the literature, such as the use of lower temperatures, the production of pure α and β phases, the possibility to avoid mixtures of both phases, or the use of cheaper solvents avoiding organic ligands that have to be removed at the end of the synthesis process. Furthermore, the nanoparticles obtained are already dispersible in water and biological compatible fluids, without requiring any post-growth treatment, which is a clear advantage when one expects to use such nanoparticles for biological applications.

We selected three representative sets of nanoparticles from the experiments performed: NP1, synthesized at 453 K for 6 h with an ethanol/water volume ratio 70/30; NP2, synthesized at 453 K for 3 h with an ethanol/water volume ratio 80/20; and NP3, synthesized at 423 K for 3 h with an ethanol/water volume ratio 90/10. An ESEM image of the NP1 nanoparticles is shown in **Figure 1a**. They show a prismatic shape with a hexagonal base, 300 nm in diameter and 600 nm long. This is the morphology we labeled as long rods in **Table 1**. Instead, samples NP2 and NP3 show nanoparticles with an almost spherical shape with average sizes of 50–70 and 20 nm, respectively, as observed in the TEM pictures shown in **Figures 1b,c**. They correspond to the morphologies labeled as irregular and spherical, respectively, in **Table 1**. The sizes of the nanoparticles corresponding to NP2 and NP3 samples, determined from the TEM pictures, match the crystallite sizes determined using the Scherrer equation. In the case of the NP1 sample, however, a large discrepancy was observed. This can be due to the fact that the size of these sub-micrometer particles is at the limit of the validity range for size determination using this equation, established at around 500 nm, and also to the fact that the Scherrer equation only accounts for one of the dimensions of the particles, that in this case were constituted by hexagonal prisms (Muniz et al., 2016). **Figure 1d** shows the X-ray diffraction (XRD) patterns recorded for these samples. We observed that samples NP1 and NP2 crystallize in the hexagonal system, with space group $P6_3/m$ corresponding to the β-$NaYF_4$ phase, as confirmed by the comparison with the JCPDS reference pattern 16–334, also included in the figure. In contrast, the nanoparticles in sample NP3, which were synthesized at a lower temperature and for a shorter time, crystallize in the cubic system, with space group Fm3m corresponding to the α-$NaYF_4$ phase, as confirmed by the comparison with the JCPDS reference pattern 39–723, also included in the figure. Additionally, we confirmed that the β-$NaYF_4$ nanoparticles obtained with this procedure were highly crystalline, as confirmed by the SAED pattern obtained by electron diffraction of one of these nanoparticles included in the inset of **Figure 1b**.

Temperature-Dependent Luminescence Measurements

The emission spectra of these nanoparticles after excitation at 980 nm are shown at room temperature and at 333 K in **Figure 2**. These spectra consist of two green bands centered at 520 and 540 nm, assigned to the $^2H_{11/2} \rightarrow {}^4I_{15/2}$ and $^4S_{3/2} \rightarrow {}^4I_{15/2}$ transitions of the Er^{3+} ion, respectively. An additional red band was observed at 630–670 nm, assigned to the $^4F_{9/2} \rightarrow {}^4I_{15/2}$ transition of Er^{3+}. While this red band shows a lower intensity than the green bands in samples NP1 and NP2, it is the main band in sample NP3, associated with the different crystalline phases of these nanoparticles.

The pathways for the generation of these emission lines through an upconversion process are well-known and have been previously used for luminescence thermometric applications (Vetrone et al., 2010; Dong et al., 2014; Jiang et al., 2014). Excitation at 980 nm promotes electrons of Yb^{3+} from the $^2F_{7/2}$ fundamental state to the $^2F_{5/2}$ excited state, from where an energy transfer process to Er^{3+} occurs, populating its $^4I_{11/2}$ energy

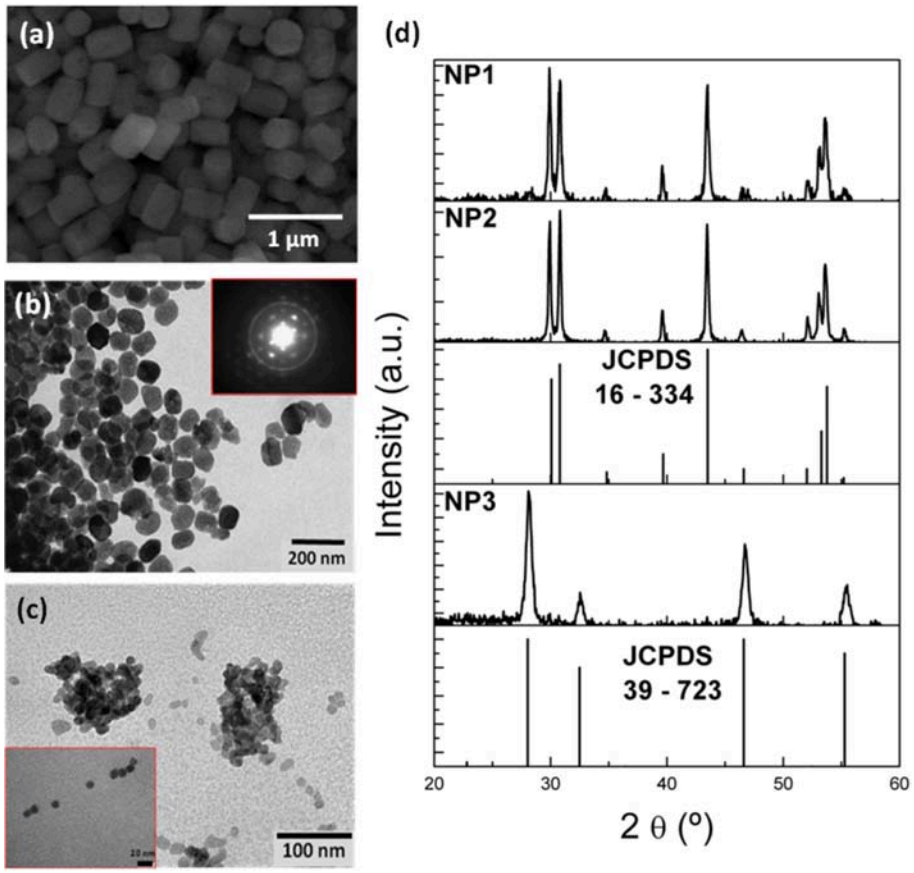

FIGURE 1 | (a) ESEM image of the nanoparticles obtained in the NP1 sample. TEM images of the nanoparticles obtained in the **(b)** NP2 and **(c)** NP3 samples. **(d)** X-ray diffraction patterns of the samples, together with the reference diffraction patterns for the α- and β-$NaYF_4$ crystalline phases.

level. A second energy transfer process from Yb^{3+} promotes the electrons of Er^{3+} from the $^4I_{11/2}$ to the $^4F_{7/2}$ level. Then, non-radiative relaxation processes populate the $^2H_{11/2}$ and $^4S_{3/2}$ states, which results in the $^2H_{11/2} \rightarrow {}^4I_{15/2}$ and $^4S_{3/2} \rightarrow {}^4I_{15/2}$ radiative decays, emitting photons at 520 and 540 nm, respectively. The $^4F_{9/2}$ energy level is populated by a new energy transfer process from Yb^{3+} to Er^{3+} that occurs after a non-radiative relaxation process from the $^4I_{11/2}$ to the $^4I_{13/2}$ energy level.

As observed in **Figure 2A**, the intensity of the visible emissions decreased when the temperature increased for all samples.

The fluorescence intensity ratio (FIR) technique has proven to be an efficient tool to evaluate the luminescence thermometry properties of the green emissions generated by Er^{3+} in several materials, including Er,Yb:$NaYF_4$ nanoparticles (Vetrone et al., 2010; Dong et al., 2014; Jiang et al., 2014). This technique is based on the comparison of the intensities of two emission bands arising from two closely spaced energy levels, the $^4S_{3/2}$ and $^2H_{11/2}$ levels of Er^{3+} in this case, whose populations are in thermal equilibrium governed by a Boltzmann distribution. **Figure 2B** shows the evolution of the FIR with temperature. FIR can be calculated based on a Boltzmann distribution equation defined as (Wade et al., 2003):

$$FIR\left(\frac{I_{520}}{I_{540}}\right) = \frac{g_1\gamma_1\sigma_1}{g_2\gamma_2\sigma_2}e^{\left(-\frac{\Delta E}{kT}\right)} \quad (1)$$

where I_{520} and I_{540} are the intensities of the emission bands located at 520 and 540 nm, respectively, g_i are the degeneracy of levels, γ_i are the spontaneous emission rates, σ_i are the absorption rates, ΔE is the energy difference between the two thermally coupled energy levels involved in the radiative transitions, k is the Boltzmann constant, and T is the absolute temperature.

Experimental points for the different samples were fitted to Equation 1, and the obtained expressions are included in **Figure 2B**. The nanoparticles that show the highest slope are those corresponding to the NP1 sample.

The qualitative performance of these nanoparticles to sense small changes in temperature was obtained by calculating the relative thermal sensitivity as the first derivative of FIR with respect to temperature divided by the FIR (Brites et al., 2012). The relative thermal sensitivities of the analyzed samples are included in **Figure 2C**. The NP1 sample, with nanoparticles exhibiting bigger sizes, possesses the highest thermal sensitivity

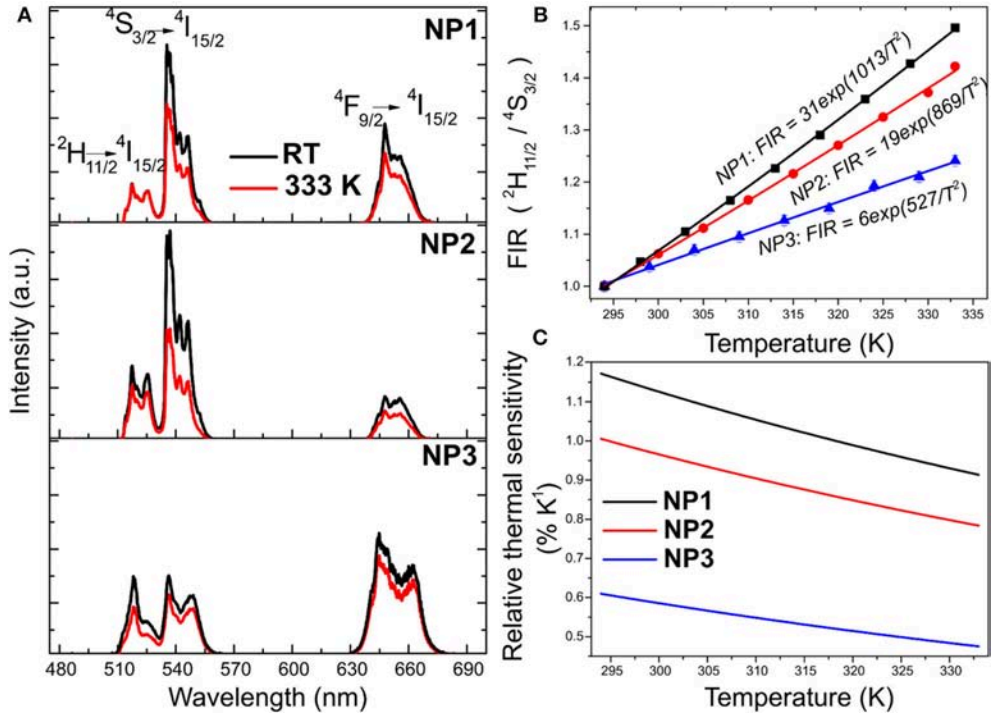

FIGURE 2 | (A) Upconversion emission spectra at room temperature (black) and 333 K (red) for NP1, NP2, and NP3 samples. **(B)** Normalized FIR as a function of temperature for NP1 (black), NP2 (red) and NP3 (blue) samples with the corresponding fitting following a Bolzmann thermal distribution. **(C)** Relative thermal sensitivity as a function of temperature for the three samples [NP1 (black), NP2 (red), and NP3 (blue)].

with a maximum of around 1.2% K^{-1} at 333 K. The thermal sensitivity of the NP2 sample is smaller than that of NP1. Thus, based on the presented results we can conclude that at the sub-micron and nanoscale, smaller β-Er,Yb:$NaYF_4$ nanoparticles would show smaller thermal sensitivities. This can be explained by the presence of a higher concentration of luminescent active ions close to the surface of smaller nanoparticles due to their higher surface to volume ratio. These ions would interact with the ligands attached to the surface of the nanoparticles, leading to concentration quenching processes that would affect negatively their thermal sensitivity. This might seem at odds with the data reported by Dong et al. (2014), since they reported that β-Er,Yb:$NaYF_4$ particles with smaller sizes presented a higher thermal sensitivity. However, they analyzed micron-size particles, while the nanoparticles here presented lay in the sub-micron and nanoscale. Nevertheless, the thermal sensitivity of the β-Er,Yb:$NaYF_4$ nanoparticles synthesized by this microwave-assisted solvothermal method is similar, or even slightly higher, than that reported for the same nanoparticles synthesized with other methods, in the range 0.21–1.24% K^{-1} (Vetrone et al., 2010; Fischer et al., 2011; Wu et al., 2011; Sedlmeier et al., 2012; Dong et al., 2014). Finally, α-Er,Yb:$NaYF_4$ nanoparticles in the NP3 sample showed the smallest thermal sensitivity. This is not surprising since the luminescence efficiency of the α-phase has been reported to be smaller than that of the β-phase, despite its thermal efficiency for luminescence thermometry has not been reported before. The thermal resolution that can be achieved with these nanoparticles, calculated by dividing the precision of the detection system (0.5% in our case) by the relative thermal sensitivity, is presented in **Figure S2**.

Temperature Distribution Mapping in Graphene by Luminescence Thermometry

In order to prove the potentiality of the Er,Yb:$NaYF_4$ nanoparticles synthesized through the microwave-assisted solvothermal method, we used them to map the temperature distribution generated on a glass coated with graphene when illuminated with a laser beam. In order to do this, we took a 100 μm thick microscope slide cover glass and we coated it with graphene flakes on one side, generating a continuous film with a thickness varying from 700 nm to 1.2 μm, and Er,Yb:$NaYF_4$ nanoparticles (corresponding to the NP1 sample) on the other side. Two spatially overlapped lasers were focused on both sides of the slide cover glass. A fiber-coupled diode laser emitting at 808 nm with a beam diameter of 9 μm was focused on the face of the cover glass coated with graphene. Graphene efficiently absorbs the 808 nm laser light and converts it into heat (Savchuk et al., 2016). The propagation of the heat generated by graphene on the opposite side of the cover glass was measured by determining the temperature through the spectra generated by the Er,Yb:$NaYF_4$ nanoparticles when excited with a fiber-coupled diode laser emitting at 980 nm with a beam diameter of 10 μm and by using the calibration curve shown in **Figure 2B**. The scheme of this experimental setup is shown in **Figure 3A**.

First, we measured the temperature that can be achieved in the system when the power of the 808 nm laser focused on

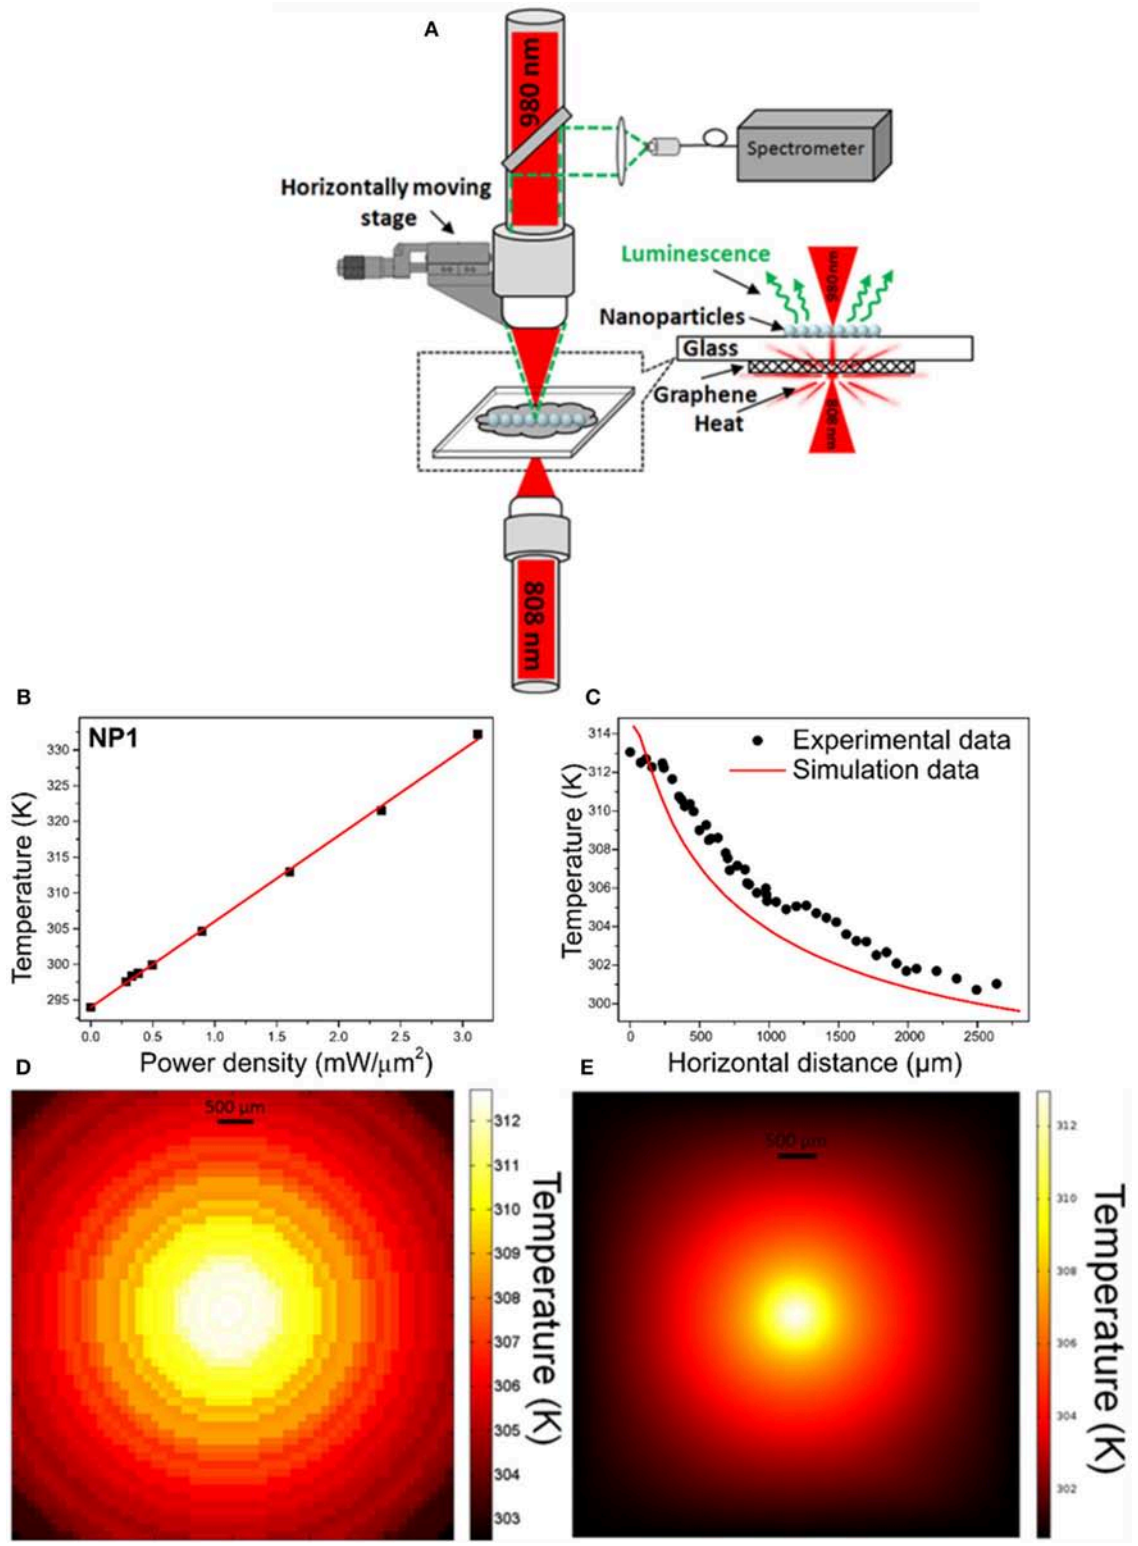

FIGURE 3 | (A) Scheme of the setup used to map the temperature distribution generated by graphene when illuminated with a 808 nm laser on a microscope slide cover glass. **(B)** Temperature achieved on the surface of the graphene-coated glass as a function of the power of the irradiating laser at 808 nm. **(C)** Temperature distribution generated by graphene on the slide cover glass determined from the luminescence spectra of the Er,Yb:$NaYF_4$ nanoparticles and comparison with the temperature distribution calculated from a heat transfer model in a 3D geometry. 2D temperature contour map generated from the data obtained **(D)** experimentally, and **(E)** with the 3D model.

graphene was increased. The results are shown in **Figure 3B**. We observed that the temperature increased linearly with the power of the laser. Based on these results, we decided to set the power of the laser at 100 mW, which allows for the temperature to achieve ∼312 K on the opposite side of the glass in order to get a constant heating and generate a thermal gradient high enough on the surface of the cover glass coated with the Er,Yb:$NaYF_4$ nanoparticles to be easily detected with them. The 980 nm excitation laser with a fixed excitation power of 100 mW was attached to a motorized stage that allowed to scan the sample below the microscope setup. We recorded the spectra of the Er,Yb:$NaYF_4$ nanoparticles in 50 μm steps. It took 60 s to record each spectrum, and the total scan duration was of 1 h. We did not observe any reduction of the emission intensity during the excitation with the 980 nm laser at a particular position of the setup, and this could be attributed to a possible heating of the nanoparticles. Thus, the power of the excitation laser we used was low enough to avoid the introduction of any artifact on the mapping of the temperature distribution in graphene. **Figure 3C** shows the temperature profile measured from the heating spot (corresponding to the 0 position) to the external part of the film along the horizontal direction and **Figure 3D** represents 2D temperature contour map of experimental data. The temperature decreased slowly along this direction, dropping down from 313.0 to 300.5 K. We were able to detect temperature changes as small as 0.2 K, smaller than the one predicted by the thermal resolution calculated from the thermal sensitivity (see **Figure S2**).

To contrast these results, the temperature distribution on the glass substrate was numerically analyzed by a finite element method (FEM) based on the commercial software COMSOL Multiphysics. The simulation was performed in a three-dimensional (3D) geometry using the heat transfer model for a steady-state study. To model the experiment, the computational domains were defined by two attached blocks which represent the glass substrate and the deposited graphene layer. The glass block used had an area of 10 × 10 mm^2, and a height of 100 μm. The graphene block was constructed with an area of 10 × 10 mm^2, and a height of 1 μm, based on the mean thickness value determined for the graphene film. In order to assign the laser beam as a heating source, a cylindrical domain (9 μm diameter, 1 μm height) was additionally created in the middle of the graphene domain corresponding to the waist of the pumping laser. A triangular mesh was defined with a well-defined size (minimum 1 μm) within the small domain (the cylindrical heat source domain) and a coarser size (maximum 1 mm) within the big domains (glass and graphene domains). To solve the heat transfer problem in the stationary state, the following thermal conductivity values of the materials were assigned to the corresponding domains: $k = 3{,}100$ W m^{-1} K^{-1} for graphene (Pop et al., 2012), and $k = 1.38$ W m^{-1} K^{-1} for the silica glass (Bansal and Doremus, 2013). The heating source was introduced to the cylindrical graphene domain with an overall heat transfer rate of 100 mW. The boundary conditions were specified with a convective heat flux in all the boundaries in which a convection coefficient (h) was determined from the best fit to the measured temperature distribution. The value of h obtained was 80 W/m^2 K, which is reasonable for the natural convection conditions taking place in the experiment.

Figure 3E shows the heat gradient calculated within the approximate range of 300 and 314 K, which closely matches the experimental results. The exponential decay trend deduced from this model is followed by the temperature profile determined experimentally with the luminescent nanoparticles. The small discrepancies that can be observed between the two profiles might be attributed to the fact that the thickness of the deposited graphene layer was not homogeneous, and also to the grain boundaries generated in this kind of films, as well as to the poor bonding between the graphene film and the glass slide, parameters that are critical in a heat transfer process, while these factors were idealized in the simulation. Also, in the model, the thermal conductivity of graphene was assumed to be isotropic whereas this might have an anisotropic behavior. Finally, by switching on the 980 nm emitting laser only during the time required to record the luminescence in each point, it would produce even more precise values of temperature. Nevertheless, and despite these considerations, the thermal gradient we measured using the Er,Yb:$NaYF_4$ nanoparticles followed the same trend than the simulated one.

As previously reported in the literature (Vetrone et al., 2010; Fischer et al., 2011), we believe that, by internalizing these luminescent nanoparticles on living cells, with the required suitable chemical functionalization of their surfaces as prior steps, thermal contour maps would also be obtained by *in vitro* procedures with the same thermal sensitivity, allowing for the illustration of the internal temperature gradients in the cells.

CONCLUSION

In summary, we synthesized Er,Yb:$NaYF_4$ nanoparticles with a microwave-assisted solvothermal method at lower temperatures and reaction times than previously reported methods. Furthermore, this synthesis method allowed to produce the α- and β phases of Er,Yb:$NaYF_4$ separately, avoiding the production of mixtures and avoiding also the use of organic solvents and ligands not miscible with water or difficult to eliminate after the reaction. An additional advantage of this synthesis method is that the produced nanoparticles are hydrophilic and can be dispersed in water or other biological compatible fluids without requiring any post-growth chemical functionalization procedure.

We analyzed the temperature dependence of the upconversion emission of these nanoparticles for their use as luminescent nanothermometers. We observed that nanoparticles with bigger sizes possess higher thermal sensitivities. Their thermal sensing capabilities were proved by determining the temperature distribution induced by the light to heat conversion generated by a graphene layer deposited on a microscope slide cover glass when illuminated with a laser emitting at 808 nm. With this experiment we wanted to show that these nanoparticles can be used to monitor the temperature increase generated by graphene and derivatives when illuminated with a laser, one of the most promising techniques nowadays for tumor

treatment by hyperthermia. We believe that by using the suitable chemical functionalization steps, these nanoparticles can be internalized in living cells to visualize their internal temperature distribution maps through *in vitro* procedures with a similar thermal resolution.

Black phosphorus, an emerging layered material, exhibits promising applications in diverse fields, ranging from electronics to optics. However, controlled synthesis of black phosphorus, particularly its few-layered counterparts, is still challenging, which should be due to the unclear growth mechanism of black phosphorus. Here, taking the most commonly used Sn-I assisted synthesis of black phosphorus as an example, we propose a growth mechanism of black phosphorus crystals by monitoring the reactions and analyzing the as-synthesized products. In the proposed mechanism, $Sn_{24}P_{19.3}I_8$ is the active site for the growth of black phosphorus, and the black phosphorus crystals are formed with the assistance of SnI_2, following a polymerization-like process. In addition, we suggest that all Sn-I assisted synthesis of black phosphorus should share the same reaction mechanism despite the differences among Sn-I containing additives. Our results shown here should shed light on the controlled synthesis of black phosphorus and facilitate further applications of black phosphorus.

Keywords: black phosphorus, growth mechanism, tin iodide, chemical vapor transport, 2D materials

INTRODUCTION

With the rapid development of two-dimensional materials, orthorhombic black phosphorus (BP), assembled by puckered phosphorus layers of interlinked six-membered rings via van der Waals interactions, recently has attracted much research enthusiasm due to its layer-number-dependent properties (Hirsch and Hauke, 2018; Liu H. et al., 2018; Liu Y. et al., 2018). Specifically, few-layered BP possesses tunable band gap, ranging from 0.3 to 2.0 eV (Xia et al., 2014), and high carrier mobility ($\sim$1,000 $cm^2V^{-1}s^{-1}$) (Li et al., 2014), which makes it promising for diverse applications, including field effect transistor, battery, sensor, and electrocatalyst (Liu et al., 2015; Zhang Y. et al., 2017; Hu et al., 2018). Despite the outstanding properties of BP and the recent inspiring studies, the exploration of the properties of BP and corresponding applications are still constrained to some extent because of the difficulties in synthesizing BP and its layered counterparts (Hu et al., 2018; Zhang et al., 2018).

In fact, BP is a thermodynamically stable form of phosphorus but does not exist naturally. Formerly, BP was synthesized by transforming red phosphorus or white phosphorus under harsh conditions (Bridgman, 1914, 1935, 1948). It was until 2007 that a simple synthetic approach based on Sn-I assisted chemical vapor transport reactions was developed for producing BP crystals in high quality and high yield (Lange et al., 2007). In this method, BP is synthesized, in an evacuated ampoule, by programmed heating of red phosphorus with the

mineralizers (e.g., Sn/SnI_4). It should be emphasized that the mineralizers, particularly Sn and I elements, are decisive in this chemical vapor transport based method. Currently, this Sn-I assisted method is the most commonly used strategy for the large-scale preparation of high quality BP crystals, which indeed boosts both the scientific research and technological development of BP (Nilges et al., 2008; Köpf et al., 2014). Nevertheless, controlled synthesis of BP, particularly the synthesis of uniform thin BP film (few-layered BP), has not been achieved by chemical vapor transport based methods yet (Yang et al., 2015; Smith et al., 2016).

In order to realize controlled synthesis of BP, it is crucial to fully understand the corresponding formation mechanisms. Unfortunately, the formation mechanisms of BP in the Sn-I assisted method are still unclear, although several efforts have been devoted to revealing the detailed formation processes (Zhao et al., 2016a,b; Li et al., 2017; Zhang Z. et al., 2017; Shriber et al., 2018). Furthermore, the currently proposed formation mechanisms are different from each other, although they share some opinions. For example, in 2016, a molten alloy based mechanism was proposed (Zhao et al., 2016a). In this mechanism, BP crystals were believed to precipitate from the molten alloy of red phosphorus and metallic Sn when the temperature decreased. At almost the same time, a phase-transfer mechanism was proposed, in which BP crystals were proposed to be transformed from Hittorf's phosphorus with the assistance of a certain P-Sn-I ternary compound (Zhang Z. et al., 2017). Later on, BP crystals were suggested to grow, obeying a vapor-solid-solid mechanism, through the diffusion of excess P atoms from a $Sn_{24}P_{22-x}I_8$ ($x \approx 2.7$) intermediate compound (Li et al., 2017). In addition to the studies based on experimental observations, another BP formation pathway was advised recently according to first-principle calculations (Shriber et al., 2018). According to the density functional theory calculations, BP is favorably formed, in the presence of Sn-I containing mineralizer at high temperature and pressure, by a series of additions of P_4 molecules in a polymerization-like process. Collectively, more efforts are desired to elucidate the formation mechanisms of BP crystals in the Sn-I assisted synthetic method.

In this study, taking the previous studies into account, we propose a new formation mechanism of BP crystals in the Sn-I assisted reaction according to a series of reaction observations and product characterization. In our proposed mechanism, the Sn and I containing mineralizers first decompose, forming SnI_2 and Sn, and then the decomposed compounds react with phosphorus vapor at elevated temperature to form $Sn_{24}P_{19.3}I_8$. Subsequently, the $Sn_{24}P_{19.3}I_8$ molecules transport to and partially deposit at the zone with slightly low temperature (∼550–500°C) during the cooling stage, generating the growth sites for BP crystals. The $Sn_{24}P_{19.3}I_8$ molecules at the deposition zone can decompose to release SnI_2, P_4, and even P_2 at the temperature of ∼550–500°C, and thus are highly active. Meanwhile, the remaining SnI_2 in the gas phase, functioning as a mineralizer, can transport P_4 molecules to the growth sites by forming a Sn-P-I intermediate compound, yielding BP crystals in a polymerization-like process. In addition, we suggest that the Sn-I assisted synthesis of BP crystals should have the same growth processes, although different Sn and I containing additives can be used as mineralizers. We believe that this study can improve the understanding of BP synthesis, and facilitate controlled synthesis of BP for future applications.

EXPERIMENTAL SECTION

Materials

Tin powder (Sn, 99.99%) and iodine granule (I_2, AR, 99.8%) were purchased from Aladdin (Shanghai, China). Red phosphorus (99.999%, metals basis) was purchased from Alfa Aesar. Acetic acid (AR), acetic anhydride (AR), toluene (AR), and other chemicals were purchased from Shanghai Lingfeng Chemical Reagent Co., Ltd. All chemicals were used as received without further purification unless otherwise noted.

Synthesis of SnI_4, SnI_2, Sn_4P_3, $Sn_{24}P_{19.3}I_8$, SnIP, and Black Phosphorus (BP)

Synthesis of SnI_4 (Köpf et al., 2014)

To a mixture of acetic acid (25 mL) and acetic anhydride (25 mL), 0.5 g Sn powder and 2 g I_2 were added. The resulting mixture was refluxed at 120°C for 90 min, during which the Sn powder completely disappeared. After the mixture was cooled to room temperature, orange-colored SnI_4 crystals appeared and were collected. The obtained SnI_4 crystals were recrystallized in chloroform for further use.

Synthesis of SnI_2

Typically, a mixture of SnI_4 (1.2956 g) and Sn (246.2 mg) powders (molar ratio: 1:1) was loaded in an evacuated silica ampoule (∼10 cm in length and ∼10 mm in inner diameter). Subsequently, the ampoule was heated to 400°C within 1 h in a muffle furnace, annealed for 5 h, and cooled down to room temperature naturally. The SnI_2 powders, on the wall of the silica ampoule, were collected for further use.

Synthesis of Sn_4P_3

A mixture of grounded red phosphorus powder (72 mg) and tin powder (364 mg) was sealed in an evacuated silica ampoule (∼10 cm in length and ∼10 mm in inner diameter). The sealed ampoule was then annealed at 400°C for 8 h in a muffle furnace, and cooled to 200°C in 2 h. Finally, the ampoule was naturally cooled down to room temperature and the resulting Sn_4P_3 was collected.

Synthesis of $Sn_{24}P_{19.3}I_8$ and SnIP
